Children and adolescents, as well as their families, who have primary psychotic disorders and affective disorders with psychotic features, are often devastated by these illnesses. These illnesses are frequently characterized by recurrent crises, interruption of normal developmental processes, a deteriorating course, and treatment resistance. Further, the care of affected youth is associated with very high societal costs since these youth often require extraordinary care from their parents, frequent hospitalizations, and multiple long-term interventions from mental health, educational, and social service agencies. However, many believe that if effective treatments can be identified and implemented early in the course of illness, youth may prove more responsive and resilient than adults with psychosis. In addition, many researchers believe that it may be easier to identify the neurobiological processes involved in the pathogenesis of schizophrenia and related disorders in affected youth because they have a more severe but clearly developmental form of the disorder that appears more strongly associated with genetic factors.

DEFINITION

Positive psychotic symptoms consist of hallucinations, delusions, and bizarre or disorganized thinking and behavior including catatonia. Negative psychotic symptoms consist of flattened affect, apathy, avolition (difficulty making choices), poverty of speech, and poverty of thought content. The diagnoses of psychotic disorders in children and adolescents are generally

made using the same criteria as in adults. Youth with schizophrenia, like adults with the disorder, are required to demonstrate positive or negative symptoms for at least 6 months and to have significant social or occupational dysfunction or failure to achieve expected levels of social development. In addition, although not yet formally part of the fifth edition revised text version of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) criteria, schizophrenia is associated with marked neurocognitive declines in general cognition, executive functioning, social cognition, and memory. Indeed these symptoms, not positive symptoms, seem most closely related to long-term functional outcome.

Early-onset schizophrenia is defined as schizophrenia with onset of clear positive symptoms prior to 18 years of age. Schizophrenia with onset between ages 13 and 18 is also frequently referred to as adolescent onset. Onset of schizophrenia prior to age 13 is referred to as very early onset or childhood onset. Schizophrenia spectrum disorders include schizoaffective disorder and schizophreniform disorder. Schizoaffective disorder is defined by the prominence of psychotic symptoms, presence of significant periods of co-occurring major depression or mania, and psychotic symptoms present for at least 2 weeks in the absence of any mood symptoms during the lifetime duration of the illness. Schizophreniform disorder is defined by its short duration of psychotic symptoms (1 to 6 months) and generally evolves into either schizophrenia or schizoaffective disorder. Major depression with psychotic features and bipolar affective disorder meet all diagnostic criteria for the affective disorder but also include positive psychotic symptoms that are present only during periods of affective disturbance. Key distinguishing features of these disorders and other disorders with psychotic symptoms presenting during childhood are presented in Table 53–1.

Judith Rapoport and colleagues have defined a developmental disorder associated with transient episodes of psychosis during periods of stress called multidimensionally impaired (MDI) disorder, which is not yet recognized by DSM-5. Diagnosis of MDI disorder requires poor reality testing, daily affective lability, poor social skills, information processing deficits, and absence of a formal thought disorder. MDI disorder is frequently confused with early-onset schizophrenia, appears to have a poor prognosis, and carries increased risk of the development of bipolar disorder, type I. This should be distinguished from multiple complex developmental disorder (MCDD), which is characterized by more impaired social behavior (similar to the severe social deficits seen in autism spectrum disorder), greater evidence of formal thought disorder, high levels of anxiety or disruptive behaviors, and onset before age 5. Disruptive mood dysregulation disorder, which is new to DSM-5, is characterized by severe, frequent verbal and/or behavioral outbursts and chronic, persistent irritability with intact reality testing, and lack of hallucinations or formal

thought disorder. Disruptive mood dysregulation disorder is distinct from bipolar disorder and carries an increased risk of unipolar depression and/or anxiety disorders. Table 53–2 presents key characteristics of disorders that have overlapping features to assist with differentiating complex clinical presentations. These latter three disorders have great clinical significance but their biological roots and relationships with one another are poorly characterized at this time.

HISTORY

Schizophrenia has been reported to occur in children since the diagnosis was introduced by Emil Kraepelin. From the early 1900s to 1980s, the term childhood schizophrenia or prepubertal schizophrenia was used to refer to a range of severe psychiatric disorders presenting in youth including autism, leading to uncertainty about the diagnosis of research subjects during this period. In the 1970s, Israel Kolvin and colleagues conducted seminal work to distinguish between primary psychotic disorders and autistic disorder. Beginning with the ninth revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-9) and DSM-III, autism has been recognized as a distinct disorder and schizophrenia has been diagnosed using identical criteria in youth as adults. Most available research has supported this decision, although there appear to be a small group of individuals who have both autism and schizophrenia.

Table 53–1.
Disorders Presenting with Psychotic Symptoms in Children and Adolescents

Disorder	Distinguishing Features
Early-onset psychosis (EOP)	Any of a number of disorders in which positive psychotic symptoms are a prominent feature.
Early-onset schizophrenia (EOS)	Schizophrenia with onset prior to age 18. ► Involves a change from usual functioning, typically within 1 to 5 years of diagnosis, often has negative and neurocognitive symptoms rather than just positive symptoms. ► Affective symptoms may occur, but are not present for a substantial part of the illness. ► If patient also has an autism spectrum disorder, positive symptoms must include hallucinations or delusions. ► Impact on functioning may include failure to achieve developmentally expected social functioning or deterioration in social or occupational functioning. ► DSM-5 requires symptoms be present for 6 months, ICD-10 requires symptoms for only 1 month.
Very early-onset schizophrenia (VEOS)	► VEOS and COS are used interchangeably. ► Schizophrenia with onset prior to age 13, almost always after 5.

Childhood onset schizophrenia (COS)	► Onset prior to age 3 should raise strong suspicion of autism spectrum disorder.
Schizoaffective disorder (SA)	► During a substantial portion of the psychotic illness, the affected individual also meets criteria for a major depressive episode, manic episode or mixed manic/depressive episode. ► There are at least 2 weeks during the lifetime duration of the illness which psychotic symptoms are present in the absence of any affective symptoms.
Schizophreniform disorder	► DSM-5 diagnosis reflecting schizophrenia criteria for at least 1 month but fewer than 6 months. ► Not included in ICD-10. ► Generally evolves into schizophrenia or schizoaffective disorders, but may less frequently evolve into bipolar disorder.
Early-onset schizophrenia spectrum disorders (EOSS)	► Includes EOS, schizoaffective disorder and schizophreniform disorder with onset prior to age 18 and VEOS or COS. ► At this point there is not clear evidence that the treatment or prognosis of early-onset schizoaffective disorder is significantly different from EOS.
Multidimensionally impaired disorder (MDI)	► A developmental disorder beginning during childhood characterized by transient hallucinations, daily affective lability, poor social skills, and extreme emotional reactivity. ► Distinguished from VEOS by absence of negative symptoms and a formal thought disorder and from pediatric bipolar disorder by absence of decreased need for sleep, grandiosity, hypersexuality, and euphoria.
Multiple complex developmental disorder (MCDD)	► A developmental disorder with some characteristics of autism spectrum disorder (social disinterest, detachment, avoidance or withdrawal) as well as impaired affective regulation and thought disorder. ► Differentiated from early-onset schizophrenia by greater evidence of autism spectrum disorder and onset before age 5.
Major depression with psychotic features	► Youth describes clear depressed mood versus numbness or apathy. ► Psychotic symptoms are only present if mood symptoms are present. ► Psychotic features are usually mood congruent. ► Formal thought disorder is not usually present.
Bipolar disorder with psychotic features	► Psychotic symptoms are only present if mood symptoms are present. ► There is decreased need for sleep rather than insomnia. ► Negative symptoms are absent.
Substance-induced psychosis	► Psychotic symptoms are limited to periods of substance intoxication or withdrawal. ► Psychotic symptoms did not precede substance use. ► Psychotic symptoms generally resolve with 7 to 30 days of abstinence.
Posttraumatic stress disorder (PTSD)–associated psychosis	► Positive psychotic symptoms relate directly to trauma, and are not associated with other areas of life or random events. ► There are other symptoms of PTSD.
Anxiety-related hallucinations	► Positive psychotic symptoms are limited to periods of high anxiety. ► There are not negative symptoms or signs of a formal thought disorder.

COMPARATIVE NOSOLOGY

The diagnostic criteria for schizophrenia and schizoaffective defined by the ICD-10 are similar to those of DSM-5. The only difference is that ICD-10

requires a total duration criterion of only 1 month, compared to the 6 months' duration specified by DSM-5. Jorge Armenteros and colleagues found a high rate of diagnostic agreement between DSM-III-R, DSM-IV-TR, and ICD-10 in hospitalized psychotic adolescents. Similarly there is good agreement between the diagnostic criteria for major depression with psychotic features and bipolar affective disorder with psychotic features between ICD-10 and DSM-IV-TR. It is highly likely that the same level of agreement will be found with increased use of DSM-5 criteria.

EPIDEMIOLOGY

There are very few studies of the population prevalence of positive psychotic symptoms or schizophrenia in children and adolescents. The diagnostic challenges associated with making these diagnoses are likely to lead to marked underreporting in population-based surveys such as the Smoky Mountain Survey. In clinical samples, which are likely to over-report, positive psychotic symptoms seem to occur in a significant minority of children. A meta-analysis of 19 population studies described a median prevalence of psychotic symptoms of 17 percent among children aged 9 to 12 years and 7.5 percent among adolescents aged 13 to 18 years, indicating that the prevalence of psychosis appears to decrease with age. In one outpatient pediatric mood and anxiety clinic, 2,031 children 5 to 21 years (mean age 14.3 years) were evaluated using a structured diagnostic interview. Nearly 10 percent had definite or possible psychotic symptoms. Among those with psychotic symptoms, 62 percent had depressive disorders, 24 percent had bipolar disorder, and 14 percent had schizophrenia or schizoaffective disorder. Inpatient samples of children with depression have reported that as many as 60 percent will have psychotic symptoms. However, few depressed youth are hospitalized, so this is likely a significant overestimate. Clinical and research samples of youth with bipolar disorder have shown similarly high rates of psychosis.

Table 53–2.
Clinical Features Differentiating Complex Disorders of Childhood That Have Overlapping Characteristics

	Early-Onset Schizophrenia	Multidimensionally Impaired	Multiple Complex Developmental Disorder	Disruptive Mood Dysregulation Disorder
Cognitive deficits	+	+ (informational processing)	–	–
Delusions	+	+/–	+	–
Developmental delay	+	+	+	+/–
Emotional lability	+/–	+	+	+

			(affective dysregulation, anxiety)	(temper outbursts)
Hallucinations	+	+ (typically transient and stress induced)	+	–
Irritability	+/–	+	+	+
Social deficits	+ (social cognition deficits)	+ (impaired interpersonal skills, despite desire for friendships)	+ (social withdrawal, detachment, ambivalence)	+ (outbursts and irritability impair ability to initiate or sustain friendships)
Thought disorder	+	–	+	–
Long-term outcome	Schizophrenia	Increased risk of bipolar disorder, type I	Not yet well characterized	Increased risk of unipolar depressive disorder or anxiety disorders

Less information is available about the incidence of schizophrenia, although it appears very unusual for children, especially those less than 10 years old, to experience schizophrenia. In one area in Germany, only 3 of 100,000 children between 6 and 10 years old who presented for treatment were diagnosed with schizophrenia. Based on this clinical sample, the incidence of schizophrenia appears to increase by about fourfold between 10 and 14 years to 13 of 100,000 and by another four- to fivefold between 14 and 18 years to 20 to 55 of 100,000. At least 5 percent of individuals with schizophrenia become ill prior to age 14 years and up to 40 percent have been estimated to become ill prior to 18 years of age.

Given the greater prevalence in youth with major depression and bipolar affective disorder, but the pervasive presence of psychosis in youth with schizophrenia spectrum disorders, it is likely that as many or more cases of pediatric psychosis will be related to affective disorders as to schizophrenia. Furthermore, in prepubertal children, affective psychoses are considerably more likely than schizophrenia spectrum disorders. It appears that early-onset schizophrenia and affective psychoses are more common in individuals with family histories of the respective disorders. Early-onset schizophrenia appears slightly more common in boys than girls, whereas major depression is much more common in female adolescents than in male adolescents. Both genders appear equally affected by bipolar disorder. A clear relationship with onset of puberty has not been demonstrated.

ETIOLOGY

Schizophrenia is a heterogeneous disorder of unknown etiology. Similarly, the etiology of positive psychotic symptoms, which occur in many disorders, is unknown. However, research on schizophrenia consistently

suggests that there are subtle differences in neuronal connectivity, especially in the hippocampus and parietal, temporal, and frontal cortices. These differences appear to lead to less efficient cortical processing as demonstrated by functional magnetic resonance imaging (fMRI). Further, these differences seem to involve disruption of normal neurodevelopmental processes, particularly those that involve maturation of the frontal cortex and its connections during the second and third decades of life. In adults, alterations in the morphology of specific subclasses of γ-aminobutyric acid (GABA)ergic interneurons and of the volume and synaptic density of pyramidal neurons that receive thalamic afferents have been repeatedly demonstrated. These differences suggest aberrations in the normal developmental processes of synaptic refinement and pruning. Some researchers have speculated that multiple disruptions or "hits" to these normal neurodevelopmental processes are required for schizophrenia to develop. Such disruptions might result from genetic vulnerabilities; intrauterine adversities as a result of famine, infection, or inflammation; or various environmental exposures later in life including severe psychological stress including trauma and exposure to drugs of abuse, particularly cannabis.

Early-onset schizophrenia appears to be associated with more profound neurodevelopmental disruptions than adult onset schizophrenia. Frequently individuals with early-onset schizophrenia have social and attentional difficulties during early childhood. Many even have evidence of autism spectrum symptoms. Structural imaging studies have repeatedly demonstrated an exaggeration of the normal pattern of cortical volume loss that occurs throughout adolescence, with excessive and progressive reductions being especially prominent in the cingulate, temporal, and frontal cortices. In addition, studies of prodromal individuals, many of whom are adolescents, have shown regional gray matter volume reductions are present before overt positive symptoms and progress during the first few years of the illness particularly in cingulate, temporal, and frontal cortices.

Genetic vulnerabilities also appear more prominent in early-onset schizophrenia. Youth with early-onset schizophrenia are at least twice as likely as individuals with adult onset schizophrenia to have a parent with the disorder and morbid risk of schizophrenia for parents of individuals with early-onset schizophrenia ranges from 14 to 25 percent. Further, individuals with early-onset schizophrenia are significantly more likely than those with adult onset schizophrenia to have chromosomal abnormalities and DNA copy number variants. Genetic abnormalities suggest involvement of immunological and neurodevelopmental functions.

DIAGNOSIS AND CLINICAL FEATURES

All types of early-onset psychosis other than MDI and MCDD are diagnosed

using the same criteria as the adult forms of the disorder. However, the characteristics of specific symptoms often show important developmental characteristics that may be confusing for clinicians who infrequently work with pediatric patients. Hallucinations are frequently multimodal, with the affected youth seeing, hearing, and/or feeling the hallucinated being. Children will frequently name the hallucinated being, often using stereotypes such as “an angel,” “the devil,” or “a monster” or will refer to it on the basis of a physical characteristic such as “the red sweater guy” or “the man with no skin.” Youth very seldom complain about their hallucinations if not asked directly. Family members often are not aware of hallucinations but may endorse that the child asks about being called when no one has said anything. Delusions are seldom highly complex or systematic prior to age 16. Instead youth often report vague symptoms like “everyone is out to get me” or “people are laughing at me.” Often reports from collateral sources are needed to determine whether such reports are delusional or reality based. Frequently, youth with early-onset schizophrenia present with nonspecific symptoms such as poor attention or increased aggression.

Onset of early-onset schizophrenia is often insidious, occurring over a few years. In addition, premorbid symptoms such as being odd and socially isolated or having multiple (but generally mild) developmental delays in cognitive, motor, sensory, and social functioning are common and appear more severe than in adults with adult onset schizophrenia. Thus, when assessing youth for early-onset schizophrenia, it is important to ask about changes in functioning and behavior that have occurred over the past 3 to 4 years, to specifically inquire about hallucinations and delusions using language that the child understands, and to encourage the child to describe his or her experiences in detail using his or her own words. One should ascertain whether the child is in control of the phenomena, which is not seen with true hallucinations, or whether he or she can only moderate his or her own response to the phenomena. It is also crucial to determine the frequency and persistence of positive symptoms and associated negative symptoms. Finally, often, but not always, early-onset schizophrenia is associated with a formal thought disorder.

Clinicians are frequently reluctant to diagnose early-onset schizophrenia even when there is clear evidence of the disorder. Although the reasons for this are unclear, unfamiliarity with the developmental variations in symptoms, concerns about over-labeling, likely poor outcome, and stigma are frequently involved. However, failure to make the diagnosis when indicated may reduce access to appropriately intense interventions and relevant psychoeducational resources, increase the likelihood of treatment nonadherence, and result in hopelessness if the youth does not robustly respond to treatment. Further, longer duration of untreated psychosis has been consistently associated with poor prognosis in adult

onset schizophrenia.

Jack was first brought to a psychiatrist at age 12 when his parents were divorcing. He was obviously upset, was doing less well in school over the past year, and had gone on a hunger strike for the past month because he thought it would make his parents get back together. His parents noted that he had always been somewhat socially awkward, had a limited number of friends, and seldom had extended conversations. He was treated with fluoxetine (Prozac) and psychotherapy. After about 2 months, he was eating normally and seemed less preoccupied with his parents' divorce. However, he would make frequent statements that he needed to protect his younger brother, because he did not trust his parents to take care of the brother. He also said he was trying to find a house where he, his brother, and his father could live together.

A year later, after his mother remarried, he became markedly more irritable and was frequently noncompliant with her requests. His mother reported that there were episodes in which he would suddenly become extremely upset with little or no provocation. For example, she described an episode when they were out walking and he suddenly jumped on her back, saying that she looked like a prostitute. On another occasion, when his stepfather had instructed his brother to wash a glass that had been left out in the living room, Jack became very upset and said he planned to beat his stepfather to death with a golf club while his stepfather was sleeping. Jack's band instructor noted that he frequently seemed preoccupied and sometimes seemed not to know what to do next. Between these episodes, Jack was frequently pleasant and engaged superficially with the family, but had very seldom seen his friends or left the house. He experimented with marijuana by himself three or four times and said it made him feel calmer.

When asked about the incidents with his mother and stepfather, Jack seemed minimally concerned and did not provide an explanation. During his psychiatric evaluation, Jack reported that he often felt extremely angry without really knowing why. He acknowledged some periods of confusion. When asked directly about ever hearing anyone or anything talking to him, he said that his legs often talked to him and told him what to do. He denied significant mood symptoms and described his mood in nondescript ways. He had some poverty of content. At times his speech was disorganized and hard to follow. Organic workup including MRI and electroencephalogram (EEG) was noncontributory. Family history was significant for a great uncle who had been odd, socially isolated, and had been hospitalized multiple times at the state psychiatric hospital.

Jack was started on an atypical antipsychotic and showed a remarkable improvement in his oppositionality and irritability. He also became more engaged with family members and his grandfather noted he was having conversations with Jack for the first time ever. However, Jack continued to have increasing trouble in school, particularly as he entered high school. Although his positive symptoms were well controlled, he was failing all but one class. It was unclear to what extent his difficulties in school were related to sedation from the medication or cognitive limitations. Cognitive testing showed he was now functioning in the low average to borderline range and had particular difficulty with abstract thought and problem solving. Reading achievement was grade appropriate but he was significantly behind in math. Several meetings with the schoolteachers were held and an individualized education plan was developed. However, he continued to have difficulty. Various medication changes were tried without significant change in his presentation. When the antipsychotic dose was lowered to try to reduce possible sedation, he became more irritable and had thoughts of beating his mother to death while she slept because she had removed his video games for 2 days as a punishment. His school program was changed from a college preparatory program to an occupational preparation program. He felt much less stressed by this but was unable to find and maintain work at a part-time job as required for graduation. He did not seem particularly concerned by this and had no specific plans for the future. His family was considering applying for disability so that he could maintain his insurance after he turned 18 and was trying to figure out how to more effectively structure his time. Use of clozapine (Clozaril) was also discussed given the persistence of negative symptoms and vulnerability to positive symptoms when his antipsychotic dosage was reduced.

FIGURE 53–1. Features of chromosome 22q11 deletion syndrome (velo-cardio-facial syndrome [VCFS]). **A:** Demonstrates fluorescent in situ hybridization. One bright probe marks the end of each of the two chromosome 22s. Another probe, which binds to a marker within the typical large deletion in VCFS, is present on the upper chromosome 22 (noted with the larger *gray arrow*) but not on the lower chromosome 22 (noted with a smaller *white arrow*). **B:** Illustrates the facial features of three youth with VCFS. Note the elongated face, tubular nose with a wide nasal bridge, bulbous tip, and small lateral nares. Frequently individuals with the 22q11 deletion have low facial tone, small mouths, learning disabilities, or mild mental retardation and a variety of congenital malformations, especially of the heart and palate. A history of feeding problems in infancy is common.

PATHOLOGY AND LABORATORY EXAMINATION

The physical examination of youth suspected of having early-onset schizophrenia should include a careful neurological examination. If there is a focal neurological finding or impairment of consciousness, structural MRI is indicated. However, the volumetric, spectroscopic, and diffusion tensor imaging abnormalities consistently reported to show differences in group comparisons within research studies are not of sufficiently great magnitude to be used for diagnostic purposes. If there is any indication of episodic psychosis in the absence of mood symptoms or excessive sedation or confusion following psychotic behaviors, an EEG should be obtained to rule out a seizure disorder. Exposure to illicit substances should be assessed with a urine toxicology screen. Blood work should include screening for thyroid abnormalities, electrolytes, complete blood count, liver function tests, ceruloplasmin, and urinary copper (using a penicillamine test in children) for Wilson disease, heavy metals, and serum organic and amino acids to rule out a metabolic disorder. Antinuclear antibodies and serum and cerebrospinal fluid (CSF) antibodies to the *N*-

methyl-D-aspartate (NMDA) receptor should be considered to rule out lupus or anti-NMDA receptor encephalitis, especially if the onset of psychotic symptoms is very sudden or if subtle neurological complaints are present. Genetic testing including fluorescent in situ-hybridization (FISH) or evolving genetic techniques for chromosome 22q11 deletion syndrome (also known as velo-cardio-facial syndrome [VCFS]) should also be considered, particularly if the youth has a dysmorphic appearance, any congenital abnormalities or learning disabilities or other cognitive limitations. Approximately 25 percent of individuals with VCFS become psychotic during adolescence, with most experiencing schizophrenia. Since the incidence of VCFS is estimated at 1 in 4,000 live births, as many as 10 percent of individuals with schizophrenia may have VCFS (Fig. 53–1). Projective psychological testing may be useful in confirming suspected cognitive disorganization. However, failure to demonstrate psychotic disorganization during projective testing is not sufficient to reject the diagnosis. In addition, neurocognitive evaluation including intelligence quotient (IQ), auditory and visual memory, working memory, problem solving, processing speed, and attention measures may be useful in helping adapt academic expectations for individuals with early-onset schizophrenia who often are expected to perform at the same level as prior to onset of their illness despite significant changes in their capabilities.

DIFFERENTIAL DIAGNOSIS

Misdiagnosis of early-onset schizophrenia is a major concern. Factors that may lead to misdiagnosis include children's inherent difficulties in describing psychotic symptoms that are outside their normal experience, overinterpretation of transient psychotic symptoms, and the high prevalence of positive psychotic symptoms in child psychiatric disorders other than early-onset schizophrenia. However, failure to recognize early-onset schizophrenia when present may slow implementation of appropriate treatments and worsen the youth's long-term prognosis.

Evaluation of a child or adolescent who may have psychotic symptoms should always include separate interviews of the child and his/her guardian with a focus on clarifying the child's developmental trajectory, changes in functioning, internal experiences elicited in a developmentally sensitive way, past exposure to trauma, and environmental stressors. Family history, including information about extended psychiatric hospitalizations and suicides, should also be obtained. The clinician can usually make an accurate diagnosis with attention to co-occurring symptoms and their time course and strict adherence DSM-5 criteria (Table 53–3). However, affected youth and their families should be educated that the diagnosis will be re-evaluated over time as additional information becomes available.

Table 53–3.
DSM-5 Criteria for Schizophrenia

A. Characteristic symptoms: At least two of the following are needed for a period of at least 1 month: Delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, or negative symptoms. The duration of these symptoms may be less than 1 month if they have been alleviated by treatment.
B. Social/occupational dysfunction: The level of social, occupational, and self-care functioning has markedly deteriorated below the highest previously obtained level. In children and adolescents, this includes the failure to achieve expected levels of social development.
C. Duration: The disturbances must be present for a period of at least 6 months. This includes an active phase of overt psychotic symptoms (Criterion A) with or without a prodromal or residual phase. A prodromal phase involves the deterioration in functioning before the onset of psychotic symptoms, whereas the residual phase follows the active phase. Symptoms characteristic of both prodromal and residual phases include marked social isolation, deterioration in occupational functioning, peculiar behavior such as food hoarding, poor hygiene, blunted or inappropriate affect, disordered thought processes (tangentiality, circumferentiality, poverty of speech, or speech content), odd beliefs or perceptions, and anergia.
D. Exclusion of mood disorder: Schizoaffective disorder and mood disorder with psychotic features must be ruled out. If mood episodes are present, their duration must be brief relative to the course of the schizophrenic symptoms. This exclusion criterion is especially pertinent for adolescents with bipolar disorder, as manic episodes in this age group frequently include schizophrenic-like symptoms at onset. This needs to be systematically reassessed in patients, as continued follow-up may be the only accurate method for distinguishing the two disorders.
E. Substance/general medical condition exclusion: The symptoms are not due to either the direct effects of a substance or a medical condition.
F. Relationship to a pervasive developmental disorder: If there is a history of autism, or another pervasive developmental disorder, prominent delusions or hallucinations (for at least 1 month unless successfully treated) are required to make a diagnosis of schizophrenia.

Schizoaffective Disorder

Like early-onset schizophrenia, schizoaffective disorder is characterized by persistent positive and/or negative psychotic symptoms and functional decline or failure to realize expected developmental progress. However, during a substantial period of the active and residual phases of illness, the individual also experiences prominent mood symptoms that meet criteria for a major depressive episode, manic episode, or mixed manic episode. Psychotic symptoms must be present in the absence of any mood symptoms for at least 2 weeks during the lifetime duration of the illness. If an individual is in the midst of their only psychotic episode and has had significant mood symptoms throughout, it may not be possible to distinguish between schizoaffective disorder and an affective psychosis. However, the presence of negative symptoms would increase the likelihood of a schizoaffective disorder. Early-onset schizophrenia with a secondary major depression may be distinguished longitudinally because the depressive symptoms are not present for a substantial period of the illness.

Major Depression with Psychotic Features

Individuals with major depression are generally able to describe their mood vividly rather than simply label it as depressed. In contrast, individuals with early-onset schizophrenia may say they are depressed but instead describe a state of apathy and emotional numbing that reflects their experience of negative symptoms. Insomnia, failure to enjoy activities, social withdrawal, lack of motivation, cognitive slowing, agitation, suicidality, and psychomotor retardation may be seen in both disorders. Likewise weight loss and decreased food intake may be seen in either disorder. However, in early-onset schizophrenia these symptoms are usually the result of delusional beliefs about the food or one's weight. Although mood-incongruent hallucinations and delusions may occur in major depression, they are not common.

Bipolar Affective Disorder with Psychotic Features

It can be extremely difficult to distinguish a mixed manic state from early-onset schizophrenia or schizoaffective disorder because hallucinations, delusions, irritability, and agitation are common to all three disorders. The primary distinguishing factors are the presence of decreased need for sleep and hypersexuality in bipolar disorder versus negative symptoms in the schizophrenia spectrum disorders. Youth with bipolar disorder, especially those who require hospitalization, appear to have greater numbers of varied psychotic symptoms than adults hospitalized with bipolar disorder.

Substance-Induced Psychosis

In substance-induced psychosis, positive symptoms are limited to periods of substance intoxication or withdrawal and are not better accounted for by a diagnosis of early-onset schizophrenia, schizoaffective disorder, or affective disorder. DSM-5 notes that such symptoms should resolve within 1 month of discontinuing the substance, although in clinical practice most substance-induced psychoses in youth resolve much more quickly (e.g., 7 to 10 days). If positive psychotic symptoms have been present prior to onset of substance use or during periods of sustained abstinence from substances, one of the other psychotic diagnoses is more appropriate. In addition, one is much more likely to see negative symptoms in schizophrenia spectrum disorders than in substance-induced psychosis, although decline in functioning is common in both. Comorbid substance use is common in older adolescents with early-onset schizophrenia. Substance use, particularly cannabis use, appears to be both a precipitating and exacerbating factor. Nonetheless, many youth with early-onset schizophrenia appear to self-medicate with drugs of abuse.

Autism Spectrum Disorders

Autism spectrum disorders and early-onset schizophrenia are distinguished by their developmental course and the presence of hallucinations and formal thought disorder. Although autism spectrum disorders may not be diagnosed until late childhood, onset of symptoms prior to 3 years of age is required to diagnose an autism spectrum disorder. Such abnormalities may be present in individuals with early-onset schizophrenia and schizoaffective disorder, but additional symptoms should present later in life that lead to the psychotic diagnosis. Onset of early-onset schizophrenia prior to age 10 is extremely rare. Further, although individuals with autism spectrum disorders may be extremely concrete and rigid in their thinking and verbal responses, they do not exhibit a formal thought disorder. However, it is also possible for individuals with autism spectrum disorders to develop a primary psychotic disorder. In this case, the individual must demonstrate clear hallucinations or delusions and negative symptoms alone cannot be used to satisfy diagnostic criteria. Some researchers feel the risk of schizophrenia is increased among individuals with autism spectrum disorders, although results of a small case study are frequently used to dispute this contention.

Anxiety Disorders and Posttraumatic Stress Disorder

Transient hallucinations may occur in youth with severe anxiety disorders. However, these youth seldom experience negative symptoms and are less likely to experience delusions or a formal thought disorder. In individuals with PTSD, the psychotic symptoms are generally limited to reliving events that occurred during the trauma and to the perpetrator of the trauma. Data regarding the long-term course of individuals with these symptoms is lacking. Some studies report frequent personality disorders, whereas a recent study found that a large proportion of individuals reporting hallucinations at age 11 but not appearing to have a primary psychotic disorder had developed one when reassessed as adults.

Multidimensionally Impaired Disorder

MDI disorder is distinguished from early-onset schizophrenia by the absence of formal thought disorder, the transient and reactive nature of the hallucinations, daily affective lability, and less profound social difficulties. Reductions in brain volume appear less profound than in early-onset schizophrenia. Long-term outcomes are not yet clear, though there may be an increased risk of bipolar disorder, type I.

Multiple Complex Developmental Disorder

MCDD presents with more prominent features of autism spectrum disorder than seen in early-onset schizophrenia. In addition, youth have greater incidence of formal thought disorder (hallucinations, delusions, magical

thinking), anxiety and affective dysregulation, and primitive or violent episodes of behavioral disorganization. Initially criteria for MCDD were conceived within the framework of autism spectrum disorder, though more studies are needed to characterize the incidence and long-term outcomes of this disorder.

Organic Disorders

The list of potential organic etiological agents of early-onset schizophrenia is extensive. Entities that must be considered include (1) delirium, (2) seizure disorders, (3) central nervous system lesions (e.g., brain tumors, congenital malformations, and head trauma), (4) metabolic disorders (e.g., endocrinopathies and Wilson disease), (5) autoimmune disorders (e.g., anti-NMDA receptor encephalitis and lupus), (6) neurodegenerative disorders (e.g., Huntington chorea and lipid storage disorders), (7) infectious diseases (e.g., encephalitis, meningitis, or human immunodeficiency virus [HIV]–related syndromes), and (8) toxic encephalopathies (both substances of abuse and medications). Individuals should be specifically asked about the use of solvents, phencyclidine, hallucinogens, cannabis, stimulants (including street-acquired amphetamines), synthetic or designer drugs, corticosteroids, and anticholinergic agents. Also, it is important to examine for comorbid medical or developmental disorders that will likely impact the type and extent of psychosocial treatments required. For example, there is an increased risk of psychotic disorders associated with VCFS, which is also associated with significant learning disabilities.

Emily, a 16-year-old girl with no previous psychiatric history, was brought to the emergency room due to a sudden behavioral change and suicidal ideation. A previously cheerful and accommodating girl, for the past 2 weeks she had been increasingly irritable, moody and easily frustrated. The day prior to presentation she began endorsing suicidal ideation and expressing a belief that her thoughts were controlled by an external presence (whom she referred to as "the man"). She also reported that her eyes had been replaced by cameras that allowed her to see ghosts. She was admitted to an inpatient psychiatric unit, where she was agitated, pacing and continuing to endorse hallucinations. Her physical examination was notable for ataxia and movement disorder (semirepetitive orofacial and limb movements). Routine labs (electrolyte, blood count, liver enzymes, thyroid function, and urine drug screen) were unrevealing. An EEG was grossly normal and her brain MRI showed no evidence of mass lesion or midline shift. She was treated with risperidone in escalating doses with little benefit.

On hospital day 7 she developed increasing fluctuations in her blood pressure and pulse, and then experienced a generalized tonic–clonic seizure. She was transferred to the intensive care unit due to worsening dysautonomia and central hypoventilation. Lumbar puncture results showed protein, glucose, neutrophils, and lymphocytes within the normal range. Though CSF anti-NMDA antibodies were negative, serum anti-NMDA receptor antibody panel was positive, increasing the suspicion of anti-NMDA receptor encephalitis as a cause of her symptoms. Imaging for an underlying tumor revealed an ovarian teratoma, which was surgically removed. She was concurrently treated with corticosteroids and experienced a gradual improvement in her psychotic symptoms and remission of her movement disorder. At a follow-up visit 3 months later, she had returned to school part-time. She denied psychotic symptoms but reported residual fatigue and impaired concentration.

COURSE AND PROGNOSIS

Subtle developmental symptoms are frequently present throughout childhood in individuals who have early-onset schizophrenia. The onset of overt psychotic symptoms is frequently insidious, particularly in individuals younger than 15 years. Afterward, approximately equal proportions of youth have insidious and subacute onset, with rapid onset over the course of several days being rare. Rapid recovery from the initial episode appears rarer than in adult onset schizophrenia. In contrast, many youth with early-onset schizophrenia show improvement but continue to experience significant positive symptoms despite medication adherence for 2 to 5 years. The course tends to be chronic rather than episodic as is reported in adult onset schizophrenia. Further, there appears to be significant decline in cognitive functioning during the 4-year period surrounding onset of illness. This cognitive decline appears to reflect both biological brain processes and interruption of normal development and learning. A recent study found that 30 percent of individuals with early-onset schizophrenia attempted suicide over the first 10 years of illness with one of six of those who attempted completing suicide. Suicidality was associated with more depressive symptoms and fewer negative symptoms at first episode.

FIGURE 53–2. Comparative course of early-onset schizophrenia (EOS) and adult onset schizophrenia. Note the lower premorbid functioning of EOS, more insidious onset, and more chronic course with more limited periods of recovery.

Long-term prognosis in early-onset schizophrenia also appears worse

than in adult onset schizophrenia. A meta-analysis of 320 studies of outcome in adult onset schizophrenia found that about 40 percent of individuals had good outcomes, whereas about 60 percent had a chronic disabling course. In contrast, a number of studies have found that very few individuals with early-onset schizophrenia (5 to 25 percent) experience good outcomes and that 75 to 80 percent have poor outcomes with about half of those having extremely poor outcome. Few live independently as adults (7 to 29 percent), participate in full-time education, or are employed in the open market (17 to 28 percent). Another study found that fewer (25 percent) individuals with psychosis complete high school compared to age matched peers (84 percent). Treatment resistance may also be more common, although this has not been adequately studied. Figure 53–2 schematically illustrates the differences in course between early-onset schizophrenia and adult onset schizophrenia.

TREATMENT

The treatment of early-onset schizophrenia is multimodal and should include pharmacotherapy, family and patient psychoeducation and psychotherapy, and interventions in the community to support ongoing education and transition to employment when appropriate. The evidence is strongest for pharmacotherapy. A variety of traditional antipsychotics have demonstrated efficacy for reducing psychotic symptoms. A series of studies have compared various atypical antipsychotics to placebo in adolescents with early-onset schizophrenia and have demonstrated considerable antipsychotic efficacy, frequently reducing the Positive and Negative Syndrome Scale (PANSS) by about 20 percent. In these studies, olanzapine (Zyprexa) has been demonstrated to be associated with the greatest acute weight gain and lipid changes. Risperidone (Risperdal) seems to have more moderate acute weight changes and aripiprazole (Abilify) more limited acute weight changes. Extrapyramidal symptoms appear infrequent, but do occur. Only a few comparative trials have been done. These studies have generally found that the various antipsychotics differ in their side-effect profiles but have few differences in efficacy. Specifically, midpotency traditional agents appear to have relatively little impact on weight, lipids, and glucose tolerance, but are modestly more likely to cause moderate or severe extrapyramidal symptoms including akathisia. Significantly, these symptoms are generally well controlled with the addition of anticholinergic medications or propranolol. There is also a strong body of work indicating that individuals with treatment-resistant early-onset schizophrenia respond significantly better to clozapine than to haloperidol (Haldol) or olanzapine.

Compared to the literature in adult schizophrenia, few studies of psychosocial interventions have been conducted thus far. However, both cognitive remediation therapy (CRT) and supported employment

interventions show promise in improving the functioning of affected youth. A recent study found that clinically stabilized youth who received CRT experienced significant improvements in verbal memory and executive functions, and modest improvement in daily living, adaptive functioning, and reduced family burden compared with controls. Most of these changes were maintained after 3 months. Similarly a small Australian study of supported employment (Individual Placement and Support [IPS]) found that youth engaged in IPS gained significantly more jobs (23 vs. 4), earned significantly more money ($2,432 vs. $0), and worked for a longer time period (45 vs. 19 days). An overall positive vocational outcome (return to work or education) was achieved by 85 percent of the subjects, compared to 6 percent in the control group. Therapeutic interventions must focus on functional improvement in addition to symptomatic improvement in order to facilitate recovery. Targets of treatment include reduction in self-stigma and caregiver burden and restoration of self-esteem, self-efficacy, hope, and optimism.

FUTURE DIRECTIONS

Improving the recognition and timely diagnosis of early-onset psychosis will be important in reducing the disability, personal, and societal costs associated with these debilitating illnesses. It will be important to further characterize the long-term course of early-onset schizophrenia and other early-onset psychotic disorders, particularly with regard to neurocognitive and biological outcomes. In addition, it is essential that psychosocial treatments such as cognitive remediation, social skills training, and supported education and employment programs are rigorously evaluated and manualized where appropriate. More effective and safe medication strategies are also required to provide the most effective and safest treatment for these highly vulnerable individuals. This will require both more comparative trials and more studies of long-term outcomes. Development of additional psychopharmacological treatments, particularly those that are more focused on the neurodevelopmental processes that appear so prominent in early-onset schizophrenia, is also essential. Finally, early-onset schizophrenia also can serve as a more homogenous model for understanding the pathophysiology of schizophrenia and identifying key neurodevelopmental pathways in which to intervene.

Child Psychiatry: Psychiatric Treatment

▲ 54.1 Individual Psychodynamic Psychotherapy (Child Psychiatry)

DAVID L. KAYE, M.D., AND ZHANNA ELBERG, M.D.

INTRODUCTION AND DEFINITION

Psychodynamic psychotherapy (PDP), rooted in psychoanalytic theory and used interchangeably with psychoanalytic psychotherapy by most practitioners, has a long and storied tradition in child and adolescent psychiatry both in the United States and internationally. Although for many years the backbone of child psychiatric theory and practice, it has been under siege for much of the past four decades from different quarters. The ascendancy of neurobiological approaches and understanding, third-party payers' demands for briefer and less expensive treatments, and the public's demand for empirical support all contributed to the diminished influence of psychoanalysis. Despite this, psychoanalysis has remained a vibrant, and still the most comprehensive, framework for understanding psychotherapy and the human mind. In the last decade, increasing empirical support for PDP with adults and children has energized the approach. The groundbreaking review by Shedler, *The Efficacy of Psychodynamic Psychotherapy,* published in American Psychologists in 2010 was a landmark in establishing the efficacy of PDP with adults. Since then, Leichsenring has published a recent systematic review (2015) that concludes that PDP is efficacious for a wide range of adult mental disorders. In 2012, the American Academy of Child and Adolescent Psychiatry published the first ever practice parameter for PDP with children. Two volumes of the *Child and Adolescent Psychiatric Clinics of North America* (January, April 2013) were devoted to PDP. Evidence-based, manualized approaches such as interpersonal therapy (IPT) and mentalization-based therapy (MBT) are based solidly on PDP principles. Further, there has been a softening of the boundaries between psychotherapy treatments with inclusion of aspects of different therapeutic approaches now commonplace in child therapy.

Although the place of psychoanalytic psychotherapy within child and adolescent psychiatry has declined from the hegemony it once held, it has remained a primary framework for many practitioners and a psychotherapeutic foundation of many, if not most, residency training programs. In the past it was often seen as a stand-alone treatment of child psychiatric disorders. In current clinical work, practitioners work pragmatically, flexibly, and in concert with other approaches including family therapy, behavior therapy, cognitive-behavior therapy, psychopharmacology, and school interventions. Regardless of approach, the understanding of patients stems from an overarching psychoanalytic framework. Psychoanalytic concepts also continue to be applied broadly to clinical work in residential or other intensive treatment milieus, social services, police and juvenile justice settings, and schools. In looking over his career Leon Eisenberg, a long-time critic of psychoanalysis, observed that:

> Where I erred was in failing to appreciate the powerful and lasting contribution psychoanalysis made to psychiatry by teaching trainees to listen to patients and to try to understand their distress, rather than merely to classify them by some diagnostic algorithm, or snow them with drugs, or lock them away, or release them to homelessness. Basing care on what is unique to the individual patient is central to clinical competence, whether in medicine or surgery or psychiatry.

Far from a single and monolithic set of ideas, psychoanalysis encompasses a wide diversity. Disagreement exists about the nature of the mind, development, psychopathology, and treatment. Despite this, psychodynamically oriented practitioners share the following precepts:

1. The primary emphasis and focus of PDP is the individual's subjective, inner experience of self and others. A primary goal in treatment is self-acceptance and self-understanding through the instrument of a relationship. The primary "tool" of psychoanalytically informed therapy is the relationship between the doctor and the patient.
2. Unconscious mentation is critical to understanding patient's subjective experiences and relationship patterns. Unconscious affects, motivations, and processes (including defense mechanisms) are accepted as critical determinants of normal and abnormal human behavior.
3. Behavior, emotion, and relationship patterns can be understood through the lens of psychic determinism. Human behavior has a logic of its own, happens for psychological "reasons," and is understandable through following a link of multiple impulses, affects, defenses, and their associated relational experiences. Often these links are unconscious and the work of therapy includes greater awareness of the impact of defenses and warded-off emotions and wishes.
4. The child is father to the man. Early experience in a child's life is critical in initiating important and enduring patterns in perceiving, thinking, feeling, and behaving that are carried forward in life via internalized

beliefs, working models, assumptions, expectations, and attitudes (i.e., transference).

5. Treatment critically focuses on transference. Focusing on the here-and-now transference reactions of the patient are central to understanding the patient and promoting growth in the psychoanalytic process.
6. Treatment goals are focused on psychological growth broadly, not just symptom amelioration. For example, in child psychotherapy goals often include a return of the child to a healthy developmental pathway, including greater self-acceptance, self-awareness, and self-expression.
7. Emotional barriers ("resistance") to psychological growth or resolution of symptoms can be expected in the course of treatment.

HISTORY

The first psychoanalytic reference to child cases was Sigmund Freud's case of "Little Hans" in 1909. Although Freud was skeptical that children could be analyzed, in this case he provided supervision to Hans' physician-father, who successfully analyzed the 5-year-old boy's phobia of horses. A few years later Sandor Ferenczi reported his attempt to directly treat a child, but found that the child quickly became bored with the analytic process and wanted to return to his toys to play. It was not until a series of women psychoanalysts who entered the scene that it became appreciated that play was the central medium of expression for children, and should be incorporated into work with those with emotional disturbance. Hermine Hug-Hellmuth, a teacher by prior training, was the first psychoanalyst to report the use of play in the treatment of children in 1921. She believed that treatment of children was primarily educational and limited in its goals.

By far the major figures in the early development of psychoanalytic treatment of children were Anna Freud and Melanie Klein. Klein began to develop a technique for working with children while in Berlin in the early 1920s, and in 1926, moved to London where she continued her work. She saw children as a cauldron of passionate drives (both aggressive and sexual) with rigid, harsh superegos. Her technique relied on equally powerful and direct interpretations of unconscious impulses. She appraised play as the equivalent of adult-free association and eschewed any role for parents in the treatment. Anna Freud, also a teacher by training, began her psychoanalytic training in the early 1920s and shortly thereafter formed a child psychoanalysis study group in Vienna. She viewed children as immature and undeveloped, necessitating a gentler and educative approach that was careful not to interpret too deeply for fear of overwhelming the child. She recognized work with the parents as difficult but necessary to further the development of the child and also to support treatment with the child. She saw the goals of treatment as being to return the child to his/her developmental path, and not to effectuate a definitive or complete cure. In 1927 Anna Freud wrote the first book on child analysis, *Introduction to the*

Technique of Child Analysis. The differences between Klein and Freud led to a confrontational Symposium on Child Analysis in May 1927. These "controversial discussions" brought points of disagreement into sharp focus, and this schism has persisted to the present day, albeit lessening in the recent past. The Kleinian school became dominant in the United Kingdom and South America, while the Freudian school held sway in North America.

Into this fray entered the analysts of the "independent school" in Great Britain in the 1940s, including Donald Winnicott, Wilfred Bion, and others associated with the object relations perspective. Starting in the Kleinian camp, they attempted to bridge the divide with the Freudians. Winnicott contributed enormously to the analytic understanding of child development and treatment, remaining perhaps the most well-recognized influence in the field. His rich body of work included an emphasis on the importance of the early mother–child relationship; the role of play, mirroring, and the establishment of the "holding environment" in healthy development and in analysis; the meaning of the transitional object; and the true versus false self.

In North America an additional perspective was emerging, beginning with Kohut's work in the 1970s on the development of the self. This evolution has continued to the present with major contributions from interpersonal, relational, and intersubjective theorists. Harry Stack Sullivan, Robert Stolorow, Stephen Mitchell, Joseph Lichtenberg, James Fosshage, and Irwin Hoffman among others have been major figures representing these perspectives. All of these authors have written primarily about clinical work with adults, with a few current authors applying the concepts to work with children (e.g., Neil Altman). These theorists have also been informed by convergences with infant and attachment researchers such as Daniel Stern, John Bowlby, Mary Main, and Mary Ainsworth. Rather than emphasizing the role of drives, defenses, resistance, conflict, and other traditional concepts these authors assert that the basic building blocks of mental life are relations with others upon which major psychic structures are built. This reflects a shift in the foreground from an intrapsychic focus to a relational field model, from objectivism to constructivism. Consequently there has been a shift in emphasis in treatment from *interpretation* to the *"co-creation of developmentally needed relational experiences"* (Jay Greenberg and Mitchell). Recently there has been a convergence of attachment, self-psychological, and relational perspectives. This is embodied by the work of Peter Fonagy, Mary Target, Efrain Bleiberg and others who have written about the central importance of *mentalization,* or self-reflective function. This ability to read and understand the feelings, thoughts, and impulses associated with human behaviors is fundamentally dependent upon the establishment of secure attachments. In the past several years this has led to MBT, a

manualized therapy approach that has been evaluated empirically, primarily in adolescents. Even more recently, neuroscience-based understandings have begun to be integrated into PDP with books such as Siegel's *The Developing Mind* and Delgado, Strawn, and Pedapati's *Contemporary Psychodynamic Psychotherapy for Children and Adolescents: Integrating Intersubjectivity and Neuroscience*.

While clinical work with infants is beyond the scope of this chapter, a great deal of parent–infant psychotherapy has been based on psychodynamic principles. Psychodynamic theory has influenced the field beginning with Selma Fraiberg and early programs developed by Alicia Lieberman, up to present-day evidence-based treatments such as parent–child interaction therapy.

It should also be noted that the term "psychodynamic" was originally used to describe the ever-changing balance of mental and neurophysiological energy intrinsic to man's inner life. This was contrasted with an approach that emphasized behavior, descriptive phenomenology, or anatomic structure. In this sense, psychodynamic and psychoanalytic are not synonymous. In the United States there have been a number of influential writers who would be considered within this broad psychodynamic tradition, even though they were not psychoanalysts. These psychodynamic therapists (e.g., Frederick Allen, Clark Moustakas, Ann Jernberg, John Meeks, Virginia Axline, and more currently Charles Schaefer, Garry Landreth) have also had a major place in the history of child and adolescent psychotherapy and continue to influence current practice.

THEORETICAL ISSUES IN PSYCHODYNAMIC WORK WITH CHILDREN

Beginning from its earliest days child psychodynamic psychotherapists have recognized that there are developmental differences between child and adult patients. While the overarching theoretical issues in PDP reviewed above hold, there are fundamental differences in work with children and adolescents as compared with adults.

Children are not "little adults." Child patients differ in significant ways from adults. These differences are crucial in informing practice. Firstly, children's limitations in language, cognition, and experience must be taken into account to engage and sustain children in treatment. Because of cognitive and emotional limitations, their understanding of the problem or the need for treatment is likely to be incomplete or inaccurate. Children tend to externalize problematic issues and have little ability to understand how therapy might help them now, let alone in the future. Further they have limited capacity for tolerating pain and anxiety, creating another barrier for keeping child patients in treatment. Meeting with a stranger who will meet and talk intimately with the child is certainly extraordinary, and may be confusing and threatening. For all these reasons the child

therapist must *actively* woo, educate, and work with the child to create the secure space needed to establish a therapeutic alliance.

Another major difference is that children do not come to treatment at their own request. They are brought by their parents, often for reasons that are more of concern to the adults rather than to the child. Further, the stigma associated with treatment is often difficult for children (especially adolescents, who are struggling to feel "normal" and "like other kids"). The reasons for treatment must be explored and explained in a way that is understandable and meaningful to the child. The rationale that engages the child may be different from the reasons the parents bring the child in.

A 7-year-old boy was brought for treatment by his working-class parents who were concerned about his depressive irritability and argumentativeness, which had created great tension in the family. When seen individually, the therapist asked the child about his understanding of why they were meeting. The boy responded "I don't know." The therapist then asked why he thought the parents had brought him, and he again avoided the question. Later in the interview the therapist returned to the issue while the child played out a puppet scene of different animals fighting. The therapist explored how the animals felt and the child said "sad." As the play developed, the therapist explored whether the child might also be sad. This seemed to resonate and the child nodded his head "yes" and went back to playing with the puppets. As the session closed, the therapist suggested that in meeting together they might come to understand "why you feel sad and what we can do to help you feel better. How does that sound to you?" The boy looked up shyly and nodded his approval.

The child psychotherapist must recognize the critical and central role of the parents or caretakers in the child's life. At a minimum the therapist must be able to sustain enough of a relationship with the parent(s) or caretaker(s) to support the treatment of the child. The parents must be engaged sufficiently to bring the child to treatment, pay for the treatment, and withstand their own emotional reactions that may arise as the child changes. Further, a positive alliance with the parents can sustain a child patient through the usual feelings of reluctance to coming to treatment. Ideally the parents can be assisted in fostering sturdier attachment, boundaries, and mentalization. This all requires the psychodynamic child therapist to develop a solid working relationship with the parents while at the same time preserving a sense of confidentiality and trust with the child.

A 10-year-old girl was seen in twice-weekly PDP. As the child left her sessions, her mother each time asked "how is she doing?" The therapist made a separate appointment with the parents to discuss these concerns further, while also exploring how the child felt about this meeting. The girl had concerns about "what they are going to say about me," but assented with support and understanding from the therapist. After discussion with the parents it was agreed that the therapist would meet with the parents once every 3 weeks to discuss the child's progress and current functioning, provide support and guidance to the parents, and monitor the parents' anxiety. Once this plan was initiated, the mother's anxiety seemed to lessen and she no longer waited expectantly after the sessions with her daughter.

The child patient is dependent on the parents materially, physically,

and emotionally. This has profound implications and has led to the conviction, even among the most traditional child psychoanalysts, that therapeutic work with the parents is essential and necessary in working psychodynamically with children. Furthermore, the ongoing interactions with caretakers have a continuing effect on the growth and progress of children in therapy. Because a child's personality is unfolding and shaped strongly by continuing developmental experiences, the ongoing parent–child interactions have a "double-barreled" effect. They not only affect the child's developing internal world of expectations, assumptions, and beliefs about self and others, but then in turn impact on the child's exposure to future developmental experiences. By inhibiting or encouraging exposure to growth-promoting developmental experiences, the ongoing parent–child interaction exerts a multiplier effect on the child. This observation strongly influences the overall aim of PDP with children, which, as initially articulated by A. Freud, is to restore the child to the path of normal development. Once back on track, normal development can then take over and provide the experiences needed for internal growth. From a psychological perspective, the child's dependency also impacts the individual treatment directly. Adolescents, especially during the early teen years, are struggling mightily to separate from their parents and establish an independent sense of self (i.e., identity). As a result, looking to and depending on another adult, like a therapist, can be fraught with complication and ambivalence. This can interfere with the establishment of a therapeutic relationship even when the adolescent recognizes a need for help.

Children and adolescents evoke stronger emotional responses in psychotherapists attempting to help them. As is known by anyone who has spent any time working in child mental health settings, children evoke strong feelings in the therapists who work with them. This often results in desires to protect and rescue the child, especially when therapists observe here-and-now pathogenic interactions and traumatic experiences enacted by parents. At other times the child's behaviors can be exasperating, infuriating, and frightening. All of this results in feelings within the therapist that are generally much higher in intensity than those generated in adult work. This places a premium on the therapists' recognition and containment of their own emotional responses. While these reactions may be helpful clues in understanding the child's world, they can make for highly challenging work.

Play is the central medium for communicating with younger children. Since its initial recognition by early psychoanalysts, play has been recognized as the critical in communicating with children in PDP. This is especially true for younger children whose language skills have developed to a limited degree and for whom play is their "natural" language. Older children are increasingly comfortable talking about their own inner states

and by 9 or 10 may find playing "babyish." Whether or not to use play materials with an individual child must be determined on a case-by-case basis. Psychodynamic psychotherapists will encourage play by having a number of toys visible and accessible to the child. This helps to engage the child and conveys that the therapist is willing to meet him or her on "their turf" and create a safe space for talking about their problems. Much of the "talking" is done "in the displacement" of the play as opposed to the direct discussion that occurs in therapy with older adolescents and adults. Most therapists recommend a limited number of toys that allow for the symbolic expression of a wide array of affects and themes (e.g., doll house, dolls, puppets, animals, blocks). Art materials (drawing, painting, clay) and techniques (e.g., Winnicott Squiggle Game), storytelling (e.g., Gardner Mutual Storytelling Technique), and role playing are often incorporated into dynamic therapy. Therapists also may utilize structured games (e.g., checkers, chess) or therapeutic games (e.g., The Talking, Feeling, and Doing Game) in some circumstances.

As Winnicott has pointed out, play exists "in the space between" the inner world and external life, *between* the patient and the analyst. Play requires active participation from both the patient and the analyst. It is aimless and nonpurposeful; there are no social consequences. As such, play allows for the safe exploration of affects, conflicts, areas of concern, ideals, roles, and wishes. This accords play a self-healing effect in and of itself. Play is a forum for problem solving and experimentation. Play also offers a window into the inner life of the child. This allows for a deepening of the understanding of the child and may be the basis for targeted interventions. As Winnicott has written, when play is not possible then the work of the therapy is to help the child to be able to play.

A 4-year-old boy from a poor urban family was brought for treatment because of severe aggression and destructiveness of long-standing duration. In addition to an evaluation for medication the child was seen in twice-weekly psychoanalytically oriented psychotherapy. The beginning sessions were marked by the repeated need to set limits and contain the child's aggressive behaviors. Two months into treatment he began to pump himself up, roar, and announce that he was "the incredible hulk." He would then proceed to stomp around the play therapy room, at times attempting to hit the therapist and kick the door. The therapist then said: "You know you can't really *be* the hulk. You can *feel* like the hulk ... you can *pretend* that you are the hulk. Then maybe we can play this hulk thing together." After a number of similar exchanges the child gradually became able to contain his behavior and play at being the hulk, without becoming the hulk.

Transference in children and adolescents is more complex than with adults. Much controversy has surrounded the concept of transference in work with children. Children's internal representational world is still being actively formed and altered by ongoing current interactions with parents and others. As such, transference reactions, while organized to a degree, are still in flux. Nevertheless, transference reactions occur ubiquitously in

PDP as children enact the beliefs, assumptions, and expectations they are developing. These reactions are here-and-now examples of the prototypical interactions that are interfering with their growth and development. Interpretations of transference phenomena primarily address this here-and-now aspect ("perhaps the nervous feeling you have is because of some anger you are feeling") and much less so, address genetic roots (i.e., the analyst would less often make interpretations about the child's reaction being connected to previous experiences with parents). PDP focuses its greatest attention on these transference reactions, seeing this as the most powerful arena to help children gain flexibility and greater freedom in their understanding of themselves and their interactions with others. Psychodynamic work with children is made more complex because the child's transference reactions intersect with the parent's emotional needs and vulnerabilities. This can lead to divided loyalties between the child's desire for growth and the parent's needs. Countertransference reactions are seen as invaluable clues to understanding the transference reactions and warded-off self-experiences of the child.

Barriers to change exist within the child patient (i.e., resistance) and within the family system. Resistance is a concept that originates in classical theory to describe the inevitable intrapsychic barriers to growth. Traditionally, this is thought to derive from conflicts between the patient's ego, identity, and superego. Subsequent theorists have conceptualized this differently. Some have understood these barriers as attempts to master traumatic experience. Others have seen the terror and dread of changing and giving up familiar ways of seeing oneself and others as central. Still, other contemporary theorists discard the term entirely as implying an adversarial and passive attitude that resides within the patient. Instead, they account for these impasses as the child's understandable emotional response to the absence of needed relational experiences and empathic failures by the therapist.

While resistance is typically seen as intrapsychic, there are also systemic barriers to change. As the child becomes less symptomatic and grows psychologically, the parent's self-concept, parent–child or marital relationship may become challenged. This, in turn, can create an additional impediment to the child's progress and requires the therapist to attend and respond to the parents' anxiety about change.

An 8-year-old boy was seen in individual PDP for separation anxiety disorder. As the child's symptoms lessened and he developed greater confidence, he began to experiment with desires to move out from the orbit of his family and expressed interest in playing on a soccer team. This, in turn, stimulated the mother's worries about the child's physical and emotional safety. She turned to her husband for increasing support and empathic understanding, revealing a long-standing issue in the marriage. The parents were not able to negotiate this in a more satisfactory way. These systemic implications impinged on the child, and created a check on his progress.

There is an increasing focus on attachment, mentalization, and self-regulatory issues versus oedipal issues. Classical theorists have highlighted the central importance of oedipal issues in understanding both psychopathology and treatment. Early case descriptions appear to explain clinical phenomena almost entirely through this lens and treatment appears to hinge on adequately addressing through interpretation these oedipal issues consistently. Triadic relationship patterns and issues of competition, sharing, sexuality, and rivalry are paramount. In contrast, contemporary theorists have instead placed the primary focus of understanding psychopathology and treatment to early parent–infant interaction, "basic trust," attachment, separation-individuation concerns, self-reflective process (mentalization), and self-regulation. While not disavowing a place for triadic issues, this has prompted a major shift in emphasis to dyadic issues.

An 8-year-old boy is brought for treatment because of his multiple fears and poor academic performance. Toward the end of the psychotherapy, after the child had made much progress, his father attempted suicide. While the original symptoms could be understood as a reflection of oedipal issues (e.g., castration fear and guilt over rivalry with the father, leading to academic inhibition and fearfulness), contemporary theorists would also emphasize the boy's anxiety over separation and loss due to his father's own attachment issues and tenuous commitment to living. Consideration would also be made of the security of the boy's attachment with his mother and his sense of a "home base."

While interpretation was seen in classical viewpoints as the central determinant of how psychodynamic psychotherapy works ("therapeutic action"), alternative explanations are now in ascendancy. Classical analysts have emphasized the central role of interpretation and "making the unconscious conscious" in the treatment of children. Interpretations proceed from that closest to consciousness to those mental contents furthest away (i.e., unconscious). This is especially important with children. These interpretations may be directed toward defenses, wishes or intentions, or transference phenomena. Interpretations are traditionally made in a specified order, from the manifest level to what is unconscious: first affect or behavior, then defense, then impulse. In other words, the analyst first would interpret the affect or behavior ("You appear to be feeling angry right now"), followed by the defense ("perhaps you are angry because you were disappointed that I did not remember your birthday"), and finally, the underlying impulse ("perhaps you were really hoping that someone would remember your birthday"). Timing of interpretations must be aligned with the patient's readiness and the state of the therapeutic alliance. Theorists differ in what they see as the primary impulses or fundamental motivators. Classically oriented analysts follow Freud's original drive theories and see sexuality and aggression as primary; contemporary analysts might emphasize self-cohesion, self-regulation,

attachment, mastery, and assertion as the most powerful organizers of motivation. Contemporary theorists hence would see therapeutic action as stemming from the provision of needed relationship experiences that allow for the development of a cohesive and vital self. Fonagy, Bateman, and others have attempted to bridge these views, attachment theory, and cognitive neuroscience by highlighting the goal of mentalization. Mentalization, or the self-reflective capacity, enables the child to perceive and process mental activity in the self and others. This allows the child to develop a model of the inner thoughts and feelings that underlie human behavior. Optimally, this capacity develops out of the child's early attachment with parents who relate to the child as an intentional being with underlying thoughts, feelings, and intentions. As a result of these experiences, the child is then able to understand others' behaviors and inner states. These theorists posit that this is the centerpiece of psychoanalytic work with children (and adults) and success depends on the degree to which this develops.

PRACTICAL MATTERS

Psychodynamic psychotherapy with children and adolescents can take differing forms and the principles can be applied in work with individuals, groups, and families. Classically, child psychoanalysis involved seeing the child four or more times per week, lasting over a period of years. In this form, psychoanalysis is rarely used currently, although there is some research to suggest it may have a place with particularly disturbed children (see Research section). PDP occurring once, or perhaps twice, per week over a period of months to years, is much more common in both private practice and public clinic settings, although it is increasingly difficult because of payment issues and the hectic pace of family life in the United States. The nationalized health systems in the United Kingdom and Canada continue to support such treatments widely.

While typically open-ended in length, there have been recent adaptations of brief, time-limited PDP to work with children. For example, IPT has been applied to work with adolescents and likely will be adapted to work with children. Psychoanalytic principles have also been widely applied to group and family therapies. As noted previously, psychoanalytically informed principles often are integrated into all treatment efforts with the child. Owen Lewis has delineated such a model of integrated treatment in which psychodynamic principles fundamentally inform the gamut of treatment interventions (e.g., behavior therapy, psychopharmacology, family therapy, and so forth). The more recent review by Malberg and Mayes (The Contemporary Psychodynamic Developmental Perspective) elaborates on this evolution.

Perhaps, even more than in work with adults, the therapeutic frame and setting are critical in working with children and adolescents. Child

therapy requires a dedicated office that can serve as a concrete reminder of safety, security, and predictability for the child. Using the same office for every session fosters these goals. Some analysts create special cubby holes or boxes for children to keep their particular toys, drawings, and so forth. This also serves to personalize the space for the child. The office should be neither so small that the child feels closed in, nor so large that the child is overwhelmed and overstimulated. An explicit therapeutic contract should be discussed with the child and parents. Children should not be forced to attend therapy although reluctance is not uncommon. Assent (vs. consent) is a more appropriate goal. It is generally recommended that therapy occur at the same time, on the same day of the week. This also strengthens the predictable frame necessary for successful work. All these ingredients contribute to establishing what Winnicott referred to as the "holding environment."

Confidentiality is a particularly complex issue with children. On the one hand, there is a clear need to maintain a sense of safety and security in order for the child to reveal his/her deepest worries, hopes, thoughts, and desires; on the other hand, therapists have a legal and ethical obligation to safeguard the child's welfare. When issues of safety (e.g., suicidality) arise, parents must be informed. At other times, the involvement of child-protective authorities may be needed, which in some situations may end the treatment. In any event, the limits and extent of confidentiality should be carefully explained to both the child and parents at the beginning of treatment.

Working with parents is essential in psychotherapy with children and adolescents. As already noted, parents are decisive players in PDP with children. Although there are times that the parents need to honor the necessary boundaries of treatment with the child, it is seldom appropriate that the parents are excluded from the treatment. Typically, parents are included from the beginning to obtain the history and to begin to establish a working relationship that can sustain the treatment of the child. At the conclusion of the evaluation period, it is helpful to explicitly review the assessment and establish a treatment plan with the parents. The analyst must reach concordance with the parents on the nature of this treatment contract from the beginning and may need to revisit this throughout the course of treatment. Regular meetings with the parents (with or without the child) are routine parts of PDP. These ongoing meetings serve to maintain the working relationship, provide further information about the child, and create a forum for parent guidance or exploration of parental psychological issues that impede the child's growth. When it becomes apparent that the parent(s) are in need of their own treatment then referral is generally made to another therapist. Providing PDP to two members of the same family contemporaneously is discouraged due to the inherent conflict of interest and encroachment on confidentiality that may undercut

the alliance with one or both persons.

CLINICAL CONSIDERATIONS

The aims of psychoanalytic psychotherapy are ambitious. Psychoanalytic psychotherapy aims to go well beyond the relief of symptoms and/or greater coping or adaptation. With adults, the goals have been to seek a "cure," broadly improving the quality of life (i.e., "to work and to love") and inoculating the patient from future stressors. In contrast, A. Freud first articulated the aims of child psychoanalysis as a return to the path of normal development. Subsequent analysts have emphasized the aims of increased mentalization, self-understanding, self-regulation, personality integration, self-expressiveness, self-esteem, flexibility, increased frustration tolerance, and capacity to play. It is assumed that the reaching of these goals in a "good enough" fashion will result in a diminution of symptoms as well as improved functioning in school, in the community, with peers, and family members.

The indications for psychodynamic psychotherapy generally include children with internalizing disorders. Indications for PDP have historically focused on the presence of certain strengths, or loose categories of problems generally seen as due to intrapsychic conflict. Typically, indications have included those children with neurotic level disorders and sufficiently good internal and external resources such that the gains will be sustainable following termination of treatment. This situation rarely exists in clinical practice. Further, research has indicated that this group of children may benefit as well or better from less intensive treatment efforts involving the school, family, or community resources. At the same time children with more severe disturbances, often subsumed under the category of borderline conditions, may require an intensive effort such as psychoanalysis for effective results to be achieved (see section on Research and Evaluation). Another way to look at indications is to consider the goals of the treatment. For example, if the goal is to understand one's feelings, thoughts, and the connections between this inner world and the outer world of behavior (mentalization or self-reflective function) then a PDP is likely to be helpful. Because PDP is now generally integrated with other treatment approaches, it is not necessary for this treatment to be all encompassing but rather to aid in forwarding critical developmental processes.

There are some children for whom psychodynamic psychotherapy is not likely to help or is contraindicated. Contraindications include children with externalizing problems, especially when there are "callous-unemotional" features or when there is no comorbid internalizing disorder or an inability to restrain impulses consistently enough to play. Another group of children for whom there is little to justify this treatment would be in children with more than mild mental retardation, classical autism and

many autism spectrum disorders, and traumatic brain injury (and other neurological conditions) when receptive language abilities are substantially compromised. These may be relative contraindications as there may be focal psychodynamic goals even in some of these cases. Again, treatment for many of these individuals will be multimodal and other treatment modalities may be more critical (i.e., school interventions for children with autism-spectrum disorders).

AN OVERVIEW OF THE PHASES OF TREATMENT

Beginning Treatment: Focusing on the Establishment of a Working Alliance

This requires not only creating a therapeutic ambiance for the child but also establishing a supportive, working relationship with the parents. The initial goal with the child is to create a playful, confidential environment in which he/she and the therapist can explore the world of the child's thoughts, feelings, and behaviors. In the beginning, some exploration and understanding of why the child is meeting with the therapist is useful as well as an explicit clarification of the treatment frame and contract ("we will be meeting for 45 minutes every Tuesday at 4:00. This time will just be for us. We'll try really hard to meet every week"). It is also helpful for the therapist to explain to the child that he/she is "someone who meets with kids to help them with their feelings," "to see if we can understand you," "to help you feel better," "to help you understand how you feel and why you do some of the things that cause you trouble," and so forth. The gist of these comments is to explain the role of the therapist and to convey a steadfastly hopeful attitude to the child (and parents) through what will be inevitable ups and downs. For the playroom to acquire a "specialness" to the child, these messages must be communicated repeatedly. The ground rules also should be explained ("we will talk and play together during the time we are together. Anything is okay as long as no one gets hurt and nothing gets broken.") Of course once the child begins to express him/herself, they will see what the therapist is "made of." This is the true acid test for the child. Only over time can the child get the sense that the therapy is not a punishment, that the therapist has hope for the child, the child can feel understood, and problems can be solved. For the most part, in the initial phase the therapist keeps his/her comments and interpretations focused on the displacement of the play rather than making direct comments about the child's real life situation. This initial launching typically takes a few weeks (in the healthiest children) to a number of months to achieve a secure working relationship.

Mid-Phase Treatment

Begins when the child has established a clear working alliance. The child has a familiarity with the frame of treatment, even though emotional

upheavals may continue in the sessions. During this phase, the primary emphasis is on the "work" of therapy, that is, the slow and repetitive recognition of feelings, defenses, and their relationship to behaviors. Over this time the same theme in a play session may occur for months at a time. The therapist continues to create with the child a sense of hope and comfort, as increasing recognition and understanding of the child's inner world accrues. It is in this phase that interpretation of prototypic problematic patterns and transference reactions occurs. The focus on the here-and-now reactions of the child with the therapist is especially fruitful, although much work continues to be done in the play displacement. Gradually in this phase, the child becomes more able to connect this displacement with his/her own life. Reconstructive statements linking current emotional or behavioral patterns with previous life experiences are generally not emphasized in work with children.

A 10 year old is in PDP three times per week because of severe obsessive compulsive disorder. In most sessions, beginning from the fourth month of treatment and lasting until the eighth month, the child would crawl under a table, conducting conversation from this womb-like space they had created. The analyst commented to the child, who had been born 2 months prematurely, "It feels like a really good place to go to when *you* want, and to be able to come out when *you* want." This interpretation emphasized the current emotional experience of the child, rather than linking this in some direct way to the child's real life experience (e.g., "you want to climb back in your mother's womb and are angry that you can't"). Connecting the here-and-now with the past must be timed carefully so as not to be experienced as confusing and overwhelming to the child.

Ending Treatment

Optimally, treatment ends when the child is free from symptoms, has made sufficient progress in psychological growth and maturity, and is back on track developmentally. In the real world, termination generally comes about for other reasons. Frequently, termination occurs when partial improvement has been made and practical considerations (insurance, finances, transportation, moves, graduation) become paramount. Termination provides an opportunity for the child to focus on issues of separation, loss, and mourning. Paulina Kernberg has elegantly stated:

> "As the child approaches the end of her treatment, the same issues that brought her to therapy once again come to the fore: (1) Do they (the parents) care? (2) Does the therapist care? (3) Do I care for you (the therapist)? (4) Do I care for them (the parents)? (5) Can I care for myself? (6) Will you remember me? (7) Will I remember you?"

In the process of ending, it is important to include the child actively in setting a final date. Generally 6 weeks to 3 months is sufficient time to allow the child and family to meaningfully concentrate on these issues. Setting the date so that it does not coincide with other real-life endings (e.g., graduation, moving dates) permits the child and family to experience the fullest impact of the termination. During the ending phase children

frequently regress, with a recurrence of symptoms and defenses in the face of this stressor. Denial of the importance of the relationship by the child, parent, and therapist is not uncommon and should be understood as reactions to the impending separation and loss. In the course of ending, the child should have an opportunity to explore and claim the gamut of feelings that inevitably arise: anxiety, guilt, anger, sadness, satisfaction, ambivalence, and so forth. This frees the child from developing defensive patterns to face the inevitable future losses of life.

After 8 months of weekly psychotherapy an 11-year-old girl's symptoms of perfectionism and severe recurrent abdominal pain had improved sufficiently that the child came in and stated that "I don't have pain! I don't need to come here anymore." She later added that "maybe I need help with boys." This led to a series of discussions about termination, which resulted in the setting of a final date 6 weeks hence. In the first meeting after the termination date was set, she revealed that she was able to comfortably talk with the therapist, unlike with her parents with whom she felt she could not be open. The next week she became irritated by a comment of the therapist and said "If I had known you would say that I would have left weeks ago!" She continued to talk about other separations in her life, especially the death of her grandmother. In the final sessions she alternated between denial and recognition of her emotional reactions about the upcoming termination. She continued to discuss other endings, moves, friends leaving. In the last session she said: "Okay. I have something to say. I think I'll miss you. You helped me." To which the therapist responded: "Well we have worked well together. And I will miss you too." She left the session knowing that she could make future appointments if the need arose.

RESEARCH AND EVALUATION

Although virtually nonexistent 30 years ago and lagging behind that with adults, research into the efficacy of psychoanalytic psychotherapy with children has been growing. Because of psychoanalysis' emphasis on the fundamental uniqueness of each individual, single case studies have been preferred traditionally. These have typically been reported as detailed narratives without the systematic or objectified approach typically taken in reports of behavioral or psychopharmacological treatments. With the ascendancy of the randomized controlled trial (RCT), this traditional psychoanalytic approach has been widely seen as lacking. While there remains persistent criticism within psychoanalytic circles of the overvaluation of the RCT, there is greater acceptance of the need for RCTs involving PDP. RCTs are seen as necessary, but not sufficient, to establish a treatment as "evidence-based." Patient values and preferences, long-term outcomes, and clinician's observations also are held as important factors as well (see Palmer, 2013). Its typical length, ambitious aims, the complexity of operationalizing goals, and the difficulty in manualizing the approach have been serious barriers to applying the RCT model to psychoanalytic psychotherapy. Despite this, there have been increasing efforts to evaluate PDP with adults as well as children and adolescents. A more recent problem is that the evolution of psychotherapy has occurred in such a way that psychodynamic principles are increasingly integrated into more focal

or modular treatments. For example, IPT is clearly rooted in psychodynamic principles and has been adapted in adolescents. Many other branded therapies, for example, parent–child interaction therapy, mentalization-based treatment, adolescent-focused therapy, attachment-based family therapy, and floor time, among others, have strong psychodynamic foundations. Further, the emphasis on the therapeutic alliance that began with psychoanalysis now is accepted as a key component for virtually all psychotherapy. Many of these treatment approaches have been investigated empirically although, are not generally included in reviews of the traditional research base for PDP. Much of the literature on PDP has been conducted on small numbers of real-world patients with multiple diagnoses and with broad definitions of PDP. While the largest studies have been observational, there have been a limited number of RCTs and some quasi-experimental design studies. The largest empirical study of psychoanalytic therapy with children has been carried out at the Anna Freud Centre (formerly known as the Hampstead Clinic) by Fonagy, Target, and others there. Recently there have been several systematic reviews of the literature, the most recent by Midgley (2011), Abbas (2013), and Palmer (2013). Following extensive searches and rigorous inclusion criteria, they identified over 30 primary studies that involved over 1,200 patients. This represents a significant increase in studies from 10 years ago but still must be considered limited, especially when compared to studies of other psychiatric treatments. These systematic reviews come to generally, though not completely, concordant conclusions:

1. There is some evidence to support the effectiveness of psychoanalytic psychotherapy of children and adolescents.
2. Children with internalizing disorders tend to respond more favorably than those with externalizing disorders; further, externalizing disorders require greater intensity of treatment to be effective. In particular, there is evidence to support PDP for children with depression, GAD, separation anxiety, anorexia nervosa, traumatized children (especially younger ones); conversely there is little evidence to support its use in OCD.
3. Support and involvement of parents in treatment is essential and may highlight the narrowing distinction between family and individual psychodynamic approaches.
4. Younger children respond more favorably to this treatment than older children and adolescents, but sufficient frequency of sessions must be achieved to produce positive outcomes. For adolescents length of time in treatment appears relevant, although there seems to be little benefit from increased frequency of sessions.
5. Children with conduct disorders appear least likely to respond; children

with psychotic disorders, receptive language disorders, and intellectual disability (i.e., mental retardation) are also unlikely to respond to this form of treatment. Children with autism generally do not respond well, although there is evidence that there may be a place in the broader autism spectrum group for approaches influenced by psychodynamic principles.

6. The typical "good patient" (i.e., "neurotic," higher functioning, less disturbed child) responds as well to low-intensity treatment as high-intensity psychoanalysis. As such, from a cost-effectiveness perspective, it is hard to justify psychoanalysis for this population.
7. Conversely, the more disturbed child (e.g., what have been referred to in the past as "borderline," multiple complex developmental disorder, multidimensionally impaired) may require high-frequency treatment to produce any positive results; lesser forms of treatment appear to offer little benefit and may even worsen the outcome.
8. Some studies indicate that patterns of improvement may reveal a "sleeper effect," whereby positive effects continue to accrue after treatment has ended.

Of note, recent national guidelines have included PDP as recommended treatment for two conditions. The NICE guidelines now include PDP as an evidence-based treatment for depression in children and adolescents. In 2015, the AACAP Practice Parameter for Eating Disorders included adolescent-focused therapy as a recommended treatment in cases of anorexia nervosa when family-based treatment was not available or acceptable to the patient and family.

While the empirical data supporting psychoanalytic psychotherapy with children is growing, larger-scale studies for more targeted populations and improved case studies continue to be needed. Recently, a number of studies have been initiated to better address the research gaps. In the best example, Goodyer has embarked on a large RCT (540 adolescent subjects) testing the efficacy of PDP in the prevention of relapse for moderate to severe depression. The other two arms of the study include cognitive-behavior therapy and specialist clinical care (a nonspecific supportive approach). This study is also using magnetic resonance imaging to identify neural mechanisms that may predict response to targeted treatments in individual patients. Other studies are underway, targeting children with severe anxiety, bulimia, personality pathology, and social anxiety. All of these studies will be welcome additions to support the use of PDP. At the same time, psychodynamic approaches will continue to be incorporated into other forms of therapy as the field continues to strive to find "what works for whom."

FUTURE DIRECTIONS

Psychoanalytically informed psychotherapy has a long tradition in child and adolescent psychiatry. Many practitioners over many decades have found this orientation extremely helpful for large numbers of child and adolescent patients. While it has remained vital intellectually and clinically, there is better empirical support for PDP with adults and additional research support for its effectiveness with children and adolescents is needed. Larger studies are underway and by the next edition of this textbook, this approach may be on much stronger empirical ground, clarifying the indications and contraindications for this approach (especially understanding those patients or clinical problems for which this technique is especially or uniquely relevant), its mechanism of action, and critical areas of technique. Increasingly elements of psychodynamic thinking and practice have been incorporated into other brands or modalities of psychotherapy. This trend is expected to become more prevalent as the field moves to more targeted, individualized therapies.

▲ 54.2 Brief Psychotherapies for Childhood and Adolescence

ANTHONY L. ROSTAIN, M.D., AND MARTIN FRANKLIN, PH.D.

INTRODUCTION

Improvements in the current understanding of developmental psychopathology in children and adolescents have prompted a shift from nonspecific interventions toward more problem-focused treatments that target specific diagnostic categories and, within diagnoses, symptoms. Indeed, in the past several decades a diverse range of empirically supported cognitive-behavioral and pharmacological therapies have been developed that cover a broad range of childhood-onset disorders. Herein, first a brief overview of the theoretical rationale for cognitive-behavioral therapy (CBT) treatment of youth with psychiatric disorders is provided, combined treatments are discussed briefly, and then the extant literature on short-term psychosocial treatments for internalizing and externalizing disorders is summarized. Though still widely used in clinical practice, psychodynamic approaches, "play therapy," and other therapies that have not evaluated empirically via randomized controlled trials (RCTs) are not reviewed. Interpersonal psychotherapy (IPT), a short-term psychosocial approach to depression that was developed for adults but has now been extended down the developmental spectrum for use with adolescents, is a notable exception to this rule. Experimental interventions that are not best classified as psychotherapies, such as response inhibition training, attentional bias training, or other such procedures are not discussed. Their role in augmenting short-term treatments such as pharmacotherapy and psychotherapy needs to be further explicated, but at present they do not constitute "treatments" in the truest sense, nor does their collective evidence base justify placing them on equal footing with these other empirically validated interventions.

PROTOCOLS AND TECHNIQUES

Cognitive-Behavioral Therapy for Anxiety Disorders

Traditional treatment models in child psychology and psychiatry were guided by theories positing that psychological problems have their origin in historical relationship problems that must be uncovered and processed in therapy. CBT clinicians do not adhere to this view, believing instead that more direct methods should be employed to reduce symptoms, such as identification and correction of mistaken beliefs, confrontation with feared and/or avoided stimuli in a therapeutic environment, and/or by teaching the patient a set of adaptive coping skills for specific symptoms that are associated with distress and impairment. Befitting its deep roots in learning theory, there is also an inherent belief in CBT that change is

measurable, and thus a strong interest in assessing changes in symptoms over time in order to evaluate progress in treatment and to identify when modifications to the chosen approach need to be made. There is strong emphasis that the application of treatment procedures brings about changes in behavior, cognition and, down the line, emotion, rather than the positive interaction with the treatment provider. That said, CBT is still thought to be a collaborative process in which the therapist–patient alliance also plays a role in treatment success, and these nonspecific factors must therefore also receive attention in CBT supervision and training. With children especially, CBT should contain elements of fun and enjoyment in order to foster this important alliance and provide positive reinforcement for effort both during and between sessions.

Notably, the CBT approach, though rooted in cognitive and behavioral theories about the nature of psychopathology, is procedurally heterogeneous. CBT can involve working with parents, changing social, peer, and other environmental influences, as well as the use of behavioral contingencies and cognitive processing. Further, considerable tailoring to the individual disorder and associated symptoms is necessary for successful treatment, as is a full appreciation of the developmental and family factors likely to influence symptoms and hence require attention in therapy. Accordingly, CBT protocols vary, sometimes considerably, in their emphasis on behavioral versus cognitive mediators of change, in part depending on the nature of the disorder being treated and also in response to the many contextual factors discussed above. Nevertheless, an emphasis on the fundamental tenet that behavior and cognition are the horses whereas emotion is the cart cuts across CBT protocols for myriad disorders and problems.

Psychosocial Approaches for Depression

Just as with anxiety disorders, CBT programs for depression in children and adolescents vary considerably with respect to procedural emphasis but share some core theoretical and therapeutic assumptions. For example, a shared theoretical assumption is that depressed mood can be reduced by helping patients to identify and challenge faulty thinking, reduce certain behaviors such as avoidance and increase others such as engaging in pleasant, mood-enhancing activities, and improving interpersonal interactions and conflict resolution skills. Here again, protocols vary in the degree to which they emphasize one therapeutic component over another in order to affect change in mood symptoms and to improve psychosocial functioning but, according to experts such as Curry and Reinecke, successful CBT for mood disorders in youth should include providing psychoeducation about the nature of depression, assisting adolescents in monitoring moods; identifying and modifying maladaptive cognitions; and improving problem solving, affect regulation, and social skills.

IPT is a form of treatment for depression that posits that adolescents' depressive symptoms can be reduced and interpersonal functioning improved by focusing treatment on one of four problem areas: grief, role disputes, role transitions, or interpersonal deficits. The treatment is present focused and the development of skills to manage problems in these identified areas is a clear goal of treatment but, befitting its roots in psychodynamic theory, the importance of the therapeutic relationship is also strongly emphasized; a manual that is based on IPT is used to guide treatment with adolescents as conducted with adults. Unlike most psychodynamically oriented treatments, IPT is a brief psychotherapy that has been delivered in 12 sessions conducted over 12 to 16 weeks in school-based clinics for depressed adolescents and in an even shorter form when modified for use in a depression prevention study that was conducted by Horowitz and colleagues.

Internalizing Disorder: CBT Case Example

As a specific example of how the CBT model might be applied, take the case (composite) of a 9-year-old girl with separation anxiety difficulties that have resulted in occasional school refusal behavior. A diagnostic work-up determines that the primary diagnosis is separation anxiety disorder, with a secondary comorbid diagnosis of generalized anxiety disorder (GAD). The review of specific symptoms indicates that the child is intensely fearful of separation from her parents although more so from her mother than her father, is worried that something bad might happen to her parents or to herself during separations, reports increased muscle tension and uncontrollable worry that are associated with nausea, headaches when thinking about being separated from parents or when separated. Accordingly, the child will beg, plead, and cry to prevent her parents from leaving her at home with family members or with sitters. When she believes that something at school is likely to be stressful or unpredictable (e.g., performances, substitute teachers), she refuses to attend school, a behavior that her parents have decided for now not to challenge. Both parents report that the school refusal, the refusal to allow parents to leave her, and her increasing sense of withdrawal from activities in which she might be separated from parents (e.g., travel team soccer) are sources of significant tension in the home that is now spilling over to affect the marriage and the other younger siblings.

The CBT therapist in this case would first need to determine the parents' and patient's motivations for change, their recent history of how they have been managing separation issues, and their current understanding of the nature of the problem and the associated symptoms. If this discussion leads the therapist to believe that CBT targeting separation anxiety primarily (as opposed to primarily targeting GAD or family processes in this case) is appropriate for reducing these specific symptoms as well as overall family distress, he or she would likely work within the framework of one of the established protocols for separation anxiety such as Kendall's Coping Cat program. A detailed review of what happens in the family currently around separation, such as who drops off the child at school, what is said in the morning about compliance with parental requests and what is the child's typical response to requests to get

ready to go to school, how sitters are selected and how the child responds when the plan for the parents to go out without her are conveyed. The child's physical, emotional, and behavioral reactions must also be surveyed so that the therapist can begin to consider which elements to target first, which situations evoke the most distress, etc. It is also imperative to explain that the physical sensations of anxiety often mirror those of illness, and that differentiating between the two will assist the family in knowing when to proceed with the original plan and when the child is physically ill for other reasons.

The therapist must also assess the child and parents' motivation for change as well as the various things that the child finds reinforcing, which will then be used as part of the reward system that will help sustain motivation during the most anxiety-provoking aspects of treatment. A symptom hierarchy will then be developed that will reflect the key variables that influence anxiety around separation, such as duration of separation, degree of separation, which parent is instituting the separation, whether the event is parent or child oriented (e.g., child's soccer vs. parents' night out), and the rungs on the hierarchical ladder will be assigned a rating on the "Fear Thermometer" from 0 (no anxiety) to 10 (maximum anxiety). The reward system will be worked out in detail with both parent and child, so that accomplishments (e.g., staying at home with a sitter without calling parents' cellphone) and effort (e.g., monitoring progress between session) have a clear "point value" that can then be depicted on a sticker chart and reimbursed by approved items from the reward system.

Planned exposure to feared situations will play a key role in treatment, as will discussion of the nature of cognitions likely arise in anticipation of and during separation. Although CBT protocols vary greatly with respect to the degree of emphasis on cognition and the procedures used to identify and change mistaken or inaccurate beliefs, the essential ingredients all involve helping the child to recognize anxious thinking when it occurs, label it as such, treat these cognitions as testable hypotheses rather than as facts (e.g., "If I'm anxious now, I will be worse in an hour"), and then perform the experiments that will allow the child to see whether the anxious thinking is realistic or not. The development of alternative "coping thoughts" is then used to help the child manage anxiety in anticipation of or in the context of exposure, allowing the child to gain from distance from these unpleasant cognitions and continue to confront the feared situations without engaging in avoidant behaviors. In their seminal paper on emotional processing theory and its application to understanding the efficacy of exposure-based treatments, Foa and Kozak suggested that by doing so, exposure will provide corrective information (e.g., "My mom left me for the day but she came back, and I was able to handle it"), which in turn weakens the fear structure and results in between-session habituation that is characteristic of successful CBT for anxiety disorders. Some CBT

protocols will also include anxiety management training (AMT) such as relaxation exercises, but multiple RCTs in anxiety disorders for youth that have not included AMT have been found efficacious. Moreover, a dismantling study in adult panic disorder conducted by Schmidt and colleagues indicated that inclusion of breathing retraining in an exposure-based treatment actually compromised outcome rather than enhancing it, perhaps because the use of anxiety management strategies to prevent anxiety from escalating is inconsistent with the panic protocol's more general message, which is that anxiety and panic are simply false alarms, are not inherently dangerous, and are best ignored.

Treatment progresses as the child chooses exposures from the fear hierarchy and succeeds at conquering the lower and middle range situations, which in her case will likely involve permitting her parents to leave for specified amounts of time, minimizing the amount of delaying she does in preparing for school by rewarding her for on-time behavior (e.g., lunch packed and dressed by 8:15 AM on school days can be charted, as can 5 consecutive days of "on-time" behavior as defined above), and reducing avoidant behavior such as declining invitations to visit at friends' houses. Parents will be instructed by the therapist in how best to proceed when arguing and tantruming behavior does occur. They will be vigorously encouraged to follow the reward system faithfully and to provide social reinforcement (e.g., praise) for the child's efforts to confront feared situations using the new coping strategies of exposure and challenging anxious thinking.

Most protocols for anxiety in youth including separation anxiety recommend 12 to 20 weekly treatment sessions, the first several of which are devoted to psychoeducation and skill building, followed by exposure and cognitive training, then by the development of a tailored relapse prevention program to help the child and family maintain gains made during the core treatment phase. The efficacy data reviewed below are quite encouraging with respect to the degree and durability of improvement associated with CBT, and the current challenges facing CBT researchers involve determining which patients are likely to respond well to initial treatment, which are likely not to respond or to have clinically significant residual symptoms at the end of a full course, and what course of treatment to pursue next with those who fail to respond completely.

Cognitive-Behavioral Therapies for Disruptive Behavior Disorders (ADHD, ODD, and CD)

At the present time, the most empirically validated psychosocial treatments for disruptive behavior disorders (DBDs) in children and adolescents are based on CBT techniques adapted to the specific context of interest (e.g., family, school, residential treatment facility). These interventions include

carefully delineating and measuring positive and negative behaviors, identifying key antecedents and contingencies reinforcing these behaviors, developing a plan for increasing positive behaviors and extinguishing negative behaviors, finding appropriate rewards and consequences for the child's behaviors (including token economy systems), and closely monitoring the patient's responses to the plan. While differing in their emphasis, these therapies are directed at altering the behaviors of key adults in the child's world (e.g., parents, teachers, caregivers) so as to affect changes in the child's or adolescent's behavior. In addition, cognitive techniques are often employed to teach the child alternative responses to typically stress-inducing situations such as being directed to comply with instructions from an authority figure, being told "No" to a request or demand, not having wishes/desires gratified immediately (i.e., being frustrated), or having to share toys or activity space with peers.

As with treatment for internalizing disorders, DBD treatments are usually administered on a weekly basis for anywhere from 12 to 30 sessions. Initial sessions include delineating basic principles, teaching observation skills to parents and/or self-observation skills to children and adolescents, measuring baseline rates of key positive and negative behaviors, setting initial target goals (e.g., 25 percent fewer tantrums, 50 percent greater compliance with directives), developing rewards and consequences schedules, practicing the administering of rewards and consequences, and monitoring impact of the schedules on target behaviors. In most treatment approaches, instruction is provided in recognizing and managing one's own negative affects/behaviors/cognitions, and in developing alternative strategies to typical ineffective reactions to stress- or anger-inducing situations. For example, typical parental emotional reactions to oppositional defiance on the part of a child are highlighted and discussed in the context of a broader framework of spiraling negative interaction cycles leading to parental aggression or to parental relinquishing of authority, either of which are reinforcing the child's noncompliance. Patient-focused approaches provide tools for developing alternative responses to challenging or frustrating situations. Opportunities for practicing alternative responses through role modeling and rehearsal are provided during sessions, and assignments are given to carry out between meetings. Subsequent sessions include reviewing homework, obtaining feedback from participants about their ability to implement behavior management strategies, identifying barriers to implementation of the plan, and designing modifications to increase success during the intervening time between visits. Periodically, participants are asked to measure progress made toward desired treatment goals, to reinforce successful strategies where possible and if appropriate, to move on to other target behaviors. The greatest advantages of CBT for DBD are its adaptability to a variety of diagnoses, problem behaviors, and contexts; its

emphasis on practical and measurable outcomes; its inclusion of multiple participants (i.e., patients, families, teachers, and significant others); and the availability of a wide variety of treatment manuals.

Combined Treatments. A comprehensive review of the evidence base for pharmacotherapies for pediatric disorders is beyond the scope of this chapter, but there is a wealth of evidence supporting the efficacy of pharmacotherapy for many pediatric–psychiatric conditions, and that combined treatments have also proven efficacious, especially with DBDs. Careful inspection of the associated outcome data also reveals that although active medication has been found consistently superior to placebo virtually across the board, response to the available pharmacotherapies has been neither universal nor complete. Moreover, some children and adolescents have unfavorable side effects to these treatments that preclude their use altogether or compromise outcomes by limiting the doses that can be used. Accordingly, there is certainly still room for treatment development within pharmacotherapy, and for considering combined treatment approaches that include pharmacotherapy plus time-limited psychosocial interventions of established efficacy. If the evidence bases for pediatric disorders were truly comprehensive, selecting an appropriate treatment for a child or adolescent from among the many possible options and combinations would be reasonably straightforward. In the complex world of research and clinical practice, however, choices are rarely so evident. This is perhaps more so the case with those disorders in which few RCTs have been conducted, and hence the evidence base is insufficiently developed to provide confident conclusions about which treatments are most likely to be effective for a given child or, more specifically, whether combined treatment is necessarily superior to monotherapy with CBT or with medication. Few studies published to date have compared the relative and combined efficacy of CBT and pharmacotherapy for anxious youth, for example, and thus pediatric mental health practitioners are left without a substantive evidence base to inform their treatment recommendations regarding this critical question. In light of this reality, initial decisions to select monotherapy with CBT or pharmacotherapy or combined treatment are influenced by primary diagnosis, symptom severity, comorbidity, family factors, and readiness for change. Combined treatments should also be considered if an attempt at monotherapy with medication or CBT proves only minimally efficacious; in such cases, a second treatment can be introduced to address symptoms that are thought to be limiting efficacy, such as adding an SSRI for an anxious child whose comorbid depression negatively affects his ability to participate actively in CBT.

Developmental Considerations in Time-Limited Treatments

The treatment manuals for youth that have been evaluated empirically

typically run across the developmental spectrum, although the majority of the studies conducted thus far have involved children between the ages of 8 and 13 years. In the view of some in the field and perhaps best articulated by Westen and colleagues, manual-based treatments have acquired the reputation of being somewhat rigid. However, in contrast to this characterization, those who regularly conduct RCTs involving treatment manuals actually encourage therapists working with this framework to remain flexible with the application of the session goals, as life must be "breathed" into the manual to better fit the needs and functioning of the patient. The debate about the advantages and disadvantages of using manualized treatments in clinical practice has been the topic of many papers and books in the last decade. The authors are confident that this will lead researchers as a field to be both responsive to the evidence base for clinical interventions as well as to the practical realities of the clinical contexts in which most children and adolescents who seek treatment for psychiatric problems will receive their clinical care.

With respect to the flexible application of core treatment principles, it is essential that therapists using CBT protocols are fully cognizant of developmentally related differences across the targeted age ranges in physiological functioning, emotional vulnerability, social and peer pressures, and comorbid conditions, as well as any other changes that these children may be experiencing. The nature and extent of family involvement in treatment will also necessarily vary depending on the age and developmental level of the child. This important treatment consideration is explained below.

Experts such as Kazdin and Kendall recommend that the structure and process of manualized treatments should differ somewhat for children and adolescents, respectively, although the general format and goals may well be the same across development. Even within more truncated age ranges, developmental factors still have to be taken into account as treatment is conducted. Perhaps this is best illustrated around the issue of parent involvement in treatment. Indeed, parental involvement is likely to vary based on developmental factors on the following dimensions: (a) amount of time a parent/parents will be present in each treatment session; (b) the role parents will play in assisting patients with implementation of treatment techniques such as self-monitoring, incentive plans to enhance motivation, and use of core techniques at home and in school; (c) the role of parents in interacting with relevant school personnel regarding the child's efforts to combat specific symptoms with treatment techniques in the school setting; (d) degree of emphasis on privacy and respect for the importance of individuation; and (e) parental assistance in helping patients negotiate the increasing importance of peers and dealing with concerns that others might discover the patient is in treatment. For example, a 10 year old might benefit from more formal parental assistance with self-monitoring tasks

and with the development of an incentive plan to promote motivation to use the treatment strategies in "high-risk" situations at home; doing so might necessitate more time in session with the parent present to ensure that all parties are in agreement and that the parent's role is made clear. Treatment for the typical 17 year old should take into consideration the adolescent's need for individuation and privacy, and provide them control over the amount of disclosure about treatment that they are comfortable with while also helping parents feel like they remain "in the loop." As a guiding principle, it is important to note that the treatment protocol is designed to allow for what Kendall calls "flexibility within fidelity." This means that while the general principles that serve as the foundation for the treatment and specific procedures that flow from these core principles must be adhered to, the application of the treatment for a given patient must at the same time be sufficiently flexible to accommodate that patient's developmental level, symptom picture, family context, and learning style.

Review of the Evidence Bases for Time-Limited Psychosocial Treatments

Anxiety Disorders and Related Conditions. Pediatric anxiety disorders have received quite a bit of attention from clinical researchers in the last 25 years, and the efficacy of several CBT protocols for youth has now been established. As reviewed above, many of these protocols contain common elements, such as exposure to feared situations, contingency management, positive reinforcement, shaping, modeling, and hierarchy development. Moreover, these common principles and the similarity of presentation across anxiety disorders led many investigators to conduct anxiety disorder treatment studies that included multiple anxiety disorders rather than any individual diagnostic entity (e.g., social anxiety disorder), although there have been some diagnosis-specific treatment developments.

One of the best researched multicomponent CBT packages for anxiety disorders is the protocol known as the Coping Cat program, which was developed by Kendall for the treatment of separation anxiety disorder, social anxiety disorder, and GAD (formerly overanxious disorder). The Coping Cat protocol has been the subject of multiple treatment studies and the stepping stone for many others in the last 15 years. The first randomized comparison of CBT for pediatric anxiety disorders compared the Coping Cat protocol to a waitlist control condition. Forty-seven children ages 9 to 13 participated, and results indicated that those who received CBT had superior self-reported, parent-reported, and observational outcomes compared to those who received WL. Moreover, treatment gains were maintained long term. A second RCT from the same laboratory replicated and extended these findings, this time with a considerably larger sample ($N = 94$).

The Coping Cat protocol was directly compared to sertraline and combined treatment in the context of the multisite Child Anxiety

Management Study (CAMS), an NIMH-sponsored, multisite, placebo-controlled evaluation of the relative and combined efficacy of CBT and sertraline for separation, social, and GAD. With 488 participants of ages 7 to 17 with either social anxiety, separation anxiety, or GAD randomized to one of four conditions, CAMS has provided extremely valuable information about CBT, pharmacotherapy, combined treatment, and moderators and mediators of response to these conditions. Baseline data indicated that the sample had moderate to severe anxiety and was highly comorbid; anxiety symptom severity and comorbidity patterns did not differ by race or gender. Major depressive disorder was a rule out, which limits the degree to which conclusions can be drawn about this population. Acute treatment outcomes indicated that all three of the active conditions were superior to pill placebo control (PBO) on both continuous outcome measures as well as dichotomous CGI-I responder rates, which were 81, 60, 55, and 24 percent for COMB, CBT, SER, and PBO, respectively. Adverse events between SER and PBO did not differ, which indicates that the side-effect profile does not contraindicate the use of SER as one of the first-line options for pediatric anxiety; at the same time, adverse events in CBT were lower than those reported in SER, which thus offers a potential reason to start with CBT if available.

Accordingly, all three of these treatments can be offered to families of anxious youth, which allows clinicians to take into consideration family preferences and burdens, treatment availability, and associated costs. The search for moderators, baseline characteristics that associated with differential response to conditions, or nonspecific predictors, yielded a few key findings: low anxiety severity and caregiver strain predicted, but did not moderate, anxiety severity at posttreatment. With respect to moderators, having a principal diagnosis of social phobia was associated with less favorable outcome to CBT or PBO, but not to the conditions that included medication (COMB or SER). Accordingly, the authors recommend that medication may be more helpful or necessary for those with a principal diagnosis of social phobia. Importantly, African-American participants did not differ from Caucasians with respect to treatment response, remission, or relapse. Follow-up analyses are presented below in the section on maintenance of gains.

Since the completion of Kendall's initial randomized study, a number of other investigators from around the world have examined the efficacy of CBT for anxiety disorders in youth using the same sampling frame as Kendall and colleagues. Barrett completed an RCT comparing a family-based, group CBT intervention with group CBT alone and WL for 60 youth ages 7 to 14 with social, separation, or overanxious disorder. Results indicated that the CBT interventions were superior to WL though not different from one another. Flannery-Schroeder and Kendall also examined the relative efficacy of individual and group CBT compared to WL, albeit in

a smaller sample (*N* = 45), and found that individual was superior to group CBT on some measures but that both were clearly superior to WL. Group CBT has received empirical support in several other studies that employed mixed anxiety disorder samples, although the feasibility of running groups versus conducting individual therapy outside the context of academic medical settings in large population centers is highly dependent on adequate patient flow.

Following on from Barrett's study of CBT with and without a family component, several investigators have directly compared the two modalities in youth with anxiety disorders. Though the answer might initially appear obvious, the findings from these studies have proven to be equivocal. Some of these studies have found that the family component was associated with superior outcomes relative to individual CBT, whereas other studies failed to find an additive effect. The inconsistent findings are puzzling given the central role that family factors play in the development and maintenance of anxiety in youth. Low statistical power in some of these studies might also underlie the failure to differentiate these two approaches; it may also be the case that there is enough family contact in the "individual" child-focused protocols to promote family support for and involvement in the child's attempt to confront fear-provoking situations rather than to avoid them routinely. In light of the importance of knowing whether formal parental involvement above and beyond what is already incorporated into child-focused CBT is necessary, Kendall and colleagues (2008) published the largest study of its kind in 161 youth ages 7 to 14 with separation anxiety, social anxiety, or generalized anxiety disorder. Family-based CBT was compared to individual CBT and to a psychoeducational control condition that constituted a more active comparison group than had typically been employed since the majority of other studies used a WL condition. Results again provided evidence for the efficacy of both forms of CBT, although the control condition did yield statistically significant and clinically meaningful reductions in anxious symptoms as well. In the direct comparison of the CBT protocols, the two failed to differentiate from one another on most outcome measures. The large sample size allowed the investigators to identify several putative moderators of response; notably, although comorbidity did not differentially affect outcome by condition, participants whose mother and father were diagnosed with anxiety disorders themselves fared better when assigned to FCBT than ICBT. These findings further underscore the efficacy of CBT, and suggest that more intensive family involvement in CBT may not be needed for all patients and families.

The studies described above included at least a subset of participants diagnosed with social anxiety disorder (social phobia) or the previous diagnostic term, avoidant disorder. However, individual treatment protocols for social anxiety disorder in youth have also been developed, and

their efficacy evaluated in RCTs. Findings from these studies support the use of social phobia-specific treatments delivered both in the clinical and school context, although they also indicate that there is room for further improvement and hence treatment development. Based on meta-analyses of adult social phobia treatment studies, Beidel and colleagues concluded that exposure in some form may be a key ingredient in CBT programs for social anxiety disorder in youth, and that treatment interventions which combine social skills building, as well as anxiety reduction, may be necessary for optimal outcome. Following on from an initial encouraging test of such a program for socially anxious youth in which treatment gains were maintained for up to 5 years, Beidel and colleagues in 2007 completed an RCT in 122 youth ages 7 to 17 with social anxiety disorder, comparing social effectiveness therapy (SET) to fluoxetine (FLU) and to a PBO. Both of the active treatments were superior to PBO, and differences favoring SET over FLU were found. Initial responders' relapse rates following FLU and SET discontinuation were relatively low at 1-year follow-up (17 and 10 percent for FLU and SET, respectively), suggesting the durability of improvements over time.

In addition to studies that have specifically targeted social anxiety disorder, several other RCTs have been conducted examining the efficacy of CBT for other anxiety disorders in youth. Silverman and colleagues, studying treatments for specific phobias, examined the relative benefits of an operant-based contingency management treatment and a cognitive-based self-control treatment, in comparison to an education support control group. Graduated in vivo exposure was used in both the self-control and the contingency management conditions but not in the education/support condition. Phobic children (N = 81) between 6 and 16 years of age and their parents were evaluated using child, parent, and clinician measures. Although all three conditions were found to impart improvement in the child's functioning as measured by the reports of children, parents, and clinicians, clinically significant improvements were noted only in the two cognitive-behavioral treatment conditions. Specifically, on a measure of clinical distress at posttreatment, 80 percent of the participants in the self-control and 80 percent of the participants in the contingency management conditions reported very little or no distress compared to only 25 percent in the education/support condition. Notably, 88 percent of the participants in the self-control condition no longer met diagnostic criteria at posttreatment, compared to 55 percent in the contingency management and 56 percent in the education/support condition. This study underscores the importance of using active comparison groups in RCTs for anxiety disorders in youth, who may be responsive to less active forms of intervention than adults with anxiety disorders have proven to be.

In an example of a CBT intervention tailored to a particular end of the

developmental spectrum, Pincus and colleagues (2010), conducted the first RCT of any treatment for panic disorder in adolescents, randomizing 26 adolescents to either 11 weeks of panic control therapy for adolescents (PCT-A) or a self-monitoring control condition. PCT-A was superior to self-monitoring on IE-rated panic symptoms as well as self-rated anxiety, depression, and anxiety sensitivity. Posttreatment discussions with participants led the investigative team to develop a more intensive protocol in light of feedback that the treatment could have been delivered more efficiently.

In a particularly novel innovation, Öst and colleagues evaluated the effects of a CBT program referred to as "one-session treatment" (OST) with phobic children and adolescents ages 7 to 17 years. The treatment was designed to be maximally effective in one session, with patients progressing to the top of the symptom hierarchy by the end of the session, which lasted 3 or more hours. As was the case in several of the studies discussed above, children were randomized to CBT conditions in this study (conducted either in the presence or absence of a parent) or to WL. Results indicated that the active treatments produced significant gains immediately after treatment and at 1-year follow-up. WL was associated with no change at posttreatment. Here again, no differences were found between CBT conditions with or without a parent present in this comparison as well. Even with the relatively short treatment, CBT gains in this study were found to be comparable to other, longer treatments with more sessions, and perhaps superior to some other published results on specific phobias. These findings were confirmed in a large, multinational (US, Sweden) study of OST versus educational support and a waitlist control in which Ollendick and colleagues (2009), randomized 196 phobic youth ages 7 to 16 to one of the three conditions: OST, education/support, or waitlist. Findings indicated a clear and durable advantage for OST over the other two conditions; education/support was also superior to WL. A subsequent randomized study was conducted by Ollendick and colleagues (2014), in which the efficacy of OST with and without parent involvement was examined in 97 youth ages 6 to 15. Contrary to expectations, there were no differences between the two conditions, with each yielding response rates (loss of diagnosis) of approximately 50 percent.

Studies of CBT for school phobic children have also been conducted, although it is clear that school phobia is far from a simple condition and that such samples are diagnostically heterogeneous, with separation anxiety and social anxiety being quite common. King and colleagues found that 4 weeks of CBT was superior to a waitlist control: school attendance was higher in the treated than untreated children (89 vs. 60 percent), and ratings of anxiety also showed meaningful differences. In contrast, Last and colleagues found no significant difference in improvement rate between CBT and standardized educational support treatment: mean percentages of

school attendance were 67 and 60 percent, respectively. The more stringent criterion of 95 percent school attendance was met by 22 percent of the CBT group and 21 percent of those receiving educational support. Bernstein and colleagues extended this work by comparing augmentation of CBT with imipramine to augmentation with pill placebo in a school refusing sample, and found that the children who received combined treatment had superior outcome. Bernstein and colleagues' sample also included children who were diagnosed with primary depression, so the conflicting evidence likely driven by methodological heterogeneity confounds recommendation of treatment approaches for school-refusing children.

Depression. RCTs of CBT for depression in youth have been conducted for years, and collectively these studies indicate that CBT is a valuable treatment, either alone or in combination with pharmacotherapy (for a comprehensive review, see Curry, 2014). Randomized studies that have specifically examined CBT in clinical samples of children diagnosed with depression (as opposed to epidemiological or school-based samples) have been fewer, however, and their results indicate that although the majority of the samples meet criteria for clinical improvement, response is usually partial and relapse is common. The very nature of depression itself makes studying the efficacy of its treatments extremely complex, since mood disorders are known to be less stable than anxiety disorders usually are. Diagnostic heterogeneity within depression and other mood disorders also contributes to difficulty comparing across samples and drawing firm conclusions based on studies with different inclusion and exclusion criteria.

It is in this context that the Treatment for Adolescents with Depression Study (TADS) was initiated and conducted. TADS was a multisite, placebo-controlled examination of the relative and combined efficacy of a CBT package against FLU, and represents the largest study of its kind (N = 439). Reflecting the extant outcome literature and expert opinion about essential and optional procedures to include in a CBT protocol, the CBT intervention selected for TADS was conducted in 15 sessions over the course of 12 weeks, and was largely skills-focused. The required elements in the CBT protocol were delivered in the first 6 weeks, and included psychoeducation about the nature of depression, goal setting, mood monitoring, increasing pleasurable activities, social problem-solving, and cognitive restructuring designed to identify and challenge mistaken beliefs. At week 7, the therapist and the adolescent chose modules for use that reflected their mutual perspective as to what other problems were central. Modules on problems in social engagement, communication, negotiation, compromise, and assertion were available. TADS also included at least two parent-only sessions and, depending on the specifics of the case, conjoint sessions to focus on specific parent or adolescent concerns. TADS' findings were convergent with the prediction that combined treatment would be superior to both of the

monotherapies and to PBO. FLU also appeared to be superior to CBT on many of the outcome measures, and CBT failed to separate from PBO on most outcome measures. The CBT-alone condition did not fare as well with respect to response rate (43 percent) as it had in other published CBT studies, although it did enhance FLU-alone outcomes. Sample severity and comorbidity might have influenced CBT-alone outcomes, although the authors also note that modifications to the manual made to ease cross-site dissemination might also have played a role in producing this unexpected outcome. In terms of prevention of depression in adolescents with a prior history of depression, Brent and colleagues (2015), found an efficacious and durable effect for a group-based CBT program compared to treatment as usual, with positive outcomes still evident after 6 years postintervention.

Disruptive Behavior Disorders. There is ample evidence from randomized trials that CBT for DBD is moderately effective in achieving improvements in targeted outcomes. As seen in treatment studies of depression, the heterogeneous nature of DBD, the complexity of variables that affect treatment response, and the wide variation in treatment study designs make it difficult to compare studies and draw firm conclusions about which specific form of CBT is most effective for any given patient. The largest and most comprehensive randomized control trial is the Multimodal Treatment Study of Children with ADHD (MTA). The study enrolled 579 children with ADHD between the ages of 7 and 9, of which 40 percent had comorbid oppositional defiant disorder (ODD) and another 14 percent met criteria for conduct disorder. Subjects were randomly assigned to receive one of four treatments over 14 months: medication management only, intensive behavioral treatment, combined medication and behavioral treatment, and standard community care. The behavioral treatment consisted of 27 group-administered and 8 individual sessions of behavioral parent training, a school-based intervention including consultation with the subject's teacher and the assignment of a paraprofessional aide trained in behavior management, and an 8-week summer treatment program.

The results of the study showed improvements in ADHD symptoms in all four groups, with the greatest improvement in the medication only and the combined groups. Behavioral treatment compared favorably with community care which consisted of medication management in two-thirds of the cases. When outcomes such as reductions in oppositional and aggressive behaviors were examined, combination treatment was superior to the other groups, and the children in this group required lower doses of medication to attain equivalent or superior outcomes. Thus, while there is no question that stimulant medication is effective in reducing the symptoms of DBD, behavioral interventions added additional benefits and had a clear impact on oppositional and aggressive behaviors as well as

anxiety symptoms cooccurring with ADHD.

With respect to other outcomes, behavioral treatments showed the most significant impact on reductions in parenting stress and increases in child social behavior and peer acceptance. Moreover, behavioral treatment of children with comorbid anxiety disorder was more effective than combined, medication, or community care.

At 36 months, 22 months after the end of the study, all groups showed substantial improvement over baseline but there were *no* differences found across the original treatment groups. Symptoms remained above those of a control group with half the children still meeting criteria for ADHD and almost one-third meeting criteria for either ODD or CD. Thus for the majority of children in the study, CBT for DBD, either alone or in combination with medication, showed moderate efficacy, although the beneficial effects were not consistent. As might be expected, poorer outcomes were seen in children with greater symptom severity at the outset, along with more adverse family situations (e.g., maternal depression, lower socioeconomic status) and lower intelligence. The complex interplay of moderating and mediating variables on long-term outcome measures is well summarized in reviews by Owens and colleagues (2003), and by Swanson and colleagues (2008).

Recent reviews of other published studies of CBT for DBD have supported the central findings of the MTA study. In addition to behavioral parent training, school-based classroom interventions (such as daily report cards and contingency management programs) have been shown to improve both classroom deportment and academic performance of ADHD children with effect sizes in the range of 1.44 (although better results were observed in behavior compared with grades). Academic interventions such as task and instructional modification, homework assistance, peer tutoring, computer-assisted instruction, and organizational skills training all seem to benefit children with ADHD. Moreover, programs emphasizing family–school partnerships through behavioral consultation, family involvement in homework, and daily report cards have shown promising results in enhancing school functioning and reducing behavior problems. Behavioral peer interventions have also been shown to improve social skills and reduce peer rejection. Large behavioral effects on both core symptoms and functional measures (e.g., following rules, sports skills, self-esteem) have been demonstrated by summer treatment programs, such as those that were incorporated in the MTA study. Last but not least, treatment sequencing for ADHD has been studied. Preliminary evidence suggests that beginning with behavioral management is preferable to medication because it generates greater parental involvement and results in better treatment outcomes.

CONCLUSION

The above review reflects the prevailing belief that CBT is a valuable addition to the treatment armamentarium for childhood disorders, either alone or in combination with pharmacotherapy depending on the specific disorder, case severity and complexity, and availability of expertise in its delivery. The latter point is however a major stumbling block, as the number of pediatric mental health professionals trained in and competent to deliver CBT to children and adolescents is nowhere near enough to meet the clinical need if the various published practice parameters were actually to be followed. The movement from CBT efficacy studies, which emphasize internal controls and are necessarily restrictive in both patient and therapist sampling, toward effectiveness studies that are more generally inclusive may help to bridge the gap between science and clinical practice and thereby promote dissemination. On the other hand, it is also imperative to conduct CBT research that incorporates state-of-the-art measurement techniques so that the underlying neurobiological factors associated with change can be better understood especially given that placebo responding is not uncommon in childhood psychiatric disorders. Stepped care models may also help reduce the burden on centers of CBT expertise by finding creative ways to disseminate CBT principles through other means, such as websites, CD-ROMs, paraprofessionals, bibliotherapies, and other methods.

Although the data are generally encouraging, CBT is by no means a universal panacea, and a return to the laboratory is imperative if the field is to make progress in refining and improving the currently available CBT programs for youth with psychiatric illnesses. It is also important to conduct larger studies that will allow for the identification of moderators and mediators of response to CBT, which can then be used to inform treatment recommendations. Recent examples include the study by Kendall and colleagues, who found that family-based CBT was more effective for anxious youth if both parents had been diagnosed with an anxiety disorder, as well as one by March and colleagues, who found that pediatric OCD patients with comorbid tics responded less favorably to pharmacotherapy (sertraline) alone than they did to CBT or combined treatment. Improvements in treatment outcome are likely to be seen if clinicians have this kind of knowledge prior to making their treatment recommendations to patients and families. Clinical researchers must remain cognizant of the imperative to design and conduct studies with sufficient statistical power to identify these kinds of influences on outcome, some of which are likely to be somewhat subtle and yet clinically meaningful; this approach is highly convergent with the broad goals of precision medicine, wherein research-based algorithms are used to identify those more or less likely respond to a given treatment regimen. Despite continuing limitations in the current knowledge base, great strides are being made in establishing the evidence base for time-limited structured

psychotherapy for children and adolescents, and in applying these treatments to patients and families across the entire diagnostic spectrum. Over time, the effectiveness and acceptability of these approaches should become more universal.

▲ 54.3 Cognitive-Behavioral Psychotherapy for Children and Adolescents

ANNE MARIE ALBANO, PH.D., AND SANDRA S. PIMENTEL, PH.D.

INTRODUCTION AND DEFINITION

The terms *cognitive-behavioral therapy, cognitive therapy,* and *behavior therapy* are often used interchangeably. *Cognitive-behavioral therapy* (CBT) is a form of psychotherapy that combines behavior therapy and cognitive therapy into a broad approach composed of empirically based methods built on the fundamentals of social learning theory and experimental psychology. It is the treatment of choice for various mental health problems due to its efficacy. CBT is widely taught in various mental health training programs and is a mandated component of psychiatric residency training in the United States. CBT is a mandated first-line treatment in the United Kingdom for specific mental health problems such

as anxiety, eating disorders, and depression.

HISTORY

CBT is best viewed as a multifaceted theoretical approach with a strong allegiance to the experimental method and a resultant set of techniques applied within a CBT formulation. The cognitive-behavioral approach is the convergence of distinct movements in the study and science of human behavior, including classical conditioning, operant conditioning, and the cognitive revolution. In the early 1920s, Ivan Pavlov's work demonstrated the processes of classical (otherwise known as respondent) conditioning and established the stimulus–response learning paradigm. Essentially, classical conditioning is a form of learning in which a neutral stimulus is repeatedly paired with a stimulus that elicits a reflexive response. In his classic experiment, Pavlov paired the neutral stimulus of a light with food, a stimulus that naturally produces salivation. Eventually, presentation of the neutral stimulus (light) by itself elicited the conditioned response of salivation. This process is illustrated in Table 54.3–1. This work greatly influenced John B. Watson, who applied Pavlovian classical conditioning principles to understanding the origins of psychological disorders in humans. Known as the "father of behaviorism," Watson promoted the tenet that psychology should be concerned only with directly observable stimuli and responses and rejected any notion of unconscious and dynamic processes (i.e., mentalistic constructs) underlying behavior, including cognitive processes. Early laboratory research with animals demonstrated the acquisition of the fear response through classical conditioning learning trials.

Table 54.3–1.
The Process of Classical Conditioning

Before conditioning	
Food →	Salivation
(Unconditioned stimulus)	(Unconditioned/reflexive response)
During conditioning	
Light + Food →	Salivation
(Neutral stimulus) + (Unconditioned stimulus)	(Unconditioned response)
After conditioning	
Light →	Salivation
(Conditioned stimulus)	(Conditioned response)

Watson and colleagues demonstrated that fear reactions are also conditioned in humans who previously did not evidence such a reaction. In their classic experiment, Watson and Rosalie Rayner conditioned a fear reaction to a white rat in a young child named Albert. Initially, Albert played happily with the rat and showed no evidence of fear or avoidance of

this animal. Next, the experimenters followed the introduction of the rat with a loud noise made in close proximity to the child, causing him to startle. The pairing of the loud noise (aversive stimulus) and the rat (neutral stimulus) in a sequence of trials resulted in Albert developing fear of the rat (conditioned response). Subsequently, not only did Albert become fearful of the presence of the rat, eventually his fear generalized to other white, furry stimuli, such as cotton balls. Inasmuch as this experiment demonstrated the process of Pavlovian learning principles in the etiology of psychological disorders, Mary Cover Jones demonstrated that one could eliminate human fear conditions in children through a similar learning paradigm that would foreshadow later methods of behavioral treatments for anxiety disorders. With Watson as her dissertation mentor, Jones used an approach involving the techniques of modeling and graduated exposure to treat 3-year-old Peter's fear of rabbits. Initially, Peter was exposed to observing other children playing happily with a rabbit (i.e., modeling), and, subsequently, while Peter was eating his favorite food, the rabbit was shown to him during a time when he was in a calm state. Gradually, the rabbit was moved closer to Peter until he was able to pet and play with it without experiencing fear (exposure). Although many will recognize Jones' work as straightforward examples of the basic behavioral procedures of modeling and graduated exposure, her approach to treating Peter was revolutionary at the time. In fact, it was decades before the techniques employed in Peter's treatment were systematically studied and identified as valuable therapeutic procedures.

At the same time that Pavlov and Watson were experimenting with classical conditioning paradigms, Edward Thorndike of Columbia University was beginning pioneering work in understanding the processes of operant (instrumental) conditioning. Thorndike demonstrated that by changing the consequences of behavior, the occurrence of the behavior is either increased or decreased—that is, providing a reward after the occurrence of a certain behavior increases the probability of that behavior occurring again, whereas withholding the reward, over time, results in the decrease of the behavior. These principles are widely used today in therapy and educational settings, such as in parent education and training. A common example is that of a young child who throws a temper tantrum in response to being denied a treat. If the parent provides attention to the child through admonishing, coaxing, or giving in and providing the treat, the tantrum behavior is likely to occur again at the next instance of the child's being initially denied the treat. Note that the reward in this case is parental attention, regardless of whether it is the positive attention of coaxing or giving in or the negative attention of admonishment. In any case, the child gets the parent's attention. However, if the parent refrains from giving attention and ignores the child's crying and whining, the tantrum will stop and subsequent tantrums are unlikely to occur when the

child is denied or frustrated. The child will learn that tantrum behavior does not result in positive outcomes. This type of learning is central to parent management training (PMT), an empirically-based treatment approach, and similar parent training programs. Change in child behavior (decrease in tantrums) is facilitated and enhanced through the simultaneous pairing of positive child behavior with parental attention, so parents are also taught to give attention and praise when their child behaves in acceptable and desired ways (e.g., "I like the way you are playing nicely with your sister"). The procedures of systematically ignoring undesirable behavior while systematically reinforcing desired behavior are known together as *differential reinforcement of other behavior*. Throughout the 1950s and 1960s the principles of operant conditioning were greatly expanded and researched by Harvard psychologist B. F. Skinner and his students; eventually, this work moved from the laboratory analogue studies of learning processes with animals to applied evaluations of the utility of operant procedures in the treatment of adult psychiatric inpatients. For example, Ted Ayllon and Nate Azrin introduced the first comprehensive token economy program at Anna State Hospital in Illinois. Despite initial resistance and skepticism from the hospital staff, the token economy resulted in significant changes in targeted behavior of inpatient adults with severe mental illnesses and disabilities. Token economy systems flourished in psychiatric settings and training schools and were adapted for widespread use in programs serving youth, such as hospitals, residential facilities, and schools.

The emergence of behavior therapy as a distinct field of study began in the 1950s, in part due to advances in the understanding of both classical and operant learning processes, and also because of a growing discontent with traditional psychoanalysis. A major goal of psychoanalytic treatment is for the patient to develop insight into his or her problems. *Insight* refers to the emotional and intellectual understanding and acceptance of one's problems and is a crucial step in achieving therapeutic benefit, and gaining insight is associated with uncovering the unconscious conflicts and motivations underlying the problematic behavior. The assumption of unconscious conflicts is a major premise of psychoanalysis that is rejected by the behavioral approach. The focus on achieving insight, along with the often inordinate length of time spent in psychoanalytic therapy, contributed to discontent with the approach. South African psychiatrist Joseph Wolpe, dissatisfied with his patients' progress in psychoanalysis, was among the founders of contemporary behavior therapy and moved its applications from experimental settings and institutions to more mainstream psychotherapy contexts. In the 1950s, Wolpe developed procedures of systematic desensitization and assertive training, directly stemming from Cover Jones' work with children in the 1920s. In each procedure, phobic and anxious patients are taught to replace fear reactions

with deep relaxation and proactive communication behaviors respectively. These procedures provided a more rapid therapeutic response than traditional analysis and proved to be more cost-and time-effective to patients. Very quickly, Wolpe's procedures were extended to individual and group therapy contexts and adapted for use in children and adults. Worldwide, behavior therapy was developed, advanced, and promoted by pioneers such as Wolpe, Cyril Franks, Hans Eysenck, Stanley Rachman, and Arnold Lazarus. As a field, behavior therapy took shape through the systematic study of behavioral principles and the testing of its methods in single-case and large research trials. In 1966, Franks became the first president of the newly formed Association for Advancement of Behavior Therapy (now the Association for Behavioral and Cognitive Therapies), the flagship professional organization whose missions remains that of promoting the development and dissemination of behavior and CBT.

Radical behaviorists, steeped in the tradition of Watson, eschewed the study of cognition, in that thought processes were viewed as mentalistic constructs not readily observable or verifiable by others. From a purely behavioral perspective, directly addressing inappropriate or abnormal behavior will change any upsetting or inappropriate thoughts and feelings associated with the behavior, and, hence, direct access to thoughts is not necessary. During the 1960s however, the cognitive revolution began with the work of Albert Bandura, Aaron T. Beck, and Albert Ellis. The cognitive therapist takes a different view, espousing that, if one changes dysfunctional thoughts, change in functional behaviors will follow. The cognitive therapist assumes that thoughts are made observable through methods such as direct interviewing, paper-and-pencil self-report scales, journal or diary entries, and listing of thoughts. At Stanford University, Bandura integrated the principles of classical and operant conditioning with observational learning to formulate the tenets of social learning theory. Through observational learning, the process of observing the actions and reactions of others can effect a change in the behavior of an individual. In essence, observing the actions of others and their resulting consequences, without the individual needing direct experience with a situation, can shape the emotional and behavior repertoire of an individual. Of course, risk and protective variables interact with observational learning to shape behavior such that the temperamentally inhibited child may learn to respond with anxiety and withdrawal when watching the distress of a peer who is teased by the class bully, whereas the child with a more rambunctious disposition may focus on the behavior of the bully and learn to respond in similarly aggressive ways. This theory places critical importance on the role of cognitions in the development and maintenance of behavior, both normal and abnormal, in that cognitions involve thoughts, images, beliefs, expectations, memories, and attributions, among other simple and complex cognitive processes. In the bully example, the

inhibited child may think, “oh no, that can happen to me and embarrass me.” This type of thinking leads to anxious withdrawal and fear reactions. Conversely, the more extroverted child may think, “It is fun making this kid cry and I want to do it next,” leading to imitation of the aggressive behavior. The response of the environment to either child’s response then becomes involved in the complexities of this learning paradigm to further influence the observational learning by either rewarding/accepting or punishing/extinguishing the particular response. The process of observational learning is the basis for concern expressed by parents and other concerned parties over violence depicted in television, movies, and video games and one of the reasons for parental ratings found in the media and music industry.

The cognitive revolution continued with the work of psychiatrist Aaron T. Beck at the University of Pennsylvania, who observed within the course of his psychoanalytic treatment of patients that certain problems were evident in the thoughts of depressed individuals and that traditional psychoanalysis did not allow for the direct confrontation of these thoughts. Beck’s study of depressed patients revealed a certain negative triad of thoughts related to pessimistic views of the self, the world, and the future. Through the Socratic method of questioning the veracity of these thoughts, Beck was able to assist patients with gathering evidence to refute the thought and engage emotional and behavioral resources to counter the depression and increase healthy functioning. Cognitive therapy emerged from this work and became a mainstay in treatment of a wide range of emotional disorders, including depression, anxiety, personality disorders, and, more recently, psychoses. Concurrent with the development of Beck’s approach, psychologist Albert Ellis took note of the irrational beliefs guiding his patients and undermining their ability to proactively manage activities and stressors in everyday life. Ellis developed rational emotive therapy, which seeks to challenge certain core irrational beliefs such as “I must be loved by everyone” and “I must be perfect in my performance/relationships.” According to Ellis, irrational beliefs are conditioned cognitive responses that serve to render an individual vulnerable to disappointment and failure and engender a sense of helplessness and eventual psychopathology. Both Beck’s and Ellis’ therapies integrate behavior principles and processes, such as behavioral exposure and behavior activation, to activate and challenge negative, irrational thinking. From these roots, the cognitive approach, integrated with behavior therapy in forming contemporary CBT, was expanded and adapted to meet the needs of children, adolescents, adults, and families to address a wide range of psychological and behavior problems.

THEORETICAL ISSUES

The value of CBT as an evidence-based and front-line treatment, is ever

expanding and evolving. Since its inception and integration of the behavioral and cognitive movements, treatment packages such as self-instructional training, problem-solving therapy, harm reduction, behavioral family therapy, and behavioral couples therapy have been advanced. Problem specific treatments have emerged and include: the Coping Cat for childhood anxiety disorders, the Adolescent Coping with Depression Course, CBT of Childhood OCD: It's Only a False Alarm, The Incredible Years and Parent–Child Interaction Therapy for disruptive behavior in young children, Multisystemic Therapy for serious child and adolescent disruptive behavior and substance abuse, and the Maudsley Approach for adolescent eating disorders. All CBT protocols are based on the principles of social learning theory and several basic theoretical assumptions of CBT (Table 54.3–2). First, the cognitive-behavioral therapist does not assume that an underlying, unconscious process or drive is fueling the behavior of any individual. Rather, the cognitive-behavioral therapist assumes that all behavior, whether adaptive and pathological, is subject to conditioning principles, although there may be limits on learning due to constitutional constraints (e.g., intellectual capacity, physical limitations) or contextual constraints (e.g., dysfunctional home, depressed community settings). As such, the therapist works with the patient (and with the parents in child cases) to examine samples of behavior across contexts to uncover the antecedents and consequences of behavior. The *ABCs of therapy* refer to the antecedents–behavior–consequence chains that serve to establish and perpetuate behavioral patterns. Rather than assume that an individual is predisposed to behaving in a certain way due to traits such as aggressiveness, introversion, or obsessiveness, the cognitive-behavioral therapist takes a more interactionist approach and assumes that the individual is interacting with the environment in developing response patterns to discrete and specific stimuli that may bear resemblance to prior similar stimuli or experiences, thus shaping apparently trait-like responses. Through the process of CBT, triggers to behavior and resultant consequences are identified and dealt with within the treatment plan. The cognitive-behavioral therapist, based on empirical findings, applies procedures steeped in the principles of learning to change or modify the patient's behavior. Through a process of collaborative empiricism, the therapist and patient (including parents or caregivers in the case of dependent youth) specify clearly defined goals for treatment and establish a time frame for achieving subgoals and overall goals. Therapist and patient will then engage in a continual process of evaluating whether goals are achieved, and if not, examining impediments to change including resistance throughout the course of therapy. CBT is applied flexibly to meet each individual patient's needs. That is, techniques are adapted to be developmentally appropriate for a given age or cognitive level and otherwise adapted to meet the needs of an individual patient.

Table 54.3–2.
Assumptions of Cognitive-Behavioral Therapy

Cognitive-behavioral therapy, relative to traditional psychotherapies, concentrates on behavior (this includes verbal behavior and covert behavior, such as thoughts, beliefs, memories, attributions, and images), rather than on some presumed unconscious underlying cause.
Cognitive-behavioral therapy assumes that maladaptive behaviors are acquired through learning in the same way that any behavior is learned.
Psychological principles, especially learning principles, are highly effective in changing and modifying maladaptive behavior.
Cognitive-behavioral therapy involves setting specific, clearly defined, and observable treatment goals.
Cognitive-behavioral therapy rejects classic trait theory—that is, the notion that an individual has an inherent predisposition to similar behavior in a wide range of situations.
The cognitive-behavioral therapist adapts the method of treatment to a patient's problem.
Cognitive-behavioral therapy is focused on the here and now.
Cognitive-behavioral therapists place great value on the empirical testing of their techniques and protocols.

Contrary to popular belief, CBT does not ignore historical information. The patient's history is essential for understanding the original setting events and learned reactions comprising the etiology of the problem. However, the work of CBT is focused on the present maintaining factors that prevent healthy functioning and allow the persistence of the patient's problem. Thus, CBT is focused on the here and now, with emphasis on understanding the current reinforcement paradigm, allowing persistence of the problem and teaching new skills to promote adaptive behavior. Finally, scientific rigor, whether on a large-group scale or within the single-case approach, is highly valued by the cognitive-behavioral therapist. It is expected that the cognitive-behavioral therapist will be current with the empirical literature and apply the scientific method to his or her practice of therapy. Thus, within the clinical practice, each patient is regarded as an individual case study in which the therapist and patient again collaborate to test hypotheses of behavioral change and refine their techniques or approach to maximize the potential for therapeutic benefit.

TECHNIQUES

Techniques are not the essence of CBT, nor are they sufficient for the resolution of any clinical problem. A thorough understanding of the empirical bases and theoretical principles of CBT, along with appropriate training and experience, is a prerequisite to the development of competency to formulate a sound treatment plan and deliver CBT to persons in need. In addition, CBT is a very action-oriented approach focused on the here and now. It requires a directive rather than passive stance. Therapists must be ready to teach, model, guide, and reinforce the patient in working toward their goals. Cognitive-behavioral therapists are very active in treatment and often conduct sessions in vivo—that is, in the situations in which the child or adolescent may be experiencing distress.

The cognitive-behavioral therapist should expect to make a trip to the school, home, or other settings in which the child has difficulty, as appropriate, with careful planning to maintain confidentiality while promoting therapeutic benefit. Moreover, certain disorders, such as the phobias and obsessive-compulsive disorder (OCD), require the therapist to model the handling or touching of phobic or feared objects such as dogs, insects, and potentially "contaminated" objects such as doorknobs or toilet seats. Cognitive-behavioral therapists take care to devise these in vivo experiences to be maximally beneficial to the child while minimizing risk.

Table 54.3–3.
Comparison of Adolescent and Parent Reports in the Assessment of Social Anxiety Disorder

Interview Question[a]	Adolescent Report	Parent Report
Do you worry about what other people think of you or that you may do something to embarrass or humiliate yourself in front of others and then they'll think badly of you? Do you think you worry about this social anxiety more than other kids your age?	Yes, I worry about this sometimes. But I don't think it's any more than anyone else. I don't think so.	He is always worried about what he says and often says he does not know what to say. He fights with us about this. We try to push him to go out and talk to people, but he's too shy. He won't speak up and he is anxious that others will think he's stupid or awkward. This is different than our other kids who are quite social.
Do you think you have the same number, fewer, or more friends than other kids your age?	The same number as other kids.	Fewer. Actually, we don't think he has any friends that we're aware of and hasn't had since elementary school.
How often do you see your friends outside of school? What kinds of things do you like to do with friends?	Well, not much, maybe once a month. There's not much to do and nothing's really going on. And I have a lot of homework.	He doesn't see anyone outside of school. He just stays in his rooms and plays videogames or is on the computer. He doesn't go to any parties or to school events. We feel like we are constantly nagging him to go.
Do you call or text your friends to do things, or do you wait for them to call or text you?	I text them back sometimes.	He doesn't seem to call or text anyone. We see our other kids always texting or on social media. Not him. One classmate called to get homework and even that was hard for him.

[a]Questions are modified appropriately when addressed to parent.

Behavioral Assessment

A classic phrase found in most reviews of CBT is that "behavioral assessment is the cornerstone of (cognitive) behavior therapy." In essence,

CBT is dependent on a carefully constructed and thorough functional analysis of the patient's presenting problem. The functional analysis involves the use of appropriate assessment methodologies to uncover the relationships and conditions under which the patient developed and has maintained his or her problematic behavior (the ABCs defined earlier). Assessment in CBT involves multiple methods, multiple informants, and multiple time periods. Assessment involves multiple methods to capture the most useful and valid information concerning the patient and his or her functioning across a variety of contexts. Thus, diagnostic interviews, self-report questionnaires, diary forms, and behavioral observation techniques can all be used, given time and cost restraints. The use of multiple methods and multiple informants allows for data to be captured without relying on any one form of assessment or individual that may be subject to biases or limited in scope. For example, although children generally are able to report internal states with accuracy, younger children tend to report what is within their immediate experience, and, as such, even recent events may be distorted or inaccurately represented. In addition, the nature of some disorders may interact with youth report on any particular method of assessment. Adolescents with social phobia in general have difficulty admitting to this form of anxiety and tend to minimize or deny symptoms. In contrast, parents of youth with social phobia are able to identify and report the behavioral avoidance associated with the syndrome. Consider, for example the comparison of responses to questions from a diagnostic interview by a 15-year-old boy with social phobia and that of his parents (Table 54-3–3). Although the youth denies a lack of friendships and minimizes his social anxiety, the parents' report establishes his isolation due to avoidance of social interaction and activities with peers. In this case, the youth may be defensive or unable to admit to the anxiety due to self-presentational demands; however, the parents are readily able to identify the specific behavioral contexts (after-school activities, telephone use) in which behavioral avoidance is apparent. This information, taken within the broader context of a diagnostic interview, will be compiled to establish a diagnosis and specify goals for treatment (e.g., engage in social activity outside of home and school; engage with friends on the phone or texting).

Behavioral assessment often involves obtaining samples of behavior through behavioral approach tasks. The behavioral approach task can be individually tailored for each patient or standardized for a particular disorder. Standardized behavioral tests for youth with social phobia involve giving a speech in front of a camera or a small, live audience. Youth with separation anxiety disorder may be asked to stay in the clinician's office while the parent is sent on an errand. The behavioral approach task allows the clinician to assess the behavioral limits of the patient. If the child refuses to attempt the task, important information about his or her initial reactivity and ability to manage anxiety is accessed. No child or adolescent

is ever forced to attempt a behavioral approach task; rather, he or she is allowed to avoid or quit the task at any point. The behavioral approach task also provides information on how long the patient can stay in the situation and what methods make the situation better or worse for the patient. For example, children who fear the dark may be better able to sit in a darkened room with the use of a flashlight or with another person with them. These safety signals provide information about what coping strategies the child is using and whether the strategy needs to be refined or removed through treatment. The behavioral approach task also allows for access of specific cognitive, physiological, and behavioral content by having the patient list his or her top six thoughts that occurred during the task, taking measures such as heart rate or respiration, and recording the length of time engaged in the task or how close the patient can be to a feared stimulus. Overall, the behavioral approach task provides both qualitative and quantitative information to establish baseline functioning and evaluate the progress of treatment. Sample behavioral approach task situations for anxiety disorders are given in Table 54.3–4.

Table 54.3–4.
Sample Behavioral Approach Tasks for Child and Adolescent Anxiety Disorders and OCD

Social anxiety disorder: Reading aloud in front of the clinician and office staff, initiating a conversation with an unfamiliar person, asking for assistance from a store clerk, asking for directions to the restroom.

Selective mutism: Whispering to the parent in front of the therapist, speaking at a low volume/whispering to the therapist, asking a question in a normal voice to the therapist, speaking on the phone with a relative, asking the teacher a question, calling and inviting a friend to get together.

Separation anxiety disorder: Staying alone in the therapy room for 10 minutes, staying alone in a darkened room for 10 minutes, parents leaving the child at the clinician's office to run an errand.

Generalized anxiety disorder: Purposefully making mistakes on a homework assignment, being late for an appointment, reading an upsetting story online or watching an upsetting news clip about crime or world events.

Animal/insect phobia: Being in the same room with a caged animal, staying in the room with the animal on a leash, touching the animal, allowing the animal to roam free in the room, allowing the animal to interact freely with self.

Injections/doctor phobia: Entering an examination room, looking at the medical instruments, holding a syringe, allowing self to be examined by a physician, allowing needle to rest against skin.

Darkness phobia: Sitting in a dimly lit room with another person, sitting in the dimly room alone for 10 minutes, sitting in the room for an unknown period of time, sitting in complete darkness while holding a flashlight, sitting in complete darkness.

Obsessive-compulsive disorder: Touching "contaminated" objects (e.g., doorknobs, shoe soles), not washing hands, shaking hands with various office staff, saying "forbidden" words or thoughts aloud (e.g., "God is dead"), using "unlucky" or "bad" numbers on purpose.

The use of multiple informants involves obtaining information from the child, parents, teachers, and, potentially, peers, other relatives, and former caregivers or therapists. The use of multiple informants addresses issues of

responder bias while accessing the opinion of individuals who have experience with the child over a sustained period and in multiple contexts. Information gained from parents and teachers, for example, may reveal the occurrence of behaviors that are not likely to present in the therapeutic environment. However, reports from others may be limited by an inability to appreciate the antecedents or consequences of behavior and the inability to understand the child's internal dialogue or ideas. Finally, assessment occurs throughout the course of CBT. The initial assessment is used to establish a baseline diagnostic picture and establish the limits of functioning and identify behavioral excesses, strengths, and deficits. The goals for treatment are defined through data accessed during the assessment, and specific treatment protocols or techniques are chosen based on the assessment results. Assessment continues throughout the course of treatment to track progress, continue to gather data in specific domains (e.g., daily ratings of anxiety or depression, number of social contacts, diary forms to elicit though patterns and beliefs), and inform the therapist and patient about treatment response.

Psychoeducation

A core component of CBT for just about any disorder or problem is psychoeducation for the child or adolescent and parents. Psychoeducation typically begins in the first treatment session and is carried on throughout therapy. Developmentally appropriate information is delivered to the youth and parents concerning the nature of the disorder in question (e.g., addressing the proposed etiological pathways and maintenance of depression) and the process and procedures of CBT. It is important for patients and parents to learn that certain emotions may be "charged up" or "cooled down," given changes in the environment (being teased by a bully, getting an A+ on a difficult examination, canceling a picnic due to rain), physical state (e.g., hunger, fatigue), time of day or year (school holidays, final exams) and other internal and external factors. Individuals may be born with a predisposition or vulnerability to experience certain emotions more strongly and readily than others, and over time, by interacting with the wider environment, a person can develop a style of thinking or psychological bias to interpret things in a more emotional manner (the "negative filter"). Although these biases exist, children and parents are further taught that individuals can learn strategies to manage their emotional reactions to a large degree, either with or without the assistance of medications. Emotions are broken down into three components—the physical (e.g., tension, irritability, physical symptoms of anxiety and depression), cognitive (e.g., automatic thoughts, beliefs, cognitive distortions), and behavioral (e.g., actions, aggression, withdrawal, avoidance). The relevant cognitive-behavioral techniques and principles tied to each component are offered as the ways in which the child will learn

to recognize the triggers of his or her emotional reactions and use appropriate coping strategies effectively to manage the emotion and situation. Parents are also given specific information to address any gaps in their understanding and expectations for normative child development.

Psychoeducation also involves the introduction and training of the child and parents in self-monitoring. Structured diary forms are often used to guide the monitoring of triggers to emotional states (both positive and negative) and rating of the intensity of emotion (e.g., from 0 to 10). Monitoring sets the stage for later tracking of cognitive and behavioral responses that become the focus of other treatment components. A sample monitoring form for an adolescent with depression is shown in Tables 54.3–5 and 54.3–6.

Somatic Management Techniques

The vegetative and physiological symptoms accompanying anxiety and depression are addressed through structured relaxation and exercise assignments. Deep diaphragmatic breathing and progressive muscle relaxation training form the mainstay of techniques used to dampen anxious or aggressive arousal and increase a child or adolescent's ability to control his or her unhelpful or inappropriate responding. Mindfulness exercises may also be introduced to teach children and adolescents strategies for nonjudgmental awareness of their bodies. Prescribed exercise regimens involving dancing, walking, bicycling, playing team sports, and engaging in similar physical activities are geared toward behavioral activation to reduce fatigue and increasing stamina and energy in the depressed adolescent. Nutritional counseling and sleep hygiene methods are also used as indicated to address the concomitant problems of weight control and sleep disturbance accompanying the internalizing disorders.

Table 54.3–5.
Daily Diary for an Adolescent with Major Depressive Disorder during the Early Phases of Treatment

Column A What was happening? (trigger)	Column B Mood Rating (0 = best, 10 = most depressed ever)	Column C What was I thinking?	Column D What did I do?
Parents were arguing.	8	This is miserable. I hate it here at home. Why don't they stop?	Went to my room and cried. Didn't eat dinner and stayed there all night.
Had an essay due in English class.	7	I can't think of anything to write about. There's nothing interesting to write. I can't do this.	Listened to music and lay in bed. Tried to write but couldn't. Watched some TV and then went to sleep.

Friend called to go to the movies.	5	I don't feel like going anywhere. I'm no fun and I'm too tired.	Told my sister to make up an excuse for me. Didn't talk to my friend.

Cognitive Interventions

The goals of cognitive interventions are to build on psychoeducation and provide corrective information concerning the presenting problem while systematically uncovering and refuting the automatic thoughts and schema that drive the youth's emotional distress. Automatic thoughts are discrete, rapid, and often context-specific thoughts that vulnerable individuals treat as fact about themselves, the world, and their future. All individuals have automatic thoughts each day. Typical automatic thoughts for youth with anxiety and depression are listed in Table 54.3–7. Cognitive restructuring involves identifying these thoughts through the use of diary forms, employment of Socratic questioning in the therapy room, and then developing rational responses based on actual evidence for the thoughts to assist with their emergence in everyday life. In effect, patients are taught to treat the thoughts as hypotheses, not facts. The therapist then guides the patient in planning home-based behavioral experiments to test whether the thoughts are true through the process of gathering evidence to either accept or refute them. Dispute handles, also shown in Table 54.3–7, are questions used to examine the evidence for the thought and guide the child or adolescent toward considering alternatives to his or her negative biases.

Depending on the age and cognitive developmental level of the child, cognitive interventions can be simplified or rendered more complex. Young children and those who are more concrete in thought processes can be presented with a simple cue to "stop and think" when experiencing strong emotions such as fear or disappointment. A picture of a stop sign or favorite cartoon character holding up a stop sign may suffice to teach the child to resist the negative emotion and engage in proactive coping. Emotive imagery is a technique by which the child's favorite superhero or character provides "guidance" in managing the difficult situation. For example, a 7-year-old boy with separation anxiety disorder might be taught to imagine how Spider-Man's parent was late in picking him up from school. The therapist would coach the child to imagine Spider-Man handling each situation and then have the child imagine himself in each situation, with Spider-Man "standing by" in the image and assisting the child with coping strategies, such as deep breathing and thinking realistic, helpful thoughts. Older children are often provided acronyms to remember a series of steps in cognitive restructuring: Feeling frightened? Expecting bad things to happen? Actions and attitudes to help me cope with this situation. Results on how the situation turned out and how I handled it and reinforce myself for trying. Homework in cognitive restructuring involves

the use of additional columns in the diary for (Tables 54.3–5 and 54.3–6). These forms are reviewed in session, whereby the therapist and patient evaluate each step of the restructuring process and work through plans to overcome challenges and reinforce success experiences.

Table 54.3–6.
Daily Diary with Cognitive Restructuring Component for an Adolescent with Depression

Column E Which dispute handles can I use?	Column F What is my Rational Response?	Column G New mood rating based on evidence and realistic thoughts	Column H What is my action plan?
How often do they argue? Is this the worst thing that could happen? What are they usually like together?	Mom and dad are loving to each other, and all couples disagree and argue at times.	3	Focus on what they are usually like together. Sit with the family for dinner and, if the time is right, let them know I was upset hearing their argument.
How many times have I written an essay? How likely is it that I wont be able to think of anything if I try? Do I have to do this all at once?	I've prepared for class and read all the material, so I do have ideas to use in this essay. I still have 4 days to get this finished and that gives me plenty of time to work on this.	3	I will review my notes from class and make an outline for the essay. After a short break for a snack, I will begin to prepare the content of the essay. If I get this done tonight, I can rest and finish tomorrow.
How do I know it won't be fun to go to the movies if I don't try? Did I ever enjoy going to the movies? Is it possible that I'm tired because I haven't gotten out?	My friend called me because we have had fun together, so I will likely also have fun at the movies.	2	Call my friend back, apologize for not being available, and tell him I'd like to get together for a movie or to do something else that's fun.

Table 54.3–7.
Typical Cognitive Distortions and Dispute Handles for Youth with Anxiety and Depression

Cognitive Distortions
I'm not as smart as other kids.
I don't know what to say to others.
I'm not as attractive as others.

No one wants to hang out with me.
They think I'm a geek because I was nervous giving that oral report.
What if I do something stupid?
Nothing will work out for me.
This is the worst situation anyone could ever be in.
I know I'm going to fail.
If I don't ace this test there's no point in trying anymore.
I should have done better.

Dispute Handles

Am I 100% sure that ____ will happen?
Do I have evidence that ____ will happen?
How many times has ____ happened before?
Is ____ really so important that my whole future depends on its outcome?
What is the likelihood that ____?
Does ____'s opinion reflect that of everyone else?
Do I have a crystal ball?
Am I responsible for this entire conversation?
What is the worst that could happen?
What can I do to cope/handle the situation?

Exposure/Behavior Change Techniques

In the anxiety disorders, behavioral exposures are used to provide systematic success experiences while managing difficult situations and refining cognitive restructuring skills. Anxiety is partly maintained by avoidance of or escape from challenging situations, and thus the child does not gain experience to refute anxious thoughts and learn that the feared negative outcomes are unlikely to occur or can be managed. An child with separation anxiety disorder tries to avoid, at all costs, the experience of being away from loved ones for fear that something terrible will happen to result in permanent separation. By avoiding separation situations, the child maintains a focus on the catastrophic fear and does not learn that the feared negative outcome is highly unlikely. Moreover, avoidance prevents the child from learning that, when adverse or less-than-desirable or expected events occur, such as a parent returning home late from work, the event is independent of the child's fear and avoidance behavior. Exposure directly addresses the fear and avoidance partly through the process of habituation, by which the anxiety response naturally dissipates during the exposure. Exposures also provide opportunity for inhibitory learning, in which the child can learn that catastrophic feared events did not occur and new beliefs about potential outcomes come to inhibit previous beliefs. The child concurrently gains experience with coping and interacting with the feared stimulus or situation. Exposure is usually conducted in a stepwise manner of introducing increasingly challenging situations. Flooding, which is not recommended for young children or those with more severe anxiety levels, involves having the patient confront a situation that provokes the

highest levels of anxiety and stay in the situation until the habituation occurs. Exposure may be imaginal or in vivo but is typically arranged hierarchically for children, from least to most challenging. Role plays with the cognitive-behavioral therapist may be included in preparation for exposures; however, they do not substitute for exposures. During imaginal exposure, the therapist may construct scripts about anxiety-provoking situations and ask the child to listen to the scene as if it were really happening. As the child's subjective anxiety decreases, scenes of greater intensity are presented in succession. In contrast, in vivo exposure involves having the child actually engage in the feared situation. Again, when the child reports tolerable levels of anxiety, the situation may be enhanced to produce a greater challenge to the child and require a new level of cognitive and behavioral coping. In contrast to situational exposures, interoceptive exposure involves inducing the sensations of panic through certain exercises and activities that cause physiological responding, such as tachypnea, tachycardia, palpitations, diaphoresis, and paresthesias. Again, these exposures are designed to break the fear of internal sensations of anxiety and increase tolerance for normative changes in body functioning. Recent experimental studies indicate that habituation may not be necessary to reduce anxiety, but rather, exposure may assist in the learned tolerance of expected anxiety reactions that would previously have resulted in avoidance. For example, learning to tolerate the discomfort of dental procedures, the arousal accompanying asking someone for a date, and other situations that are inherently challenging to anyone, can result in improved functioning and quality of life, and reduced anxiety overall. In all types of exposures, children are encouraged to use their somatic management skills, as well as cognitive restructuring. Use of safety signals may be allowed for less challenging exposures, but systematic removal may be necessary for increasing exposure potency and testing potential feared outcomes.

Behavioral activation tasks are structured experiences planned for youth with major depression or dysthymia. The reinforcement theory of depression asserts that low rates of contingent reinforcement contribute to depressed mood and anhedonia and set up a cycle by which withdrawal behavior occurs and, thus, the youth is even less likely to engage in or have access to reinforcing events. For example, withdrawal from team sports, procrastination in homework assignments, and loss of interest in self-care may occur over time in depressed adolescents. By withdrawing from the team, social reinforcement and contact with peers comes to halt. Withdrawal also may have transactional effects on the teen as peers may disengage and taper contact in response, thereby further reinforcing potential distorted beliefs about himself or herself. Procrastination leads to a sense of dread and failure in school activity, and the drop in self-care compounds the youth's negative self-image. The result is a systematic

decrease is positive reinforcement and corresponding increase in negative feelings about the self. In CBT, the therapist surveys the youth for activities that may bring social reinforcement, success (self-efficacy or accomplishment), or pleasant feelings (e.g., relaxation). Typically, monitoring of mood occurs concurrently with the monitoring of these activities to provide feedback to the youth that engaging in such activity that the youth is likely to attempt, setting up parameters for engaging in the activity, and self-monitoring and processing the outcome of the event. Planned activities increase in type and number as treatment progresses, with the goal that the youth will assume the responsibility of planning these activities and that they will again become a natural and fixed part of his or her behavioral repertoire.

Parent Involvement in Treatment

Parents and family members are often inadvertently drawn into the cycle of negative affect accompanying the internalizing disorders. Family members may provide reassurance or reinforce escape and avoidance as a way of calming the anxious child or protecting the child from becoming upset and anxious. In depression, parents may take over tasks the adolescent is unable to complete due to anhedonia and vegetative symptoms, such as doing the teenager's homework or other compulsory acts. The intention of the parents is to prevent the child or adolescent from becoming even more anxious or depressed and, thus, to allay the distress experienced by their child. Unfortunately, although well intentioned, these parent behaviors are incorporated into vicious cycles of continued anxiety or withdrawal. In CBT, parents are provided a model of negative affect and education about the proposed etiological mechanisms and maintenance of these states. The therapist and parents collaborate to examine maintaining variables in the child's environment and family system, to develop plans to change parental behaviors when necessary, and to rearrange contingencies in the immediate environment to foster the child's recovery. For example, in selective mutism, usually another child or family member will speak for the child and reinforce the child's mutism. The parents of adolescents with social phobia order for their adolescent in restaurants, speak to teachers on the adolescent's behalf, and have fewer expectations for their adolescent's social life. Parents of depressed youth may fear worsening the child's depression by challenging or encouraging participation in activities and thus prefer to "leave well enough alone." Parents are often taught to be good CBT "coaches" for their child. In essence, parents are taught to ask questions (use the Socratic method) to guide their child in arriving at a coping/action plan rather than providing an answer for the child. Much like a good coach, parents are taught to provide opportunities to practice the skills learned in CBT while refraining from judging the child. Reinforcing and praising the child's effort at coping, no matter how small, is essential

for parents to learn in CBT. Parents are also taught systematic skills to ignore certain child behaviors (e.g., whining, refusal to speak, irritability) and to reinforce with positive attention those behaviors that approximate the goal behaviors. Parents are also trained in the use of contingency management procedures that may involve setting specific goals and contracts, such as "If Jonathan sleeps alone is his bed until 7 a.m., he gets 15 minutes of extra iPad time after school." The goal of contingency management procedures is to rearrange the reinforcement paradigms in the child's environment such that the child receives contingent positive reinforcement for appropriate behavior—in some cases, this may be stickers, small treats, or special privileges—whereas reinforcement is removed or withheld when inappropriate behavior occurs. These procedures also provide structured and, if necessary initially, scripted opportunities for parents to attend to positive behaviors and to effectively communicate this reinforcement. Cognitive-behavioral therapists do not advocate the use of punishment, which has been found to be ineffective in maintaining long-term behavioral change, in addition to being ethically unacceptable.

There are a few guidelines and caveats when planning the level and type of involvement of parents in the child or adolescent's therapy. First, the greater the distress and impairment for the child, the more likely it is that the parents are needed to reinforce the treatment program in the home environment. This is especially indicated in cases involving school refusal behavior, in which the parents must rearrange contingencies in the home and actively work in cooperation with the school and therapist to promote attendance. Second, externalizing disorders or other complex comorbid conditions tend to fare better in CBT with parent involvement. Third, younger children have been found to respond better in acute treatment when parents are actively incorporated into the treatment plan. Fourth, the developmental goals of adolescence involve forming independent self-identity and behavioral skills; thus, parent involvement should take this and other developmental issues into consideration. Finally, in cases in which parental psychopathology or marital or family discord is present, involvement of the parents may hinder rather than help the child's progress in treatment. In these cases, involvement of the unaffected parent or minimal parent involvement may be indicated, with referrals given as appropriate for concurrent martial or family therapy, parent management training, and individual parent therapy.

Relapse Prevention

As treatment draws toward a close, the therapist begins the process of transferring the responsibility for continued progress from the therapist to the child. That is, specific strategies and techniques are used to consolidate gains, reinforce coping skills, generalize gains to a wide range of contexts,

and bolster the child's sense of self-efficacy. In the initial phase of relapse prevention, treatment sessions are moved to a biweekly and then monthly schedule to allow the child time to practice skills on his or her own and decrease reliance on the therapist. By identifying upcoming events or changes in the child's life (e.g., starting school, moving to a new neighborhood, facing developmental challenges calling for increased independence), the child is encouraged to develop a coping plan for each event and to plan his or her self-guided exposures in advance of the event. Hence, if a child is changing to a new school, plans to visit the school and meet the teacher or some peers are encouraged and cognitive restructuring is completed for any negative thoughts or expectations that may occur. Similarly, booster sessions can be planned for anticipated tough times (e.g., start of school, before annual examinations) to reinforce coping skills and assist with transitions. Throughout treatment, therapists can work with parents and children to incorporate technology to optimize coping. For example, deep breathing or mindfulness exercises can be recorded into smartphones or coping reminders can be set for a specific date or time to encourage regular practice or situation-specific coping. In addition, smartphone applications and websites are available that provide age-appropriate CBT support (e.g., Kids Feelings App; Camp Cope-A-Lot). Finally, the child's diaries, workbooks, and journals from treatment become excellent relapse prevention aids for the child to refer to after the end of treatment. Photos taken during exposures or behavioral activation tasks that illustrate the child's accomplishments are pasted into these journals, bookmarked on the child or adolescent's smartphone, or put on posters in the child's room to reinforce gains. Finally, the Coping Cat program for anxious youth advocates the development of "commercials" by which the therapist and child produce a recording that incorporates all of the skills acquired during treatment. The child is the "star" of the recording and is shown as if teaching others how to overcome a problem. Commercials can also be produced in the form of comic strips, short books, poems, and other creative method that inspires the child. Whatever the form the commercial takes, the child can refer to it for relapse prevention purposes and to reinforce gains. A resource for parents' "Do's and Don'ts" can also be generated for the parent component of relapse prevention. Table 54.3–8 presents a summary of the CBT components reviewed here.

CLINICAL ISSUES

Indications

CBT is indicated for the treatment of the range of disorders of childhood and adolescence, including anxiety and mood disorders, attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder, conduct and oppositional disorder, habit disorders, OCD, PTSD, substance

abuse, eating and feeding disorders, and parent–child discord, in addition to other conditions and behavioral disturbances. CBT is generally accepted as the first-line treatment for the range of disorders in childhood, with combination treatment of CBT and medication preferred for more intractable or complex cases.

Table 54.3–8.
Summary of the Main Components of Cognitive-Behavioral Therapy

Component	Focus/Goals	Associated Techniques
Psychoeducation	Provide corrective and accurate information about the nature of the disorder or problem in question.	Didactic instruction, self-monitoring (diaries, journals), assigned reading
Somatic management techniques		
Anxiety-related	Target autonomic nervous system arousal and related physiological symptoms.	Breathing retraining (deep diaphragmatic breathing), relaxation training (progressive muscle/cue-controlled/applied relaxation), meditation, exercise
Depression	Plan behavioral activation tasks involving increase in activity to counteract negative, vegetative symptoms.	Exercise and related physical activities
Sleep hygiene	Restructure sleep cycle through scheduling of awake activities and self-soothing activities to promote healthy and restful sleep.	Set tasks and guidelines geared toward decreasing arousal and promoting relaxation prior to bedtime; decrease/extinction of arousal activities such as exercise or use of stimulants (caffeine) in close proximity to bedtime.
Cognitive restructuring	Identify maladaptive (automatic thoughts, schema, irrational beliefs) thoughts, beliefs, and images and challenge thoughts with realistic, coping-focused thinking; in children, uncover "unhelpful self-talk" and replace	Monitor thought processes through the use of diaries or questionnaires to reveal thinking styles, identification and labeling of automatic thoughts; teach rational disputation of automatic thoughts using realistic evidence and problem-solving steps.

	with coping-focused self-talk ("coaching").	
Exposure/behavior change techniques	Systematic exposure to avoided situation(s) to provide experience with using cognitive restructuring and other deficient skills (e.g., social skills, problem-solving skills, conflict resolution, affect regulation).	Imaginal exposure, in vivo exposure, gradual or massed (more intense) exposure to anxiety-provoking situations; in depression, use of behavioral activation tasks or behavioral experiments to counter negative and self-defeating behaviors and gather evidence to refute depressive ideation.
Reinforcement techniques	The systematic application or withdrawal of stimuli to either increase desired behavior or decrease undesirable behavior.	Patient earns reinforcement through behavioral contracts, level programs, or parent-administered contingency management programs; reinforcers can include tangible items (stickers, money, food), social reinforcers (praise, positive attention, elevation in status), or desired activities (free time, movies, extended curfews); time out from positive reinforcement is the removal of the individual from a reinforcing situation for a set period; punishment, which is the application of a noxious or undesired stimulus, does not result in long-term behavioral change and is not recommended for use by child behavior therapists.
Positive reinforcement	Provide a desirable stimulus (praise, attention, tangible reward) after a desired behavior to increase the probability of the behavior occurring again.	
Negative reinforcement	Remove an undesirable stimulus after the production of a desired behavior to increase the probability of the behavior occurring again.	
Punishment	Apply a noxious stimulus after an undesirable behavior to decrease the probability of it occurring again.	
Relapse prevention	Focus on consolidating cognitive-	Fading of sessions (from weekly to biweekly), role reversal (patient acts as therapist for a session), planned booster sessions.

	behavioral therapy skills and generalizing treatment gains over time; decrease reliance on therapist and others (e.g., parents, spouse) for managing problems.

Limitations

Child or adolescent-focused CBT may not be the treatment of choice in situations involving extensive parent–child discord or marital problems. In such cases, as noted previously, the preferred course of treatment would involve family or marital therapy. The level of training and experience of the therapist typically the limit the effectiveness of CBT and, despite the widespread dissemination of CBT manuals and workshops, partially trained or inadequately trained therapists are no substitute for specialists in CBT. Hence, families and referral sources must be fully informed as to the degree of expertise in CBT of the therapist and adjust expectations accordingly. Similarly, the motivation and adherence to the treatment plan demonstrated by the patient and family may limit CBT. The therapeutic relationship, contrary to popular belief, is of critical importance to the cognitive-behavioral therapist. Thus, the cognitive-behavioral therapist will work to establish trust, positive regard, openness, and collaboration with the patient and family, no matter how rapid a course of treatment is planned, to facilitate treatment progress.

Complications

Incomplete assessment and failure to uncover fully the antecedents and consequences of behavior may result in complications in therapy. It is not unusual for younger children or those who have successfully avoided phobic stimuli to underestimate their true level of fear. Hence, an exposure may be too complex or overwhelming for a child, requiring the therapist to break the situation down into smaller, more manageable parts. Therapists who allow a child to escape or prematurely end an exposure session before adequate habituation and processing of the exposure can reinforce the anxiety and escape. Thus, it is essential that enough time be allotted for an exposure session and that the parameters of the exposure to be clearly and fully examined with the child or adolescent. CBT does not purport to teach positive thinking, but rather to teach optimistic, realistic, and coping-focused thinking. As such, exposure to less-than-ideal situations and outcomes is a part of treatment.

Contradictions

CBT is a flexible set of techniques and approaches that has been effectively applied to a wide range of child and adolescent disorders. There are no known contraindications for the use of CBT in young people.

SOCIAL ANXIETY DISORDER

Michael was a 16-year-old boy from an intact middle-class family enrolled in the 11th grade of a public school. His parents sought evaluation and treatment for him for a long-standing history of "shyness" and anxiety in social situations. Evaluation revealed social anxiety disorder as the primary disorder. Michael was motivated for treatment and reported that he wished to make friends and feel more comfortable with other people and in social situations. Consequently, Michael was treated with cognitive-behavioral group treatment for adolescents with social phobia—a 16-session course of treatment combining psychoeducation, cognitive restructuring, social skills, behavioral exposure, relapse prevention, and four sessions of parent involvement. As treatment progressed, Michael gradually increased his visibility at school-sponsored social events such that he caught the attention of a female classmate and was asked to attend the prom with her. The therapists designed several prom exposures, by which the various things that could happen at a dance or on a date were present to Michael and the group, including being offered alcohol, dancing, having an argument with the date, and having other girls ask him to dance. As it turned out, Michael's date did, in fact, ignore him and leave him at the dance. Michael was prepared for this less-than-desired outcome by the group experience, and asked other girls to dance and interacted with other peers. He considered the evening a success and subsequently went on to other social events with friends made at the prom. In this case study, the importance of exposing youth to the range of potential outcomes for a given social situation was crucial to Michael's trust in the therapy and therapists and belief in the credibility of treatment. Moreover, he was appropriately prepared through behavioral exposure and practice to handle what could have been an awkward and discouraging situation.

SELECTIVE MUTISM

Anna was a 5-year-old girl from an intact middle-class family referred by her kindergarten teacher due to selective mutism. Anna was described as always having been a shy child who was behaviorally inhibited. Although she would speak and interact with immediate family members, she would withdraw and become quiet around peer and strangers. When she started preschool, she did not speak to her teachers or any school personnel and also began to withdraw from speaking around extended family members at holidays and parties. She also experienced distress about separation from her mother, who would generally respond for her and make requests for her. The school had also allowed her to nod and use nonverbal cues to communicate her preferences, and she was not required to read aloud or speak in front of her peers. She occasionally played and engaged with peers on the playground and was otherwise pleasant and friendly. During evaluation, it was revealed that Anna enjoyed eating Skittles as a treat. Treatment was designed to provide an incentive for speaking through the delivery of a contingent reinforcer of high value, the Skittles. Hence, Skittles became available only in the school and therapist's office and, temporarily, were not available in her home. The therapist enacted a process of graduated shaping of communication behaviors—first nonverbal and then vocal noises—and trained the teachers to do the same. Skittles were kept in full view of Anna at all times during the initial phase of treatment, and when she was "caught" gazing at the package, the therapist or teacher would prompt her for acknowledgement that she wanted the treat. Pointing, looking, and nodding in their direction resulted in receiving two Skittles. While in session the therapist would also leave the room while she and her mother were left to play; if the therapist returned and she continued to vocalize or speak, she would receive additional reinforcement via Skittles. Next, the therapist and parent spent time "making noise" with objects (e.g., rattling keys, pressing telephone buttons) and then with their mouths (e.g., animal sounds, silly sounds), and Anna was prompted to join in and make similar sounds to receive the Skittles. Finally, prompts to ask for the Skittles were enacted, first with an "Ssss,"

then the full word, and finally the full sentence/question (e.g., "Can I have a Skittle?"). This shaping procedure took three extended-length sessions and collaboration, along with telephone consultation with her school teachers. In addition to treat requests, Anna was increasingly reinforced for additional situations on her fear and avoidance hierarchy: making eye contact, saying hello to neighbors, ordering her own food in a restaurant, purchasing her own Skittles from a drug store, singing in the park, etc. The treat was faded over time—that is, delivered on a variable ratio schedule of every three to eight times that she spoke, to promote further speaking and decrease the association with the treat. As a part of their relapse prevention plan, Anna's parents were reminded to allow or prompt Anna to speak for herself in various pre-identified possible situations.

OBSESSIVE-COMPULSIVE DISORDER

Joanne was a 13-year-old girl with a family history of anxiety and mood disorders. Her parents brought her to treatment due to recurrent obsessions involving contamination and germs, and corresponding compulsions by which she had her parents overcook her food, checked her food for contaminants, and washed her hands repeatedly to the point of their becoming raw and bleeding. Evaluation revealed a fear that, unless her parents checked her food for bugs or germs, the meal was contaminated and she would get sick and die. Hence, after cooking it, her parents had to pull apart her food physically and examine it to her satisfaction, which could take upward of 1 hour for each meal. This caused much distress and family discord. In addition, Joanne washed her hands repeatedly after opening a door, using a cell phone, tying her shoe laces or putting on or taking off her shoes, or touching any object that she deemed dirty. First, Joanne, her parents, and the therapist mapped her OCD and constructed a hierarchy based on her compulsions, rituals, and avoided situations (from least upsetting, checking food prepared by her mother, to the most upsetting, touching something that was wet and slimy and then touching her mouth). The process of exposure and response prevention was introduced in combination with a contingency reinforcement plan for Joanne's completion of "brave challenges." Systematically, the therapist had Joanne first engage in imaginal exposure to a scene (e.g., "You watch dad take a bite of his medium rare burger, then you imagine taking a bite of a medium rare burger with the red juice oozing out. You realize it is not super well done and they did not check it for germs.") until her anxiety dropped to minimal levels. This usually occurred after 20 to 30 minutes. Next, in vivo exposures were gradually introduced, by which foods were introduced with "contaminants" in them (e.g., putting pieces of uncooked rice into the burger to mimic "grit"), phasing out the parents' checking of meals as well as her own checking behaviors. As treatment progressed, Joanne learned that her feared consequence of becoming sick was not likely to occur. Washing rituals were addressed by having her touch items with various substances coating them and then touching her face and mouth. At first, she was asked to delay washing her hands over increasing time increments, and then to resist for larger blocks of time. Importantly, it was critical to address some of Joanne's mental ritualizing of thoughts regarding when she would be next able to wash her hands. Treatment occurred over a 14-session program, with some sessions including extended time to allow for exposure and response prevention to occur. Her parents were taught to assist her with these exposures in the home and refrain from engaging in her rituals or accommodating them (e.g., removal of antibacterial sanitizing gels). They were also provided coaching scripts so as not to engage in disputes over meals. Relapse prevention plans were enacted to expand her range of food choices and situational contexts (cafeterias, food stands, restaurants) for exposure. By the end of treatment, Joanne was eating without the need for checking and with minimal to no anxiety, and her handwashing had decreased to within normative range of daily washing.

Goals of Treatment

In the abstract, the overall goals of CBT are to increase an individual's freedom of choice—that is, to free the individual from confines of a disorder which removes the opportunity to make decisions and choices for one's self

out of personal preference and which, instead, determines an individual's choices as a result of fear, depression, anger, or other emotional constraints. The goals of CBT are symptom relief, education about the nature of one's symptoms, vulnerabilities, and patterns of behavior, and the teaching of adaptive, coping-focused, realistic, and optimistic behavior (cognitive and overt) to maximize the person's potential, prepare him or her to meet the challenges of everyday life, and improve his or her quality of life.

Ethical Issues

CBT is a safe, tolerable, and effective treatment for a range of behavioral health problems, with increased efficacy linked in some clinical studies to more seasoned and well-supervised therapists. The main risks of CBT may lie within exposure-based treatments, which are associated with temporary emotional discomfort when confronting feared situations. Contrary to a myth that exposure may result in adverse reactions (e.g., unrelenting anxiety, psychosis, breach of therapeutic alliance), any discomfort and boundary issues in conducting exposure can be skillfully and carefully managed by the experienced therapist. When conducting exposure in community (in vivo) settings, such as schools, parks, and playgrounds, therapists need to be mindful of confidentiality concerns and take precautions to minimize compromising the patient's right to privacy.

Research and Evaluation

CBT has demonstrated efficacy in the treatment of childhood internalizing and externalizing disorders through a number of controlled, randomized trials, including combined trials of medication and CBT. Long-term follow-up of youth treated for anxiety, OCD, or depression suggests maintenance of treatment gains, in addition to further improvement over time. It is incumbent on clinical trial researchers in CBT to test this approach in youth presenting with variations in cognitive and developmental functioning, comorbidity patterns, and various environments adversities to test the effectiveness or therapy programs in mental health service settings. Further research is needed to evaluate treatment algorithms, discontinuation procedures, and pretreatment factors that predict the maintenance or relapse of treatments over the long term. The critical issue faced by today's clinical scientists involves moving treatments from the laboratory to the community. This rests on the collaboration and cooperation of clinical scientists, clinicians, patient advocates, and consumers for critical feedback to flow in multiple directions to adapt and adopt evidence-based treatments in community settings.

▲ 54.4 Group Psychotherapy

MARGO L. THIENEMANN, M.D., SONAL RANA, M.D., AND NICOLE QUITERIO, M.D.

DEFINITION

Group therapy is the counseling, guidance, or training of children and adolescents involving interactions of three or more members that has the potential for reciprocal influence. The literature describing group therapy for children has, until relatively recently, consisted of anecdotal reports—rich in description but thin in providing scientific evidence to substantiate its assertions. Empirical support for group therapy for children and adolescents is growing. In 1997, Matthew J. Hoag and Gary M. Burlingame published a meta-analysis of the 56 English-language studies of child group therapy that used randomization or matching in their experimental designs. Compared to wait-list or placebo control, group therapies helped to a moderate degree (effect size 0.61, range –0.04 to 2.99).

Group interventions for children and adolescents can be categorized by the goals of the group, therapeutic processes used, duration, and population served, and may be referred to as *psychotherapy groups, psychoeducational groups, support groups,* and *self-help groups*. Delivering therapy via groups may be better than individual therapy for addressing specific illnesses, or may more effectively address treatment issues such as motivation for change or need for social reinforcement of learning.

HISTORY

Therapists have been describing group treatments for children for approximately 100 years. Early in the 20th century, adolescents met for psychodrama groups in Vienna. In the 1930s, *activity group therapy* developed. In these groups, children played among therapists who used nonverbal, noninterpretive interactive strategies to effect ego repair. After World War I and during the Depression, youth needed constructive supervision, although resources and manpower were short, and so delinquent adolescents were treated in groups. After World War II, understaffed military hospitals in the United States and England used groups to deal with psychiatric casualties. The 1960s saw the emergence of encounter groups, the community mental health movement, antiestablishment groups, and an increased tolerance in society for talking openly about one's feelings.

Today, groups are used frequently and ubiquitously. Psychotherapy, support, psychoeducational, and self-help groups may be found in all human service facilities, including schools, hospitals, and clinics and on the

Internet. For example, in an outpatient clinic in Leon, Nicaragua, 80 percent of all outpatient visits are in a group format.

Multiple environmental factors have shaped these historical trends. Pollock and Kymissis, discussing the future of adolescent group therapy, hypothesized that theoretical and clinical developments, training opportunities, scientific research, economics, social change, and public and professional attitudes all influence the type, quality, and availability of group therapy. Psychoanalytic theory informed early groups, which aimed to use group interactions to recapitulate family interactions. Developmental theory, considering the peer group's role in identity formation, pointed to using the group for adolescents' therapy. The development of learning theory and cognitive-behavioral therapy has led to problem-focused, time-limited group interventions.

Societal attitude change and economic factors have increased the appeal of group interventions. According to Moffitt, the current health care climate of high demand and limited resources makes the group therapy format cost effective and fiscally responsible. Due to the developmental tasks of adolescence, which include identity formation and self-concept through peer relationships, peer approval, and belongingness, group modalities are perhaps even more useful for pre-adolescent and adolescent children (paraphrased from Miffitt, 2014). Countering these currents, psychiatric training in psychotherapies, including group therapy, has received relatively less emphasis because of growth of reliance on and teaching about pharmacological treatments.

Other factors serve as potential obstacles to the use of group psychotherapies. Some group interventions developers fear that, because of the difficulty of manualizing and researching psychodynamic group therapies, potentially effective modalities might not make it into clinical practice. Managed care, because of group therapy's potential cost-effectiveness, initially provided incentive for increasing the use of outpatient group therapy. This has not borne out with reimbursement for inpatient or outpatient groups. An increased societal comfort with self-disclosure may increase the likelihood that a patient will participate in a group, but until more research demonstrates an advantage for group therapy, therapists and patients may reject group therapy, considering it diluted and less effective. Finally, Pollock and Kymissis noted that few training programs include adequate training in group psychotherapy. Perhaps, as has been the case for pharmacological, individual, or other modalities, research will demonstrate that specific group therapies for specific problems administered by specifically trained individuals help, and the interventions may gain adequate support for dissemination.

THEORETICAL ISSUES

Therapeutic Power of the Group

Gathering individuals together for therapy may help them more than working with them alone. A number of factors, many described by Irving Yalom, make psychological treatment in groups especially effective. Yalom listed instillation of hope, universality, imparting of information, altruism, corrective recapitulation of the primary family group, development of socializing techniques, imitative behavior, catharsis, the addressing of existential factors, cohesiveness, and interpersonal learning as factors leading to change. In children and adolescents, the use of the group to address developmental issues also may be an advantage.

Hope. In groups, children can meet other children with similar pathology. As they see peers overcome obstacles, they can develop hope that they, too, are capable of helping themselves get better. By observing others addressing problems actively, individuals may expect that their participation in therapy will help them. A parent of an unmotivated anxious child remarked that seeing other children tackling their anxieties gave her hope that her child would be able to do so in the future. Similarly, in multifamily groups, parents often remark that seeing other children improve behavior-wise gave them hope that their families could also begin to function more healthily.

Universality. Children with psychiatric disorders frequently feel they are weird, crazy, or losers. Getting to know worthwhile, admirable individuals with similar issues can lessen the pain and hit to one's self-esteem that can come with having a mental health disorder. Adolescents are in the midst of exploring and consolidating their identities during the time that a number of major psychiatric illnesses begin to manifest themselves. Having the opportunity to interact with others with similar troubles can help teenagers constructively to integrate having a psychiatric illness into their sense of self. In a recent pilot study by Straub et al., reviewing the most positive evaluations of their time-limited cognitive-behavioral group for teen outpatients, the most positive elements identified by participants were being with other adolescents and feeling comfortable in the group. By seeing others in the group, teens can come to see a disorder as only one of many aspects of themselves.

Imparting Information. Children learn together at school, on teams, and in families. In group therapy, children can learn about the course and characteristics of their disorder. In addition to presenting live examples, the group format is suited to teaching via leaders' instruction, educational videos, and structured learning activities. When the child teaches and helps other members, his or her learning is reinforced. Following the Coping Cat anxiety protocol model, members of one adolescent group treatment for obsessive-compulsive disorder (OCD) ended the group by making a

didactic video. The group members delighted in their educational video, which taught about etiology, symptoms, treatments and impact of OCD. They watched it repeatedly and shared it with their families.

Altruism. Supporting others in the group is gratifying. Altruistic actions can boost one's sense of well-being and self-esteem and help to defend against upsetting feelings. Children and adolescents in group therapy often make thoughtful suggestions to other members. One study of adolescents participating in cognitive-behavioral group therapy reported that most participants tried to help their peers to design behavioral interventions in each session.

Corrective Recapitulation of the Primary Family Group. Through examining psychodynamic processes and addressing treatment resistances, the group format can provide a wealth of opportunities for addressing family conflicts. In a group setting, children develop transference relationships with leaders and peers. Providing a safe, constructive atmosphere in which maladaptive interpersonal patterns are addressed and reworked may provide group members a chance to work through dynamic conflicts originating in the family.

Development of Socializing Techniques. Yalom stated that all therapy groups help patients develop social skills. Social deficits, social dysfunction, and isolation are prominent symptoms of children with psychiatric disorders, including those with pervasive developmental disorders, learning disorders, attention-deficit disorder and other externalizing disorders, and social anxiety and depressive disorders. The group allows patients to practice new skills and receive feedback from professionals and peers in real time. In one controlled group therapy study of girls without friends, girls in the treatment group did learn to approach peers and begin conversations. Reinforcement and criticism from peers may be the most meaningful feedback possible for adolescents.

Imitative Behavior. Seeing how others behave greatly influences what children and adolescents do. Children in groups observe other children working on solving problems similar to theirs. Group leaders often demonstrate strategies, like social problem solving and conflict resolution, as ways to deal with these. Many group protocols call for role playing and rehearsal of skills that leaders demonstrate. Sexually abused children practice acting assertively, and impulsive children practice entering an ongoing conversation successfully. In the pilot study by Straub et al. examining a CBT group for teens with depression, participants reported that they felt understood by and comfortable with the group leaders, and rated their advice as helpful. Imitating effective behaviors modeled by

leaders who children respect and peers with whom children may identify effectively teaches functional behaviors.

Catharsis. Group therapy can allow one to express one's distress in the presence of individuals who can truly understand one's suffering. Although catharsis provides some relief, catharsis alone is insufficient for change. Members of one adolescent trichotillomania treatment group noted that talking at support groups had helped initially but left them feeling dejected after hearing about others' experiences. They felt more hopeful when they could learn new tools with which to address their behaviors.

Existential Factors. In the trichotillomania group just mentioned, one member openly expressed hopelessness and refused to address her hair pulling. The other group members challenged her stance, urging her to take responsibility for attempting to change her behavior. Unwilling to take charge at that time, she left the group. Issues of personal responsibility, will to change, loneliness, and demoralization frequently had emerged in the context of group therapy, which provided a rich format in which to discuss these universal existential concerns. Adults in one substance abuse group rated the group's ability to address existential issues as its most powerful component.

Cohesiveness. The experience of being part of something, being accepted, sharing and working together feels good and can improve children's motivation to work in therapy. When children and adolescents are secretive about their disorders, they may have a sense they do not belong anywhere. In a group, they can enjoy a sense of closeness when they can be open about their troubles, are accepted, and are understood. A study by McConachie et al. investigating group therapy for anxiety in children with autism spectrum disorder found that the most helpful strategies were learning alternative coping strategies, sharing experiences, and feeling accepted.

Interpersonal Learning. By working in the here and now of relationships in the group sessions, individuals have an opportunity to address dysfunctional interpersonal difficulties. The group can be a safe place to develop and practice healthy ways of interacting. For example, in a mentalization-based therapy group, teens are often encouraged to discuss when they find other participants' behaviors confusing or distressing.

Developmental Factors

Each stage of development has its tasks. Younger children's egocentric focus differs from preadolescents' yearning for same-sex soul mates and from adolescents' empathic, individuating, and affiliative capacities.

Understanding the developmental needs and capacities of a set of children or adolescents is necessary for designing and enacting a successful group therapy intervention. A parent-only, group cognitive-behavioral intervention for children with anxiety disorders has been used to take advantage of the working relationship between school-age children and their parents (and of the benefits of parents working together at their common stages of parenting). Aronson delightfully discussed ways in which adolescent developmental issues are addressed in a paper, "Where the Wild Things Are." In it, he likened the journey of Maurice Sendak's Max in the book of that name—trying on his new identity, affiliating with peers, individuating, and returning with a new relationship to his family—to psychological processes occurring in an adolescent group therapy. Whether the group is a cluster of same-age peers or contains a range of ages, the group interaction can foster stage-appropriate maturation.

Other Factors

Most geographic areas have an inadequate number of psychotherapists, and most individuals have little surplus money for psychotherapy. The group format uses therapist resources in a low-cost way to provide care that otherwise might not be available due to lack of resources.

TECHNIQUES

Gains made in symptom resolution and psychosocial development in groups result from general therapeutic factors and from learning specific information and skills. Before discussing specific diagnosis- and problem-focused interventions, this subsection reviews general technical issues.

Selection of Patients

Number. A typical group contains 6 to 10 members—a size large enough to allow for a rich exchange but small enough to prevent members from being neglected. Having an adequate number at the outset ensures against depletion due to dropouts and absences. Sometimes, goals call for a smaller or larger group. In one treatment study, aggressive young boys practiced coping with being teased. Because of the intensity of the intervention and potential for strong emotions and behavioral acting out, the interventions were done in triads. On the other hand, Meezan and O'Keefe studied a large-group format used to address abusive and neglectful caregivers and their children. Two or more members of at least two generations of each family met with five to seven other families and four therapists. More change (including a reduced incidence of child abuse and improved child behavior) occurred in the families in the intervention group than in a control group using an individual family treatment. The authors believed that families improved more because they met families

who had "been there" and other families who motivated them and encouraged them to change. Families felt that compared to feedback from therapists, feedback from other families was easier to take and helped them the most.

Describing an inpatient community group of 18 severely disturbed and conduct-disordered boys between the ages of 11 and 16 years, another author remarked that although maintaining structure and creating a safe environment presents a challenge with a large group of disturbed children, the larger group was powerful and a good choice for reluctant participants and those limited in their capacity to share their thoughts and feelings.

Age and Sex. Participants' age defines the nature of the interactions and structure of the intervention. Some investigators have included children of different ages and have found that members benefit from the interesting modeling and teaching opportunities provided from the family-like grouping. Most often, groups are composed of children at similar developmental levels, (e.g., 8 to 12 years and 12 to 18 years). When patients are of elementary school age, mixed-sex groups are often appropriate, especially for the younger grades. For this age group, games and activities can be fun while they facilitate interactions and learning. As the children age, they can tolerate a format increasingly focused on verbal interaction. Children in preadolescence prefer same-sex peers and can be distracted and inhibited by members of the opposite sex. Adolescents enjoy and can use mixed-sex groups again. Mixing high school–aged adolescents with younger ones may expose the younger children to topics with which they are not comfortable.

Excluding Patients. Certain individuals in group therapy may undermine the process sufficiently that, although the individual may benefit from participating, his or her detriment to the group calls for exclusion. Particularly in adolescent groups, individuals who actively use drugs may disrupt the group by showing up under the influence or reveling in escapades. When this does not serve the group's goals, these individuals should be excluded. Other fragile children and adolescents may experience the group as so stressful as to contraindicate their participation. Most group protocols exclude actively suicidal or psychotic individuals, who may monopolize the leader's attention, upset other members, and require the leader to leave the session to appropriately triage the patient. On the other hand, crises and decompensations are part of the territory of treating mentally ill children and adolescents. Witnessing the therapist compassionately and competently handle a troubled peer may be reassuring to a group member. Including an unwilling "captive" member in a group could drag the group down in a mutinous way or, skillfully handled, highlight issues of motivation and personal responsibility for each

member.

Investigating the importance of carefully selecting members (considering such factors as level of acting out or ego development), Johnson and Gold sorted 34 latency-aged boys into four groups based on a measured leadership quality score. Groups met weekly for 20 sessions. All group-treated boys improved in popularity ratings and leadership. The authors remarked that the therapist's ability to match techniques to the characteristics of the group members was more important than group composition.

Parents

Parents spend many more hours with children than therapists can and have the opportunity to influence their children by teaching, shaping, and modeling. A growing literature supports including parents in group interventions, often in parallel parent groups and sometimes as a sole intervention. A University of Michigan group tested the effects of a child-only, child-plus-mother, and waiting-list intervention for children who had witnessed intimate partner violence. The children participated in a 10-week group therapy aimed at increasing their knowledge about families and family violence, managing their emotions, and managing interpersonal conflict. The separate mothers' group taught the mothers about the influence of violence on children's development and worked to improve parenting and disciplinary skills. The child-plus-mother therapy was the most effective in improving externalizing behaviors, with gains continuing after the group ended.

When sexually abused children aged 3 to 12 (n = 617) were treated using group therapy with a concurrent parent group, it was found that children who participated in the group improved significantly in their symptoms, which included somatic complaints, interpersonal difficulties, psychological state, and behavioral problems. These children were less likely to be revictimized or themselves become sexual offenders, particularly when the parents also attended a group. Parents are an important resource for the reinforcement of skills and psychoeducation taught in groups.

Setting

Group therapies for children typically take place in the clinic or school. Advantages of clinic-based groups include confidentiality and coordination of care. The more available school setting offers the specific advantages of convenience for the children, opportunities for developing friendships with schoolmates who are accessible, and potential for doing primary prevention work. Some social skill group therapies based in clinics have improved socializing with group members, but results have failed to generalize to

school peers. Conducting social skills groups in the schools increases the chance for generalizability of skills. Unfortunately, with declining school budgets, schools are becoming less able to provide such care.

Therapist

The effective group psychotherapist understands child development, psychodynamic concepts, and characteristics of the child-targeted psychopathology. In addition, the therapist needs knowledge of factors particular to groups and the specific intervention curriculum. The therapist must foster a climate of security, tolerance, and acceptance for differences in feelings and behaviors; be able to control the tensions and anxiety level in individual group members within acceptable limits; and control group phenomena such as bullying, scapegoating, monopolizing, and instigating. Groups benefit from therapists who are flexible, playful, can regress without becoming a peer, have an ability to provide structure in an authoritative (not authoritarian) manner, and provide a good co-therapy relationship. The group therapist must be aware of and contend with his or her countertransference to the group and its members. As with all countertransference reactions, the therapists' anxiety and resistance can be used to further understand group process. By analyzing one's countertransference, one can alert oneself to possible enactments. It is important to remember that group resistance may reflect the therapist's own anxiety.

Co-Therapist Relationship

Having more than one therapist expands the capacity for processing multiple members' reactions and input and more efficiently administrates the group. Having a co-therapist also provides back-up in case a leader is absent. The co-therapist relationship has been likened to a marriage or sibling relationship: It takes a cooperative, complementary partnership that must withstand multiple potential stressors. Often, co-therapists are individuals with unequal training and experience. The pair must withstand group members responding to them as a parental duo and/or mentally splitting them into good and bad therapists. Throughout the therapy session, co-therapists must negotiate the dips and turns of members' (and their own) emotions in front of the group. Witnessing co-therapists problem solving together provides the group's child and adolescent members with an opportunity for modeling and recapitulation of the family. The co-therapist relationship requires a respectful, egalitarian stance in which therapists are open to processing their interaction and their reactions to the group. Unfortunately, due to declining reimbursements, co-therapy is becoming less feasible in community settings.

Tools

Creative group therapy tools range from simple games to high-tech video interventions and can facilitate the therapeutic process. One author described a low-tech approach—a variation of pass the parcel, in which a package is passed around the group for each member to remove a layer of wrapping and answer the question written on it.

Heiman and Ettin used a variety of interesting techniques in a therapy group for sexually abused girls. They began with a puppet-making exercise included to promote disclosure and build group cohesion. Girls built puppets in dyads and used them to introduce each other and as a supportive "friend." Girls named the group in the second session, a task that began their working together as a group and set the stage for them to take ownership and define the goals of the group. Other tools included a board game that asked questions about specifics of abuse, a coloring book about girls' rights and bodies, a collage project about girls at different ages used to facilitate a discussion of appropriate sexual behavior at different ages, letter writing to perpetrators to express strong feelings, and throwing into the trash drawings and writings symbolizing things they would like to put into the past.

A group for sexually abused boys made a group flag, which required creativity and compromises that led to group solidarity. This same group rolled a "feelings cube," which directed them to describe a situation causing a certain feeling, act the feeling out, or answer questions posed by group leaders and members. They made and photographed clay figures portraying their abuse. Each of these tools was chosen to help the girls and boys confront and process difficult issues.

Videos can facilitate learning and discussion in groups for children. Prevention films for sexually abused children can be used to teach self-protection skills. Films of social vignettes can provide a take-off point for discussion and role playing for social skills groups for children with attention-deficit disorder. The film *The Touching Tree* provides psychoeducation and models exposure/response prevention training in the context of a drama about a boy with OCD. Watching the video stories together is an efficient teaching medium and provides a shared experience from which discussion can flow in a lively way.

Games can also serve to introduce levity that promotes camaraderie and communication. In dialectical behavioral therapy groups, games are often used to enforce mindfulness techniques. In one activity, members choose a favorite from a bowl of mixed candies. Then they are asked to pass the favorite to the person on their left and mindfully eat the new piece of candy. In a mentalization-based therapy technique, teens are encouraged to "play doctor" using a stethoscope and dressing in white coats to empower themselves in discussing what they think may be going on in the minds and

hearts of other family or group members. Similarly, playing freeze tag where participants "freeze" showing how they look when feeling a certain emotion can help teens understand the concept of the "opaque mind" and illustrates that they can only guess at what goes on in another mind. Role play is yet another effective tool to promote perspective taking and communication.

In the era of YouTube, creating original video recordings is an exciting developmentally appropriate and available tool. For instance, to consolidate knowledge of information and skills acquired in one anxiety group, members chose to make an instructional video. In one report, therapists introduced a continuously recording video camera to a group in order to spark group interest when it was waning. They observed that the camera's eye acted as both an additional group member and as a transference object.

Food, obviously symbolically and physically nurturing, may be included in group therapies for practical and therapeutic reasons. Children coming to the clinic after school may be hungry, and feeding them may help to improve their attention. Some treatment protocols use a snack break to practice less structured socializing for socially phobic or impulsive children. Others use food as reinforcement for specific behaviors. The group therapist must decide whether the distraction caused by food is a reasonable cost for the gained therapeutic benefit.

Length of Intervention

The rate of improvement is greatest in early therapy sessions. With increased emphasis on cost containment and measuring outcome, most recent group therapies are scheduled to last only between 8 and 12 sessions. Therapeutic factors may also call for time-limited work. Formally dividing time into phases like introductory/group forming, working, and consolidation/termination phases may help with focus and momentum. This is not to say that longer interventions are not beneficial. Some youth may take longer to benefit and some benefit by reinforcement and taking a relative leadership role having acquired skills and knowledge.

Group Rules

In order for individuals to feel safe in taking the risks necessary for change and for therapists and group members to serve multiple individuals' needs, groups need rules. Developing a set of rules is usually a group activity early in the intervention. Fairly universal rules include those regarding confidentiality, personal safety, and attendance, not coming to the group while intoxicated, and respecting others. While, at first glance, prohibiting socializing with other group members outside of sessions may seem unnecessary, it has proven consistently to be an important rule. For

example, after members of a structured adolescent cognitive-behavioral group met with each other outside of the group, one member left the group, uncomfortable with feeling pursued by the other. Members of a trichotillomania group requested permission to use instant messaging on the Internet to seek support from each other when they had urges to pull. Although most felt that this was helpful, some eventually desisted, feeling that boundaries were impinged on.

Family Involvement

Families may be involved in group therapies for children and adolescents in a variety of ways: they may be included with the children in the session (multifamily group), in parallel parent groups, with families included in parts of each session, certain sessions, or not included at all. Childhood anxiety disorder researchers have examined the role of family involvement in treating anxious children. One study compared outcomes of group therapy in three conditions: parent-and-child parallel group therapies, a child-only intervention, and a parent-only intervention. Its authors found that, although all groups improved, those children in the parent-and-child intervention group used new coping strategies more actively outside of the group. Barrett and coworkers included parents in group therapy for anxiety disorders because the parents were at increased risk for having anxiety disorders and because the therapists believed that family interactions play a major role in the development of children's anxiety. They randomly assigned 79 children to group cognitive-behavioral therapy, group cognitive-behavioral therapy with family involvement, and wait-list control. The family component encouraged parents to reinforce courageous behavior and ignore excessive complaining and anxious behavior and it taught them communication and problem-solving skills to deal successfully with their children's emotional upsets and anxieties. After treatment and 1 year later, those in the combined-treatment group had a better outcome than those in the child-only condition (95 percent diagnosis-free vs. 70 percent).

Similarly, in a recent multi-center randomized controlled trial by Scholten et al., parent involvement for children with chronic illnesses did reveal additional positive effects on parent-reported internalizing, child-reported externalizing, information seeking, and social competence, when compared to the child-only arm. Parental involvement also appeared to contribute to effect persistence of the group intervention.

Process in the Structured Group

Group therapies increasingly use structured and manualized treatment protocols. Critics and skeptics of manualized treatment fear that therapy from a manual will be stiff and "cookie-cutter." Kendall, who developed the

most-researched manual for treating childhood anxiety disorders, the Coping Cat, noted that the therapist cannot be a "cookbook" therapist but must have a sound understanding of the theory behind the intervention and adequate flexibility and creativity to use the tools in a way that suits the needs of each patient. Manuals and outlines of therapy interventions inform and guide but do not control the group therapist. The therapist will lose effectiveness and opportunities to help if he or she ignores psychodynamic forces and other resistances to treatment. In an article on group therapy for sexual abuse patients, Heiman and Ettin stated that group dynamics and collective process do not disappear even within a highly structured psychoeducational group. If group members' affective reactions are not monitored and the collective dynamics are not acknowledged, then the group curriculum may have little impact. Especially in a group of adolescents, joining is crucial to promote learning. In some cases, the group process can act to disrupt the viability and stability of the group. For example, if a group member decides that a game or activity is silly, it may be difficult to have the rest of the group participate. At times, it may be necessary to pull such an individual out of the group to explore their reasons for disagreement or isolation and encourage rejoining. Group processes can be harnessed to maximize therapeutic impact. By responding to the messages underlying children's behaviors, rather than suppressing them, an opportunity exists to respond and transform the function of children's actions and maximize the efficacy of structured activities.

CLINICAL ISSUES

Indications

Group therapy should be considered if the child or adolescent has a condition for which there is evidence that group therapy is effective. This subsection provides descriptions of empirically supported group therapy interventions for specific pediatric populations. Rather than being an exhaustive review of all reported studies, it presents examples of treatments with support to describe the treatment elements and factors that made group therapy the choice. For some children, group therapy alone may be sufficient, whereas others require concomitant pharmacological, individual, or family intervention.

After the Events of 9/11/2001. The nation was stunned by the 9/11 terrorist attacks. At least 6,000 children lost a parent, and many others developed posttraumatic stress disorder (PTSD). Group psychotherapy served as a place where children could put their experiences into words and play, find support, and begin self-repair. Scheidlinger and Kahn made several observations during their group work with children after 9/11. They

used play, drawings, and discussion questions with elementary school–aged children to help them to express their feelings and fears. Play was especially important for traumatized children aged 4 to 8 years, helping them to describe their experiences. Expressing feelings and thoughts in the group setting allowed other group members to share their experiences and relate to others, a significant step toward building trust and unity within the group. The clinicians observed that traumatic events can continue to affect processes of social and mental development, and they emphasized the importance of making effective interventions like group therapy available in events with global impact.

Haen described a group therapy intervention for Connecticut children directly affected by 9/11. The group therapy consisted of two phases: an acute stage and a working-through phase. Many children felt alone and feared for their safety after experiencing the sudden loss of loved ones. It was imperative to provide a safe environment to bring together clients with similar experiences to minimize the sense of isolation they often felt. The first phase of group therapy aimed to develop trust, safety, and security and included work toward psychoeducation and connecting to one's support system.

The second phase in Haen's group therapy was designed to provide an open forum to address and discuss distortions and misconceptions developed by the children after 9/11. When children blamed themselves for the loss of their parent(s), work focused on correcting cognitive distortions. To facilitate the second phase of group therapy, Haen used play, art, and other nonverbal tools to communicate feelings and thoughts. In one example, drama therapy allowed group members to role-play and alter endings to traumatic events. In some cases, they were able to prevent imagined disasters. These tools helped participants to accept and cope with losses and improved the perception of security and safety for young clients.

Attention-Deficit/Hyperactivity Disorder. Although the Multimodal Treatment Study demonstrated that stimulant medication is the treatment of choice for uncomplicated attention-deficit/hyperactivity disorder (ADHD), children with additional difficulties require additional psychosocial interventions to optimize function. Hinshaw and coworkers designed a cognitive-behavioral therapy intervention for boys with hyperactivity, in which peers were a necessary component for practicing social skills. An initial study compared outcomes for a group cognitive-behavioral therapy intervention for 21 boys between the ages of 8 and 13 years treated with methylphenidate (Ritalin) or placebo. The boys were first taught problem-solving strategies: define the goal or problem, generate multiple solutions, consider the outcome of the various solutions, and choose and operationalize a behavior. Working in groups of three, the subjects applied these problem-solving strategies, first to a series of

academic and fine-motor tasks, and then to interpersonal problem vignettes. In addition, the boys practiced maintaining self-control while actually being teased by peers in the group. After this intervention, both groups improved in self-control and in the intensity of their response to teasing.

In a second study, 24 boys with hyperactivity and ADHD participated in daily 80-minute cognitive-behavioral training groups in the context of a 5-week summer enrichment program at the University of California, Los Angeles. Following a scripted protocol, therapists instructed participants in problem-solving skills, self-talk strategies, and discussion about medication issues. One subset of subjects practiced recognizing signs of their own anger, rehearsed strategies for dealing with provocation, and then experienced provocation in the form of teasing from group peers and group leaders. The other subset talked about perspective taking without actively rehearsing specific strategies or undergoing the teasing stress inoculation. All boys were randomized in a double-blind manner to receive placebo or methylphenidate. Those boys trained by rehearsing self-control with peers demonstrated significant improvements in self-control and engaged in purposeful coping strategies. Post hoc analysis suggested that those with more experience seeing peers model coping behaviors in the group benefited most. The medication influenced outcome ratings of self-control intensity but not frequency of reaction to teasing.

Pfiffner and McBurnett randomized 27 children with ADHD to receive 8-week group social skills training, social skills training with a parent group and teacher feedback, or wait-list control. The group format was selected so children could practice newly learned social skills and receive social reinforcement from peers. The therapy included having the children report on their behavior (measured as points earned) during the week, pool their points together for a group pizza party, role-play specific social skills with immediate peer feedback on performance, and share fun activities. Outcome results after several months supported the utility of social skills training, with or without parents'and teachers' involvement. The authors noted that strong group reinforcement in a stimulating, developmentally appropriate program led to significant improvements in social skills and problem behavior.

Waxmonsky and coworkers designed a group cognitive-behavioral therapy, along with a parent-training intervention to manage both behavioral and emotional dysregulation elementary school boys treated with psychostimulants. The intervention consisted of nine parallel 105-minute child and parent groups that were run simultaneously. After 9 weeks, the boys showed improvements in mood symptoms. Their parents reported that they were parenting more effectively.

Aggression/Conduct Disorder. Children who are aggressive and have

conduct disorder have social difficulties, especially in frustrating circumstances. Concerned that parent training for oppositional defiant and conduct disorder did not help all families or generalize to school, Wester-Stratton and coworkers designed a social skills and problem-solving training protocol (Incredible Years: Dinosaur Curriculum) for children between the ages of 4 and 8 years. The investigators used the group as a supervised place to practice social skills. Ninety-nine children with the diagnosis of Oppositional Defiant or Conduct Disorder were randomly assigned to a control condition or a group intervention that included directly taught social skills, problem solving, and anger management. Groups of five or six children met weekly for approximately 6 months. Children in the treatment condition watched videotaped vignettes of children coping with stressful situations. They discussed the vignettes and collaborated to practice a repertoire of acceptable solutions and coping skills. They also discussed feelings they had about troubles caused by their own behaviors. To enhance motivation, attention, and learning and provide a developmentally appropriate milieu, therapists used puppets, cue cards, coloring books, small reinforcements, group activities, and games. The treatment group demonstrated significant clinical improvement in conduct problems as rated by parents and teachers to a greater extent than did controls. Those gains were persisted at 1-year follow-up. The authors noted that many of the children made their first good friends in the group therapy and postulated that intervention might be even more effective if delivered in the subjects' actual peer setting.

In response to a paucity of resources for treating conduct disorder in South Africa and in hopes that group cognitive-behavioral treatment could help children and adolescents with conduct disorder to respond more appropriately to social situations, a group of investigators designed and studied a 12-week intervention program. An occupational therapist and a psychology student were trained and supervised by an experienced adolescent group therapist. The sessions included: (1) an overview of rules, expectations, and rewards; (2) teaching problem solving/decision making; (3) impulse control, response gap thinking; (4) assertiveness training; (5) requesting behavior change; (6) reward session; (7) empathy, perspective taking; (8) sex differences, interactions, relationships; (9) sex education video, relationships; (10) norms, values, role models; (11) giving compliments; and (12) closure. Parents of treated and control subjects were invited to six sessions of parent behavior management training. The treatment group showed significant improvement in defiance, physical aggression, and delinquent aggression posttreatment and at 6 months, whereas the control group demonstrated improvement only in defiance and a remarkable increase in truancy. The authors noted that this brief intervention using community workers showed promise as a sustainable intervention.

Anxiety. Withdrawal, social isolation, and difficulty with social skills are significant troubles for most anxious children and adolescents. An opportunity for direct exposure to peers, practicing social interaction, and receiving social support and reinforcement make group therapy a theoretically attractive treatment modality for anxious youth.

Cognitive-behavioral therapy for anxious children and adolescents has empirical support. Several manualized treatments have been researched and are readily available. Most include psychoeducation about the somatic, cognitive, and behavioral components of anxiety and build coping skills (relaxation, cognitive restructuring, active approach to feared situations, problem solving). Most use graded exposure to anxiety-provoking situations, homework, and reinforcements to achieve symptomatic change.

In 1998, Barrett reported results of a cognitive-behavioral therapy group for anxious children and their families. The manual-based treatment focused on providing children and families with skills in managing anxiety and avoidance, problem solving, and mutual family support. Posttreatment and 12 months later, 65 percent of children in the child-only group, 85 percent of those in the group with family involvement, and 25 percent of the wait-list control group were free of diagnosis.

Using a different cognitive-behavioral protocol with a strong emphasis on contingency management, Silverman and coworkers also compared a group intervention for anxious children and their parents to a wait-list control group. They considered disadvantages of group therapy—dampening of the therapist–child relationship, overly taxed therapist resources, possible negative modeling—along with possible advantages. Sixty-four percent of the treated subjects versus 13 percent of the wait-listed subjects were free of their primary diagnosis posttreatment. At 6 months, 79 percent of the treated group no longer had their primary anxiety diagnosis. This investigation's finding elevated group cognitive-behavioral therapy to "probably efficacious," according to the American Psychological Association's task force, and took it closer to being a "well-established" therapy, in that it used a manual, had clearly specified subject characteristics, and had been successful with more than one set of investigators.

Building on evidence supporting individual cognitive-behavioral therapy efficacy in treating childhood anxiety, and predicting that group therapy would lead to gains in social competence, friendships, social activities, and improvements in social isolation and loneliness, Flannery-Schroeder and Kendall treated children between the ages of 8 and 14 years with individual or group manualized cognitive-behavioral therapy. Posttreatment, 73 percent of individually treated, 50 percent of group-treated, and 8 percent of wait-listed children no longer met diagnostic criteria for their primary anxiety disorder. Anxious distress and coping improved. The hypothesis that social functioning would improve more in

the group was not supported. The authors noted that the protocol did not specifically address social functioning and that only a small proportion of the sample endorsed problems in social functioning at outset, each of which may explain this finding.

Beidel and coworkers compared a combined 12-week group and individual treatment for latency-age social anxiety disorder with an active control condition—the Test Busters study skills protocol. The treatment condition consisted of child and parent education about social anxiety, social skills training, peer generalization experiences, and in vivo exposure. In the group social-skills training component, children learned about greetings, starting conversations, maintaining conversations, listening and remembering skills, skills for joining groups, positive assertion, negative assertion, and telephone skills. One topic was covered each week, using instruction, modeling, behavioral rehearsal, corrective feedback, and homework. Immediately after the social skills training session, the anxious children joined a group of not-anxious peers for a 90-minute fun, unstructured group activity (such as bowling or in-line skating). During another session, each week, children met individually with the therapist to accomplish exposure activities, practicing one task, such as reading aloud in front of others, per week.

The control group met once individually and once weekly in a group to learn and practice study and test-taking skills. At the end of the group, 67 percent of those in the treatment condition and 5 percent in the study skills condition no longer met diagnostic criteria for social anxiety disorder. Gains were maintained at 6 months. In this treatment, investigators thoughtfully combined two forms of group intervention and an individual session. The first group session allowed for economic use of resources for teaching and an opportunity to practice skills in a structured session. The second, unstructured group included non-affected peers and provided an opportunity to expand on and generalize the skills in a more challenging situation. The individual exposure session allowed for customized, individual, symptom-driven intervention.

In another exploration of the benefit and duration of early intervention for anxious children, an in-school group treatment study compared cognitive-behavioral group therapy with and without parental inclusion with a waiting list control group. In this sub-clinical sample, identified by a questionnaire or by teacher identification, children in the group treatments sustained improvement in their function and anxiety symptoms more than the control group over the 12 months examined. This study by Bernstein and colleagues advanced knowledge in three ways: by including a control group throughout the study, by serving as an early intervention for anxious children and by bringing the intervention to the children in their schools.

Recently, a group piloted a school-based group therapy targeting at-risk adolescents with sub-clinical social anxiety and depression. They chose

students who had been victimized by peers: physically, by rejection or by damaging their reputations. After 3 individual and 10 group sessions based on Interpersonal Therapy for Depression, social anxiety, depression and peer victimization had each improved.

Bereavement. Universality may be an especially powerful therapeutic factor in groups gathered to deal with loss. Pfeffer and coworkers used manual-based group therapy to assist children after the suicide of a parent or sibling, with the goal of decreasing depression and anxiety. Families of children between the ages of 6 and 15 years were contacted within 3 weeks of the suicide death of a parent or sibling and were randomly assigned to receive or not receive intervention. Children with psychiatric diagnoses were excluded. The intervention consisted of ten 1.5-hour weekly group sessions of two to five children within 3 years of age of each other, with simultaneous parent groups. The children's curriculum consisted of offering psychoeducation about death and its permanence, identifying feelings of grief, defining what suicide is, and discussing why people commit suicide. Children's groups discussed preventing suicidal urges and presented problem-solving skills. The therapy facilitated expressions of grief and promoted identification with the positive aspects of the deceased. Parents learned about childhood bereavement, learned to help their children express their grief and discuss the suicide, learned to identify morbid reactions in the children, and learned to promote children's healthy functioning. The parents' grieving was also supported. Children in the therapy developed new supportive relationships. They showed greater reductions in anxiety and depression than did the nonintervention children.

Depression. Group therapy is among the most empirically supported therapies for adolescent depression. A large study compared group cognitive-behavioral therapy, group cognitive-behavioral therapy with families, and a wait-list control group and three intensities of follow-up care for depressed adolescents. One hundred and twenty-three adolescents with major depression were randomly assigned to 16 sessions of group cognitive-behavioral therapy, group cognitive-behavioral therapy plus nine sessions of parent group, or a wait list. Mixed-gender groups of up to 10 adolescents met for 2 hours twice weekly for 8 weeks. The therapy used a manual and workbooks and taught skills of mood monitoring, improving social skills, increasing pleasant activities, decreasing anxiety and depressogenic thoughts, and improving communication and conflict resolution. In the parent condition, parents reviewed the adolescent course content and met once per week and twice jointly with the adolescents. Posttreatment, 67 percent of treated and 48 percent of wait-listed subjects were diagnosis free. Neither parental involvement nor booster sessions

made a significant difference in measured outcome.

Hypothesizing that treating depressed Latino youth in groups would be successful, researchers recently compared group and individual cognitive-behavioral therapy (CBT) and interpersonal therapies (IPT). Authors considered that Puerto Rican cultural value placed on *personalismo* (preference for personal contact in social situations) and *familismo* (placing the interest of the family over the individual) would be served in the group therapy format. Analysis of outcome favored CBT over IPT, which may have resulted from its increased structure and directiveness (consistent with *respeto*) and found results to be similar in the individual and group formats.

The next study described addresses incorporation of new referrals into an ongoing group treatment. This is important because difficulty gathering a cohort of patients at once can impede the initiation of group work. Wood and coworkers studied a group format for treating adolescents who deliberately harm themselves. Sixty-three adolescents who had intentionally injured themselves were randomly assigned to either group therapy along with routine care or routine care alone. The group format was chosen for clinical and administrative reasons: because poor peer relationships and impaired problem solving were thought to be amenable to group intervention, and because group therapy was hoped to decrease use of individual therapy and train of a team of therapists for dealing with self-harm. The authors advanced the field in writing a manual describing necessary complex psychotherapeutic techniques. The manualized therapy —a developmental group psychotherapy—included a variety of techniques, including problem solving, cognitive-behavioral therapy, positive corrective therapeutic relationships, dialectical behavior therapy, and psychodynamic group therapy. After assessment, six acute sessions were followed by long-term group therapy, which was open-ended. Group members could join the groups any time. Themes of acute sessions included relationships, school problems and peer relationships, family problems, anger management, depression and self-harm, hopelessness, and feelings about the future. While the group therapy did not reduce levels of depression or suicidal thinking, participation in the group (the median number of sessions was 8; the range was 0 to 19) did lead to a change in the incidence of deliberate self-harm and the use of other therapy resources. Those who had more group sessions were less likely to harm themselves again, whereas those who had more individual sessions were more likely to repeat self-harm. This study is interesting not only for the clinical outcome, but also for a model for running a continuous group, adding newcomers after a six-session lead-in.

Stallard and coworkers designed a clinical and cost-effective study of classroom-based CBT for depression in high-risk adolescents. Of the 5,030 students that were asked to participate, 1,064 adolescents aged 12 to 16

years old were considered high-risk, and were randomized to a CBT group, the usual school curriculum: Personal, Social, and Health Education (PSHE) delivered by teachers, or an attention control group (the usual school PSHE with two additional facilitators). This study examined whether these preventative interventions for depressive symptoms could be both clinically effective and cost-effective. All three groups showed decreased depression scores with no significant differences between groups. Because it required trained therapists, classroom-based CBT was not shown to be cost-effective compared to the teacher-administered groups. The study did suggest that a preventive school-based group intervention could decrease adolescents' degree of depressive symptoms.

Internet-based interventions may be useful to decrease social isolation, which may contribute to depression. Van der Zanden et al. studied a treatment that involved groups of six or fewer people aged 16 to 25 in 90-minute chat-room therapy sessions. Participants were randomly assigned to this online cognitive-behavioral group course known as Master Your Mood (Grip op Je Dip) and a wait-list control group. The therapy focused on restructuring thinking patterns by recognizing one's unproductive, unrealistic thoughts and transforming them to more helpful, realistic thoughts. Performance of daily activities and mood monitoring was also done. Reductions in depression and anxiety and an increased sense of mastery were seen after intervention and at 3-month and 6-month follow-up. A functional MRI study found alterations in strengths of brain area connectivity after only 5 sessions of group psychotherapy for depressed adolescents.

Borderline Personality Disorder/Self-Harm. Few empirically validated treatments for self-injurious behaviors and suicidality exist. In a study of brief group therapy, Green and coworkers randomized adolescents that had had 2 episodes of self-harm in the past 12 months into two arms: group therapy intervention with routine care vs. routine care. The manualized intervention incorporated cognitive-behavioral therapy and dialectical behavioral therapy. Therapists with 3 years of experience administered the therapy over 6 weekly sessions. There were no differences in terms of frequency of self-harm and severity of self-harm between the intervention and routine care in this brief trial. However, in a longer intervention, Fleischhaker and coworkers conducted a pilot study of 12 adolescent females who were engaging in non-suicidal self-injurious behaviors. Each female completed Dialectical Behavioral Therapy for Adolescents (DBT-A) over a period of 16 to 24 weeks. Prior to therapy, 8 of 12 adolescents had attempted suicide at least once. Results were examined 4 weeks post-DBT-A and at a 1-year follow-up. No suicide attempts were reported during DBT-A or at the 1-year follow-up.

Substance Abuse. Many interventions for substance abuse are in use, many with little empirical support. Kaminer and coworkers compared two different group therapies in a randomized study of substance-abusing adolescents. Subjects assigned to a cognitive-behavioral group therapy and those assigned to a psychoeducational group therapy each improved. In discussing this outcome, the authors noted that group therapy for this population may be useful, in part because of exposure to the type of peer who could be a negative influence under other circumstances (a credible peer), in the setting in which each has a goal of not using psychoactive substances. This provided the adolescent with positive modeling, positive reinforcement for efforts, and an alternative peer group within the group.

The mutual self-help group, Alcoholics Anonymous (AA), has had 2 million recovering alcoholic members attending meetings in over 100,000 groups since 1935. In adults, participation in AA improves outcome and reduces health care costs. Many adolescents are referred to AA for continuing care. In an attempt to assess AA's effects on adolescent substance use, Kelly and colleagues followed 160 adolescents at intervals for 8 years (84 percent) after an inpatient stay for substance abuse. They found that participation was high initially and dropped consistency over the 8 years, with those whose lifetime frequency of alcohol intoxication and whose perception that they had a problem with alcohol attending most. Those who attended treatment most frequently during the first year had significantly better outcomes over the 8 year duration of the study. Those who perceived that they could use alcohol in moderation attended fewer groups and were consistently less abstinent. The data suggested that in adolescents with substance abuse, attendance at one or two AA meetings per week increased abstinence and that attending at a frequency of three times per week was associated with *complete* abstinence. The authors speculated that the mutual self-help group model succeeds because it may help maintain motivation, provide a new social context of sober peers, enhance coping skills and improve self-efficacy.

Motivational interviewing (MI) has been typically used in individualized treatments, but D'Amico and coworkers developed a group MI intervention called *Free Talk*. They compared substance abuse of youth in a teen court setting who were randomized to receive either *Free Talk* or usual care. *Free Talk* was administered by psychology doctoral graduate students and focused on MI strategies that included pros and cons of continued alcohol and other drug use vs. cutting back or quitting, used willingness and confidence rulers to determine if teens wanted to change or not change their drug use, and supported teens where they were in terms of their drug use. While *Free Talk* teens reported higher quality and satisfaction ratings, alcohol and drug use and delinquency were not significantly different at 3-month and 12-month follow-up.

Internet Addiction, Online Multiplayer Video Gaming. With the Internet being one of the most commonly used methods of communication and entertainment, Internet "addictions" are emerging among adolescents.

There have been growing concerns that online video game play may be addictive and invite people to escape from their problems or daily responsibilities. Snodgrass and coworkers sought to explore some of these concerns using the online game World of Warcraft (WoW), which may be played by groups of people regularly, simultaneously, internationally, and all night. They also investigated online gamers' motivation, looking at the factors of achievement, social connectivity, and immersion, factors that tend to foster problematic play in the online worlds. "Achievement" refers to competitiveness drawing players deeper into game, where they spend more time online than they might wish. "Social connectiveness" refers to getting drawn into communities or associations that also demand more of their time. "Immersive play" refers to players who not only temporarily escape but more persistently or maladaptively avoid real-world problems. Researchers conducted 30 formal interviews and 252 people participated in a web survey. Results showed that subjects' online play could be a source of distress in their lives. They also showed that players with low levels of offline success (i.e., good job, high income, having a good social network of family and friends) may attempt to compensate by playing excessively and players with high levels of offline success are less likely to overplay. Players who experienced dissociation (losing track of the real world immersed in the virtual world) were more likely to have problematic play. Playing multiperson WoW to be socially connected correlated with such dissociation and problematic play. While WoW group interaction can be seen as restorative for some individuals, it can be problematic when players who dissociate too fully, losing themselves in the virtual world of WoW, use it as a primary social outlet and thereby risk more problematic behaviors both online and offline.

In another online survey in the United States and Germany aimed at exploring group online interaction, 523 respondents were asked questions regarding their "character attachment," defined as internalization and psychological merging of the player's and character's mind, to explain their prosocial and antisocial gaming motivations. Bowman and coworkers showed that players who were strongly attached to their character had stronger motivation to use their social skills. Less attached players tended to care less about negative consequences such as developing a negative reputation, losing other players' confidences, and difficulty forming offline relationships. More attached players has desires to form more good relations with others.

Du used a cognitive-behavioral group therapy to treat Internet addiction in adolescents. Fifty-six adolescents aged 12 to 17 were randomly assigned to an active treatment group or a control group. Group CBT

involved 6 to 10 students participating in an eight-session group CBT run by two child and adolescent psychiatrists. Each session was of 1.5 to 2 hours. Topics included recognizing and controlling one's feelings, healthy communication between parents and children, techniques for dealing with relationships and content via the Internet, techniques to control one's impulses, techniques for recognizing when behavior is becoming addictive, and ways to stop addictive behavior. A group parent session was conducted simultaneously with the adolescent group CBT. Parents learned how to recognize teen's feelings, how to promote good communication, problem-solving principles and techniques, controlling one's own feelings and behavior, and managing adolescents with Internet addiction. Subjects had higher levels of anxiety at baseline compared to the control group. After the intervention, and 6 months later, the intervention group had more control of their time and used time more efficiently. They had fewer emotional symptoms, anxiety, conduct problems, and attention-deficit problems and better peer relationships.

Eating Disorders. Heinicke and colleagues completed a study of manualized group therapy for girls who identified themselves as having disordered eating, using a self-help manual, My Body, My Life: Body Image Program for Adolescent Girls. The intervention consisted of six weekly group sessions facilitated by a trained therapist, and postintervention sessions at 2-month and 6-month follow-up. Individuals were asked to read the manual and complete the activities each session. Seventy-three adolescent girls aged 12 to 18 years old were randomized to the intervention group or a delayed treatment. The 28 girls who completed the intervention showed improvements in body dissatisfaction, disordered eating, and depression, post-intervention and also at 2-month and 6-month follow-ups.

Gender Identity Issues. Choosing group therapy as a way to address shame and isolation, Rosenberg used supportive group therapy as a component of treatment for children with gender identity issues. In a case report, she described her regimen of individual plus group treatment for working with 12 children and their parents. All but one child had comorbid symptoms of anxiety, inattention, and social isolation. All of the children had been taunted and derided. The child group component to treatment was proposed to help self-esteem through the experience of universality. In the parent group, parents expressed relief to talk openly, for the first time, about their children. They shared their experiences and fears that their children might be harmed physically, emotionally, or by sexually transmitted illnesses. They were coached on ways to interact assertively with school personnel, friends, families, and neighbors and on how to access resources. The author reported that the children made significant

clinical improvements in comorbid symptoms and began to express acceptance of their biological gender.

Menvielle and Tuerk also reported benefits of a group for parents of non–gender-conforming children. In the monthly parent support group, therapists focused on child themes and parent themes. Discussions focused on reducing the polarity of gender-based interests (girl stuff vs. boy stuff), communicating acceptance of the child's thoughts and feelings about gender and interests, setting limits on behaviors that invite trouble, facilitating peer relationships, dealing with bullying, and discussing the possibility that the child will be homosexual as an adult. Parent-focused themes included helping parents to grieve, developing coping mechanisms for dealing with embarrassing situations, and learning to intervene when necessary in social and school situations. The authors noted that the group helped to destigmatize the nonconformity for parents and that humor helped the group to build cohesiveness and reduce tension, elicited compassion, and provided insights.

Posttraumatic Stress Disorder/Sexual Abuse. Group therapies are widely used to treat individuals who have been traumatized by molestation or other events. In an Indonesian community plagued by poverty and a decade of armed violence between religious groups, Tol and colleagues introduced a 15-session school-based intervention administered in schools by volunteers with no formal mental health training. The manualized cognitive-behavioral therapy protocol included 18 group sessions, with an individual pull-out session to establish a stimulus hierarchy at week 10. Elements, in order of presentation, included overview, information gathering, group rules, relaxation training, anger management through problem solving, examination of self-talk and cognitive restructuring around PTSD, introduction of a narrative about the trauma, imaginal and in vivo exposure, confrontation of PTSD-induced dysfunctional beliefs, summary, and graduation party. Subjects treated with trauma-processing activities, cooperative play, and creative-expressive elements improved and maintained over 6 months in measurements of posttraumatic stress disorder symptoms and hope, in the setting of continued environmental conflict and stress. Girls improved more than boys did. Authors concluded that a classroom-based intervention can be an appropriate approach to target large numbers of children with stress-related symptoms, in which the start dates but not the psychometric assessment dates were staggered. The authors hoped that such time-limited manualized treatment might help in situations of severe natural or human traumas.

British investigators Trowell and coworkers randomly assigned 71 symptomatic, sexually abused girls between the ages of 6 and 14 to participate in either 30 sessions of manualized, focused, weekly individual psychoanalytic therapy or 18 sessions of manualized psychoeducational

and psychotherapeutic group psychotherapy (hours spent in therapy were comparable). In the individual psychoanalytic therapy condition, play materials were provided, topics to be addressed were designated in the manual, but the topics were addressed as they arose, and each was covered. The group topics were prearranged, with notebooks, task sheets, and play material. Time was also allowed to address the relationships between the girls and their relationships with the co-therapists, and this was linked to past and current relationships, losses, and disruptions. Outcome was measured posttreatment at 1 and 2 years. Individually treated subjects had significantly greater improvements in PTSD symptoms. Each treatment led to improvement in general functioning and in anxiety and depressive symptoms.

In the specific context of child sexual abuse, group psychotherapy is considered the "treatment of choice" because of its impact on negative effects of sexual abuse: isolation, stigma, and self-esteem. The group format can foster a sense of belonging among peers and help overcome the element of secrecy, which is a common component of child sexual abuse. Group and individual treatments of sexually abused children and adolescents have now been found to be equally efficacious, finding that the adjusted expense of individual therapy is 64 percent more than group treatment formats.

Deblinger and coworkers performed a randomized comparison study of group supportive versus group cognitive-behavioral therapy for young children who had been sexually abused and their mothers. The interventions aimed to improve the adjustment of these young children by helping them to learn to communicate about their feelings, identify inappropriate touching, and learn abuse response skills. In the children's support group, material was presented in a didactic format. The children's cognitive-behavioral therapy format was interactive, using a workbook, role play, behavioral rehearsal, and joint parent–child exercises. In groups parallel to the children's, the parents were randomly assigned to cognitive-behavioral group therapy or support groups. In the cognitive-behavioral therapy condition, parents were assisted in coping with their emotional reactions to the abuse and their children, taught about effective communication with their children in general and with regard to sexual abuse, and provided behavior management skills to assist them in handling their children's difficult behaviors. The support group was run with a manual guiding the therapist with skills of active listening, unconditional positive regard, reflecting feelings, and empathy and provided information about group dynamics.

The magnitudes of effect sizes for changes posttreatment and at 3 months for children and mothers who participated in the cognitive-behavioral therapy groups were large on most measures. For the support group subjects, effect sizes were medium. Parents in cognitive-behavioral

therapy expressed greater satisfaction with the therapy. Children in the cognitive-behavioral groups (which used interactive behavioral methods) demonstrated greater knowledge and retention of body safety skills.

Improving Adherence to Medical Regimens in Chronic Illness. Parents of children with chronic illnesses must deal with many demands: attending to their sick children, interacting with the health care system, their employers, while caring for the rest of their families and their own emotions. In New Zealand, investigators developed and tested a Strong Parents–Strong Children 6-week group intervention to help parents to manage these stresses and learn practical skills for accessing services. Parents learned to plan time for themselves, address catastrophizing cognitive distortions, and use relaxation techniques. They practiced strategies for obtaining and sharing information from relevant health professionals and maintaining family life and social contacts with the goal of handing off aspects of illness management to the child when developmentally appropriate. Parents who participated in the group perceived themselves as more effective and more able to manage stress and perceived the family as more cohesive, less anxious, and better able to cope than did those on the waiting list.

For some adolescents, adherence to life-saving medical regimens is poor. Some preliminary studies suggest that treating adolescents in groups together with parent or "treatment buddy" involvement may help. Viner and colleagues compared a measure of diabetes control (hemoglobin A1c) in adolescents who elected group therapy with that in adolescents who were assessed but declined therapy. Intervention consisted of motivational enhancement therapy, analysis of strategies that help (solution-focused therapy), and a parallel parent group. Those treated in group therapy improved in glucose control (decrease of hemoglobin A1c of 1.5 percent). In a pilot of a group intervention involving "treatment buddies" and adolescents aimed at improving adherence to antiviral medication therapy, nearly all participants increased adherence to medication, as well as other important health behaviors.

Social Skills. Group treatment settings provide obvious opportunities for learning and practicing social skills. Children and adolescents with various disorders may have impaired ability to perceive important aspects of social intercourse, deficient knowledge of what to do to interact effectively, and/or ineffective means of being with others. Social skills have improved using therapy in groups for children and adolescents with autism spectrum disorder, aggression, or ADHD.

A German group recently reported results of an 11-month intervention for youth with communication difficulties using the manualized Frankfurt Social Skills Training (KONTAKT). Seventeen subjects aged 9 to 20 attended weekly (for children) and biweekly (adolescents) sessions in

groups of 4 to 7 participants. The protocol encouraged flexibility within structured sessions. Flexible elements included social interaction games, role play, group discussion, group discussions, pantomime games, and computer-based affect recognition games focused on recognition of emotions on human faces and eyes. In this pilot study, the youth showing the most improvement included those with higher IQs and higher initial levels of communication difficulties.

Fifty-two peer-nominated, socially rejected, inner-city, fourth-grade boys participated in a controlled study of social relations training program by Lochman and coworkers. Over 7 months, this program combined 26 individual sessions with 8 small-group sessions to focus on social problem solving, positive play training, group entry skill training, and dealing effectively with strong negative feelings. For example, in learning how to enter a group, children were trained to assess the general climate of the group, analyze the leadership structure, and match their style of entry to the ongoing play and activities of the group. Only the children who were aggressive showed significant treatment effects in reduced aggression, reduced social rejection, and improved peer prosocial behavior at the end of the intervention and at 1-year follow-up. This study illustrates the successful use of a group component of an intervention chosen for its use as a practicing ground.

Targeting social perception, knowledge of social rules, and peer group behavior in hospitalized boys with ADHD and conduct disorders, Kolko and coworkers compared outcomes of group social skills training with social activity group participation. Fifty-six boys were assessed by self-report on assertiveness and loneliness, by staff reports on social problems and social acceptance by peers, and by peers on popularity. The subjects were rated on 15 role-plays for competence and on behavioral observations that detailed social involvement, gaze, physical space, appropriate voice loudness and inflection, using openers and compliments, making assertive requests, responses to provocations, and appropriate play.

The manualized treatment groups of four to five boys met for three 1-hour sessions per week for 5 weeks. In each session, group rules were read, the last lesson was reviewed, and questions were asked to assess retention. Skills training was accomplished by reviewing and rating videotaped role plays of situations handled correctly and incorrectly. Incorrectly played situations were correctly role-played, discussed, and then rehearsed in the group. Points earned in the unit's token economy were recorded in the group. Outside the group, a "Secret Agent" awarded stars when the group members were caught appropriately putting the skill learned into action.

The social activity groups of five to seven boys met for semistructured group activities and games designed to demonstrate specific concepts likely to promote improved relationships, such as cooperation, friendship, empathy, and telling the truth. These sessions also began with a rule

review, followed by a description of the planned activity and its underlying concept, and then the activity. Leaders provided the boys with feedback about their overall participation and awarded points.

Outcome was assessed posttreatment and at 1-year follow-up. Those in the social skills training group showed significant improvement in loneliness, in staff-rated peer relationships, and in social competence as measured by the role-play assessment. Children in the social skills training group also showed improvement in almost all of the behavioral observation measures, whereas those in those social activity groups showed none. Both groups improved in assertiveness and social initiations. At 1 year, teacher reports revealed more improvement for the social skills group than for the social activity group. Providing a format with opportunities for rehearsal and both therapist and peer feedback likely led to better results.

Limitations of Group Therapy

When nonbehavioral approaches such as nondirective and psychodynamic models are used, meta-analysis found that group therapy demonstrated a smaller effect size. In group therapy, the therapist is constrained in his or her ability to attend to specific individual troubles and has less flexibility in a crisis. Gathering sufficient group members may prove difficult for individual practitioners.

Complications

A patient's ability to discuss emotional issues and be vulnerable in practicing new skills in a group is dependent on his or her feeling safe and respected. When confidentiality is breached, when occurrences of disrespect are inadequately processed, or when individuals feel physically unsafe or threatened by interaction outside of the group, the group is acting counter-therapeutically. Adequate therapist training and supervision, careful screening of patients, and close attention to the group rules and process may guard against these occurrences.

Goals of Treatment

Each group therapy aims to ameliorate symptoms and promote psychosocial growth. The rationale for choosing to provide therapy in a group format must be that group therapy, in particular, either has evidence to support its choice or has qualities that make it theoretically suited to address the patient's individual problems.

ETHICAL ISSUES

As implied previously, group therapy, although possibly cost-effective, should not be prescribed with that sole consideration in mind. It is properly used as one tool of many in the armamentarium of psychotherapists when

evidence supports its use or, lacking other more empirically supported therapy, theory provides a rationale.

RESEARCH AND EVALUATION

As delineated by the Task Force on Promotion and Dissemination of Psychological Procedures, those treatments possessing empirical support should be identified, developed, disseminated, and used. According to its criteria, most traditional group therapies fell into the experimental category. A bustling movement is growing to develop well-established treatments. Doubtless, group therapies for children and adolescents will be among those whose use will be supported.

▲ 54.5 Family Therapy

JOHN SARGENT, M.D., AND NEHA SHARMA, D.O.

Family therapy represents an organized, well-developed, and variable set of interactions with family members that addresses mental health and substance use problems that affect them. It also has been used to assist with recognized relationship problems, including communication difficulties and difficulties occurring within spouse and parent–child relationships. (In this section, "parent" refers to any adult with custody of the child and responsibility for the child's well-being and development.)

These interventions take advantage of the importance of family relationships to individuals and the willingness of individuals to alter their behavior and thinking to help family members. Family therapy theory and practice are based on a range of ideas and ideologies (Table 54.5–1) and oriented to respond to a wide range of problems. The therapist's responsibility is to appreciate the nature of the problem, develop a shared appreciation of the problem with family members, and collaborate with the family to develop the best overall adaptation of family members, including ameliorating the manifestations and effects of the problem.

Family interventions address problems that have neurophysiological

and genetic elements and have developed in relation to unique environmental occurrences. Interactional responses often naturally occur that reinforce the problem. Family members are also emotionally affected by their relatives' difficulties, leading to a further mismatch between family members' needs and others' behavior. A child may be identified as the patient while the family struggles with a poor marital relationship or with parental mental health concerns. Family therapy is much more interested in the solutions to problems and improvement in the overall well-being and functioning of the family than in the etiology of the problem. This leads to a future-oriented focus of treatment and also suggests that assessment is carried out in a manner that is engaging and therapeutic. Often, family members are frustrated and frightened, and often their interactions are unproductive and repetitive, reinforcing and maintaining the problems. Therapy occurs through the interventions of the therapist and the relationships he or she develops with family members and with the family as a whole. The therapist's behaviors are intentional and carefully chosen and carried out to facilitate engagement, mutual care, support, and a resolution of problems that the family is experiencing. The therapist also appreciates that improving family relationships and interactions often leads to improved overall functioning, which can become mutually reinforcing and self-perpetuating.

Table 54.5–1.
Family Tasks as Child Development Unfolds

Infancy
Ensuring parental availability
Ensuring resources to enable parental caretaking
Providing support to parents when stressed
Providing education about infants and parenting
Encouraging balance between jobs of adult and parent, especially during times of transition
Preschool Children
Enabling parents to respond to separation/individuation efforts of the child
Encouraging parental consistency in discipline and limit setting
Supporting positive parent–child connections based on individual nature of the child and the child's competencies
Encouraging play, use of fantasy, and creativity in the interactions between parents and child
Encouraging child's relating ability with other children and with other caretaking adults
School-Age Children
Ensuring parental consistency in understanding, accepting, and being available for the child
Developing rule-based behavioral expectations and consequences for the child
Encouraging the child's competent engagement with school, friendships, and community activities
Gradually assisting the family in developing a consistent, positive, and hopeful appreciation of the child
Encouraging the child's independent perception of and participation in family life
Adolescence
Assisting the parents with adolescent problems that require rules, consequences, and consistency
Encouraging parental figures in assuming a supervisory role with children, with parents willing to allow for experimentation and learning, although also establishing essential rules

Encouraging the adolescent's voice and role in family life, as well as his or her competency and involvement in extrafamilial experiences
Assisting the parents in encouraging self-direction, self-definition, integrity, and values in adolescent children
Assisting parents with refocusing on important aspects of their lives as they separate from their children

This section focuses on the use of family assessment, family interventions, and family therapy to address the problems that families have with their children's development (Table 54.5–1), emotions, cognitions, and behavior. It is based on the premise that the practice of child and adolescent psychiatry always involves interacting with and understanding family interactions and functioning, and always involves engaging the family in the treatment and monitoring process (Table 54.5–2). The section includes case examples demonstrating the range of applications of family therapy, as well as the various forms that family treatment may take. Tables reviewing these significant models of family therapy (Table 54.5–3), the theoretical foundations of family therapy (Table 54.5–4), specific treatment approaches for common child mental health problems (Table 54.5–5), and unique family treatment approaches to differences in family composition, family history, and the culture and ethnicity of the family (Tables 54.5–6 and 54.5–7) are included.

Table 54.5–2.
Assumptions of Family Treatment

Family therapy is an integral part of the practice of child and adolescent psychiatry.
Child and adolescent emotional and behavioral difficulties always affect family life and relationships.
Family relationships always affect child development, emotional status, and behavioral capacity.
Adaptation of the child and adolescent with psychopathology to the family is always a goal of treatment and requires change on the part of the family, accommodation by the child when possible, and consideration by treating professionals.
The family can always be a source of understanding, support, and healing for children and adolescents.
The family should agree to, participate in, and assist in directing all mental health interventions at all levels of care.
Family involvement in all treatment should be defined and structured to achieve family goals and facilitate achieving goals for the child with psychiatric difficulties.
Various therapeutic interventions and classes of interventions can be used to achieve these goals.

Over the last 20 years, manualized family therapy treatments have been developed and identified as evidence-based treatments through randomized, controlled trials. These treatment approaches have been developed for specific child and adolescent disorders, such as traumatic stress, substance abuse, anorexia nervosa, and conduct disorder.

PROCESS OF FAMILY THERAPY

Engagement

The key to successful family treatment is successful engagement of the therapist with the family and with family members. This process requires that the therapist possess the skills of connecting with more than one person at the same time and making each person feel understood, comfortable, and cared about. Engagement conveys the therapist's hope for the family's successful future and his or her belief that with effort, patience, and mutual care and concern changes can occur and that a successful future can be realized. Family therapy in whatever fashion is always a creative act, an act of vision. The therapist's connection with the family and its members is based on his or her assertion of the meaning and value of this family. Through the acceptance inherent in engagement, the therapist works to create a context of safety that promotes greater flexibility in the interactions of family members and greater possibility that the situation can be accepted and improved. In addition to warmth, curiosity, hope, and vision, the therapist must be able to hold and act on opposite ideas: that the family possesses strengths and has difficulties, that the family is doing the best it can and that the family needs to change, and that the family and its situation are unique and also resemble other families in their connections to each other, their concern for each other, and their wish that every other family member have the best life possible.

The therapist also engages with the family as an entity. By acting in a manner that reflects the therapist's belief in the integrity of the family, family members can begin to relax, see each other differently, and behave in a manner that reflects their interest in membership in their family and their commitment to its well-being. The therapist asks about the family's history, culture, rituals, and beliefs; respects what he or she hears; and treats the family as an entity in which he or she believes in and cares about. This helps the family members to come together, work together, and change the ways in which they treat each other. In doing this, family members begin to understand that relationships can improve, conflicts can be dissolved, and mutual understanding and mutual support can develop. Through successful engagement with individual family members and with the family as a whole, the therapist creates a solid foundation for family change and symptomatic improvement.

Table 54.5–3.
Varieties of Family Therapy

Psychodynamic

Assumptions and Major Concepts

- Family relationships are based on previous parent–child relationships of each parent.
- Difficulties arise from developmental arrest, current interactions and projections, and current stressors.
- Improvements develop through the process of family members gaining insight into problematic relationships from the past.
- Therapy consists in shared exploration of past relationships and current distortions and role

confusions.
Therapy also encourages the development of mutual appreciation of the needs and limits of family members.

Major Theoreticians and Practitioners
Nathan Ackerman
James Framo
Ivan Boszamenyi-Nagy

Experiential/Existential

Assumptions and Major Concepts
The family is a developing organism, and the goal of therapy is to encourage the growth of the family and its members through the process of therapy.
This process is best supported by encouraging expressiveness, openness, and communication within the family throughout the therapeutic encounter.
The family is responsible for its solutions; the therapist is a facilitator who encourages growth and confronts stagnation.

Major Theoreticians and Practitioners
Carl Whitaker
Virginia Satir

Intergenerational/Bowenian

Assumptions and Major Concepts
The family is an emotional relationship system, with the goal of relationships to promote engagement, foster differentiation, and avoid fusion.
In conflictual situations, engaging a third party (triangulation) stabilizes the family system.
Individuals marry partners at the same level of differentiation, leading, at low levels of differentiation in married couples, to severe personal and relationship difficulties.
Therapy is aimed at clarifying current relationships, promoting individuation, resolving current conflictual interactions, and working through intergenerational and introjected difficulties and patterns of behavior.

Major Theoretician and Practitioner
Murray Bowen

Structural

Assumptions and Major Concepts
Focused on current organization of the family as demonstrated through repeated patterns of interaction.
Particularly attentive to how the family's organization promotes or inhibits task performance, especially child rearing.
Analysis of interactions allows the therapist to determine the nature (distance vs. closeness) and the flexibility of family relationships in relation to task performance.
The therapist promotes interactions in sessions to determine family relationships and then intervenes in those interactions to introduce greater flexibility, alternative patterns and structures, and more effective task performance.
Enmeshment (ineffective closeness) and disengagement (excessive distance), as well as rapid fluctuations between extremes, are manifestations of dysfunctional family relationships when associated with significant symptoms in a family member.
This form of family therapy was developed to respond to child and adolescent emotional and behavioral problems and is particularly effective in those situations.
The therapist is both the director of therapeutic action and participant in the process of therapy.

Major Theoretician and Practitioner
Salvador Minuchin

Systemic/Strategic

Assumptions and Major Concepts
Symptomatic behavior is embedded within the patterns of communication and relationships in a family.
Ineffective attempts at solutions to problematic behavior become part of the pattern also and

thus part of the problem.
The therapist is responsible for developing and prescribing tasks and behaviors that disrupt usual patterns of interaction while strengthening other, more productive patterns.
The therapist maintains a stance of neutrality and distance with respect to the family as whole and individual members.
Specific methods of questioning designed to elicit information about family relationships (circular questioning) are used; posing hypotheses, reframing, externalizing blame, and the use of positive connotation are common techniques.

Cognitive-behavioral

Assumptions and Major Concepts
Concepts of learning theory—conditional contingency, reinforcement, extinction—explain problematic behavior and identify therapeutic interventions.
Sessions are entirely problem- and solution-focused in the present.
Skills training is emphasized throughout treatment; homework, record keeping, and between-sessions tasks are used regularly.
Therapy is aimed at changing both cognitions and behavior and uses new cognitions among family members to direct and evaluate behaviors.
Particularly useful for managing mild to moderate disruptive behaviors in children and adolescents, focusing treatment on parent skills training.

Gerald Patterson
James Alexander

Table 54.5–4. The Theoretical Foundations of Family Therapy

General Systems Theory

The whole is greater than the sum of the parts.
Actions that affect one part of a system affect the whole.
Each part of a system is in a constantly changing relationship with all other parts.

Cybernetics

Interaction among family members is circular and continuous, with each behavior being the effect of one behavior and the cause of another.
Circular causality encourages attention to pattern of interactions and feedback between behaviors and relationships.

Communication Theory

All behavior is communication (both actions and words); behaviors define the nature of the relationships among family members.

Structural Theory

Relationships are structured in a hierarchical, potentially developmentally oriented fashion.
The structure of a family can only be determined by noting the patterns of interaction among family members.
Structures are functional or adequate insofar as they provide for the achievement of family goals.

Social Constructionist Theory

Each individual constructs or makes sense of his or her experience from his or her perspective.
Therefore, many different interpretations of a set of circumstances may be simultaneously true.
Families, therefore, must and do develop shared constructions of their situation.
The constructions may become unsatisfactory when problems or changes require interaction with systems (health care, school, extended family, community agency, etc.) that have alternative

constructions of events.

Psychodynamic Theory

Early experience is formative in defining who people are.

The capacity for projection and projective identification can seriously inhibit the flexibility, resilience, and growth of relationships.

Attachment Theory

Affect regulation occurs within close relationships.

Secure attachment facilitates social relationships and the ability to know and communicate about mental states.

Safety

Throughout the engagement and assessment process the therapist's first responsibility is to ensure the safety of the child, the family members, and others in the community, as well as his or her safety. In some families aggressiveness is a part of their interactions, emotions may run high when disappointments, hurts, and conflicts have occurred, and family relationships may feel and at times be unsafe. Thus the therapist must be attentive to signs of the possibility of violence, aggressiveness, abuse, and suicidal behavior. If there is concern about safety, consideration of hospitalization or involvement of human services or the justice system must be considered. The therapist's role is to work with the family to decide together on the level of care necessary to promote the safety of all while also beginning treatment in a manner that ensures the safety and connection of all. The therapist creates a safe space where family members can speak to and listen to each other and where hurts and disappointments can be spoken about and reconnections can be achieved. The therapist can establish ground rules for sessions and, if concerned, meet with family members individually to ensure a commitment to self-control and mutual respect in treatment and ultimately throughout family life. The quality of the therapist's engagement with the family and his or her presence, integrity, and his belief in his or her vision of successful resolution of problems are crucial in leading the family to the changes needed to ensure nonviolent family life.

Assessment

Family therapy is based on an ongoing assessment of the child's problem and family life. It is important for the therapist to recognize that the assessment is part of the therapeutic process. Assessment is completed in an interactive manner that is based on the therapist's interest in the family's strengths and individual capacities and interests, as well as the therapist's professional responsibility to appreciate the family's problems. The therapist, connected to the family in the treatment system, elicits a discussion about the questions the family has about their child and the concerns and issues the family experiences in their life.

One can view the process of assessment in child-oriented family therapy

as the iterative development of an imagined video of the child and family at home, their relationship with the child's school, and their presence in their community. This understanding appreciates not only the child's symptoms and abilities, but also the interactions within which those symptoms and strengths are embedded. Thus, symptoms—either those that are spontaneous or those that are reactive—are viewed within the interactions that precede them and those that follow them. One way to understand the patterns in which symptoms are embedded is to encourage interaction among family members in sessions and to be attentive to spontaneous interactions as they occur in sessions. Understanding these patterns provides the therapist with many possibilities for discussion and intervention.

The family and the therapist can also decide together other questions to be answered through the treatment process. Intellectual concerns, educational abilities, and vocational aptitudes all can be evaluated if questions exist. Diagnostic questions and the use of psychopharmacology also can be discussed in a collaborative fashion with the family. The guiding issues are always: What are your questions? What are your goals? What of these alternatives do you want to do? The key to understanding this process is to appreciate several key principles:

1. Assessment results are impressions and not judgments.
2. All assessments of the family are hypotheses based on limited data and thus are subject to change.
3. Because interactions can change and are largely dependent on context, the therapist holds the belief that if the context changes, the interactions can change.
4. Any intervention represents a question: will this intervention be successful in achieving the goal? If not, a different intervention is required.

The process of developing a shared opinion of both the child and the family, including an appreciation of strengths and difficulties among members of the treatment system, is another opportunity for therapeutic intervention. There may be opportunities to discuss and resolve disagreements between caregivers about the child's capacities and problems. There may be opportunities, depending on developmental ability, for the child to participate in this discussion. The therapist supports the child's voice and expects the child to participate responsibly. As this process proceeds, the family's ability to negotiate effectively can be supported and reinforced by the therapist.

Table 54.5–5.
Family-Oriented Treatment Approaches for Specific Clinical Problems

Ensure appropriate diagnostic evaluation, accurate diagnosis, and adequate antipsychotic treatment.
Psychoeducational treatment model is very helpful, providing education about the disorder, outlining family roles in treatment, and providing guidelines about how to respond to crisis and specific problems.
Efforts at reducing blaming and intensity of affective expression within the family are often helpful.
Ensuring family collaboration with the treatment approach, especially concerning communication with professionals, medication, vocational training, and work and placement, is extremely helpful.
Parent support is an important aspect of treatment.

Depression

Ensure that all involved recognize and accept the child's depressed mood.
The therapeutic orientation should include attention to building attachments and connections, reducing personalized criticism, and building support among family members.
Building individual competence is essential.
Cognitive-behavioral strategies are most effective.
Setting limits to deal with acting out, personal irritability, and poor academic performance is often helpful.
Special attention should be paid to parental psychiatric problems.
Psychopharmacology should be integrated within the therapeutic approach.

Anxiety Disorders and Phobias

Collaboration in treatment reduces the power of the child's fears and vulnerability.
Cognitive-behavioral approaches with the family are helpful.
Agreement about the expectations for the child, especially regarding fears, is necessary.
Distraction, relaxation, social skills assistance, and focus on building peer relationships all are helpful for the entire family to focus on.
Recognition of temperament and the possibility of recurrence of worries during stressful periods often aid long-term outcome for the family.

Disruptive Disorders

Attention-Deficit/Hyperactivity Disorder (ADHD)
Agreement about diagnosis is essential.
Education concerning the various aspects of ADHD is helpful.
Family involvement in measuring and monitoring the results of behavioral interventions and psychopharmacology is helpful.
Parent support groups can help long-term adaptation.
Specific plans for impulsivity, reactivity, and aggressiveness are helpful.
Independence, self-regulation, self-organization, and personal responsibility are goals of treatment.
Special attention should be directed to developing the strengths, competencies, and self-esteem of the ADHD child and the family as a whole.
Conduct Disorder
Collaboration among parents and all involved professionals and agencies is essential.
Responsibility and accountability for the child are primary goals of treatment.
Parameters of treatment must be explicitly stated.
Behavioral approaches highlighting consistency, expectable consequences, and predictable responses to transgressions are the cornerstone of treatment.
Plans must be made for responses to violence and other serious problems.
Impulsivity in treatment should be avoided; treatment must be consistent, continuous, developmentally oriented, and focused on building successful adaptation of the child, as well as on reduced behavior problems.
Medication is to be used for specific target symptoms, and its use and effectiveness must be supported by all participants in treatment.

Substance Abuse

Agreement about avoiding substance use among all involved adults in necessary.
Family tolerance for affective expression usually needs to be expanded.
The family must also attend to comorbid problems, depression, learning problems, ADHD, and so forth.

The role of consequences and limits for substance use must be expressed clearly.
Parental substance use also must be addressed in treatment.
Family participation in mutual support groups (Narcotics Anonymous, Alcoholics Anonymous) is often very helpful.
Peer problems, legal difficulties, and relapses should be addressed directly with the family.

Eating Disorders

Structural techniques build family cohesiveness and a consistent approach to the disturbed eating behavior.
Simultaneous support for individuation and connection is necessary.
Cognitive-behavioral techniques assist in establishing consistency in family relationships, as well as in responses to eating disorder symptoms.
Family therapy offers an opportunity for dealing with gender issues, as well as concerns associated with control and perfectionism.
The age of the eating-disordered individual defines how treatment is structured; early adolescents respond best to family-oriented treatment; older adolescents and young adults respond better to family therapy approaches that they arrange and manage in conjunction with simultaneous individual therapy.

Abuse (Physical or Sexual)

Safety of the child is paramount.
Parents should collaborate with the therapist and social service agency staff.
A clear role for parents in the treatment process should be outlined, with specific expectations and consequences defined.
Parent training and skills building are helpful, especially if the unique contributions of the child to the family situation are highlighted and the parents have the opportunity to practice responses and receive praise and support when they demonstrate competence.
Honesty, clarity, and directness often reduce defensiveness and evasiveness on the part of family members.
As much as possible, the child should have a developmentally appropriate, active role in treatment.
Encouragement of verbal expression can be helpful in affect regulation and maintenance of consistent responses to behaviors among family members.

Academic or Learning Problems

The child's learning or academic problem must be defined to the satisfaction of parents and school professionals.
Parents assist with developing questions to be addressed through psychological, psychiatric, and educational evaluations.
Roles and responsibilities of parents, school professionals, mental health professionals, and the child should be clearly identified.
Specific educational and school-based goals should be set; these should be development of academic competency, self-esteem, and greater connection between the child and school.
Steady progress through school marks development and achievement and builds greater maturity.
Other difficulties influencing learning (e.g., depression, anxiety, ADHD, and other disorders) need to be addressed simultaneously.

Table 54.5–6. Variations in Family Composition

Single-Parent Families

Recognize the strength, responsibility, burden, and stresses of the custodial parent.
Support the independent competence of both the parent and the child.
Encourage the parent's use of alternative caretakers and other modes of personal connection and support.
Encourage the child's exploration of his or her relationship with the noncustodial parent.
Assist with transitions that may occur with new relationships that the parent might develop.

Divorced Families

- Encourage parental collaboration in divorcing and parenting processes.
- Assist the independent emotional reactions of each family member to the separation and divorce process, including the recognition that this is a highly painful experience for children.
- Encourage the development of effective separate relationships between each parent and each child.
- Build strengths of sibling relationships.
- Assist the competency and expression of each child.
- Assist parents in collaborating in parenting tasks.

Grandparent- or Relative-Headed Families

- Recognize the effort and strength of the child-rearing adult.
- Encourage the child's emotional adaptation to not living with his or her biological parents.
- Encourage effective limit setting and adult affiliation with the child in these families.
- Emphasize the child's competency and extrafamilial engagement and accomplishment.
- Support consistency in involvement of biological parents to the greatest extent possible.

Adoptive Families

- Recognize that the child's problems may be associated with preadoptive phenomena.
- Support with sensitivity the parents' emotional reaction to their child's difficulties.
- Possible special attention to the child's background and special attributes.
- Build connections among family members while dealing with the losses and separations associated with adoption.

Families with Same-Sex Parents

- Similar strategy as adoptive families
- Support parents to feel empowered and effective in their parental role.
- Guide parents to differentiate between their personal childhood experience and their child's experience.
- Build connections in the community such that family members feel welcomed and accepted.

If other agencies or systems are involved with the family, especially in response to the child's problem, their representatives also will need to participate in the agreements about strengths and problems. This can be difficult, especially if the family has a history of conflict with these systems. The family may believe that a system with which they must be involved, such as the child's school, is treating the child ineffectively. The family will need the therapist's encouragement and potentially the therapist's coaching to be able to come to a collaborative approach with school personnel so that the child's education proceeds successfully. Similar negotiations will need to occur with the child protective system, the juvenile justice system, after-school programs, coaches, extended family, and church leaders, depending on who is involved with the child and what the child's needs, abilities, and problems are. At times the therapist will need to convene meetings of the family and those involved. The therapist, with the family's permission, may need to speak individually with the teacher, probation officer, and so on. These individuals may need to change their impressions of the child or family, and at times they may need to change the way in which they interact with the family. Supporting these new impressions is part of the therapist's responsibility for the success of his or her interventions. These changes become part of the therapeutic effort and goals for the treatment.

Table 54.5–7.
Family Therapy Approaches: The Effects of Cultural Differences

Cultural Difference and Family Worldview

Worldview defines the relationship of a family to people, institutions, and objects.

Cultural experience affects a family's worldview.

Race, religion, and traditional position within the power structure also affect a family's worldview.

These factors influence family relationships, family roles, and expectations of parenting, child rearing, and child development.

Examples of Cultural Considerations in Family Treatment

White families: focus on individuals, use verbal expression, and distinguish between physical and mental factors.

African-American families: focus on actions and behavior; realize that extended family is important, as are religion and church; also realize that history of oppression and racism affects relationships with institutions.

Hispanic families: acknowledge bilingual background with intrafamilial differences in acculturation and language use; religion and extended family are important; respect for the family's heritage and background is very helpful in ensuring engagement in treatment.

Asian-American families: recognize specific national origin; family, privacy, and saving face are central to family life; recognize intrafamilial differences in acculturation and language use.

Attending to Cultural Issues in Family Therapy

Basic Values

Any family is a microculture.

The family's culture is necessarily a synthesis and amalgam of cultures.

Problems develop when the family experiences conflict internally between the cultures of the extended family or with external cultures, institutions, or systems.

The family is responsible for defining itself and its culture and for developing the most successful adaptation with other cultures.

The therapist's responsibility is to support and facilitate that adaptation, recognizing (1) that there are many ways to be a family and raise children that are healthy and (2) that there may be issues that raise ethical concerns for the therapist, and in those situations further knowledge of the family's culture and consultation or supervision may be helpful.

Interactive Approaches

The therapist must assume a stance of respect for and acceptance of the family as it is.

The therapist should ask about the meaning of requesting mental health assistance for the family.

Honest curiosity expressed in open questioning about how the family operates and how the family's cultural background influences its operation is essential.

The therapist should refrain from judging the family, but rather should ask about how it achieves its goal.

The therapist should avoid behaviors based on assumptions about a particular cultural background.

The therapist should inquire about child-rearing practices in the family and responses to academic, emotional, behavioral, and social problems in the child as they reflect cultural beliefs and cultural expectations.

Clinical Approaches

Specific responses to the child's symptoms and assistance with parenting skill need to be embedded within the therapist's and the family's understanding of cultural beliefs and expectations.

Negotiation of the therapist's role and behavior should be based on the family's sense of their culture's expectations of professional behavior.

The therapist can help the family to understand their cultural background as a method of helping the family to define and understand themselves and clarify their approach to therapy.

Explorations of culture assist the family in assuming direction and responsibility for treatment.

Discussions about respective cultural backgrounds and what those backgrounds mean can assist in conflict resolution and enhance the development of the children.

The therapist can assist the family in making accommodating measures with schools and other

institutions based on cultural considerations.

Engaging Families in All Levels of Care

Family members should be actively involved in decisions about treatment programs, levels of care and care delivered, and inception and discontinuation of treatment. This expectation helps the parents or caretakers develop monitoring, supervisory, and organizational skills that they might be lacking. Because the parents possess decision-making power, they must learn to understand their child, make the child's behavior make sense, and begin the process of accepting the child's differences. This can accentuate feelings of support and understanding, which may have been undermined by their responses to symptoms and their consequences. This is especially true in the case of families with children with disruptive disorders, in which difficulties in school or with the justice system may have felt hurtful and shaming.

The journey to get out-of-home services often results in parents feeling ineffective and disempowered. The purpose of family intervention is to empower parents to conduct effective parenting. Thus, family involvement is essential for children being treated in treatment programs such as hospitalization, day treatment, or residential treatment. For the home environment to reinforce positive behaviors and not reinforce negative behaviors, it is necessary for program clinicians and staff to be attentive to the interactive sequences of which the symptoms were a part and intervene with the family to alter those sequences so that the home environment is different when the child is discharged or the program ends. If discipline is problematic, parents can be consulted when program rules are broken and consequences are required. Parents can be informed by the child of successful experiences so that their praise is added to that of the staff. These successful experiences can translate into hope for change for parents. Parents can be expected to meet regularly to have a meaningful voice in treatment review, learning to develop realistic expectations of their child based on how the child is able to function rather than based on everyone's wishes about how he or she might function. It can be difficult at times to share power with parents, but with patience the staff can help the parents to feel empowered throughout the treatment program. If passes home are part of the treatment program, activities can be planned for the entire family that emphasize practice with new interactions at home prior to discharge.

Ensuring a Balance between Support and Limits in Parent–Child Interactions

One of the most challenging aspects of child-focused family therapy is developing an effective balance between, on the one hand, enhancing parent–child warmth, support, and the interactions that reflect secure

parent–child attachment and mutual respect, and on the other, working to establish effective rules, supervision, and consequences for misbehavior and rule breaking. This often requires skill, focused attention, and persistence on the part of the therapist. Because parental warmth forms the foundation of the mutual respect needed for effective discipline, the therapist's first task is to build that warmth. This often occurs at a time when parents feel betrayed, helpless, angry, and victimized. At this point it is the therapist's belief in the parents, in their love for their child, and in the possibility that they might help their child grow up safely and successfully that matters most. The therapist models warmth in his or her relationship with the parents. Compassionate understanding characterizes these interactions. Interactions that caringly convey the therapist's belief that the parents care for their child and believe in the child's future characterize the therapy. This must occur even if the child expresses skepticism or disbelief about the parents caring for him or her. As trust develops between the therapist and the parents, who know that the therapist believes that they care truly about their children, a wide range of interventions is possible. These include establishing parent interactions with the child aimed at understanding the child's disagreements with his or her parents in a nondefensive way and in a dispassionate fashion while establishing expectations for their child's behavior as well as consistent consequences for failing to meet expectations. In this process, the therapist helps the parents to deal with their disappointments with their child so that consequences are not vindictive and helps the parents appreciate that their child could want their approval and could wish to earn their regard. In this approach, parents understand and support their child's emotions, disappointment, frustrations, and anger while also holding firm expectations, limits, and consequences. In a sense, parents are feeling one way—frustrated and angry—and acting another way—calm and firm—while allowing the child to act one way—frustrated and angry—and expecting the child to feel another way—accepted and respected even while adhering to parental limits and appreciating parental involvement and concern.

Parents often want advice about establishing discipline and limits, especially in situations in which the child has a disruptive behavior disorder and defies parental rules and limits. This often represents a challenging therapeutic concern. Often in these situations there is a difference in approach between parental figures. Everyone is exhausted, hurt, frustrated, and angry. The parents will frequently claim that consequences do not work. Disrespect and defeat characterize parent–child interactions. In these situations the therapist might choose to meet alone with parents to help them to begin to work together, as well as to develop strategies to reinstitute effective limits. The therapist can help parents to prioritize their expectations and plan to establish one rule at a time. In the process the therapist can also help the parents to develop realistic

expectations of their efforts with their child. The parents can receive validation of the experience of frustration and their sense of being betrayed by their child. As long as the parents hold on to their experience of being hurt by their child, it is very unlikely that they will notice small attempts at improvement on their child's part. They also will have difficulty holding to their expectations if the child becomes angry or has a temper outburst when a limit is imposed. In such frustrating situations, guided by the therapist, a parent can gain support from his/her partner that could result in decreased emotional intensity and improved ability to maintain positive expectations. Another frequent occurrence that can be discussed with the parents alone is the possibility that the child will act in a totally unaffected way when the limit is imposed, as if to say that the parents have no effect on the child. By discussing these possible scenarios, the therapist can help the parents prepare to institute appropriate limits in a planned and controlled manner. In these sessions the parents can practice talking with their child and maintaining firmness even if the child is particularly challenging. The therapist may also choose to meet alone with the child to see whether she or he has concerns that the therapy might resolve. Defiant, disruptive children and adolescents often want to be trusted and understood, and to have autonomy.

The therapist can help the child to receive parental approval if the child performs acceptably and gains autonomy in relation to his or her ability to act responsibly. When both parents and child are prepared, a session with all of them together can be held outlining the rules, expectations, and consequences. The child has the opportunity to ask for what he or she wants, and the therapist can help the parents to promise the child the desired autonomy if the child abides by the rules and accepts the consequences. The consequences should be simple, easy to undergo, brief, and have some relationship to the transgression. The key to consequences is that they are meaningful but not onerous. Losing access to a cell phone or computer for one evening is a meaningful but transient consequence. If the parents and child form a committed relationship with the therapist, the therapist can then, with patience and time, bring them back together in an initially tenuous but gradually caring manner. Building understanding and trust, establishing a realistic plan for limits, and noticing small successes provides a pattern of improvement that all can recognize and believe in.

FAMILY THERAPY FOR SPECIFIC PROBLEMS

Attention-Deficit/Hyperactivity Disorder

Families with a child with attention-deficit/hyperactivity disorder (ADHD) need to learn about the disorder, understand appropriate treatment, and support the development and functioning of their child. This requires that parents agree about the presence of the problem, agree to seek the help of a

physician, and agree to have their child take medication if prescribed. It is also important for the parents to learn to be consistent with behavioral expectations and to appreciate and reinforce the child's strengths. Often, prior to diagnosis, the child may have experienced failure at school and rejection by peers and marked negative interactions at home. Family therapy after diagnosis of ADHD may be needed to help the family assist the child with these previous difficulties, and also to help the child to be more successful at school and with friends and to feel consistently accepted at home. Comorbidity with learning disability is common, and the family may need assistance with ensuring appropriate education for the child. Transitions, including moving and changing schools, can be challenging. The family may also need assistance during the child's adolescence, particularly with impulse control, exposure to drugs and alcohol, and self-management as the child becomes a young adult. A chronic illness framework often is extremely helpful for families with children with ADHD.

Jason was a 7-year-old boy who attended the second grade and who had been noted by his teacher to be extremely active in class and to have significant difficulty concentrating and following class rules. He especially had difficulty during unstructured time in school, both in the cafeteria at lunchtime and on the playground at recess.

When his teacher checked with his previous teachers from kindergarten and first grade, they stated that Jason had difficulties with his attention and activity level in both of those grades. Despite these concerns he was quite bright and had been able successfully to complete his grades and pass to the second grade. Jason's teacher invited his mother to come to school for a meeting after having sent home reports concerning his overactive behavior and his inability to finish his work.

At the meeting with Jason's mother, his teacher spoke about her concerns and suggested that Jason should undergo a psychiatric evaluation and might need medication to help him concentrate and manage his activity. His mother reported that she was also concerned about how active he was at home and how difficult it was to help him get ready for school in the morning or finish his homework in the afternoon.

Jason lived at home with his mother, stepfather, and 4-year-old stepsister. His parents had divorced when Jason was 3 years old, and his mother remarried his current stepfather 1 year prior to Jason turning 7 years old. Jason saw his biological father on a regular basis and spent alternate weekends at his father's house. His father had also remarried, and Jason had an 18-month-old half-brother who lived with his father and stepmother.

Jason was seen by a child psychiatrist shortly after his mother and teacher met. The child psychiatrist believed that Jason was a child with ADHD and suggested to the mother that a trial of stimulant medication might be helpful for him. The mother was given rating scales to complete after Jason had started on the medication, along with written information about both ADHD and the stimulant that was prescribed for him.

The child psychiatrist also recommended that there be a meeting of all four adults involved in Jason's life—his mother, stepfather, stepmother, and biological father—so that they could talk together about Jason's difficulties and ensure consistent treatment. The goals of the meeting were: to encourage regular use of the stimulant medication and to help everyone to understand the need for clear and focused directions, focused attention, follow-through on homework, and consistent discipline in both households.

The family attended this meeting. The psychiatrist noted that Jason's biological father was concerned about the use of medication and asked about the risks and side effects of the medicine. Jason's stepmother was concerned that there was no way successfully to help Jason without medication. As the family talked together with the child psychiatrist, asking questions and gathering information, they came to the conclusion that the best approach was to institute

a trial of stimulants. The trial was begun, and Jason's teacher reported to the family that he was much more able to focus his attention and manage his behavior in school. He was noted to have less difficulty during unstructured times in school and was also able to do better academically than he had previously.

The child psychiatrist also suggested that the family come back for a second meeting, after Jason had been on medication for 6 weeks, to review everyone's impression of Jason's progress. The child psychiatrist recognized that the biological father and stepmother were now comfortable using medication for Jason. They agreed to follow through with the medicine and to help Jason manage his behavior better in their home.

Three years later, as Jason continued to do well in school on stimulants, during a routine medication review with the child psychiatrist, Jason's mother reported that his father was getting divorced for a second time. Jason tearfully admitted that he was very upset by this and that he was going to miss his times with his stepmother and younger half-brother.

The child psychiatrist asked to speak to the father, who agreed to come for a session with Jason and talk with him about what was happening in his family. Jason's father agreed to help him have continued phone contact with this stepmother as the father and stepmother proceeded with their plans for divorce.

Six years later, Jason was old enough to obtain a driving permit. He had continued to take stimulants daily and had done well in school. He had grown up without significant emotional and behavior troubles and was eager to learn how to drive. Jason's father and mother had continued to meet with the child psychiatrist every 4 months to review Jason's medication and to check in with how everyone was doing. They were concerned about Jason driving. Jason was sure that he would be able to drive perfectly well even though he was known to be more impulsive and more disorganized than other teens his age. The child psychiatrist helped the family to discuss the privilege of driving. They decided that they would let him drive with one of them in the car and not let him drive after dark for the first several months that he was driving. They decided not to allow him to drive with peers until he had driven successfully for several months. This negotiation was difficult for Jason, but Jason's father and mother both felt very supported by the child psychiatrist. They were comfortable with their decision that Jason could learn to drive as long as he was monitored quite closely and supervised very carefully.

Oppositional Defiant Disorder and Conduct Disorder

The primary goal of family therapy for oppositional defiant disorder and conduct disorder in one or more children is the establishment of a warm and mutually respectful relationship between parents and child, which forms the foundation of effective limits, appropriate supervision, and responsible prosocial behavior by the child. Often the family situation is complicated by any or several of a variety of family risk factors. These include parental stress, parental psychopathology or substance abuse, criminality and incarceration, poverty, marked parental preoccupation with time-consuming work, or preoccupation with other children. Overcrowding, living in a violent community, and domestic violence also occur frequently. Negative coercive cycles often occur in the interactions between parent and child, in which the child is demanding and the parent becomes controlling, leading the child to seek attention through misbehavior and leading the parent to believe that only direct control will make the child behave appropriately. The child fails to learn self-control and self-direction, and the parent becomes gradually and insidiously disempowered and negative toward the child. As the child grows, the parent increasingly becomes hopeless about the child and begins to believe

that the child will fail to grow up successfully. This results in parents feeling helpless and re-emphasizes that improvement must come from outside the family. Therefore, the parent hopes that something else will lead the child to develop responsibility and seeks placement of the child in residential treatment or in the juvenile justice system. This perspective localizes the problem in the misbehaving child, leaving the child feeling blamed and even more disconnected from his or her family.

Two forms of family therapy deal specifically with these issues. Parent–child interaction therapy is specifically designed to treat families with young (preschool) children with oppositional defiant disorder. Multisystemic therapy has demonstrated effectiveness for families with adolescents with delinquency who are involved with the juvenile justice system. Parent–child interaction therapy focuses on building the positive aspects of the relationship between the parent and young child. Through the therapist's praise, the parent relaxes and becomes more accepting and more openly caring toward the child. The parent receives the therapist's praise and care and passes that on to the child, leading to closeness, the experience of being understood and cared for, and warmth and attunement in the parent–child relationship. This also leads to improved cooperation between parent and child, greater compliance on the child's part, and, on the part of the child, much greater interest in the parent's praise and positive regard. Parent–child interaction therapy has been shown in more than 30 clinical trials to be effective for families with preschool children (between ages of 2 and 6 years) with oppositional defiant disorder. It has also frequently been requested by child protective services to improve parent–child relationships in situations in which mild physical abuse has occurred.

Multisystemic therapy has been shown to be effective in reducing recidivism and delinquency for children and adolescents in treatment trials and through follow-up. Trained therapists with very small caseloads help the parents to manage the stresses in their lives and supervise and set limits on their child. The therapist is available to the family consistently and the treatment is intensive, with three or four contacts with the family weekly over 4 months. The therapist builds family cohesion and encourages the child to identify and earn privileges by being responsive to parental direction. Rules are defined and consequences are specified early in treatment. Parents are expected to be available, observant, and consistent in monitoring their children. For this to occur, other difficulties that the family experiences need to be addressed through the therapy. This treatment is best suited to moderate delinquency and works best early in the course of delinquency.

Another form of family treatment for conduct disorder is parent management training. In this therapy, parents attend sessions without the child and learn and practice techniques of setting limits and imposing

consequences. Most important in this treatment is helping the parents plan and practice how they will withstand the child's demanding and defiant behavior and how they will respond if the child's behavior becomes worse before it gets better (as is expected). In this treatment the therapist supports a united front among adult authority figures and builds mutual support among these authorities. Parental self-control is another goal of these parent-coaching sessions. The therapist needs to ensure that the parents learn the skills necessary to set effective limits and manage their lives at the same time.

Isaac was a 4½-year-old boy who was brought to a child mental health clinic for evaluation of defiant, challenging, and difficult behavior. He had been referred by his pediatrician after his mother discussed his defiant and difficult behavior with the pediatrician during a regular checkup. The history also revealed that Isaac had been expelled from his preschool and had to be looked after by a neighbor in her house because of aggressive and difficult behavior at school.

When the clinician met with Isaac and his mother, Isaac appeared to be a well-behaved, quiet child who was able to focus his attention and play easily with the interviewer. However, it was noted that his mother was extremely negative about him, and was frustrated, angry, withdrawn, and sad. During the interview the clinician noted that Isaac's mother was exhausted, overwhelmed, and observably sad and irritable.

The more comfortably Isaac played with the clinician in his mother's presence, the more upset and withdrawn she became. She reported that Isaac's father had left before he was born and that she had an older, 8-year-old boy with developmental disability and cerebral palsy. That child was in special education classes. She lived alone with the children. She stated that she was estranged from her mother and that she worked as a cashier in a grocery store. The family lived in a small apartment in an impoverished area of the city, and the mother reported that at times it was difficult to have enough food for her, Isaac, and his brother to eat.

The clinician was struck by the poignancy of Isaac's mother's situation, by her isolation and lack of support, and by her level of exhaustion and sense of being overwhelmed. The therapist was also touched by Isaac's attention to his mother and his tendency to watch her and comfort her when she became sad during the interview. The clinician was attentive to and supportive of the mother, and during the interview she began to calm down and admitted to being depressed, sad, and lonely.

Isaac and his mother arrived for their second session on time and both seemed eager to talk. The mother had noticed that Isaac was a little bit better behaved at home, and she seemed more relaxed and comfortable.

The therapist continued to support the mother and encouraged her to engage with Isaac in a game during the session. The therapist was warm, caring, and praising of the mother's efforts with her son. The therapist also recommended that Isaac and his mother have some regular time to enjoy each other's company during the week and suggested 15 to 20 minutes every day, during which their neighbor could look after Isaac's older brother. As Isaac received more attention from his mother at home, their negative interactions decreased. He seemed to relax and become less quick to anger, both at his babysitter's house and at his mother's house.

The clinician also encouraged the mother to reconnect with her siblings and her mother, who were in the community, and to reach out to them for support and understanding. The mother noticed that she was more relaxed and less stressed and that she was more able to experience enjoyable times with her sister. She also began to communicate in a more open way with her mother.

As the sisters became more involved with Isaac's family, there were more family gatherings and more opportunities for the mother to experience some relief from her caretaking obligations. Over a period of 3 months of weekly sessions and 2 months of biweekly sessions, Isaac's mother became much more relaxed, was able to obtain babysitters for her children, and got more involved in her older son's special education programs. She became more assertive

about obtaining a raise at work and socialized with her colleagues. She spent more time with her family and her neighbors. She also resumed attending church, and Isaac became involved in the church-sponsored preschool kindergarten group.

The therapist stayed in touch with Isaac and his mother and heard from her that Isaac had successfully begun kindergarten during the next academic year. His behavior was much improved and his curiosity, desire to play and learn, and attentiveness to adults had helped him to learn and grow in kindergarten.

Joseph was referred to the intensive in-home treatment team after his discharge from the juvenile detention facility in his community. He was 15½ years old and had been placed in the detention facility after his arrest for vandalism and breaking curfew. The vandalism involved breaking windows in his school, and well as painting graffiti on several businesses in his downtown neighborhood. Joseph lived with his mother, stepfather, 12- and 19-year-old brothers, and 17-year-old sister.

When the in-home treatment therapist went to meet Joseph and his family, the mother was at home with the younger brother. Joseph was not at home. He had told his mother that he needed to visit his friends after school and that he would be home in time for the appointment. He was late and had not informed his mother.

The history the therapist obtained was that Joseph had been a very good student and a fine boy until the age of 9, when his grandfather suddenly died and his mother moved the family into the grandmother's house to look after her. Joseph had been close to his grandfather and had reacted to his death with sadness and withdrawal from the family.

His mother noted that he began to act up at that time and said that he had started hanging around the "wrong kids" at the age of 11 and had begun truancy when in middle school. Joseph had regularly received reprimands from the school administration, mostly for fighting, defying teachers' authority, and misbehavior during recess or lunch period. Joseph's mother said that at this point she believed that Joseph was outside of her control and she had hoped that 8 weeks in the juvenile detention facility would help him to learn to manage his behavior. Because he had not come home for the therapy appointment, she was worried that perhaps things were just as bad as they were prior to his arrest and stay in the detention center.

The therapist noted that the family lived in a cramped apartment in a rundown building that needed maintenance. When the therapist asked Joseph's mother about her husband, she stated that he also was supposed to have come home for the therapy session. She said that he often stopped at the bar on his way home to hang out with his friends and drink. Joseph's mother was increasingly worried about her 12-year-old son, who seemed to be following in Joseph's footsteps, and reported that her 17-year-old daughter would likely be moving out of the home with her boyfriend when she had her baby in approximately 3 months.

Joseph's 19-year-old brother was in and out of the house, and his mother was never sure whether she could expect him home on a specific evening. She thought that Joseph's older brother was having difficulties with substance use, and she reported that there were times when she smoked marijuana or drank just to get away from her concerns and feel better for a little while. The therapist asked Joseph's mother about the family's economic situation and learned that the stepfather had a regular job as an auto mechanic but was not paid well and that the mother worked part time in a department store as a cashier.

The family had Children's Health Insurance for the children. This managed Medicaid program would provide financial support for the intensive home-based treatment program. During the first meeting the therapist worked to understand the family's situation and recognized Joseph's mother's affection for her children and the dismay that she was experiencing because of their difficulties. The therapist spent 90 minutes getting to know Joseph's mother and her youngest son. During this first meeting, Joseph's sister came into the house during their conversation and told her mother that she had seen Joseph hanging out on the street with friends that he used to get in trouble with before he was in the detention center.

The therapist proceeded with the assessment and commented on the strengths of the family, including their strong connections with each other, and on the hopes of the family for the futures of the younger brother and the sister. The therapist developed a deep respect for Joseph's mother and closed the first session by saying that she would come back the next day and meet with the mother again. The therapist wrote a message to Joseph, saying that she had

been there and that she had heard about him and knew that she would very much enjoy meeting him and invited him to be present next evening for her visit.

Over the next 6 weeks, the therapist visited Joseph and his family in their home three to four times a week. She invited Joseph's mother to call any time if she had concerns, and she helped Joseph's mother to think about her priorities for their treatment process. Joseph's mother said that her goals included helping Joseph stay out of detention and resume school; repairing her relationship with the children's stepfather and encouraging him to take care of his chronic alcohol use; improving the family's financial situation by obtaining a full-time job; and deciding with the stepfather whether to continue to allow Joseph's older brother to come and go in the household.

Mother and stepfather set up rules and consequences for Joseph with three expectations: (1) that he would attend school all day, each school day, (2) that he would attend an afternoon program at the local Boys and Girls Club, where he could receive tutoring to complete his homework, as well as engage in basketball and video games with other young people at the center, and (3) that Joseph would return home after the Boys and Girls Club for dinner and that he would have access to his cell phone and his video game set in the evening if he followed through with the plan.

Joseph initially strongly resisted the rules and expectations, telling his mother that "she had no right telling him what to do," that he was grown, and that "he could make up his own mind and make his own decisions." The therapist helped Joseph's mother reiterate to her son that she would be happy for him to have greater freedom if he demonstrated greater responsibility and was able to comply with the house rules. The therapist also visited Joseph's school and talked to his counselor and teachers and encouraged them to be warm, engaging, and supportive of Joseph, to help him know that they wanted him to be in school every day and that they wanted to get to know him and learn about him. The therapist helped Joseph to write a biography of his grandfather, which Joseph researched by talking with other community leaders and neighbors who had known him. The therapist also encouraged Joseph to resume his interest in basketball and baseball and to learn as much as he could about the history of his family and the history of his family's role in his community.

As adults who expressed interest in him and his ideas surrounded Joseph, he began significantly to improve his mood, decrease his level of anger, and increase his hopes for the future and his interest in school and his after-school program. The intensive treatment program continued to work with Joseph and his family for 3 months and encouraged the adults in Joseph's life to express more responsibility and interest in him and to offer him more opportunities to be a part of his school and a part of his neighborhood. The therapist also encouraged the mother and stepfather to resume attending their church, which the family did, and the therapist talked to the minister about being particularly welcoming for Joseph, his older sister, and his younger brother. The therapist also talked with Joseph's stepfather about his alcohol use. The stepfather was receptive to decreasing his alcohol use and being home more in the evenings and paying more attention to his family and his wife.

Together with consistent, nearly daily contact with the family, involvement with several important adults, and child-serving institutions in Joseph's community, the therapist, by creatively using Joseph's interest in his family and in his grandfather and identifying Joseph's interest in telling the stories of his family, was able to improve Joseph's school attendance, sense of himself, and the family's overall sense of well-being in the 12 weeks of contact. When the program ceased, Joseph had several adults involved in his life, his mother had a full-time job that felt rewarding, her relationship with her daughter who was about to have her first child had significantly improved, and Joseph's younger brother had resumed his academic progress and his athletic activities.

A family therapist at the local mental health center was able to meet Joseph and his family for the last 3 weeks of the intensive program once a week at their clinic. That therapist continued to meet with Joseph and his family over the next several months on a weekly or bimonthly basis.

At the close of treatment, 1 year after Joseph had been discharged from the detention center, he was at home consistently, was attending school, had caught up academically, and had resumed regular activities with peers who were interested in sports and academic success. Joseph's mother and stepfather had decided to remain married and had improved their relationship.

Family Therapy for Depression

The core of treating depression in children is the consistent building of competence and connections for the child. The problem in accomplishing these goals is that the depressed child has problems with concentration, which directly interferes with competence, especially at school, and marked irritability, which greatly interferes with successful relationships with family, peers, and important adults. Furthermore, the depression creates a marked lack of motivation, which leads the child to not believe in or pursue treatment. Substance abuse is often a comorbid problem, which may leave the child feeling better in the short term but with a significant long-term problem in addition to the symptoms of depression. The longer depression persists, the more likely it is that such a child will develop significant and persistent secondary problems, including academic failure, legal difficulties, and further alienation from parents, who may also be experiencing stress.

In the face of these difficulties, family treatment offers several advantages. The parents can be asked to ensure that the child participate in treatment, even if the child would rather not, as long as the child's problems persist. Suicidal ideation, plans, and attempts can occur at this point and require specific focused attention by the therapist and the parents. Parental warmth and encouragement can be achieved by linking the child's problems to the experience of depression. Depression can be defined as a phenomenon that has taken over their child, and which is painful and hurtful while draining the child's energy and motivation. The therapist can reinforce and support the parents caring for and commitment to their child. As the parents express their care for the child, the therapist can build the child's trust in the parents.

The therapist can then encourage the parents to expect the child to participate in school, both in academics and in activities while enlisting school personnel to engage with the child and provide remedial support if needed. The therapist encourages parents to be available and attentive to the child's accomplishments and supportive of the child's emotional experience. Therapeutic support for building on the child's interests, strengths, and abilities is also important, as are efforts to build relationships with prosocial peers while also limiting substance use. Prescription of selective serotonin reuptake inhibitors (SSRIs) while monitoring suicidality can promote this process for the child and family if needed.

Lydia was a 14-year-old girl who was brought to the emergency room of her local hospital after ingesting an overdose of 15 acetaminophen tablets. Lydia had taken the overdose after an extremely difficult day in which she was teased by friends at school, was criticized by her teacher for not having completed her homework, and then engaged in an argument with her

mother about her wish to go out with friends that evening. Lydia challenged her mother and threatened to leave the house. Her mother was worried that Lydia might be meeting a teenage boy and got very angry at Lydia and called her a demeaning name. During the argument Lydia rushed into the bathroom and found the bottle of acetaminophen tablets and took the overdose. She then became quite frightened and told her mother that she had taken the pills. Her mother called an ambulance, and Lydia was brought to the emergency room.

Lydia maintained consciousness and talked openly with the clinician in the emergency room about her increasing distress over the last 12 months. She had become increasingly involved with peers who were in trouble, and her performance in school had declined. She also reported that she had stopped participating in her usual activities at school, including quitting the cheerleading squad. She had been sexually active with a 16-year-old boy on one occasion and reported that the boy had stopped going out with her after they had had sex, and he had talked about the experience in an embarrassing way with other young people at her school. She had previously been a good student and popular in her class but had recently become more irritable, more isolated, and less interested in academics and her friends.

Lydia's mother reported that her daughter had changed from a happy, upbeat teenager to a surly, irritable child who was very difficult to communicate with. Lydia lived with her mother and her three younger brothers, who were 9, 7, and 5 years old, respectively. Their father had left the family to work in another community and was sending money home to the mother. He was away for several months at a time doing construction work and was only in contact with the family by phone once a week. Lydia had been very close to her father, and his recent occupational absence had been distressing for her. She had felt isolated and disconnected from her family.

Lydia's relationship with her mother had always been ambivalent; she had been very helpful but not very emotionally close to her mother and had become more quick to anger and argumentative with her mother over the last several months.

Lydia was admitted to the adolescent medical unit for monitoring because of the possibility of toxicity from the acetaminophen. While in the hospital, she and her mother were seen by a child psychiatry consultant, who invited Lydia to talk openly with her mother about why she had made the suicide attempt and what had happened that day that had so upset her. The consultant also encouraged Lydia to talk about missing her father and her recent sadness. Her mother, while being somewhat defensive, was supported by the clinician to listen to her daughter's difficulties and concerns.

Lydia was able to be open with her mother about the problems she was having in school, the difficulties that she was having with peers, and the fact that school suddenly had become very difficult for her. The clinician held daily sessions in the medical hospital over the next 3 days with Lydia and her mother to enhance the closeness and supportiveness of their relationship. He encouraged Lydia's mother to listen to her daughter in a nonjudgmental and nonreactive fashion. As the mother felt the support of the clinician and his encouragement to be clear with Lydia about her concern about the impulsive suicide attempt, her mother was also able to be more understanding and available to her daughter during these meetings. The clinician also arranged a phone session with Lydia, her mother, and her father.

After 3 days of medical hospitalization Lydia was able to apologize to her mother for taking the overdose and to ask her for enhanced involvement and understanding at home. The family was then referred to an outpatient clinician at the local mental health center, where they were seen 3 days after discharge. Lydia reported improved mood and increased attention from her mother at home and had returned to school. The new therapist asked permission to contact Lydia's teachers to arrange more support at school. She strongly praised the enhanced closeness between Lydia and her mother.

Lydia was not initially placed on psychopharmacology. She had noted improved mood at home and had managed her behavior with less irritability and impulsivity in the initial week following her hospitalization. Future sessions were held weekly and were divided, with half the session for Lydia individually and half of the time with Lydia and her mother. The therapist focused with Lydia on her life at school, her schoolwork, and her peer relationships. The meetings between Lydia and her mother led to enhanced understanding, improved communication, and greater mutual support. Regular phone calls involved Lydia's father.

With the enhanced family support and Lydia's increasing competence as a teenager, her mood improved dramatically and her relationship with her mother grew closer. The telephone

contacts between Lydia and her father re-engaged them and restored the warmth they had shared.

After 3 months of outpatient treatment Lydia was doing well and came for sessions once every 2 weeks. The therapist noted that Lydia's mother was sad and missed her husband and offered the mother the opportunity to come for individual meetings to talk about this and how she could carry on at home while her husband was away.

Traumatic Stress in Children

Trauma-focused cognitive-behavioral therapy for children has been identified as an evidence-based treatment for traumatic stress in children. It is important to recognize that this treatment has an essential family component. Family education, emotional support for the parent who may be distancing themselves due to the child's traumatic experience, and family involvement in supporting the child while developing and sharing the trauma narrative are essential elements in this treatment. This often requires that parents accept the reality that they could not protect their child from harm or that one of both of them might actually have perpetrated the harm. The challenge of helping the parents acknowledge their feelings and the realities of their child's experience of exposure to or injury by trauma often can be quite challenging. The therapist has two goals: to support and care for the parents, and to assist the child in understanding and dealing with what has happened to him or her. This can be horrific and is often frightening or infuriating for the therapist. Therapists in this situation often need an opportunity to discuss cases with colleagues or with a supervisor. Attention to the safety of all participants provides the foundation for engagement, and engagement builds the trust needed to share the painful, shameful, and sad aspects of trauma and its aftermath. These realities are present regardless of the source and nature of the trauma. Focusing on a successful resumption of family life founded on the belief that the trauma has led to closer relationships and greater resilience is often healing in itself. The recognition of family resiliency is then coupled with acceptance of the unpleasant emotions that are normal responses to trauma among them all. A step-by-step therapeutic approach including the family is extremely helpful. This approach leads from providing safety to ensuring that basic needs are met. It continues with education for understanding, behavioral competence, emotional support, and narrative creation and validation. The trauma becomes a remembered but not excessively arousing experience. As with family treatment of other child problems, the treatment can lead not only to resolution of traumatic stress, but also to an enhanced awareness of family strength among all members.

Monica was 6 years old and was referred by her pediatrician to a child psychiatrist for evaluation after she had been involved in a serious motor vehicle accident. One month prior to referral Monica had been riding in the car with her mother. She had been seated in a booster

chair in the back seat. Their car was hit by another car that was driving very fast. Only Monica and her mother had been in the car, and Monica's mother was seriously injured in the accident. When the ambulance came to pick Monica up they noticed that she was crying for her mother and that she was shaking in the back seat, although she did not seem to have been physically injured in the accident.

Monica's mother had lost consciousness in the front seat and needed to be taken to the emergency room in a helicopter. The police had removed Monica from the back seat, and one of the policemen held her on his lap while she was crying out for her mother. They found the mother's pocketbook and called Monica's father at work. As Monica's mother was being flown to the emergency room in the helicopter, Monica's father came to the scene of the accident and picked up his daughter.

Monica had previously been a healthy girl attending first grade. She had two younger sisters ages, 4 and 2 years, respectively. Her father was a lawyer in a firm in the community and her mother was a part-time bookkeeper for a local physician. The family had significant resources, and the children attended either private school or private day care.

Monica was slow to warm up and approached new situations with fearfulness and reticence. Now, 3 months into the school year, she had established friends and had a very positive relationship with her teacher. When her father brought her home and got a neighbor to stay with his three daughters while he went to the hospital, everyone noted that Monica was extremely upset.

During the mother's hospitalization, which lasted for 2 weeks, she required abdominal surgery to remove her spleen and was found to have a fractured tibia and fibula in one leg and required a cast and crutches. Monica had been able to talk with her mother by phone several times in the hospital beginning on the fourth day after the accident, and near the end of her mother's hospitalization, Monica had been able to visit her in the waiting area of the hospital.

When Monica's mother came home she learned that Monica had been crying every morning on the way to school and also while at school. Monica also had become increasingly withdrawn at home from her younger sisters and at school from her peers and from school activities. Because of this withdrawal and problems with separation, Monica's pediatrician recommended that she and her family see the child psychiatrist.

The child psychiatrist obtained the history just described and noted that Monica's mother was also having nightmares and flashbacks of the accident and was increasingly hypervigilant. She had become frightened to drive the car. Monica's father was very concerned about his wife and about Monica and attended the initial session with them. He stated that he knew that his wife and his oldest daughter were both quiet and shy and were very much alike and very close to each other.

The child psychiatrist determined that Monica's father was deeply invested in his marriage and in wanting to help Monica and his wife recover from the physical and psychological effects of the automobile accident. During the conversation Monica's mother stated that she felt extremely guilty for having the accident and was frightened both about what had happened to her and also the possibility that the accident could have hurt her daughter. She began crying in the session and it was obvious that her distress deeply affected both Monica and her father.

The child psychiatrist talked with the family about the fact that they had a normal reaction to an extraordinarily frightening and traumatic event. He also explained that the trauma for Monica was somewhat different than the trauma for her mother. Monica's trauma involved not only the accident, but also her fear about her mother and her experience of being separated from her mother at the scene of the accident and during her mother's hospitalization.

The psychiatrist contrasted that with the mother's fears from her injury and treatment, her worries about her daughter, and her guilt from the car accident. The child psychiatrist also spoke about the strengths he recognized in the family: the father's intense connection to the family, his dedication to be helpful to his wife and his daughter, and their impressive closeness and love for each other. As he said this, the family relaxed. The therapist suggested that there would need to be a realignment of the family's energy now that the threat to survival was over. He suggested that the family begin to orient themselves to resuming their lives as a family while also recognizing their fragile emotional state.

The child psychiatrist recommended a family-based course of therapy over the next 8 to 10 weeks in which the mother, father, and daughter would work on reconnecting with their future lives while integrating their experience of trauma, injury, and anxiety into their past. The

psychiatrist proposed homework for the family; he suggested that the father spend time alone with Monica, talking with her about the fact that her mother was better now and that it was her job to resume being a big sister to her littler sisters, a student at school, and a regular 6-year-old girl. The therapist also suggested that mother and father talk together to help the mother to accept the accident and also to appreciate that because of her appropriate attention to her child's safety, her child was in the booster seat in the back seat and was not injured. They could discuss the fact that the mother had taken very good care of Monica and that Monica was having trouble because she continued to be frightened that her mother was not all right.

Over several sessions, Monica's mother was able increasingly to reassure her daughter that she was okay and encouraged her daughter to re-engage with her school, friends, and enjoyment of activities and fun as a child. She also gradually reassumed her role as an effective and caring mother for her three daughters. The father stayed actively involved with all of the children and maintained his belief in his wife's ability to recover and resume her role as his wife and their children's mother.

It became apparent to the therapist and Monica's parents that they had too rigidly adopted complementary roles as breadwinner and caretaker and that some readjustment of their partnership would need to be addressed in the therapy and recovery process. Monica's mother was grateful to her husband for being more flexible and responsive to her and their children's needs. He continued to be invested in his career, but with less intensity and less single-mindedness.

After 4 weeks of treatment Monica was increasingly acting as she had prior to the accident, as a successful student, a confident big sister, and someone who could more easily separate from her mother and the family home. She had fewer episodes of tearfulness and was able to sleep through the night.

After 8 weeks Monica's teacher reported to the parents that she had in fact resumed previous functioning and had caught up academically and appeared to all to have recovered. Her mother was less frightened and was sleeping well and had resumed work and driving. She and Monica could discuss the accident openly without crying.

Treatment of Anorexia and Substance Abuse

Family therapy–based treatment models have demonstrated effectiveness for both anorexia nervosa and adolescent substance abuse. In both of these problems the child is involved in an engaging, self-reinforcing, and dangerous behavior. This behavior often is pursued in an extreme fashion and ultimately leads to failure to achieve other developmental skills. The lack of these skills also often renders the child anxious and further narrows the child's orientation to his or her life. There may be genetic predisposition to either anorexia or substance abuse. Despite this, the child will need to learn to manage the impulse to diet or the impulse to use substances in a dangerous manner. In the majority of these situations, the parents will bring the child for treatment and will be concerned about their inability to lead their child out of his or her self-destructing behavior patterns. Two evidence-based family treatments have been developed for these problems, and their effectiveness have been documented through randomized, controlled treatment trials. These treatments are multidimensional family therapy for adolescent substance abuse and family-based treatment for anorexia. Both of these treatments assign responsibility to the parents for reducing the intensity of the symptomatic behaviors. In family-based treatment for anorexia the parents are given the responsibility for helping their child gain weight with the therapist's

support. As the parents take on this responsibility, the therapist helps them to be successful in attaining the child's attention and the child's compliance. The child gains greater support and autonomy as he or she participates in treatment. The therapist also supports the child's interest in and competence with activities and with peers. If treatment is initiated early in the course of the disorder, it can be effective and relapse is rare. Family treatment for substance abuse in adolescents is similar. However, often school failure, legal difficulties, a history of poor supervision, and the influence of negative peers complicate the clinical situation. The treatment manual for multidimensional family therapy identifies ways of addressing these challenges while simultaneously providing the supervision, support, and limits necessary to reduce substance use. Once again the keys to treatment effectiveness are opportunities to behave in prosocial ways with intense family support for competency and success associated with consistent unwavering expectations and reasonable but not excessive consequences.

Joan was 14 years old and lived with her parents and 12-year-old sister. She was referred to a child psychiatrist by her pediatrician, who had recently evaluated her for significant weight loss and dramatically reduced food intake.

Joan's parents were middle class, and both worked long hours. They had become concerned about her dieting and weight loss but had been unable to have it cease. When Joan and her mother met with the child psychiatrist, Joan stated very clearly that her weight was a major concern to her, that she still felt that she needed to diet and lose weight, and that under no circumstances was she going to eat what the pediatrician and nutritionist had recommended. Joan's father was a busy executive who traveled twice monthly and who had grown increasingly distant from his daughters over the last year. Joan's mother stated her concern that her husband was not as involved with his daughters as he should be and that now his sole interaction with Joan concerned her eating. He yelled at her, trying to get her to eat. Joan's mother had thought that her daughter was experiencing anorexia nervosa, and the therapist concurred. The therapist strongly suggested that Joan's mother and father come to a session later that week to discuss a plan to help Joan with her anorexia. The therapist received a phone call from the father stating that he needed to be out of town on business, but the therapist stated firmly that he should postpone his trip and attend the session with his wife and daughter.

The therapist's first efforts in the meeting were to emphasize to both parents the need for them to work together and to assist Joan with rules that would encourage her to follow through with the food recommendations of her pediatrician and her nutritionist.

As the therapist helped Joan's parents plan how they would expect Joan to eat the required amount and gain weight as suggested by her pediatrician, the therapist also suggested that Joan finish her meals before she left the table and pursued other activities or completed her homework. Joan was upset and frightened at the prospect that she would gain weight. The therapist helped the parents to be understanding but firm and to reiterate their expectation of consistent weight gain. The parents were also advised to be explicit about caloric expectations and meal planning.

As Joan gained weight, she gained more freedom to choose which foods the family had in the house, but she was still required to eat the required amount of calories. Her rate of weight gain was consistently 1 lb per week, and she went from 80% of ideal body weight to 95%. As Joan began gaining weight, the therapist noted increasing distress in her parents' relationship. The therapist suggested private couple sessions for the parents to discuss their relationship. Individual sessions were held with Joan to assist her with assertiveness, peer relationships, and ways of decreasing her perfectionism with regard to her schoolwork.

Joan participated in her individual sessions eagerly and was soon noted to be spending more time with friends and less time preoccupied with food, dieting, and her weight. When she reached 100% of ideal body weight her menses resumed. The therapist was also meeting regularly with Joan's parents. Joan's mother expressed her concern that her husband was more involved in work than with the family and that this was not all right with her. She became assertive with him, and they began to negotiate a different approach to family and work. They also were advised to spend some time alone together. Joan's father responded well to the couple sessions, and her parent's marriage improved and became more satisfying for both of them.

Over the 8 months that therapy continued, Joan resumed normal adolescence, family relationships improved significantly, and Joan's father became more engaged with his daughters.

Stephanie was a 15-year-old girl who was referred to the substance abuse treatment program because her parents were concerned about her alcohol and marijuana use. She lived with her stepmother and biological father. Prior to this school year she had been a successful student and had played in her high school band.

Stephanie's biological mother had significant trouble with alcohol and drugs when Stephanie was a preschooler. After failed attempts at treatment, Stephanie's father had separated from her mother and gained full custody of his daughter. Stephanie knew that her mother was in another state and believed that she was still having trouble with alcohol use. She had not had contact with her mother for 12 months prior to her referral.

Stephanie's father had remarried when Stephanie was 6 years old, and Stephanie had two younger half-siblings, a 7-year-old brother and a 4-year-old sister. This year Stephanie had increasingly felt disconnected from her stepmother and her younger half-siblings. Her relationship with her father had begun to deteriorate as she became more defiant of rules and more involved with peers. She was home less frequently and was less involved with the family activities. Stephanie's stepmother had been called by her school when she had been found somnolent and disoriented at school.

Stephanie's stepmother and father took her to the emergency room, where she was found to be intoxicated with alcohol. She said she had gotten the alcohol when she and some friends had gone to a friend's house during lunch period. Stephanie's father and stepmother had been concerned that Stephanie might be using substances frequently and in a problematic way. Over the last several months she had been coming in late after curfew, staying over at friends' houses frequently, and had been less involved with her previous friends and more involved with a group of friends that the family did not know very well. Stephanie had also dropped out of band and stopped playing her instrument. Her academic performance had decreased significantly.

Stephanie agreed that she was using drugs and alcohol but steadfastly stated that she did not have trouble with them and that she was only doing what her friends did. When Stephanie, her father, and her stepmother met with the family therapist at the drug treatment center it became apparent to all that Stephanie's problems were quite significant and were seriously jeopardizing her physical safety as well as her developmental progress.

In the first session Stephanie tearfully admitted to involvement with unprotected sex, especially when she was intoxicated. With guilt and shame she admitted that she did not want to be doing what she was doing but had found it very difficult to refuse substances or affection and physical intimacy when she was with peers.

The family therapist suggested to Stephanie's father that she was scared and lost rather than defiant and delinquent. Stephanie's father, with some difficulty, acknowledged that this might be true. The family met with the therapist three times a week at the program while Stephanie participated in the adolescent after-school drug treatment groups. The therapist helped Stephanie's parents to institute a curfew and ensure adult supervision after dinner and on weekends. Stephanie reluctantly, but in fact with relief, accepted these rules and adhered.

Regular drug testing was part of Stephanie's program, and over the first month of treatment she was consistently free of evidence of drug and alcohol use. The therapist also strongly recommended that Stephanie attend the adolescent 12-step program meetings with the teens in the treatment group. The therapist also spoke with Stephanie's counselor and teacher at

school. They were advised to strongly encourage Stephanie to rejoin the band, resume her musical practice, and participate in tutoring and additional homework to improve her academic standing. Stephanie responded to this with some initial reluctance, but ultimately with the support and encouragement of her teachers, school counselor, therapist, and band leader she was able, after a rocky period of a couple of weeks, to be more involved in school and more involved with the friends she had distanced herself from after she had gotten involved with her substance-abusing friends.

During this time Stephanie was also seen by a child psychiatrist. The child psychiatrist reported that Stephanie was sad, but he did not believe that she warranted antidepressant medication. The child psychiatrist told Stephanie, her father, and her stepmother that he was very pleased with the progress that they were making in the intensive substance abuse treatment program.

Stephanie's mood continued to brighten. She was encouraged to have evening and weekend times with her father and stepmother. Her stepmother was advised to spend time talking with Stephanie about her friends and her activities. She was encouraged to avoid disciplining Stephanie but to inform her father about any concerns. Stephanie responded to this with improved connections with both her father and her stepmother. She also spent more time with her half-siblings.

Three months into treatment, at the time that Stephanie's discharge from the intensive treatment program was planned, her urine tested positive for alcohol. Her parents also discovered that she had come home after curfew apparently intoxicated after attending a party without parental permission.

The therapist helped the family to recognize that Stephanie had had a difficult weekend and continued to have difficulty resisting the attraction of alcohol and the encouragement of peers to use substances. The therapist worked intensively for the next 2 weeks to reconnect Stephanie with her father and stepmother and to re-establish more-intensive supervision for Stephanie. The therapist encouraged the father and stepmother to maintain hopefulness about Stephanie's success in the future. Stephanie asked her parents to be understanding and forgiving of her episode of alcohol abuse. Her father and stepmother realized that they could not yet expect Stephanie to be able to make mature decisions when exposed to substances and that they would need to provide intensive supervision.

The therapist also spoke with Stephanie's father and stepmother about the difficulties they were having as a blended family and worked with them to understand the challenges of that experience. They worked on building one family of five, rather than two families, one with four members and another with three members. At the same time the therapist spoke with Stephanie about her experience of abandonment and hurt in her relationship with her mother and about her worries about her mother's well-being. Stephanie talked about her fear that she would grow up to be like her mother. As Stephanie held these conversations with her therapist she was able to be increasingly mature and thoughtful about herself and her previous experience of neglect and abandonment. She also was encouraged to speak about this with her father in a session.

The involvement of the entire family in treatment, the appreciation of the family's history and experiences, Stephanie's involvement in a teen substance use program, and the active involvement of her school had all been elements in treatment. Individual therapist support to help her to understand and accept her difficult relationship with her mother was also essential. All of this helped the family to bond together more openly and to be increasingly successful in the developmental challenges that they were facing.

Family Treatment for Divorcing and Blended Families

Family transitions occurring as a result of parental separation and divorce and remarriage are disruptive to children. If parents are able to be congenial with each other and to amicably resolve issues related to the divorce (including financial issues, grieving the end of the marriage, and child care and custody issues), the children, though they still grieve the end

of their family and accommodate the changes to family life with sadness, will usually do so without significant relationship problems and persistent behavior problems. However, if significant resentment, anger, and conflicts continue between the former partners, the effect on the children can be significant and persistent. Problems with academic performance and mood and behavior problems can develop. The conflicting parents often do not manage these difficulties successfully, and family treatment can be necessary. The first step in this treatment process is to identify and support the concern that each parent has for the children and for resolving the children's problems. Parents may be motivated by different concerns—for example, one by a child's academic difficulties and the other by the child's sadness. In any event, bringing together antagonistic parents is an important element in treatment. The family therapist should work extremely hard to help the parents to understand that their children need both of them and need them to work together in parenting for the children's well-being. This process may be difficult and time consuming, but it provides the best foundation for the children's successful outcome. As the therapist helps the biological parents work together, he or she can also help the children express their concerns with each parent individually in separate therapy sessions.

Several aspects of post-divorce life can be problematic for the children. Often a parent can be very involved in his or her life, including work and relationship building. This can lead the children to be unsupervised and to further engage in problematic behaviors. To address this, both parents (if possible) will need to supervise the children and to reiterate their belief in the children's strengths and capacity to be successful.

When stepparents are involved in problematic post-divorce situations, matters can worsen. Stepparents may decide that enhanced discipline is needed and may attempt to act to deliver that. As the stepparent works to impose discipline, a child often becomes indignant and defiant. The more forceful and demanding the stepparent becomes, the more defiant the child becomes. Family therapy can reorganize this situation and lead both biological parents to take a central role in the child's life and success, and to address challenging behaviors. Family therapy can also help stepparents to take a peripheral but very important role as supporter and ally for both the child and biological parent. The stepparent can express concerns and worries about the child, but rather than to the child directly, these concerns can be expressed to the biological parent, who can act on them in concert (if possible) with the biological parental partner. The therapist can also encourage the stepparent to develop a warm, accepting, and caring relationship with the child based on mutual interest. This decreases the child's antagonism toward the stepparent and may significantly improve the mood of the family while also enhancing trust and attachment between the child and the biological parent.

As time passes, the child can adapt to the changing family and maintain a supportive and engaged relationship with both biological parents and accept stepparents and step-siblings. The therapist can also help the new partners build their relationship while they manage successful relationships with all children and with former spouses.

Kevin was an 11-year-old boy who lived with his mother, maternal grandmother, 17-year-old sister, and 14-year-old high-functioning autistic brother. Kevin was referred to see a child psychiatrist because his mother was concerned about his excessive worries. The whole family had been living with maternal grandmother since Kevin's parents separated and divorced when he was a year old. Post-divorce, the parents had a long history of custody battles. At the time of the initial visit, parents had shared legal custody but the mother had physical custody. Their divorce agreement specified that if there is a disagreement regarding medical and academic needs and decisions, the mother's decision supersedes father's preference. The father's consent to provide psychiatric treatment was received, though he did not see a reason for an evaluation. Kevin and his brother would stay with their father every other weekend and have dinner with him at least once a week.

Kevin's mother wanted him to be engaged in treatment because she believes that he suffered during the custody battles. He always had difficulty academically but his performance deteriorated when his sister refused visitation with their father 3 years ago. When he was anxious, he would be short of breath and would pace around the house and scream. This would occur specifically when he was struggling with his homework and when he was supposed to visit his father. This behavior would take place every 3 to 4 days. Nightmares would wake him up shaking in the middle of the night.

His father was invited to participate in the evaluation and treatment. Initially, his involvement was limited, but when he realized that some of Kevin's difficulties were related to his upcoming wedding, he became more engaged.

Kevin and his father were encouraged to engage in conversations to communicate his difficulties with "his growing family." Kevin was able to feel safe in therapy to inform his father of his grievances including his concerns about stepmother taking over his mother's role. He worried about his mother being alone while also grieving the permanency of their divorce. With the support and involvement of his father's fiancé, his mother and his father were able to hear his concerns, to encourage him to speak-up, and to compromise when necessary. They were able to validate the loss of his original family but also to reinforce that they all had a special relationship with him individually. He was reassured that these relationships were going to remain unchanged and that one relationship cannot take place of the other. The family members were able to discuss their expectations of him at both households. They agreed to keep the rules and these expectations consistent so that it would be less confusing for Kevin. As all relationships improved, Kevin's anxiety and difficulty in school was resolved.

Family Therapy for Families with Children with Developmental or Medical Challenges

Families with children with developmental delay, autistic spectrum disorders, or chronic medical illness face unique challenges. Family therapy can help those families who are having difficulty managing emotions, behavior, and illness treatment or achieving the optimal development of the affected child or siblings. These situations often are extraordinarily sad and difficult to deal with. There can be financial challenges, career advancement can be negatively affected, illness or handicap care routines can be onerous, and opportunities for parental intimacy and family enjoyment can be threatened. Parental burden and stress can be extreme,

and at times the expected positive effects of medical treatment may not occur. Marital relationships may be threatened, and siblings may not receive adequate attention and supervision. Parental isolation may also seriously jeopardize family well-being. Family therapy can address these difficulties by offering the parents, the affected child, and siblings a safe environment in which to discuss reactions to the child's problems and to collaborate on making the situation the best that it can be. Parental cooperation and parental mutual understanding are goals. All those involved can be guided by the therapist to learn about the child's condition, current and potential treatments, and prognosis. The parents, the child, and siblings can be encouraged to ask questions and to be assertive with the medical care team. The family and child can be encouraged to recognize the areas of the child's life that are not affected by the illness or handicap and the child's strengths and abilities. The therapist can also recognize the courage and care of all in dealing with the challenges of the child's condition. As the family recognizes their commitment to the affected child, they can come to see themselves as heroic and resilient, and the child can note his or her courage and competency regardless of the illness or handicap. The therapist can help the family work with the school and teachers and with extended family members to understand and support the affected child while also helping the child engage teachers, neighbors, peers, and extended family in an assertive, positive, and confident manner. Finally, the child's active participation in his or her care can be noted and recognized as a sign of competence and mastery that will help the child throughout life. The family therapist can also support the family if the child's condition fails to improve or deteriorates. The therapist elicits and ratifies legitimate responses of sadness and powerlessness and accepts his or her powerlessness over the illness while staying involved with and attuned to family members' sadness and grief.

Dave is a 9-year-old boy who lives with his parents and 1-year-old brother. He had been undergoing treated for high-functioning autism spectrum disorder, attention-deficit/hyperactivity disorder, and anxiety disorder for 2 years. His treatment included a low-dose atypical antipsychotic, a low-dose selective serotonin reuptake inhibitor, a stimulant, and an alpha agonist. Additionally, he was receiving individual therapy every 2 weeks to increase his coping skills. The family had been referred for family therapy but, due to both parent's full-time jobs and other commitments, they had not engaged in that treatment. The family self-referred to a different child psychiatrist because they felt that Dave's treatment had become stalled.

The family's chief complaint was Dave's explosive behavior around limit setting at home and social difficulties with his peers. His father struggled to follow through with consequences, whereas his mother was always able to do it. This inconsistency had resulted in confusion for Dave and also increased conflict between the parents. Dave's mother felt that she was not being supported by her husband. Dave's father felt that his wife was very strict with Dave and would attempt to compensate for this strictness. He felt that Dave's developmental delay made school so difficult for him that he deserved to have a less demanding environment at home. As the parents talked with the therapist they realized the need to negotiate expectations and consequences for Dave. They also recognized the need to support each other more and

redevelop the warmth in their relationship. Although Dave remained difficult and challenging, he gradually improved and became much less explosive.

FUTURE DIRECTIONS

Family therapy has evolved from a therapy developed in opposition to common psychiatric care to a basic orientation to the treatment of child mental health challenges. All situations require the assessment of the involvement and education of family members. Some situations require the specific and monitored engagement of family members in the treatment plan. In many instances, treatment of the child requires the involvement of the family in the manner outlined in the manual of an evidence-based model of family intervention. Knowledge of these treatments and skills implementing them are necessary elements in child mental health care. For many child mental health problems, the problem leads to intuitive family interactions that are counterproductive and often worsen the situation. Family therapy stops these negative cycles and can introduce successful, self-reinforcing, positive family interactions that promote family life and optimal child development. These interventions can help the child's situation to improve, and the family's experience of warmth, care, and effectiveness can emerge and persist.

▲ 54.6 Pediatric Psychopharmacology

TIMOTHY E. WILENS, M.D., AND CHRISTOPHER J. KRATOCHVIL, M.D.

Psychotropic medications play a crucial role in the treatment of children and adolescents with psychiatric disorders, and the past two decades have seen significant growth in the use of these agents. Fortunately, this growth has been coupled with a tremendous expansion in the pediatric pharmacotherapy database. There have been substantial advances in pediatric research due to initiatives such as the doubling of research funding at the National Institutes of Health in the 1990s, the Food and Drug Administration Modernization Act (FDAMA) of 1997 which provided 6 months of additional market exclusivity for companies who conducted pediatric clinical trials, and the Pediatric Research Equity Act (PREA) which required pharmaceutical companies to conduct pediatric studies of medications likely to be used by children and adolescents. Numerous federally and privately funded clinical trials have, as a result, systematically evaluated the safety and efficacy of a variety of psychotropic medications, while comparator trials have helped to clarify the potential role of these agents in treatment.

In the last two decades, dozens of randomized, placebo-controlled pediatric trials have provided safety and efficacy data which led to Food and Drug Administration (FDA) approvals for multiple single and combined agents for the treatment of youth with major depressive disorder (MDD), bipolar disorder, schizophrenia, attention-deficit/hyperactivity disorder (ADHD), autism, enuresis, generalized anxiety disorder (GAD), and obsessive compulsive disorder (OCD). Additionally, several trials conducted by the National Institute of Mental Health (NIMH) in MDD, ADHD, anxiety disorders, and OCD have compared pharmacotherapy, psychotherapy, and their combinations. The expansion in controlled clinical trials has provided clinicians in practice with much-needed information regarding the role of pharmacotherapy in the treatment of mentally ill children and adolescents, and facilitated the development of practice parameters such as those put forth by the American Academy of Child & Adolescent Psychiatry (AACAP) and the American Academy of Pediatrics (AAP). This chapter will highlight data from practice guidelines, reviews, and key clinical trials including large multisite NIH and pharmaceutically funded studies that have resulted in important new findings and/or FDA approval of pediatric psychopharmacology.

GENERAL ISSUES IN PEDIATRIC PSYCHOPHARMACOLOGY

Role of Pharmacotherapy

While psychotropic medications often play an integral part in the treatment of children and adolescents with psychiatric disorders, they are usually used in combination with other modalities. Education about diagnosis, course of illness, prognosis, and available treatment options is important. Additionally, depending on the individual, a treatment plan may warrant: individual, group, and/or family therapy; educational interventions; parent training; substance use disorder treatment; out-of-home placement; or any of a number of additional interventions.

Baseline Assessments and Rating Scales

A thorough and developmentally sensitive assessment is essential prior to the initiation of pharmacotherapy. An appropriate treatment plan is predicated on a comprehensive and accurate diagnostic evaluation, with consideration of potential diagnoses beyond the primary disorder. The majority of children and adolescents presenting with a psychiatric disorder also suffer from comorbid medical, psychosocial, cognitive, and/or psychiatric conditions that can significantly contribute to the youth's impairment in functioning. Failure to address comorbidities may limit the benefits of pharmacotherapy or any therapeutic intervention.

Broad- and narrow-band rating scales can be useful in the screening and diagnosis of psychiatric disorders. Standardized measures generally provide normative data to allow clinicians to compare their patient's symptoms to those of children of similar age and same gender. Such instruments available through AACAP, AAP, schoolpsychiatry.org, and proprietary operations are available for the majority of major psychiatric disorders, and can be valuable tools for establishing baseline target symptoms and severity, as well as longitudinal tracking of changes in symptoms during the course of pharmacotherapy.

Developmental Considerations

Not unlike the importance of employing a developmental perspective in making a psychiatric diagnosis, when prescribing psychotropic medications to children, clinicians need to carefully consider developmental issues regarding the pharmacokinetics of medications as well. Unfortunately, compared to the generally large adult database, there is a more modest amount of data in grade school children and adolescents, and limited data in preschool children. This is particularly important when one considers that the data in adults cannot necessarily be simply extrapolated to a younger population. Changes in age can be accompanied by differences in hepatic metabolism, renal function, volume of distribution, and fat content, along with variations in tolerability and efficacy. Additionally, the patient's perspective on need for treatment, acceptability of pharmacotherapy, and adherence to medication may change.

DISRUPTIVE BEHAVIOR DISORDERS

Attention-Deficit/Hyperactivity Disorder (ADHD)

ADHD is one of the most commonly presenting pediatric neurobehavioral disorders. ADHD affects 6 to 9 percent of children and adolescents worldwide, and persists into adulthood in roughly 50 percent of cases. It is also one of the best studied, and is unique in that, rather than relying on information extrapolated from adult data, a pediatric focus has historically guided ADHD psychopharmacology trials. The efficacy of the stimulants for the treatment of ADHD in children was well established by the 1970s, and stimulant use as well as data supporting its safety and efficacy has grown exponentially since that time.

Research has been particularly helpful in clarifying the role of pharmacotherapy in the treatment of ADHD in children, including studies enrolling preschoolers as young as 3 years of age. Concurrently, major strides in developing delivery mechanisms have occurred, resulting in extended-release stimulant medication preparations with improved ability to sustain treatment effects throughout the day and lower potential abuse liability. Similarly, there have been successes in the development of novel medications for ADHD.

Pharmacotherapies for ADHD. The stimulants are highly efficacious medications, with more than 6 decades of randomized controlled trials (RCTs) documenting their safety and efficacy. Studies have generally demonstrated that 65 to 75 percent of patients treated with stimulants respond, with similar rates for methylphenidate and amphetamine, in immediate-release as well as extended-release preparations. The effect size for stimulants is one of the largest of the psychotropic medications, averaging 1.0. The rapid onset of action, overall tolerability and safety, extensive database, and robust treatment effects have led to extensive use of these medications.

Table 54.6–1.
FDA-Approved ADHD Pharmacotherapy

Medication	Trade Name	Mode of Delivery	FDA Approved Max/Day	Strengths Available (mg)
STIMULANTS				
Methylphenidate	Concerta	OROS delivery system: 18% immediate-release outer coating and 82% gradually released osmotically; designed to replicate t.i.d. immediate-release	54 mg in children; 72 mg in adolescents 13–17 y.o.	18, 27, 36, 54
	Daytrana	Patch worn up to 9 hours per day, gradually releasing	30	10, 15, 20, 30

		methylphenidate		
	Metadate CD	Beaded delivery system: 30% immediate release and 70% 3 hours later	60	10, 20, 30, 40, 50, 60
	Metadate ER	Methylphenidate gradually released from wax matrix	60	10, 20
	Methylin	Immediate release	60	5, 10, 20
	Methylin ER	Methylphenidate gradually released from wax matrix	60	10, 20
	Ritalin	Immediate release	60	5, 10, 20
	Ritalin LA	Beaded delivery system: 50% immediate release and 50% 4 hours later	60	10, 20, 30, 40
	Ritalin SR	Methylphenidate gradually released from wax matrix	60	20
	Quillivant XR	Once daily (up to 12 hours), extended-release liquid formulation of methylphenidate HCl	60	25 mg/5 cc
	QuilliChew ER	Methylphenidate chewable tablet	60	20, 30, 40
D-methylphenidate	Focalin	Immediate release	20	2.5, 5, 10
	Focalin XR	Beaded delivery system: 50% immediate release and 50% 4 hours later	20	5, 10, 15, 20
Amphetamine	Adzenys XR	Extended release amphetmaine-based orally disintegrating tablet	18.8 mg in children; 12.5 mg in adolescents	3.1, 6.3, 9.4, 12.5, 15.7, 18.8
	Dexedrine	Immediate release	40	5
	Dexedrine Spansule	Beaded delivery system, initial dose released immediately and remainder gradually released	40	5, 10, 15
	DextroStat	Immediate release	40	5, 10
	Dyanavel XR	Extended release amphetamine-based liquid suspension	20	2.5 mg/cc
	Evekeo	Immediate release	60	5, 10
Mixed amphetamine salts	Adderall	Immediate release	40	5, 7.5, 10, 12.5, 15, 20, 30
	Adderall XR	Beaded delivery system: 50% immediate release and 50% 4 hours later	30	5, 10, 15, 20, 25, 30
Lisdexamfetamine	Vyvanse	D-Amphetamine with lysine attached, activated in GI tract when lysine is cleaved	70	20, 30, 40, 50, 60, 70
NONSTIMULANTS				
Atomoxetine	Strattera	Immediate release: generally dosed QD, but can be dosed BID	Lesser of 1.4 mg/kg or 100 mg	10, 18, 25, 40, 60, 80,

				100
Guanfacine	Tenex	Immediate release	4	1
	Intuniv	Extended release	4	1, 2, 3, 4
Clonidine	Catapres	Immediate release	0.4	0.1, 0.2, 0.3
	Catapres Patch	Extended release	0.4	0.1, 0.2, 0.3
	Kapvay	Extended release	0.4	0.1, 0.2

Note: Not all stimulant doses and preparations will be available at all pharmacies. Often, a less frequently used stimulant preparation may need to be ordered in by your pharmacist. Some of the stimulants are generic (available usually less expensively for either private full pay or for co-pays).

ATOMOXETINE (STRATTERA). The first nonstimulant approved for the treatment of ADHD, atomoxetine, works by blocking presynaptic uptake at noradrenergic neurons. While atomoxetine has been proven efficacious in several controlled trials, its efficacy appears to be less than that of the stimulants. One meta-analysis reported atomoxetine's effect size as 0.62, while the stimulants were from 0.91 (immediate release) to 0.95 (sustained release).

ALPHA-AGONISTS. The extended-release preparations of clonidine (Kapvay) and guanfacine (Intuniv) have multiple, recent controlled trials demonstrating their efficacy as monotherapy in the treatment of ADHD in children and adolescents. The alpha-agonists may be useful for core symptoms of ADHD as well as associated impulsivity, sleep, and tic disorders. Typically the extended-release clonidine is given twice daily, and the extended-release guanfacine is given once daily either at night or in the morning with equal efficacy through the day. Extended-release alpha-agonists have been shown safe, effective, and FDA approved as monotherapy as well as in combination with stimulants. Interestingly, in stimulant partial responders, alpha-agonists appear to heighten ADHD response (effect sizes of 0.4 in addition to partial response to stimulants).

Several additional medications have demonstrated benefit in controlled trials, but have not been approved by the FDA for the treatment of ADHD.

BUPROPION (WELLBUTRIN, ZYBAN). This is a nonstimulant that acts via dopamine and norepinephrine. Data is very limited, and efficacy appears to be less than that of stimulants, but it could be a consideration in the presence of co-occurring mood disorders, substance abuse, or smoking.

MODAFINIL (PROVIGIL). Efficacy has been demonstrated in three double-blind, placebo-controlled studies in pediatric ADHD using doses higher than those typically utilized for narcolepsy, but was not approved by the FDA for the treatment of ADHD due to safety concerns (rash; erythema multiforme). Data in adolescents are lacking. Modafinil may be particularly useful for enhancing attention, motivation, and general arousal.

TRICYCLIC ANTIDEPRESSANTS. Imipramine (Tofranil), nortriptyline (Pamelor), and desipramine (Norpramin) have all demonstrated efficacy in the treatment of ADHD. The tricyclic antidepressants may be particularly useful for all-day coverage of ADHD and for comorbid ADHD. However, monitoring requirements, side-effect burden, and overdose concerns limit their use.

Select Key Studies

MULTIMODAL TREATMENT STUDY OF CHILDREN WITH ADHD (MTA). The MTA study enrolled 579 children with ADHD, aged 7 to 9.9 years. The children were randomized to either 14 months of a manualized medication management program, an intensive psychosocial treatment, a combination of the two, or community treatment. All four groups improved, with the greatest improvement in ADHD symptoms occurring in the medication alone or combined medication/psychosocial treatment groups. Combined treatment did not yield significantly greater benefits than medication management alone for core ADHD symptoms. Modest advantages were identified for certain non-ADHD symptoms and other functional outcomes.

NEW YORK–MONTREAL LONG-TERM ADHD TREATMENT STUDY. This 2-year study enrolled 133 children (aged 7 to 9 years) with ADHD who had responded to short-term methylphenidate, and randomized them to: methylphenidate alone; methylphenidate plus psychosocial treatment (parent training and counseling, social skills training, psychotherapy, and educational assistance); or methylphenidate with a psychosocial attention control treatment. Congruent with the MTA findings, combination treatment did not lead to superior functioning compared to methylphenidate alone, and all treatment groups demonstrated significant improvement that continued over 2 years. Subsequent follow-up of this sample out to 8 years has been reported including both effectiveness and safety in multiple domains.

PRESCHOOL ADHD TREATMENT STUDY (PATS). Despite current FDA warnings against the use of methylphenidate in children under the age of 6, significant numbers of young children with ADHD are treated with this medication. PATS, funded by the NIMH, enrolled 303 moderately to severely impaired preschoolers with ADHD. Less than 10 percent of the children responded to an initial course of parent training alone, and ultimately 165 were initiated on pharmacotherapy. Mean optimal dose of immediate-release methylphenidate, dosed t.i.d., was 14 mg/day. This dose, 0.7 mg/kg/day, is lower than the mean optimal dose of 1.0 mg/kg/day in the MTA study. While effective, the effect size was smaller than that found in school-aged children in the MTA study, perhaps due at least in part to the conservative dosing. Parents spontaneously reported moderate to severe adverse effects in 30 percent of the preschoolers,

including emotional outbursts, initial insomnia, repetitive behaviors/thoughts, decreased appetite, and irritability. Eleven percent of the children discontinued treatment because of intolerable methylphenidate adverse effects, compared to <1 percent of school-age children in the MTA study.

Clinical Implications and the Role of Pharmacotherapy. The combined data from the two comparator studies provides a direct comparison of well-delivered pharmacotherapy, intensive behavioral therapy, and a combination of the two. The significant improvement in ADHD symptoms, which were most dramatic in the arms with well-articulated pharmacotherapy, established pharmacological treatment for ADHD as superior to behavioral therapy alone. This role was reinforced in PATS, which demonstrated limited improvement in moderately to severely ill preschoolers with ADHD when only parent training was implemented. These data provide strong support for the role of medication as a fundamental consideration in a comprehensive treatment plan for children with ADHD. The expansion of findings to include the nonstimulants highlights the role of these agents alone or in combination with stimulants in the armamentarium for ADHD.

Oppositional Defiant Disorder

Another commonly encountered mental health disorder in children and adolescents, oppositional defiant disorder (ODD) generally presents with a complex etiology. It is often comorbid with other psychiatric disorders, such as ADHD, and can precede the development of conduct disorder, substance abuse, and severe delinquent behavior.

Pharmacotherapies for ODD. Studies addressing the use of medication for ODD per se are limited, although trials of extended release mixed amphetamine salts (Adderall XR) demonstrated improvements in ODD symptoms in youth with comorbid ADHD as well as those without ADHD. Several trials of stimulants, both amphetamines as well as methylphenidate, have demonstrated improvements of co-occurring oppositional behaviors within the context of ADHD. While an initial trial with atomoxetine suggested a similar benefit in ODD symptoms in youth with ADHD, subsequent work was not able to replicate that finding. Similarly, studies with extended-release guanfacine (Intuniv) and tricyclic antidepressants (nortriptyline) have shown improvement in ODD symptoms associated with ADHD. Several studies of typical and atypical antipsychotic agents have demonstrated benefit as adjuncts to the treatment of aggression in children with mental retardation and pervasive developmental disorders.

Clinical Implications and the Role of Pharmacotherapy. The AACAP ODD practice parameters recommend a multimodal treatment approach incorporating individual and family psychosocial interventions, with a specific emphasis on using one of the empirically tested parent training interventions. Medication often serves as an adjunct to the overall treatment program. In this role, pharmacotherapy is generally used either to address specific ODD symptoms or to treat comorbid conditions. Treatment of comorbid disorders (e.g., mood or ADHD) may also improve ODD symptoms.

Conduct Disorder

Conduct disorder has only been studied in a small number of controlled trials that generally targeted the aggressive behaviors that are frequently present.

Pharmacotherapies for Conduct Disorder. The limited number of studies of mood stabilizers such as divalproex sodium (Depakote) and lithium carbonate (Eskalith, Lithobid), antipsychotics, and the stimulants have demonstrated some promise. Atypical antipsychotics are among the most commonly prescribed medications for acute as well as chronic irritability and aggression. There does appear to be a difference in response to pharmacotherapy based on the type of aggression however. While the aggressive symptoms associated with dysphoric conduct problems may be responsive to pharmacotherapy, the predatory aggression is much less likely to improve with medication.

Clinical Implications and the Role of Pharmacotherapy. In light of the wide range of diagnoses that may be complicated by aggressive and oppositional behaviors, it is generally recommended that, when present, comorbid disorders should be the primary target of pharmacotherapy.

MOOD DISORDERS

Major Depressive Disorder

Mood changes are normal in childhood and adolescence; however, prolonged sadness, anhedonia, irritability, and potentially self-harmful or suicidal behaviors are not, and occur in up to 10 percent of youth. A thorough assessment of biological and psychosocial factors that may result in mood symptoms is warranted.

Pharmacotherapies for Major Depression. With multiple RCTs lending support, fluoxetine (Prozac) and escitalopram (Lexapro) are the antidepressants with the greatest amount of data supporting their safety and efficacy in the pediatric population—and both are FDA approved for

MDD in pediatric groups. There is also support for the use of medication in conjunction with cognitive-behavioral therapy (CBT) for initial outcome and to reduce the risk of relapse. In a recent RCT feasibility study, 46 youths (aged 11 to 18 years) who had responded to 12 weeks of fluoxetine treatment were treated with 6 months of continued medication management with and without relapse prevention CBT. The addition of CBT substantially reduced the risk of relapse (eightfold).

Other SSRIs including citalopram (Celexa) and sertraline (Zoloft) have some support in the literature as well, but to a more limited extent. Bupropion has open data supporting its use. Tricyclic antidepressants, however, have repeatedly demonstrated benefits for the treatment of adults with MDD, but have no controlled pediatric trial data to date showing benefit. Monoamine oxidase inhibitors have historically had very limited data surrounding pediatric use, which, combined with concerns regarding dietary issues and hypertension, have likely led to the limited use in this population.

SUICIDALITY. Over a decade ago, an FDA advisory Committee reviewed results of a meta-analysis of 24 controlled clinical trials of 9 antidepressants, which included approximately 4,400 pediatric patients. While there were no completed suicides, the cumulative risk for suicidality (suicidal thinking or behavior) when adverse events were simply collected by spontaneous report was approximately 4 percent on active medication vs. approximately 2 percent on placebo. This resulted in the FDA issuing a "black box" warning that any antidepressant use in children and adolescents was accompanied by an increased risk for suicide, and in mandatory distribution of a medication guide with each pediatric antidepressant prescription filled. Also, for the initial 3 years, the FDA had guidelines in place for the frequency of monitoring when initiating antidepressants. Importantly, in the Treatment for Adolescents with Depression Study (TADS), suicidality data was systematically collected, and questions regarding suicidality were posed to the youth prior to and during participation of the study, rather than relying on spontaneous report. When data was collected in this manner, almost 30 percent acknowledged recent thoughts or behaviors related to self-harm at the start of the study. All four treatment groups (CBT, fluoxetine, their combination, and pill placebo) showed diminished suicidality during the study with systematic data collection, although fluoxetine demonstrated the smallest reduction.

Select Key Studies

THE TREATMENT FOR ADOLESCENTS WITH DEPRESSION STUDY (TADS) . In this NIMH-sponsored study, 439 adolescents (aged 12 to 17 years) with moderate to severe depression were randomly assigned to one of four treatments: fluoxetine with medical management, weekly CBT, their combination, and

pill placebo. Adolescents who received fluoxetine and combination therapy had significant improvements at 12 weeks, while those receiving CBT alone did not separate from placebo. This demonstrated the key role of pharmacotherapy in the treatment of MDD in adolescents; however, when parameters beyond the primary outcome measures were examined, the combination treatment was most successful acutely. Interestingly, by the end of 9 months of treatment, combination, fluoxetine, and CBT responses were all virtually identical. A subsequent study led by Emslie demonstrated that continuation treatment with fluoxetine was superior to placebo in preventing relapse in children and adolescents with MDD.

THE TREATMENT OF SSRI-RESISTANT MDD IN ADOLESCENTS (TORDIA). This trial enrolled a more chronically depressed and treatment resistant sample than TADS. TORDIA is an RCT of 334 adolescents (12 to 18 years) with MDD that had not responded to a 2-month initial trial with an SSRI. Subjects received 12 weeks of: a second, different SSRI (paroxetine [Paxil], citalopram, or fluoxetine); a different SSRI plus CBT; venlafaxine (Effexor); or venlafaxine plus CBT. The two arms with CBT plus medication demonstrated a higher response rate (54.8 percent) than a medication switch alone (40.5 percent), with no difference in response rate between venlafaxine and a second SSRI. TORDIA demonstrated that, for adolescents with depression who do not respond to an initial SSRI, a switch to another antidepressant, combined with CBT, should be considered. Even if CBT is not feasible, those simply changing medications had a 40.5 percent improvement.

Clinical Implications and the Role of Pharmacotherapy. For managing "mild," uncomplicated pediatric depression, the AACAP practice guidelines recommend consideration of education, support, and case management. For children and adolescents who present with a more complex MDD, or have a limited response to supportive psychotherapy, a more specific psychotherapy and/or an antidepressant is indicated. Severe MDD and/or chronic recurring MDD will generally require pharmacotherapy, either alone or in combination with psychotherapy.

Dysthymia

Dysthymia is a persistent, long-term mood disorder of less intensity than MDD, with a mean episode length of 3 to 4 years. While this is a relatively common disorder, particularly in adolescents, there are no controlled trials for the treatment of dysthymia in youth. Based on the available adult literature, efficacious treatments for MDD may also be effective for dysthymia.

Pharmacotherapy for Dysthymia. In the absence of any controlled pharmacotherapy trials for dysthymia, when clinical presentation indicates

that initiation of an antidepressant is warranted, selecting an antidepressant with support for MDD appears prudent.

Clinical Implications and the Role of Pharmacotherapy. While the AACAP Practice Parameters do not provide specific guidance on the role of pharmacotherapy for dysthymic disorder, their general guidance for MDD would appear to be applicable. In light of the duration of symptoms required to meet diagnostic criteria for dysthymia (1 year), it is likely that many of the youths with dysthymia would require specific types of psychotherapy and/or pharmacotherapy as recommended by the guidelines for those who do not respond to supportive psychotherapy or have a complicated MDD.

Bipolar Disorder

Once considered rare, childhood-onset bipolar disorder is now diagnosed with much greater frequency (up to 4 percent) in children and adolescents. While controversy continues regarding the diagnostic criteria for pediatric bipolar disorder, it is clear that a number of youth suffer from explosive dysregulated mood, emotional lability, and manic symptomatology leading to significant impairment in functioning and, potentially, hospitalization. These children and adolescents frequently demonstrate rapid fluctuations in mood and behavior (ultrarapid or ultradian cycling) rather than clearly delineated manic and depressive phases. Bipolarity in youth is commonly accompanied by comorbid ADHD and conduct and anxiety disorders, as well as substance use disorders in adolescents. Juvenile bipolar disorder is a highly remitting and relapsing disorder with some estimates indicating that the disorder will persist in three-quarters of children and adolescents into adulthood.

Pharmacotherapies for Bipolar Disorder. Fortunately, despite a presentation that may be quite different to that seen in adults, several pharmacotherapies effective for adults with bipolar disorder have demonstrated benefits in youth. These pediatric mood symptoms are generally treated with atypical antipsychotics, which are both FDA approved and now considered first-line treatment.

ATYPICAL ANTIPSYCHOTICS. Olanzapine, risperidone, aripiprazole, and quetiapine are FDA approved for bipolar disorder in children and/or adolescents, with trials of other atypicals underway. The atypical antipsychotics typically manifest their action within 2 weeks and maintain effectiveness over time. Mood stabilizers are often utilized as second line treatments or used in conjunction with atypical antipsychotics. In addition to demonstrating improved manic symptoms, these agents may assist in the prevention of recurrent manic episodes and the depressive subphase of

the bipolarity. While monotherapy is certainly desired, combination pharmacotherapy is often required—such as an atypical antipsychotic and mood stabilizer, or an antimanic agent with treatment for comorbid ADHD, anxiety, and/or OCD. Additionally, once a youth with bipolar disorder responds to a pharmacotherapy, most will require ongoing treatment with medication to prevent relapse. Current practice parameters suggest the regimen needed to stabilize the acute mania should be maintained for 12 to 24 months.

LITHIUM. Lithium is FDA approved for bipolar disorder in youth 12 years of age and older, although this approval was based primarily on the adult literature with limited controlled clinical trial data supporting its use. Open-label and controlled trials of lithium with and without concomitant antipsychotics have been positive, although the effect sizes and onset of action appear less robust than atypical antipsychotics.

ANTICONVULSANTS. Early reports derived from case series and open studies showed the usefulness of the antiseizure medications divalproex and carbamazepine (Tegretol). However, controlled studies with either divalproex or oxcarbazepine (Trileptal), alone or in combination with other medications, failed to demonstrate efficacy of the anticonvulsants for the treatment of acute mania. In addition, their teratogenic and metabolic effects have limited their usefulness. The role of anticonvulsants in combination with atypical antipsychotics has yet to be further described.

Select Key Studies. Results from multisite studies of olanzapine for juvenile bipolar disorder were among the first data published demonstrating efficacy of any medication for bipolar disorder in this age group. For instance, in a 3-week RCT in 161 children and adolescents aged 13 to 17 years, olanzapine significantly improved symptoms of mania compared to placebo. Similar results were reported with quetiapine monotherapy in 277 patients aged 10 to 17 years. Additionally, a 4-week RCT of flexible-dose ziprasidone demonstrated improvement at week 1, suggesting early control of the symptoms. In most of the studies of atypical antipsychotics, weight gain has exceeded that noted in adult studies. Moreover, changes in prolactin, fasting glucose, fasting total cholesterol, uric acid, and hepatic enzymes have been reported in youth receiving atypical antipsychotics, necessitating close monitoring (at least bi-yearly to yearly).

Clinical Implications and the Role of Pharmacotherapy. The AACAP practice parameters describe pharmacotherapy as the primary treatment for well-defined DSM-IV-TR mania. Adjunctive treatment with behavioral and psychosocial therapies may be useful to address disruptive symptoms and their sequela, which often impact family and community. Due to the

difficulty of stabilizing active bipolar and frequent comorbid symptoms, atypical antipsychotics are recommended as first line treatments, although it is often necessary to employ combined pharmacotherapeutic strategies in these youth. For instance, multiple studies have shown that stimulants can be used in youth with stable bipolar disorder to treat comorbid ADHD.

ANXIETY DISORDERS

Obsessive-Compulsive Disorder (OCD)

A number of youth (1 to 2 percent) suffer from OCD characterized by rituals and obsessions with impairment that often continue into adulthood. In fact, one-third to one-half of adults with OCD are able to identify the onset of symptoms in childhood or adolescence.

Pharmacotherapy for OCD. A number of SSRIs have demonstrated efficacy and been approved by the FDA for the treatment of children and adolescents with OCD. These medications include fluvoxamine (Luvox), fluoxetine, clomipramine (Anafranil), and sertraline. It is noteworthy that serotonin-based medications are the only class of antidepressants to date to demonstrate efficacy in the treatment of OCD. The atypical antipsychotics and benzodiazepines may have an adjunctive role in the treatment of refractory OCD, but there is no support for these medications as a first-line treatment for pediatric OCD.

For cases of acute, sudden-onset OCD, particularly with a corresponding positive test for strep, treatment may increase in complexity. If a clinical diagnosis of PANS/PANDAS is appropriate, treatment efforts may require a two-sided approach. The first aim is to treat the underlying, aggravating infection with antibiotics or intravenous immunoglobulin (IVIG). Second, CBT and/or SSRIs in lower doses than normally recommended for children with OCD may prove beneficial in addressing the residual OCD, tics, anxiety, or accompanying emotional lability.

Select Key Studies: The Pediatric OCD Treatment Study (POTS). Both short-term OCD-specific CBT and the SSRIs have demonstrated efficacy in the treatment of pediatric OCD. POTS was the first study to examine the relative and combined efficacy of these two approaches, randomizing 112 patients with OCD (aged 7 to 17 years) to treatment with CBT alone, medical management with sertraline alone, the combination of the two, and pill placebo. All three active treatments were superior to placebo in reducing OCD symptoms, although clinical remission rates for combined treatment was 53.6 percent, for CBT alone 39.3 percent, for sertraline alone 21.4 percent, and for placebo only 3.6 percent.

The POTS (II) RCT assessed 124 pediatric outpatients with OCD (aged 7 to 17 years) assigned to 1 of 3 treatment strategies, all of which included

SSRIs. The positive response rates for medication management only (30.0 percent) and medication management plus instructions in CBT (34.0 percent) were significantly lower than combined medication management plus CBT (68.6 percent). These findings indicate that truncated versions of CBT are not efficacious comparatively, and that efforts should focus on making the full CBT protocol available more widely in community settings.

Clinical Implications and the Role of Pharmacotherapy. The empirical literature clearly supports the role of pharmacotherapy for the acute and maintenance treatment of pediatric OCD. In light of the POTS I/II findings, recommendations would be for children and adolescents with OCD to begin treatment with either CBT alone or in combination with an SSRI.

Posttraumatic Stress Disorder

Approximately one in four children will experience a significant traumatic event prior to reaching adulthood, with a minority who develop subsequent acute as well as chronic mental health problems. Risk factors for developing posttraumatic stress disorder (PTSD) following exposure to trauma include: prior trauma exposure, degree of exposure to index trauma, pre-existing psychiatric disorders, female gender, parental psychopathology, and limited social support.

Pharmacotherapy for PTSD. There are no randomized clinical trials published demonstrating efficacy of any pharmacotherapy in treating PTSD in children. SSRIs have certainly demonstrated efficacy in the treatment of adults with PTSD, but their efficacy remains dubious in pediatric populations with PTSD. Other medications that have demonstrated at least some evidence of support in open-label pediatric clinical trials include: atypical antipsychotics, alpha- and beta-adrenergic blocking agents, non-SSRI antidepressants, and mood stabilizers.

Clinical Implications and the Role of Pharmacotherapy. The AACAP PTSD practice parameters recommend that trauma-focused psychotherapies be considered first-line treatment for children and adolescents with PTSD, with SSRIs considered a potential treatment option (acceptable based on emerging evidence or clinical opinion) when used in conjunction with psychotherapy. New research on the role of "prophylactic" very early intervention with beta blockers and alpha agonists to protect against the long-term development of PTSD after trauma are under investigation.

"Other" Anxiety Disorders (Separation Anxiety Disorder, Generalized Anxiety Disorder, Social Phobia, Specific Phobia, Panic Disorder, Agoraphobia without Panic Disorder)

The anxiety disorders as a group are the most common of the pediatric psychiatric disorders. Youth with an anxiety disorder are at increased risk of additional anxiety disorders, MDD, and substance abuse, with an increased risk of anxiety and depressive disorders in adulthood as well.

Pharmacotherapy for Anxiety. SSRIs are considered the medication of choice in the treatment of children and adolescents with anxiety disorders when the symptoms are moderate to severe, if the impairment makes participation in psychotherapy difficult, or if psychotherapy alone leads to only a partial response. Several RCTs of SSRIs have demonstrated benefits in the short-term treatment of GAD, social phobia, separation anxiety disorder, and selective mutism with social phobia. The long-term role of SSRIs has not been studied, so clinicians might consider a trial off medication after a year of stable symptom improvement. There is no evidence of greater efficacy of one SSRI over another at this time.

Key Studies: The Child/Adolescent Anxiety Multimodal Treatment Study (CAMS). This trial helped to delineate the appropriate role for pharmacotherapy in anxiety disorders by comparing sertraline, CBT, their combination, and placebo in youths with separation anxiety disorder, social phobia, and GAD. In the trial, 488 children aged 7 to 17 years were randomized to one of the four treatment options for a 12-week period. Following this acute exposure, responders attended 6 monthly booster sessions in their treatment arm, with sertraline and combination groups continuing on their medication throughout this period. At both weeks 24 and 36, the majority (>80 percent) of acute responders in all three treatment conditions maintained positive response. The combination group maintained superiority on some but not all outcomes, whereas the monotherapies were indistinguishable across all outcomes studied, leading to the conclusion that all 3 CAMS treatments are viable alternatives.

Another significant study in pediatric anxiety pharmacotherapy was conducted by an RCT of 128 children, aged 6 to 17 years, with social phobia, separation anxiety disorder, or GAD, all of whom had failed to improve with 3 weeks of a psychosocial intervention. Following 8 weeks on fluvoxamine dosed up to 300 mg per day or placebo, fluvoxamine was found to significantly improve outcomes compared to placebo on both the Pediatric Anxiety Rating Scale and the Clinical Global Impressions-Improvement Scale.

A recent systematic review and meta-analysis investigated the efficacy, safety, and tolerability of SSRIs and SSNRIs for the treatment of pediatric anxiety disorders. Nine randomized, double-blind, placebo-controlled trials involving 1,673 patients (and 6 medications) were included. Analyses demonstrated efficacy for all individual agents with an overall modest effect size compared to placebo. The authors suggested that treatment selection

by providers should reflect tolerability, half-life, and cost, rather than short-term efficacy.

Clinical Implications and the Role of Pharmacotherapy. The AACAP Anxiety Practice Parameters recommend initial treatment of anxiety disorders in mildly ill children with psychotherapy. Exposure-based CBT has received the most empirical support of the psychotherapies in the treatment of pediatric anxiety. The addition of a medication may be in response to a need for acute symptom reduction in the moderately to severely anxious child, a comorbidity requiring pharmacotherapy, or a partial response to psychotherapy.

SCHIZOPHRENIA

While the onset of schizophrenia is rare prior to 13 years of age, numbers steadily increase throughout the adolescent years, and by 18 years of age 12 to 33 percent of patients who will ultimately develop schizophrenia will have symptoms.

Pharmacotherapy for Schizophrenia

Following several decades of practice based primarily upon extrapolation of data from research in adults with schizophrenia, RCTs of aripiprazole and risperidone have demonstrated the safety and efficacy of these medications in the treatment of schizophrenia in adolescents aged 13 to 17 years. The studies were sufficient to warrant FDA approval for these drugs in this teen population. At this point the atypical antipsychotics, particularly aripiprazole and risperidone, would be considered first-line medications for adolescents with schizophrenia. Studies involving clozapine (Clozaril) in treatment-refractory early-onset schizophrenia-spectrum disorders have demonstrated superiority of clozapine compared to haloperidol (Haldol) and olanzapine, with regard to reduction in negative symptoms and to a certain degree with overall response. Based on the results of one RCT, the use of omega-3/fish oils may help delay the onset and/or reduce the ultimate expression of psychotic symptoms in high-risk children.

Clinical Implications and the Role of Pharmacotherapy

Psychopharmacology plays a critical role in the treatment of schizophrenia, with the atypical antipsychotics considered among the first-line treatments. Fish oil may be useful in adolescents at high risk to develop fulminant psychotic symptoms. Psychosocial interventions are considered adjunctive to the medication, but are strongly recommended.

SUBSTANCE USE DISORDERS

The lifetime prevalence of drug abuse or dependence increases rapidly

throughout adolescents, jumping from 3.3 percent in 15-year-olds to 9.8 percent in 17- to 19-year-olds. The primary goal of treatment in adolescents with substance use disorder (SUD) is reducing substance use (harm reduction) or ultimately abstinence from substance use. Up to 90 percent of adolescents with SUD have comorbid psychopathology.

Pharmacotherapy for SUD

Guidance on the use of pharmacotherapy for SUD in adolescents is based primarily on controlled trials in adults. Medications targeting alcohol-related cravings, such as naltrexone (ReVia), acamprosate (Campral), and ondansetron (Zofran), have been described in a limited manner with generally open trials in adolescents. Opioid replacement such as buprenorphine (Suboxone) is FDA approved in adolescents older than 16 years and may be considered in opioid addicted youth who have failed a trial of abstinence. These medications, along with aversive agents such as disulfiram (Antabuse), are recommended to be considered for use in adolescents who fail or refuse psychotherapy. Pharmacotherapy has been shown to be useful for the treatment of the comorbid psychiatric disorders such as mood disorders, but is generally used as adjunct to SUD-based psychotherapies.

Clinical Implications and the Role of Pharmacotherapy

A number of psychotherapies including family-based treatments and individual cognitive-behavioral therapies with motivational enhancement have solid empirical support for the treatment of adolescents with SUD, and are recommended as first line for SUD. Practice parameters describe a role for medication in the management of craving, withdrawal, and for aversion therapy, but this is based primarily upon expert opinion and open studies. Treatment of comorbid psychiatric disorders should be considered concurrent with issues such as understanding the comorbid disorder, the latency to initiate treatment, selection of agents, and monitoring on a case-by-case basis. Whereas pharmacotherapy of psychotic and mood disorders should be undertaken in parallel with the onset of addiction treatment, ADHD and/or anxiety treatment should be sequenced after some stabilization in substance use.

AUTISM SPECTRUM DISORDERS (ASD)

Pharmacotherapy for Autistic Spectrum Disorders (ASD)

ASDs, including autistic disorder and the older DSM-IV Asperger disorder and pervasive developmental disorder PDD-NOS, are lifelong neurodevelopmental disorders characterized by core features of impaired socialization, communication, behavioral problems, and associated features of anxiety, irritability, aggression, and ADHD-like symptoms. Recent

prevalence rates have been increasing with more recent studies conducted in Asia, Europe, and North America reporting an average of around 1 percent in the general population. Though emerging evidence suggests efficacy of psychopharmacological interventions in improving core features of ASD such as ritualistic behaviors, there is definitive evidence for the therapeutic role of psychotropic intervention for the associated features of ASD, such as irritability and disruptive and aggressive behaviors. Risperidone and aripiprazole have been approved by the FDA for the treatment of irritability associated with autistic disorder in children and adolescents. With the advent of DSM-5, comorbidity with ADHD and other disorders may be better identified and treated within ASD.

Key Studies

Research Units on Pediatric Psychopharmacology Autism Network: Risperidone Trial. This 8-week RCT of risperidone in 101 children with autistic disorder (mean age 8.8 ± 2.7 years) showed that risperidone was superior to placebo in the short-term treatment of irritability, hyperactivity and stereotypic/repetitive behaviors, although there was a lack of response in social and communication deficits. Common adverse effects of increased appetite, fatigue, drowsiness, dizziness, and drooling were reported. Significant improvements in irritability, hyperactivity, and repetitive behaviors observed in the acute treatment with risperidone were maintained in the continuation phase of the trial without an increase in the mean daily dose of risperidone (1.8 ± 0.7 mg; range 0.5 to 3.5).

In an 8-week RCT of 218 children and adolescents (aged 6 to 17 years) with a diagnosis of autistic disorder, participants randomized to aripiprazole (5, 10, or 15 mg/day) had significantly greater improvements in irritability than placebo (but only 5 mg dose was statistically significant due to high placebo response). The most commonly reported adverse events associated with aripiprazole treatment were sedation, EPS, and weight gain.

Research Units on Pediatric Psychopharmacology Autism Network: Methylphenidate Trial. This RCT examined the efficacy and safety of low (0.125 mg/kg/day), medium (0.25 mg/kg/day), and high (0.125 mg/kg/day) doses of methylphenidate in 72 children (mean age 7.5 ± 2.2 years) with moderate to severe hyperactivity in addition to ASD. Of 66 subjects who tolerated the trial doses of methylphenidate, the medication was significantly superior to placebo in improving ADHD symptoms with a small to medium magnitude of response (effect size range 0.20 to 0.54). The medication was associated with decreased appetite, sleep difficulties, and emotional outbursts, and 18 percent discontinued the trial due to inability to tolerate methylphenidate.

Clinical Implications and the Role of Pharmacotherapy

As demonstrated in the methylphenidate trial, compared to a typically developing population, response to psychotropic medications in youth with ASD may be less robust with higher rates of adverse effects to both medication and placebo. Thus, it is advisable to be conservative in dosing during the initiation and titration of psychotropic medications in this population. SSRIs including clomipramine and fluoxetine appear to be modestly effective in improving overall global functioning, including symptoms of repetitive behaviors, anxiety, irritability, and hyperactivity in children with ASD. Mood dysregulation in the form of irritability, aggression, temper tantrums, and self-injurious behaviors is commonly associated with ASD. Atypical antipsychotics are not only effective in treating the ASD associated features of irritability and hyperactivity and core feature of ritualistic behaviors, but additionally appear useful and are suggested to be superior to first-generation antipsychotics in improving the other ASD core features of impaired socialization and communication. Stimulants are the most widely prescribed drug for target symptoms of ADHD symptoms in youth with ASD, although the rate and magnitude of response to stimulants in ASD children is less than observed in children with ADHD. Atomoxetine or low dose of stimulants is recommended for the treatment of ADHD in children with ASD.

SLEEP DISORDERS

Insomnia

Insomnia is common in the general pediatric population, and is certainly more common in youth with psychiatric disorders due to the disorders themselves as well as a sequela of the medications prescribed to treat the primary disorder.

Pharmacotherapy for Insomnia. There are no FDA-approved sleep agents for children. After aggressive sleep hygiene and education, controlled trials have demonstrated improved sleep latency outcomes with melatonin. Data regarding other agents used chronically are largely derived from expert opinion or case series, including benzodiazepines, clonidine, mirtazapine (Remeron), imipramine, trazodone (Desyrel), and, less frequently, sedating atypical antipsychotics.

Clinical Implications and the Role of Pharmacotherapy. Pharmacotherapy should be considered only after a thorough assessment for the etiology of the sleep disruption (e.g., sleep hygiene, potential iatrogenic causes, sleep apnea, insomnia as a sequela of a psychiatric disorder). For pharmacologically induced sleep disruption, consider alternative preparations, classes of medication, or medication

discontinuation. In the case of psychopathology related sleep issues or necessary medication-related sleep disruption, use of medication should be considered.

Enuresis

While a specific etiology for enuresis is not commonly identified, a careful assessment is necessary in consideration of potential urologic, developmental, psychosocial, and/or sleep-related causes. If the history, physical examination, and urinalysis are unremarkable and do not suggest a specific etiology, supportive approaches combined with conditioning is considered the first-line treatment. Supportive interventions include education as well as recommendations against punishing the child for enuretic episodes. Behavioral conditioning methods with portable battery-operated alarms have been repeatedly demonstrated to be highly effective.

Pharmacotherapy for Enuresis. Two medications have demonstrated efficacy in the treatment of enuresis.

DESMOPRESSIN (DDAVP). Desmopressin is a synthetic analog of vasopressin, which decreases urine production. It is generally given orally, dosed initially at 0.2 mg at bedtime, titrated up to 0.4 to 0.6 mg as needed. Success rates of 10 to 65 percent have been reported. If successful, a course of treatment is recommended for 3 to 6 months.

IMIPRAMINE. Imipramine is FDA approved for enuresis, and has been used for decades despite an unknown mechanism of action, with several studies demonstrating 40 to 60 percent effectiveness. It is given in a single bedtime dose of 1.0 to 2.5 mg/kg/day. If effective, treatment should be continued for 4 to 6 months. In light of the risk of cardiac arrhythmias with tricyclic antidepressants, an ECG can be considered prior to treatment and periodically during treatment. Serum levels are not recommended unless there is no effect despite dosing the imipramine at 2.5 mg/kg/day.

Clinical Implications and the Role of Pharmacotherapy. If supportive approaches and behavioral conditioning with a urine alarm are ineffective or impractical, medication may be considered as a treatment option. Medication may also be useful intermittently to allow youth to attend overnight activities such as camp or sleepovers without embarrassment.

Tic Disorders

Tic disorders are common in youth, occurring in 15 percent of the general population, and are more common in youth with other psychiatric disorders. Most tic disorders do not affect functioning adversely, are transient, abate with age and do not require intervention. Tic disorders

may include motor and/or vocal tics (the combination referred to as Tourette syndrome) and may be transient or chronic, simple or complex. Most tic disorders present *de novo,* but some may be exacerbated by stress or with certain classes of medication.

Pharmacotherapy for Tic Disorders. The antipsychotic pimozide is FDA approved for managing tics. Based on controlled clinical trials, the current armamentarium for tic and Tourette disorders includes the alpha-agonists guanfacine and clonidine, as well as the typical (e.g., pimozide [Orap] or haldol) and atypical antipsychotics (risperidone, aripiprazole). Multisite studies have demonstrated the efficacy and tolerability (e.g., non–tic exacerbation) of combination methylphenidate and clonidine in treating children with ADHD and comorbid tics. Specific psychotherapies are being tested to assist the child in focusing on symptoms of tics to help abate tic expression.

Clinical Implications and the Role of Pharmacotherapy. Tic and Tourette symptoms should be evaluated carefully to establish the level of resulting impairment. For youth with impairment related to their tics, treatment with pharmacotherapy should be considered. Give the high rates of disabling anxiety, OCD, and ADHD, consideration should be given to treating the comorbidity with careful selection of non–tic exacerbating agents. For instance, ancillary treatment of co-occurring anxiety may reduce the severity of tics and reduce the medication burden.

ENDOCRINE AND METABOLIC EFFECTS OF PSYCHOTROPIC MEDICATIONS

Accompanying the expanding use of psychotropic medications in the pediatric population is a growing awareness and understanding of the potential for endocrine and metabolic effects caused by many of these agents. Psychostimulants, antipsychotics, and mood stabilizers are some of the common classes of medication that have demonstrated these types of adverse effects.

Antipsychotics

As discussed previously, antipsychotics are used for a wide range of psychiatric disorders, including mood, disruptive behavioral, tic, anxiety, and psychotic disorders. The use of antipsychotics, particularly atypical antipsychotics, has grown tremendously over the past decade, and clinicians are faced with managing the metabolic sequela of these medications.

Weight Gain and Metabolic Issues. Children and adolescents appear to be susceptible to significant weight gain and metabolic adverse effects of the atypical antipsychotics, perhaps even more so than adults. While all of

the atypical antipsychotics may promote weight gain, particularly in patients who are treatment-naïve, some seem to be more likely than others. Correll has suggested the propensity to promote weight gain and the subsequent development of a metabolic syndrome in the pediatric population to be: clozapine = olanzapine >> risperidone ≥ quetiapine > ziprasidone ≥ aripiprazole. Body mass index (BMI) is a way to express body weight adjusted for height, and is calculated as:

$$\text{BMI} = (\text{weight in kg})/(\text{height in meters})^2$$

Up-to-date BMI tables and charts containing normal values for age are readily available from the Centers for Disease Control (www.cdc.gov/growthcharts).

Some patients who gain significant weight will develop lipid abnormalities, including elevations in triglycerides, total cholesterol, and low-density lipoprotein-cholesterol levels. Additionally, weight gain and obesity is associated with the metabolic syndrome, which includes abdominal obesity, dyslipidemia, glucose intolerance, hypertension, and insulin resistance. Clinical strategies for addressing this issue include education, reinforcement of healthy lifestyle behaviors, selecting a medication with lower likelihood of adverse effects, and intervening if weight gain and its sequela do become problematic. Monitoring of BMI, height, weight, blood pressure, waist circumference, fasting blood glucose, and fasting serum lipids should begin at baseline prior to initiating medication and continue throughout treatment with antipsychotics. For patients who do require ongoing treatment despite metabolic abnormalities, there is evidence that metformin (Glucophage) might be beneficial.

When assessing the risk/benefit relationship of initiating these medications, it is important to realize that not all children will develop these metabolic problems, and that those of normal BMI may be less prone to develop difficulties. Additionally, the clinician must factor in the fact that the greater the impairment in a child's functioning, the greater the risk of not treating.

Prolactin. Elevations in prolactin can occur with atypical antipsychotics as well as the conventional neuroleptics, although the degree of elevation varies by medication and dose. The relative potency of antipsychotic medications in inducing hyperprolactinemia, based on pediatric and adult data, is roughly: risperidone > haloperidol > olanzapine > ziprasidone > lurasidone > asenapine > clozapine > quetiapine > aripiprazole. Fortunately, while the elevation in serum prolactin is common, particularly in children and adolescents, it is often asymptomatic and frequently will decrease over time even despite continuation of

medication. Potential signs and symptoms of hyperprolactinemia include: amenorrhea or oligomenorrhea in women of reproductive age, breast enlargement/engorgement, galactorrhea, decreased libido, erectile dysfunction, and failure to enter or progress through puberty.

Stimulants and Atomoxetine

Both the stimulants and atomoxetine appear to cause a mild growth delays in certain patients; however, data suggest that height and weight delays largely attenuate by 2 to 3 years into treatment. While the effect on final adult height seems to be negligible, data following patients into adulthood is sparse. In light of this, the AACAP practice parameters recommend measuring height and weight and plotting the information on a growth chart, prior to and throughout treatment. For those patients who do experience more significant weight or height delays, clinicians may consider caloric supplementation, breaks from medication, alternative agents, and/or combinations (e.g., Periactin).

Mood Stabilizers

Lithium. Data is limited regarding lithium's potential for adverse effects on thyroid and renal functioning for children and adolescents specifically, although the potential is well documented for adults. Considering the possibility for chronic use in a child who responds to lithium treatment, monitoring for thyroid and renal dysfunction over time is essential.

Valproate. Valproate use has been associated with weight gain as well as polycystic ovary syndrome, and may be related to teratogenic effects in pregnancy. While the specific mechanism and risk factors for polycystic ovary syndrome are unclear, clinicians should monitor for weight gain, menstrual dysfunction, hirsutism, and acne in female patients taking valproate. Combining concerns of polycystic ovary disease and teratogenicity, many clinicians avoid valproate in adolescent females.

PSYCHOPHARMACOLOGICAL TREATMENT FOR VERY YOUNG CHILDREN

The Preschool Psychopharmacology Working Group, a multidisciplinary collaboration of early childhood professionals, released recommendations to guide clinicians considering psychopharmacological treatment in young children. In light of the limited evidence base for the use of most psychotropic medications in children under 6 years of age, the group recommended that a trial of evidence-supported psychosocial treatments precede psychopharmacological treatments, and concluded that medication was not indicated for preschoolers with only mild or single-context symptomatology or impairment. If medication is ultimately indicated, the

group made the following recommendations based upon the limited data available.

ADHD

In light of data from PATS and several smaller methylphenidate studies, as well as the lack of randomized controlled trials of amphetamines in preschoolers, methylphenidate is recommended as the first-line psychopharmacological treatment for preschool ADHD.

Disruptive Behavioral Disorders

Risperidone is recommended as the first-line medication for young children with disruptive behavioral disorders and concomitant severe aggression without co-occurring ADHD.

Major Depressive Disorder

Fluoxetine is recommended as the first-line medication for preschoolers with major depressive disorder.

Bipolar Disorder

Risperidone is recommended as the first-line medication, as it has the most data available on effectiveness and tolerability in preschool-age children with bipolar disorder.

Anxiety

Fluoxetine is the first-choice medication for preschool anxiety disorders in general, although for PTSD the working group did not recommend the use of medication and for OCD there was insufficient evidence to suggest one was more likely to be efficacious than the other between fluoxetine, fluvoxamine, and sertraline.

Autistic Spectrum Disorders

Risperidone is approved by the FDA for treating children as young as 5 with autism and severe aggression and irritability.

Primary Sleep Disorders

If the sleep disturbance is significant enough that the well-being and daytime functioning of the child and/or caregiver is compromised, and if behavioral treatment is unsuccessful, then melatonin 1 to 3 mg could be considered for use as the first-line pharmacotherapy.

▲ 54.7 Inpatient Psychiatric, Partial Hospital, and Residential Treatment for Children and Adolescents

DANA KOBER, M.D., AND ANDRéS MARTIN, M.D.

Psychiatric inpatient beds rose significantly after the influenza epidemic of the 1920s. This was due to the need for long-term custody of children with mental and behavioral problems post encephalitis. The number of inpatient beds reached a peak in the 1950s, prior to the deinstitutionalization movement of the 1960s. Deinstitutionalization was propagated by poor conditions of some institutions as well as changes in treatment approaches with the advent of psychopharmacological interventions.

The number of inpatient and residential pediatric beds has continued to decrease since then, particularly since the 1980s. A nationally representative study of community hospitals conducted by Case and colleagues showed that inpatient lengths of stay continued to decrease through the end of the twentieth century, going from a median of 12.2 days in 1990 to 4.5 days in 2000, a change of 63 percent. Meagher and colleagues looked at one inpatient setting in Massachusetts which also demonstrated a significant decline in length of stay, ranging from a mean of 44.5 days in 1991 and 10.7 days in 2008. Though the mean length of stay is different in these two studies, they both show the steady decline of the amount of time children spend in the hospital. The latter study also showed significantly increased number of psychotropic medications at admission and discharge, lower GAF at intake, and increased number of prior hospitalizations for patients admitted in 2008 versus 1991. There has been a concurrent increase in the number of psychiatric inpatient admissions for children and adolescents, as noted in an analysis of National Hospital Discharge Survey data between 1996 and 2007 by Blader and colleagues. One conclusion may be that the outpatient, community-based, systems-of-care approach is working for many children and adolescents; however, children and adolescents admitted currently are sicker than those admitted in the 1990s.

The effects of institutions closing their doors, a shift to managed care and other third-party funders, the privatization of Medicaid, and changing paradigms of effective psychiatric treatment options combined to result in a shift in the way in which inpatient psychiatric hospitalization is conceptualized and used, particularly in the United States: Emphasis has shifted to acute stabilization, diagnostic assessment, implementation of multidisciplinary treatment interventions, and return to the community and its available supports. The focus of inpatient psychiatric hospitalization

has shifted more toward assessment and stabilization and less toward long-term treatment, although there is recognition that for a minority of children, inpatient and highly structured care remain the preferred treatment approach.

Amanda B. Geller and Thomas M. Wickizer argued that by the end of the 20th century the reduction of inpatient services had gone too far, with lengths of stay becoming unrealistically short, leading to a rebound in readmission rates and a "revolving door" approach to inpatient and crisis care. In many states, there is a clear shortage of inpatient and residential treatment centers, resulting in youth being seen in emergency departments, waiting for appropriate treatment in juvenile detention centers, or simply floundering untreated in schools and the community at large. Emergency departments across the nation particularly have had to deal with the burden of this shifting ecology of services.

Although there are significantly fewer inpatient beds since the onset of deinstitutionalization in the 1960s, inpatient psychiatric treatment continues to be necessary and essential. Due to improvements in psychopharmacological, behavioral, and community and in-home treatment options, theoretically fewer hospitalizations would be necessary. However, rates of admission and total inpatient days increased significantly between 1996 and 2007. Nonetheless, a national shortage of inpatient beds and outpatient treatment options remains. As a temporary measure, some hospitals have adapted to "board" children on general pediatric wards, or in the emergency department itself, while they await a psychiatric bed or until they are stabilized on that unit. Wharff and colleagues studied a large urban pediatric emergency department in which one-third of patients needing inpatient psychiatric admission were boarded in the emergency department or pediatric floor. Odds of boarding were increased for patients with diagnoses of autism, intellectual delay, and/or developmental delay, as well as children with severe suicidal ideation. There is a very recent trend to provide beds for children with autism and developmental delays in a separate but attached unit, as the needs of these children are different than the typical population in inpatient units. Children who do not meet strict inpatient admission criteria may be referred to crisis stabilization programs that provide short-term treatment while longer-term services are arranged.

Table 54.7–1.
Differences among Levels of Care

Level of Treatment	Purpose	Length of Stay	Benefits	Example of Reason for Admission
Short-term inpatient	Acute stabilization	Days to weeks	Improvement in symptoms and functioning	Acute risk of harming self or others

Intermediate-term inpatient	Arrangement for appropriate placement	Weeks to months	Safe environment; ongoing therapy	Child in need of longer stay; may be awaiting residential placement
Partial hospital program (PHP) or intensive outpatient program (IOP)	Transition from, or prevention of, inpatient hospitalization	Weeks to months	Maintenance at home with structured therapeutic and school day programs; PHPs typically include a school component, whereas IOPs provide after-school care	Difficulty attending school; step down from inpatient stay
Residential	Long-term treatment	6 months to several years	Long-term, consistent, safe therapeutic environment	Unable to maintain safe behavior at home, often after extensive community-based services have been tried and exhausted

LEVELS OF CARE

Stabilization of the child's acute symptoms, coordination of family and relevant provider meetings, and rapid behavioral and pharmacological intervention occur during inpatient hospitalization to return the child to a safe environment as soon as realistically feasible. Partial hospitalization programs (PHPs) are used when the child is safe enough to stay at home yet needs structured therapeutic day supports, either as a temporary treatment or as a transition into a therapeutic school or residential program. Residential programs care for the child around the clock over a longer period of time than an inpatient hospitalization and have a different staffing approach. Table 54.7–1 provides comparative highlights of the key features of inpatient, partial hospital, and residential programs.

INPATIENT TREATMENT

Physical Structure, Staffing Organization, Daily Routine

Inpatient hospitalization is used for stabilization and return to the community with attention to setting up support structures prior to discharge. The physical structure and daily schedule of inpatient units share some characteristics with the outside environment of the child while also having unique characteristics relevant to the goals of hospitalization and specific aspects of safety. Inpatient units can be part of larger general or children's hospitals, in which case they may be better suited to address the needs of medically challenging or complicated children (e.g., the child with brittle diabetes or uncontrollable seizures, or the adolescent who has taken a serious overdose) or to pursue complex medical workups (e.g., children requiring lumbar taps or 24-hour video encephalography). By contrast, "free-standing" inpatient units in more naturalistic or child-friendly environments may be better suited for the needs of children

requiring longer-term hospitalization. Regardless of their possible affiliation with an overarching hospital structure, the principles of inpatient and milieu-based care are similar across settings.

Child and adolescent inpatient units can vary, depending on the conditions of admission and the purpose of the unit. Most units tend to be locked for safety purposes, given that one of the more common reasons for admission is to manage aggression or acute risk of harm to self or others and given the unique developmental needs of children. Open or unlocked units typically exclude patients who are at acute risk to harm themselves or others and are usually geared for older adolescents or adults. Such units tend to provide treatment over a longer stay following acute hospitalization or in cases in which acute stabilization is not necessary. For example, an adolescent struggling with long-term depression who is not suicidal but who is not improving with aggressive outpatient treatment may benefit from the comprehensive assessment available in an unlocked unit.

The schedule on an inpatient unit is often similar to a typical school day schedule. As depicted in Table 54.7–2, the therapeutic day includes schoolwork, recreation groups, group therapy, supervised free time, and time for individual and family meetings. Among the unique features of inpatient, partial hospital, and residential care is the role of milieu-based, group-wide activities such as those highlighted in the table. As part of these activities, children benefit and learn from (and are routinely challenged by) the presence and demands of their peers and staff members. One goal of treatment is for the child to successfully navigate daily routine tasks that imitate their routine outside of the hospital.

Staff hierarchy structures can vary from unit to unit. Some follow a traditionally vertical, medical hierarchical organization, placing physicians at the top. However, child units tend to be unique in having a more horizontal working hierarchy, with each staff person's assessment observations of the child being important and valued, seeking to maximize collaboration around the child's needs. Inpatient mental health services for children require especially high staff-to-patient ratios, which poses financial and organizational challenges. Thus, even as horizontal hierarchies are preferred, clear lines of accountability and reporting are still necessary for the smooth functioning of the unit. During an inpatient hospitalization, 24-hour/day observation demonstrates the child's behaviors and interactions. Nurses and milieu counselors are especially positioned to observe parent–child and child–peer interactions. The observation of challenging behaviors may take some time, given that it is not uncommon for children to have a quiescent ("honeymoon") period early in their hospitalization.

Table 54.7–2.

Typical Inpatient Day Schedule

7:30–8:00 AM	Wake up, morning activities of daily living (ADLs), such as washing face and brushing teeth Assistance with ADLs may be provided by staff.
8:00–8:45 AM	Breakfast and morning medications
8:45–9:00 AM	Community morning meeting
9:00–11:00 AM	School
11:00 AM–12:00 PM	School or recreational therapy
12:00–12:30 PM	Lunch
12:30–1:00 PM	Free time
1:00–2:00 PM	Individual therapy
2:00–3:00 PM	Outside play
3:00–4:00 PM	Group therapy or coping skills group
4:00–5:00 PM	Family visiting time. Rotating activity, e.g., music therapy, yoga, pet therapy
5:00–6:00 PM	Family time and free time: board games, reading, video games
6:00–6:30 PM	Dinner and evening medications
6:30–7:30 PM	Showers and ADLs
7:30–8:30 PM	Movie time for kids; parent education group for families
8:30–9:00 PM	Bedtime routines

Multidisciplinary team rounds typically occur daily, in which representatives from each discipline come together to discuss each patient's problems and treatment planning. In such meetings, staff can also work out the tensions of the unit hierarchy or examine how the dynamics of the children and their families may reciprocally affect that of the staff. Handover of information between shifts provides staff with a framework that helps alleviate frustrations, improves communication across different staff members and disciplines, and is critical to the smooth functioning of an inpatient unit. Daily multidisciplinary team rounds are among the best places to anchor such efforts and help to solidify the team. Coordination is further enhanced through efficient written communications (increasingly through an electronic medical record), through shift-to-shift and cross-discipline in-person sign-outs, and through the availability of ad hoc "mini-team" meetings in which to discuss cases, to problem solve, and to deal with the inevitable differences of opinion inherent in treating seriously ill children.

The physical structure of a psychiatric unit is generally different from that of medical inpatient units. There often is a multipurpose common room, similar to a living room, used for group discussions, watching TV, playing video games, or engaging in arts and crafts. This room may also be transformed into the dining area, for which the tables double as work areas during recreational therapy time. Couches, chairs, and tables can be moved to the perimeter of the room to make floor space for yoga or other activities. Some units have a secure outside playground, providing another

important outlet for physical expression and exercise. Bedrooms typically have beds for one to three children; time spent in the community room is encouraged. Inpatient units are designed with attention to safety considerations: Beds and furniture are secured to the ground; curtains are attached with the use of Velcro; mirrors and windows are plasticized and not breakable into shards; if there is a seclusion room, its walls and doors are soft or padded.

Management of Aggression, and the Use of Restraint and Seclusion Revisited

Aggression is perhaps the most common reason for inpatient hospitalization in children. As such, inpatient units are charged with dealing with safe ways of de-escalation and of stabilization of aggression and violence. Seclusion into contained spaces (such as a "quiet room") and mechanical restraint through the tying of limbs to bed railings with Velcro or leather straps have been two historical means of dealing with acute violence and the imminent risk of injury directed at self or others. The use of restraint or seclusion had been considered a therapeutic intervention and conceptualized as an external means to help children regain their internal locus of control. However, following reports of deaths due to asphyxiation during restraints and physical holds in the early 1990s, there have been concerted and federally supported efforts to reduce the use of such restrictive interventions. Indeed, restraint and seclusion are better conceptualized as treatment failures, reflecting more about the failed efforts leading to them than about the patients whose aggression they seek to contain.

Abolishing the use of restraint and seclusion cannot be accomplished unilaterally or through a top-down directive. Units in which staff members are not provided with alternative therapeutic means to prevent, approach, and contain aggression and violence are unlikely to eliminate restraint or seclusion use or to do so in a manner that maintains patient and staff safety. A number of successful approaches, such as Collaborative Problem Solving, have been introduced to help safely to reduce or eliminate the use of such practices. Even as approaches can vary, they all have certain core features, including six core elements that are deemed essential for the systematic reduction of restrictive interventions in inpatient settings: leadership support of organizational change, use of data to inform practice, workforce development, use of seclusion and restraint prevention tools, inclusion of patients and families, and rigorous debriefing following restrictive events.

Use of antipsychotics in response to aggression in inpatient units, as well as the outpatient setting, has increased. Additionally, the more severe the behavior or aggression, the more likely medication is changed by the outpatient provider after discharge, most often being the start of a new medication.

Admission and Discharge Criteria

Treating the child in the least restrictive environment should be a guiding principle of any level of care. Short inpatient stays provide a safe, containing environment for a child who is acutely at risk of harm to self or others. At the same time, as early as the process of assessment and stabilization begins, support services necessary for discharge should be explored. Stated alternatively: inpatient care should not be viewed as an endpoint, but rather as a site for stabilization and a likely way station toward longer-term treatment options, be they outpatient and home-based approaches or restrictive settings such as subacute or residential placements.

Typical admission criteria for inpatient hospitalization include the following:

1. A psychiatric condition that places the child or adolescent at imminent risk of harm to self or others
2. Psychiatric illness that poses medical complications
3. Loss of judgment or impulse control that results in dangerous, threatening, or grossly disorganized behavior toward self or others
4. Failure of less restrictive treatment options

Because one of the roles of inpatient hospitalization is to protect the child from harming self or others due to dangerousness or aggression, it follows that a discharge criterion is that the child no longer poses such a risk. In addition, the home environment or contributing factors to the child's admission must be molded enough to prevent immediate readmission. Limitations to prompt discharge from the hospital may include inadequate level of supervision and care at home or wait lists for outpatient, community-based, or subacute or longer-term placements. At other times, it is the family work or psychosocial rather than narrowly defined psychiatric reasons in the identified patient that limit discharge feasibility from inpatient or residential settings. Indeed, it is common for inpatient settings to have a bimodal length of stay, with children admitted for psychiatric stabilization and shorter lengths of stay sharing a milieu with a minority of children whose adverse psychosocial circumstances and lack of adequate discharge options translate into lengthier hospitalizations (e.g., over 3 weeks). In these circumstances, it is not uncommon for inpatient settings to serve the dual role of an acute stabilization unit and de facto residential placement, with the ensuing logistical, clinical, and administrative challenges.

Assessment

During an inpatient admission, several assessments occur. Assessment is not only individualized to the child, but it also encompasses the input of

multiple disciplines. This is not unlike the parable of the five blind men defining an elephant based on the part with which they are in contact. In assessing a child through such a multidisciplinary approach, there is an inherent risk of fragmentation of efforts that needs to be carefully avoided. At the same time, it is helpful to delegate, in a coordinated manner, parts of the assessment to those team members best suited for the task.

Assessment includes the current presentation and reason for admission, as well as a review of past treatments, including treatment failures and successes. Information regarding the child's past treatments may be evaluated by obtaining prior records and speaking with the child's outpatient providers. Observation of the child in groups and interacting with peers is a particularly helpful aspect of inpatient hospitalization. Provision of inpatient care also allows clinicians and staff to observe the external and internal deficits that may contribute to the child's presentation. There is an initial expedited assessment of the patient's strengths, weaknesses, needs, and precipitants for decompensation or aggression. The child's family dynamics are assessed in family meetings that may occur with a social worker or the primary clinician. After the initial assessment is complete, all team members come together, typically during team rounds, to discuss each part of the assessment. This process is refined iteratively throughout the length of the hospital stay.

Table 54.7–3 outlines the roles of various inpatient staff members in assessing the child within the contexts of the family, school, and community. For didactic purposes, the roles are outlined in a somewhat artificial delineation of labor. However, it is important to prevent the fragmentation of care that can take place in a staff-rich inpatient setting. The major strength of an inpatient's number of participants can devolve into its greatest weakness when communication falters or when faulty assumptions are made about the responsibilities of others.

Treatment Planning

Inpatient treatment interventions are individualized to the child's strengths and weaknesses and the family's capabilities and identified problems. It is helpful to co-construct the treatment goals with the family because they will be most involved in implementing the treatment once the child is discharged with appropriate support services in place for assistance. Several different modalities of treatment are examined and possibly implemented during the inpatient stay, including psychoeducation, individual therapy, psychopharmacotherapy, and family work. During an inpatient admission, the child's outpatient or community treaters are contacted. This serves several purposes. First, collateral information aids in understanding the longitudinal progression of the child's deterioration and resultant admission. Second, preventing replication of previously failed treatment efforts saves time and frustration. Details of the dosing of

medication, duration of treatment, likelihood of compliance, and reason for discontinuation are all to be obtained from the provider or from past records. Finally, outpatient clinicians are able to provide information about diagnostic conundrums and family dynamics. Typically the child will return to the same provider(s); therefore, collaboration about treatment is essential for continuity after discharge.

Table 54.7–3.
Role and Responsibility Highlights for Multidisciplinary Team Members

Team Member	Role/Responsibility	Example
Patient	Participate in therapeutic programming. Ask for help.	Go to groups, individual therapy, recreational therapy. Be able to tell staff when not feeling safe.
Family	Provide information about problems warranting treatment. Participate in treatment planning and behavioral strategies.	Engage in family meetings and parent education groups. Able to visit child during hospitalization.
Child Protective Services	May be legal guardian, temporary custodian, additional service provider, or involved in investigation. When serving in loco parentis, may provide background information and be responsible for authorizing necessary consent.	Attend family meetings. Provide medication history and consent. Arrange appropriate placement postdischarge. Fund and help to identify necessary services.
Home school	Can provide information about child's daily school functioning.	Have phone contact with unit school staff. Provide Individual Education Plan and past testing.
Psychiatrist	Provide diagnostic assessment. Treat child with therapy and medication and overall coordination of care. Engage family.	Admit patient. Perform physical examination. Order appropriate testing. Engage child in therapy. Assess and manage medications.
Social worker	Engage family and arrange follow-up services.	Conduct family meetings. Obtain genogram. Apply for community supports.
Psychologist	Provide diagnostic assessment and therapy.	Provide individual therapy with child. Conduct psychological testing.
Nurse	Provide assessment throughout the day of the child's mental status and attention to daily needs.	Administer medication, including emergency medication when necessary.
Milieu counselor or psychiatric aide	Manage aggression by providing external structure and daily demonstration of coping skills.	De-escalate tense situations. Provide constant assessment of child's current condition, including mental status and current needs. Help child to learn coping skills and how to solve problems between peers.
Unit teachers	Assess each child and teach to his or her level.	Provide daily teaching to children of

	May perform educational testing or screeners.	different levels. Work with individual children or in small groups. May provide recommendations to home school.
Therapeutic recreation therapists	Provide daily activities that build sense of accomplishment and help in understanding feelings and problem solving.	Provide specific games, crafts, or groups tailored toward a given lesson or goal.
Occupational therapists	Assess child's need for assistive devices or alternative means of sensory stimulation or reduction.	Provide alternative means of alleviating anxiety in a socially appropriate manner.
Consulting pediatrician	Provide medical needs not within expertise of psychiatrist.	Consult for treatment of moderate to severe medical condition or of complex subspecialized care.

An individualized treatment plan matches the child's and family's needs. For instance, a complex treatment that cannot be sustained outside of the hospital would set up the family and child to fail. Family meetings aide in facilitation of communication between child and family members, as well as between the family and the treatment team. Some treatment approaches do not translate across environments and practitioners.

In obtaining consent, it is important to ascertain the patient's and family's expectations of the particular treatment modality. Institutional transference or negative thoughts about the suggested treatment setting may or may not be easily corrected. Unrealistic hopes may result in an initially strong response, later leading to apparent failure and disappointment when such expectations are not met. Thus, equally important is communication of facts about the treatment, including adverse reactions, side effects, and time to effect. For example, a side effect of a behavioral treatment might include an extinction burst, in which behavior worsens before improvement. Common side effects of many medications are sedation and weight gain. Appropriate laboratory tests should be obtained prior to starting medications. Risks and benefits must be weighed for each treatment, and the reality of compliance with the treatment must be considered. For example, if the family does not have the appropriate skills to comply with a certain behavioral treatment, they are unlikely to be successful in supporting the child in the treatment. This can contribute to further feelings of frustration and helplessness, as well as to possible negative feelings toward psychiatric treatment more generally.

Support services, such as home-based therapeutic interventions, may be part of the discharge plan if available and appropriate. Treatment recommendations may also include recommendations for further testing or educational recommendations to the child's school.

PARTIAL HOSPITAL

The structure of a partial hospital program (PHP) or intensive outpatient program (IOP) is loosely based on inpatient programs. With current behavioral and individual assessments and interventions, families are included as part of the assessment and locus of treatment. Programs can include a school component (typically called a PHP) or may be an after-school program (often referred to as an IOP or an extended day program). Most programs have a staff structure similar to an inpatient unit, in that many PHPs are an extension of an inpatient program, and many of the children "step down" into this less restrictive setting of care after their initial stabilization. Part of the assessment occurs prior to the PHP admission to determine whether the PHP is an appropriate treatment option. If school is part of the PHP, the patient's school district is typically involved in authorizing attendance to the PHP as counting toward temporary school placement. The daily routine of a PHP differs from an inpatient unit schedule in that the child wakes up and gets ready at home and then is transported to the facility. At that point the therapeutic school day begins, and group and individual therapy also take place. The child then goes home in the late afternoon, to return again the following day. If the child continues to attend a regular school, therapeutic programming occurs after school in the afternoon.

Children are typically admitted to a PHP or IOP program because of a behaviorally related lack of school successes or consistent problems at home not responsive to outpatient treatment efforts. These children are not necessarily at acute risk of harming themselves or others. An example might be a 13-year-old girl who is depressed and school avoidant but is not suicidal or engaging in self-injurious behaviors. For such patients, once-weekly visits to their outpatient clinicians may not suffice, given the severity of their problems, but inpatient admission may not be warranted either. PHP can also be a useful step down from inpatient hospitalization.

A partial program is also useful for observing the child and for making educational assessments and recommendations. Psychological testing and educational testing can be performed, and recommendations may be given to the regular school. Partial hospitalization programs may be a transitional placement while the child awaits a more permanent therapeutic school placement. Assessment and treatment are similar to those in inpatient programs, including contact with outside providers and school personnel. There is also emphasis on making accommodations so that the child can succeed at school. Such accommodations may include a different school placement or changes within the child's current school. Discharge from a PHP or IOP program depend on the preparation of the child and family to be able to continue care at home with adequate outpatient services.

RESIDENTIAL TREATMENT CENTERS

Much consideration occurs prior to the decision to place a child in a

residential treatment center (RTC). “Residential” can have a variety of meanings, from residential placement of a child with no other home option, to a voluntary placement sought by families to provide 24 hour-care, to housing youth in the juvenile justice system, or providing therapeutic treatment with the goal of return to the community. Additionally, there are group homes, which are not the subject of this chapter. Therapeutic boarding schools have also been used as synonyms. The history of identifying residential stays as treatment began with the establishment of the American Association of Children’s Residential Centers in 1954. Even at that time, there was variation in the definition of residential treatment, though most centered around a psychodynamic orientation, requiring isolation of the child from the environment as a necessity for treatment. This trend continued through the 1960s and 1970s until the beginning of deinstitutionalization. In the 1980s, with the advent of managed care, intensive outpatient treatment became more economically advantageous as compared to residential treatment. Residential treatment also declined due to improvements in psychopharmacology and advocacy for community-based, wrap-around, family-centered outpatient care, partly due to the more current philosophy that children are better assessed in the context of the environment in which maladaptive behaviors occur. Despite the best efforts, some children will still require residential placement, whether temporary or longer term.

Children in need of residential treatment tend to have either severe psychiatric and/or developmental disorders, preventing them from being managed through community and family supports alone, or have such circumstances that prevent them from living either at home or in therapeutic foster care. The parent–child relationship may be damaged to such an extent that the child’s behavior becomes consistently unmanageable when at home. The parent(s) may not have the capacity due to severe mental illness or substance abuse, and there may be no suitable, less restrictive alternative.

RTC staffing differs from that in inpatient and PHP settings. For example, the psychiatrist on staff often serves in a consultant role, thereby lessening psychiatrist involvement in treatment. There are also fewer nurses per child, but the number of day-to-day residential staff is increased. Rather than a vertical hierarchy, the RTC relies on a horizontal stratification by nature of the interaction of the child with the childcare staff. A popular RTC model divides up children into smaller “cottages,” with a master of the cottage or “houseparent” residing with them. Attempts are made at RTCs to make the environment as natural as possible, which helps in the comfort of the child, as well as in creating the best background for generalizing skills to be used after discharge. Lengths of stay have decreased significantly since the 1950s, with further evidence since the early 2000s of 3- to 6-month lengths of stay having efficacy. The use of

cognitive-behavioral and dialectical-behavioral approaches has replaced psychodynamic orientation. Reduction in seclusion and restraint has also occurred as in inpatient hospitals.

Typically, children are stable enough to not need an inpatient hospitalization; therefore, residential programming focuses on individual coping skills, relationship building, and basic living skills, including self-care. There is a routine schedule as in inpatient units, but with more individualized free time. Focus is placed on deficient adaptive and social skills, as well as on improving impulsivity by having the children learn to better tolerate frustration. A school program may be on the RTC grounds, or the child may be transported out to a separate therapeutic school or prevocational program.

There has been more push in the past decade for integrating the family into treatment, as the ultimate goal for many children is eventual return to their homes of origin. Continued family contact preserves bonds necessary for success after discharge. Parent training and family therapy are an integral aspect of residential treatment and prepare the family for the child's return home. Rather than designating family visits as a reward for desired behavior, it is considered necessary to have ongoing family involvement to achieve the end goal of successful reunification of the family and success in outpatient treatment. For children whose families are unable to care for them due to severe dysfunction, preparations are made for discharge to a group home or to a foster placement when appropriate.

COMMUNITY SUPPORTS AND IN-HOME SERVICES

A change in admission philosophy and inpatient treatment goals has caused mental health care providers and administrators to think differently about systems of treatment. Since the turn of this century, there have been improvements in treatment system options. Preadmission function of the family and the child and different systems of family, school, and community are crucial to consider in both assessment and treatment considerations for postdischarge recommendations. With shorter hospital lengths of stay and scarce inpatient resources and their associated high costs, it is vital to establish the tools and techniques that families will need to maintain the child's behavior and safety after discharge because frequent admissions may repeat the trauma of separation. All efforts are made to have community supports in place at time of discharge. These can include in-home services, extended day services, PHPs or intensive IOPs, and mentors or case managers. Communication with outpatient providers is key to continued stabilization postdischarge.

Intensive in-home treatment is a relatively new modality of administering child psychiatric assessment and treatments. Earlier conceptualizations of in-home services had been government-funded and followed a visiting nurse model, excluding other mental health specialties

such as psychology or psychiatry. However, in the last two decades, shifts have occurred to include more mental health care services that can be paid for by insurance, whether private or state, and the creation of mental health teams to include social workers, psychologists, and psychiatrists.

The treatment team typically delivers environment-relevant assessment and recommendations several times a week in the family's home. Problem solving can occur in vivo and in an ecologically naturalistic setting. This is a significant improvement consistent with the philosophy of "meeting families where they are," both in literal and figurative terms. These types of services play a large role in the prevention of acute destabilizations that would cause inpatient hospitalizations. One of the first home-based services described and studied was multisystemic therapy (MST). Originally developed for youth with juvenile justice involvement or substance use disorders, the model has been adapted to the specific needs of children with psychiatric illness and complex family and psychosocial situations.

FUTURE DIRECTIONS

Advances in psychiatric treatment options, the availability of a range of community services, and a general shift in philosophy have gradually changed the conceptualization of psychiatric inpatient hospitalizations for children and adolescents from one of longer-term treatment to one of multidisciplinary diagnostic and needs assessment and acute stabilization. Although lengths of stay and philosophies about seclusion and restraint have changed over the past decade, basic dynamics of staff, patients, and families remain. Partial hospital programs and in-home services contribute to the capability for children to have shorter inpatient stays and possible reunification after inpatient or residential stays.

▲ 54.8 Community-Based Treatment

ANDRéS J. PUMARIEGA, M.D.

INTRODUCTION AND DEFINITION

Community-based treatment for children and adolescents has undergone significant transformation over the past 30 years. The traditional community mental health model has largely yielded to the community-systems-of-care philosophy and model. This model is based on an individualized, intensive, and flexible approach to service delivery for children and families within the context of their homes and communities as an alternative to treatment in out-of-home settings. This model also focuses on systems issues that affect care, including interagency coordination, service access and utilization, financing, and clinical and cost-effectiveness of mental health and support services provided to children and their families. Psychiatry, which was central in the traditional model, has only recently re-engaged itself as a discipline in this new model. At the same time, as the model has been scaled up to encompass regional and statewide implementation, inadequate fidelity and resource allocation continues to contribute to lack of access to community-based services and the excessive use of residential services, many of lower quality and therapeutic value. More recently, in response to the cry by pediatric primary care physicians for greater access to child mental health services, the collaborative and integrated behavioral health models have begun to emerge to form more effective alliances with this important sector of care. Psychiatrists are meeting the challenge in reaffirming their unique value in these models and in integrating their developing clinical and scientific knowledge and skills base.

The increasing need for and utilization of child mental health services in the United States has spurred their rapid growth. Recent studies suggest that approximately 20 percent of children and adolescents have a diagnosable mental, emotional, or behavioral disorder, with 5 percent for

serious mental illness and emotional disturbance. A number of morbidities have been associated with childhood emotional disturbance and mental illness, including suicide, homicide, substance abuse, child abuse, teenage pregnancy, school dropout, youth crime, and associated institutionalization and incarceration. However, less than 1 percent of children in the United States receive mental health treatment in hospital or residential settings, with another 5 percent receiving treatment in outpatient or community-based settings; greater than two-thirds of children in need still receive insufficient or no mental health services whatsoever.

In contrast, funds dedicated to the financing of public mental health services for children have grown significantly since the 1970s. Medicaid, the public insurance program for the poor and disabled, funds a significant proportion of child mental health services in the United States. In June 2013, over 28 million children were enrolled in Medicaid and another 5.7 million were enrolled in CHIP. Mental health and substance abuse services is 11.5 percent of the over 600 billion dollars of overall Medicaid costs. The federal government contributes from 50 to 75 percent of costs, depending upon the state. Additionally, 53 percent of children receiving Supplemental Security Income (SSI) disability benefits have psychiatric disabilities (a total of 640,000). The total public costs of child behavioral health care come to $247 billion annually.

The main cost containment approach to reduce these expenditures has been to control inpatient expenditures, which has more recently led to a major shortage of child and adolescent acute inpatient beds in the US. A disproportionate level of these expenditures is still dedicated to residential treatment, which is viewed with increasing skepticism, given their relatively high cost, as well as limited documentation of outcome. In addition, there has been increasing documentation of poor practices and abuses in residential treatment as a result of underfunding and decreasing standards and quality of care. As a result of the growth in expenditures, the resources available to fund community-based child mental health and human services are increasingly limited. However, the great majority of these children and youth are poor, underserved children of ethnic minority backgrounds. Children from these populations experience higher levels of stressors, such as poverty, discrimination, immigration, acculturation stress, and exposure to violence and trauma, and they are likely to have higher levels of need for services.

Minority populations have also been traditionally underserved by mental health, health, and human services, in terms of both overall access to services and the cultural competence of services. The cost of serving these populations of children and adolescents is in contrast to the high cost of the psychosocial morbidity with which they contend, including lost productivity and the costs of welfare dependency and institutionalization. The United States continues to have the highest youth incarceration rates

in the world, and the highest levels of out-of-home or community residential placement for youth. A number of health and human service agencies (schools, social welfare agencies, child protective agencies, juvenile justice, and public health) have shouldered the increasing burden of psychosocial morbidity experienced by these children and youth. These agencies typically address pieces of the service system puzzle, with little to no coordination with other agencies serving the same youth resulting in increasing care fragmentation.

These trends have increased pressures on public child mental health and social service agencies to demonstrate improved clinical and cost-effectiveness, increasingly turning to managed care approaches to finance and organize mental health and social services. The majority of children covered by Medicaid are under managed care plans, including for behavioral health services. However, most managed care approaches were developed with private sector populations in mind, relying on a priori benefit restrictions based on actuarial data on middle-class populations with adequate social supports, who are traditionally lower users of services. When applied to public child mental health services, these approaches deprive children at high risk of effective intervention and preventive services. They also contribute to fragmentation of care and burden shifting to other child-serving agencies and systems, significantly increasing morbidity and acute need. Some Medicaid entities have successfully implemented community-systems-of-care approaches and integrated them with managed care methods, but many have had difficulty integrating them. Over the last 20 years, there has been an exponential growth of class action lawsuits against state Medicaid, educational, child welfare, and juvenile justice agencies failing to meet federally required service mandates, particularly around their high representation of children with significant mental health needs. The most egregious of such lawsuits involve the practice of parents having to give up custody of their children to obtain necessary mental health services.

HISTORY

From its earliest origins, children's mental health services have emphasized a community orientation. In the United States, these services began in the 1890s in response to the perceived need for counseling juvenile offenders rather than incarcerating them with adults. At that time, much like today, the United States was undergoing rapid sociocultural changes due to immigration, industrialization, and urbanization, and these social strains contributed to marked increases in juvenile crime and status offenses. The earliest juvenile courts in Chicago and Boston established clinics that comprised the first child mental health services in the nation. Their success led the Commonwealth Foundation to commission a study in the 1920s that recommended the development of child guidance clinics throughout

the United States staffed with interdisciplinary teams of professionals that could serve children and their families. They provided low-cost services oriented to the needs of the child and the family, with treatment modalities evolving to include individual psychodynamic psychotherapy, family therapy, crisis intervention, and even day treatment programs. They served as models for the community mental health centers that, with some alterations, emerged in the 1960s, and many have survived to this day.

The "medicalization" of psychiatry, starting in the late 1970s, served to move child and adolescent psychiatry toward the more hospital-based, tertiary care model. This left the child guidance clinics, and the community mental health centers that followed them, without significant psychiatric input. Many of the children previously receiving psychiatric services in these clinics were then served in free-standing psychiatric hospitals, residential facilities, or detention facilities, often in the custody of child welfare or juvenile justice agencies.

The modern era of community-based systems of care for children was ushered in by the publication of Jane Knitzer's groundbreaking book *Unclaimed Children,* which exposed the aforementioned consequences of neglecting the provision of community-based mental health services for children and their families. Her advocacy and that of others led to the development of the Child and Adolescent Service System Program (CASSP), which assisted all 50 states in the development of an infrastructure for publicly funded, community-based services. The CASSP initiative was supported by the conceptual work of Stroul and Friedman, who coined the term "community-based system of care for seriously emotionally disturbed children" and enunciated the principles behind such systems of care. Stroul and Friedman's work spurred the development of many innovative community-based treatment modalities, as well as a number of model demonstration programs in different parts of the United States that embody the use of these modalities within the context of an organized interagency system of care. In the early 1990s, the Robert Woods Johnson Foundation established eight pilot demonstration community-systems-of-care programs in different parts of the country, which demonstrated the viability of the systems-of-care approach and demonstrated cost savings, as well as less restrictive levels of care. Starting in 1994, the Center for Mental Health Services (CMHS) of the Substance Abuse and Mental Health Services Administration established the Comprehensive Community Mental Health Services for Children and their Families Program. This program has funded 173 community-systems-of-care sites throughout the nation in widely diverse communities. The *Surgeon General's Report on Mental Health,* published in 1999, focused its recommendations for children's mental health around the systems-of-care model and its benefits for service system reform and individualized care. More recently, given the focus on school violence and the threat of

terrorism in the United States, there has been additional focus by the federal government on these two aspects of community children's mental health. The Safe Schools Health Students program has funded 240 schools and communities to develop school-based preventive and clinical programs oriented at decreasing school violence and substance abuse, and the National Child Traumatic Stress Initiative funded many sites to adapt, implement, and evaluate promising intervention approaches addressing child traumatic stress in communities. More recently, as a result of the continued school shootings in the United States, most exemplified by the Sandy Hook Elementary shooting in Connecticut, the Federal government prioritized an additional $235 million investment in programs to help identify mental health concerns early, improve access to mental health services, and support safer school environments, including $160 million for the Department of Health and Human Services and $75 million for the Department of Education.

THEORETICAL ISSUES

The CASSP initiative set forth the principles inherent in community-based systems of care. The key principles include access to a comprehensive array of services, treatment individualized to the child's needs, treatment in the least restrictive environment possible (with full utilization of the resources of the family and the community), full participation of families as partners in services planning and delivery, interagency coordination, the use of case management for services coordination, no ejection or rejection from services due to lack of "treatability" or "cooperation" with interventions, early identification and intervention, smooth transition of youth into the adult service system, effective advocacy efforts, and nondiscriminating, culturally sensitive services.

The wraparound approach is also critical for systems-of-care interventions and services. This approach is based on the principle of individualization of services, and proposes that an individualized service plan be "wrapped around" the child, including clinical, support, and nontraditional interventions. A wraparound approach is greatly facilitated by the use of noncategorical and flexible funding for services, which enables a case manager and family to purchase whatever services the child and family needs at that time (including living needs, educational, social support, and even staff security services). Wraparound plans can build a level of service intensity rivaling that of inpatient or residential settings without removing a child from his or her home, especially using systematic wraparound protocols that have measured fidelity.

Cultural competence is an integral element of community-based systems of care. It implies that practitioners in systems of care develop the necessary attitudes, skill, and knowledge base to serve minority and culturally diverse children and families in their communities, as well as

having service systems that develop policies and practices to remove barriers for access to services and make these more responsive to the needs and values of diverse communities. The community-based systems-of-care approach is congruent with the cultural values of ethnic minority populations, which emphasize strong extended family involvement in the life and upbringing of children and the use of natural community resources first in dealing with the emotional and physical problems of family members. These factors have been shown to be protective from some of the morbidities associated with emotional disturbance, such as substance abuse and suicidality. National guidelines for cultural competence for managed Medicaid services have been published by the CMHS, and the Practice Parameter adopted by the American Academy of Child and Adolescent Psychiatry (AACAP) operationalizes elements of cultural competence at both the clinical and systems levels.

Another important principle inherent in this approach is the prioritization of services to "seriously emotionally disturbed children." This designation includes the presence of an Axis I diagnosis under the criteria of the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association but places equal emphasis on the child's inability to function in at least one of his or her life domains (e.g., school, home, socially with peers). This reflects the difficulty many children and their families have in accessing necessary services when the diagnosis was not "severe enough," particularly when the child was diagnosed with a disruptive disorder (although many children with disruptive behavioral disorders have comorbid serious mental illness when evaluated systematically). These problems are more pronounced in the diagnostic assessment of ethnic minority youth with serious emotional disturbance, with serious underestimation of comorbid affective and substance abuse disorders by clinicians. Other studies indicate that the level of care received by children is only partially accounted for by their clinical diagnosis, whereas the level of function and psychosocial stressors are stronger predictors.

The movement to managed care has resulted in the application of community-based systems-of-care principles to these approaches. In fact, these principles embody a more clinically based managed-care philosophy, that is, active care management becomes the primary modality for utilization management rather than arbitrary benefits restriction. In combination with the principles of care in the least restrictive environment, systems of care result in children actually receiving higher-quality services with fewer disruptions in their lives and development at a lower cost than with more restrictive, higher levels of care. The AACAP has developed guidelines for states using managed care for children's behavioral health services funded by Medicaid, integrating community-based systems-of-care principles into their contracts with private managed care providers or into

their policies and procedures for public managed services. It also has developed (in conjunction with the American Association of Community Psychiatry) an evidence-based level of care determination tool, the Child and Adolescent Service Intensity Instrument (CASII). It uses level of function and contextual variables as the main variables for level-of-care determination, with recommended levels of care based on treatment intensity using systems-of-care and wraparound approaches. The CASII has demonstrated significant inter-rater reliability and validity with mental health, child welfare, and juvenile justice populations, and has contributed to significant systems-of-care reform in the many states, particularly the state of Hawaii.

More recently, the Federal Affordable Care Act that has promoted health care reform has promoted the establishment of Medical Homes, where individuals (including children and youth) receive their primary care and also the coordination of specialty care. This has facilitated a movement in both general and child-and-adolescent psychiatry toward collaborative and integrated behavioral health models, to enhance collaboration with pediatric primary care physicians in Medical Homes and to enhance access to entry-level community child psychiatric services. The full implementation of these models calls for systematic screening of behavioral health needs served by the Medical Home and a stepped model of care, where either: (a) the primary care physician directly delivers psychiatric care in collaboration with a care manager, (b) the primary care physician refers the child for stabilization by the child mental health service or specialist and receives the child back once stabilized, or (c) the primary care physician and child mental health service collaborate longitudinally in the child's care. The primary care physician is trained and/or supported by child psychiatric and mental health consultation in screening, assessment, and entry-level behavioral health services as delivered within the primary care setting. There is both ready access to child psychiatric consultation (direct and indirect) and case management support to enable the primary care physician to deliver these services within the medical home and assist with specialty referrals and continuity tracking of the child's course of treatment and outcomes. In integrated models, there is embedded case management and therapist support in the Medical Home, as well as access to regular child psychiatric consultation on the panel of patients served by the Medical Home.

TECHNIQUES

A community-based treatment approach to services begins with access to services facilitated through multiple portals of entry, including direct referral or referral through child service agencies (such as the school or juvenile justice, child welfare, or public health agencies). A triage system should direct children and families to services and providers appropriate to

their special needs. A full interdisciplinary team, including a child and adolescent psychiatrist, should be involved in the development of triage procedures and protocols. Comprehensive mental health assessments should be made by licensed providers who are credentialed and trained to evaluate children and families, in consultation with a child and adolescent psychiatrist. Such assessments should include clinical/diagnostic, functional, developmental, family, and cultural/community evaluations of the needs *and* strengths of the child and family. Whenever possible, standardized measures should be used that are reliable, valid, clinically useful, culturally competent to the population being served, and useful for programmatic evaluation.

Children and families who require time-limited, less intensive services should have an initial care plan developed by a licensed mental health professional in consultation with a child and adolescent psychiatrist. The initial care plan for children requiring more extensive treatment should be developed by an interdisciplinary team, including all relevant child mental health and child service professionals. The parent(s), other relevant family members, and the child, if appropriate, should be members of this team. The care plan should identify problem areas and strengths that are relevant to the child and family's functioning, as well as community-based interventions to address these needs. The patient and his or her family should be equal participants with the clinical team in the development and implementation of the plan of care. In some programs, special "child and family teams" that are composed primarily of the child, family, and other natural supports in the community develop the outlines of care plans, and these are then negotiated by case managers with interdisciplinary teams of professionals and agencies. Plans of care should be individualized to the needs of the child and family, including attention to cultural issues, and should follow the child continuously throughout all levels of care, being amended as needed. The plan of care should promote continuous coordination and integration of all applicable services and agencies that have responsibilities for providing services to the child and family (such as primary health care, juvenile justice, schools, and social services).

Treatment and other services should be specific to the unique needs of the child and his or her family and use approaches that maintain or reintegrate the child into the family and community. Child and adolescent psychiatrists, psychologists, social workers, psychiatric nurses, and other members of the team should participate in the development of service protocols to ensure that the special developmental, physical, mental, and emotional needs of the child are addressed. The system should have as many diverse therapeutic modalities with children and families as possible, particularly those modalities that have demonstrated effectiveness with seriously emotionally disturbed children. These include Medical Homes, traditional and intensive outpatient services, nonresidential community-

based interventions (including home-based, day treatment, and school-based services), flexible support services, community-based residential services (such as therapeutic foster homes and group homes), and brief, acute inpatient services when needed. These interventions are aided by the increasing effectiveness of cognitive, behavioral, family-based, and psychopharmacological therapies, which should be integrated into all community-based interventions and levels of care.

Case management services are essential in community-based treatment, including assessment of problem areas, measurement of functioning level, determination of needs, linkage with necessary resources, care coordination, advocacy, and monitoring of services provided and their outcomes. The child and family should be assigned a case manager who has the necessary skills to ensure seamless coordination of care across all levels, different providers, and the full time course of illness/disturbance. The frequency and intensity of case management services are proportional to the clinical and psychosocial needs of the child and family. The patient/family should be participants in the case management process, with shared responsibility with case managers for using and coordinating services. Case management protocols should facilitate the coordination of multiagency, multisystem interventions, integrating services from the various providers and agencies (including primary care and health providers) and the development of wraparound plans that are truly individualized for the child and family's needs. These protocols should include access to flexible noncategorical funds to enable the purchase of flexible services needed for an effective wraparound plan.

ROLES AND FUNCTIONS OF PSYCHIATRISTS

Given the complexity of these new systems of care, the skills and roles that psychiatrists must display go far beyond the circumscribed clinical roles to which they are usually limited. These roles include serving as a front-line clinician, clinical consultant and collaborator to other professionals, clinical team leader, administrative leader in delivery organization/system, quality assurance/improvement consultant, consultant to interagency teams, and outcome evaluator/researcher in systems of care. Child and adolescent psychiatrists, given their broad biopsychosocial and developmental perspectives, should be best able to integrate and coordinate community-based treatment delivered by multiple professionals with diverse skills. However, given the emphasis on tertiary care models in the training of many child and adolescent psychiatrists, they often have not developed all the skills needed to serve as effective members and leaders of these new systems. Three publications from the American Academy of Child and Adolescent Psychiatry, *Guidelines for Training Child and Adolescent Psychiatrists in Community-Based Systems of Care,* the Practice Parameters for Child Mental Health in Systems of Care, and *Best*

Principles for Integration of Child Psychiatry into the Pediatric Health Home provide guidance on the skills, knowledge, attitudes, training experiences, and practices that psychiatrists need to function effectively within community-based systems of care.

CLINICAL ISSUES

Indications

Community-based treatment approaches are indicated for the treatment of the majority of children with moderate to serious emotional disturbance or mental illness, which is often associated with comorbidities and multiple psychosocial stressors and needs. It is most indicated for the prevention of out-of-home placement of such children and for the treatment of children served by multiple agencies with limited family resources. It can be contraindicated when the child's family is too fragmented or inaccessible. It often has to be modified with more intensive and restrictive treatment elements when the child faces imminent danger from whatever source (suicide, homicide, abuse, victimization, severe substance abuse), dangerous symptomatology, or serious decrease in function (such as acute psychotic symptoms or delirium). However, community-based treatment can be delivered in these instances as long as staff and physical security and safety needs are addressed through more intensive wraparound services (such as one-to-one staffing or on-site medical services). These services can be de-escalated when such symptoms or conditions are resolved (usually after brief stabilization) or the family is able to again function to an extent to which it can safely and effectively participate in the child's care.

Limitations

The community-based treatment approach can suffer from limitations when there is a lack of appropriately trained child mental health professionals who are conversant in evidence-based psychotherapies with children and youth and when there is lack of an adequate and accessible continuum of care with sufficient options for appropriate level of care intensity to meet the child and family's clinical and functional needs. Additionally, lack of adequate services coordination and integration can lead to significant care fragmentation. This can occur when psychiatric and nonpsychiatric services are segmented and there is lack of timely care coordination services, leaving children for inadequate periods of time in inappropriate levels of care intensity (either too low when they are developing more acute needs, or too high after no longer needed).

Complications

The misapplication of the community-based treatment approach can lead to children and youth and their families being underserved. This can result

from lack of access to necessary clinical and support services, lack of access to more intensive services, excessive pharmacological treatment to compensate for lack of evidence-based psychotherapy services, and lack of timely care management services.

Contraindications

Community-based treatment services are contraindicated for children who suffer from acute symptomatology. These include acute suicidality with imminent danger to self, psychosis or mania leading to risk to self or others or inability to be adequately protected/cared for, or substance abuse that leads to risk to self or others. Additionally, the child who is at risk of victimization in their home or community environment requires out-of-home placement. In all these instances, the community-based treatment approach calls for continued coordination with services in the home community and all possible efforts to return the child back to their family or to a normalized community setting with adequate supports.

Jose was a 14-year-old Latino who lived with his mother and older brother. He came to the attention of juvenile justice authorities for truancy from school, curfew violations, defacing a neighbor's property with graffiti, and stealing some money from another neighbor. A forensic psychiatrist was asked to evaluate him, and much to the psychiatrist's surprise, he found Jose to have significant anxiety symptoms that prevented him from attending school regularly, and the psychiatrist referred him to the local partial hospital program for evaluation by a child and adolescent psychiatrist and comprehensive treatment. He also appealed to the juvenile court judge that Jose be placed on probation with the expectation of attending treatment. On admission to the day treatment program and evaluation of the youth and his family, it became evident that Jose had not only a significant anxiety disorder, but also a learning disability that had not been adequately addressed and poor parenting from his mother. She seemed overwhelmed by raising her two teenage sons in the absence of the father that had abandoned them and as a result of her chronic depression. The staff of the partial hospital treatment program called for an interdisciplinary team meeting of the school, juvenile justice, and public child and adult mental health agencies to develop a coordinated, comprehensive wraparound treatment plan for the family. The plan included continued day treatment for Jose along with cognitive-behavioral therapy and pharmacotherapy for his anxiety and disruptive behavior disorders and intervention for his learning disability. Parenting intervention and treatment for depression was recommended for the mother, but it became clear that this would have to be delivered in the home (because she would never come to the partial program) and by someone of the same ethnic background for it to have any chance of reaching this poorly motivated parent. A highly skilled Latina home-based family therapist was located in one of the local agencies, and she readily developed a close relationship with the mother. Through taking a maternal, supportive approach, this therapist was able to motivate Jose's mother not only to reassert her role as a parent, but also to resume treatment for her depression, which she had lapsed from for years. Jose was able transition back to his school and refrained from further offenses and illegal activities, and he and his brother were able successfully to follow their mothers' more effective parenting guidance.

Goals of Treatment

The goals of community-based treatment usually include the following: (1) to restore the child's function within the family, at school, with peers, and

in the community; (2) to maintain or reintegrate the child within the family and community and avert separation or disruption of the community tenure; (3) to individualize interventions to the unique clinical and psychosocial needs of the child and family; and (4) maximally to use the strengths and resources of the family and the community on behalf of the child.

ETHICAL ISSUES

Ethical issues can arise in community-based treatment when the child experiences serious symptomatology in the face of family disorganization or risk of harm within the family and home. The ethical conflict arises from the inherent tension between the child's needs for safety and security and the goals of retaining the child within their family or community, avoiding restrictive care, and avoiding disconnection from the child's natural supports. However, a home in which there is a high level of conflict or abuse can be more restrictive for a child than some out-of-home programs due to the degree to which the child's function and activities are constrained. On the other hand, the child may require a more structured or restrictive environment than the family can provide, such as when the child is experiencing suicidal, violent, or severe runaway behaviors. Interdisciplinary teams are usually well equipped to face such ethical dilemmas, given their representation of multiple stakeholders; chief among these is the voice of family and child advocates.

Another inherent clinical ethical dilemma arises when considering whether to place a child on a pharmacological regimen versus intensive community-based or psychosocial interventions for disruptive or dangerous behaviors or symptoms. In these instances, the tension is between the biases toward less "medicalized" psychosocial interventions over pharmacological interventions. The short- and long-term risks versus benefits (and evidence base) of any psychopharmacological intervention for a child should be carefully weighed. However, many community-based interventions can be adjunctively aided by targeted pharmacological interventions, which can further aid in the reduction of restrictiveness and integration into the community. The role of the psychiatrist in addressing these ethical dilemmas is critical. The utilization of some community-based treatments exclusively to reduce costs without considering the needs of the child and/or family can be another serious ethical breach in the pursuit of community-based treatment. Unfortunately, the financial incentives to provide less intensive care inherent in most managed care approaches can contribute to such dilemmas, potentially endangering the child if they place the child in greater danger or risk. Community-based approaches need to be pursued within organizational and financial structures that do not have arbitrary benefit limits and use on-site case management to avoid such situations.

RESEARCH AND EVALUATION

Research in child mental health services has particularly focused on the effectiveness of community-based treatment. Research in this area has included the evaluation of community-based residential approaches, nonresidential intensive community-based approaches, and the clinical, functional, and cost outcomes of community-based systems of care, as well as factors affecting the need and utilization of mental health services in different populations of children.

Community-Based Interventions

The Surgeon General reports on mental health and on youth violence point to research evidence supporting the effectiveness of a number of community-based interventions for children and youth, such as intensive case management, therapeutic foster care, partial hospitalization, and intensive in-home wraparound interventions (particularly multisystemic therapy). Other community-based interventions that show promise include school-based interventions, mentoring programs, family support and education programs, wilderness programs, crisis mobile outreach teams, partial hospitalization, time-limited hospitalization with coordinated community services, and family support services. Studies involving these modalities have demonstrated significantly better outcomes than traditional outpatient or residential services. These include reduced levels of externalizing and internalizing symptoms, improved family functioning, reduced utilization of more restrictive services, diversion from juvenile justice involvement or detention, and improved cost-effectiveness. In addition, a number of in-home preventive parent–child interventions with infants and young children have demonstrated long-term effectiveness in reducing child abuse, as well as adverse behavioral and academic outcomes (such as the Elmira Project by Olds and coworkers in upstate New York and the child abuse prevention projects in New Orleans by Boris Zeanah and colleagues). On the other hand, there is a lack of research evidence or actual lack of effectiveness for a number of more restrictive interventions, such as inpatient hospitalization in isolation of community services, long-term residential treatment, therapeutic group homes, and boot camps.

The wraparound model of care embodies this approach toward multimodal community-based interventions. This model emphasizes aggressive outreach, the use of least restrictive treatment options, and individualized, flexible, and unconditional child- and family-centered services for children imminently at risk or already in out-of-home placements. A number of studies of wraparound programs in different communities across the nation with diverse populations of at-risk children and families have reported positive outcomes in terms of reduction of externalizing behavioral problems, level of function, reduction in out-of-

home placement, improved family management skills and function, and consumer/family satisfaction. Multisystemic therapy (MST) combines home-based, wraparound, and cognitive-behavioral interventions within a systemic context. It has been evaluated with youth at risk of detention/incarceration and at risk of psychiatric or substance abuse hospitalization, with significant results in reducing out-of-home placement, externalizing problem behaviors, rates of recidivism, and costs of treatment. A more recent community-based intervention—Cognitive-Behavioral Intervention for Traumatic Stress—has demonstrated effectiveness in addressing traumatic stress among children of diverse cultural backgrounds in school settings.

Community Systems Evaluations

Outcome data on early system-of-care demonstration projects in Vermont, New York, Ventura County, California, and the eight Robert Woods Johnson pilot sites demonstrated reduced hospitalization rates and days, decreased out-of-home placement and less restrictive placements, significantly lower incidence of negative behaviors placing the child at risk for out-of-home placement, and significantly lower rates of overall problem behaviors. The Robert Woods Johnson pilot sites also demonstrated significantly lower costs using a managed subcapitation approach for funding flexible services for children with serious emotional disturbances. Studies of the Civilian Health and Medical Program of the Uniformed Services (CHAMPUS)–funded Fort Bragg Demonstration Project and the Stark County CMHS system-of-care site compared their outcomes to those of usual service sites. These programs achieved significantly lower restrictiveness of care, higher family and consumer satisfaction, increased access to services, and greater funding spent in less restrictive services. However, clinical and functional outcomes and costs were not significantly different overall. Critics of these studies point to their short-term nature, and more recent studies have supported that significant clinical and functional outcomes from system-of-care programs are found on longitudinal evaluation.

The Comprehensive Community Mental Health Services for Children and their Families Program has included both a centrally designed evaluation, with required systematic data collection on all children served, and locally administered evaluations. Two main designs have been used: a longitudinal design with multiple assessment baselines at program entry and every 6 months until 36 months (and after program exit in newer sites), and two sets of comparison studies of system of care demonstration and control community sites. Children and youth in the system-of-care programs have had significant results in improved child behavior, improved child functioning, fewer contacts with law enforcement, increased stability in living situation, improvements in child and family

strengths and resources, reduced caregiver strain, and improved family function. The most recent cumulative results from the national evaluation reported in 2005 indicate that the program had reduced inpatient and residential utilization by 25 percent, decreased juvenile probation involvement by 30 percent, decreased detention or other secure facility use by over 50 percent, reduced the number of children with suicide attempts by over two-thirds, increased regular school attendance by youth by more than 10 percent, and significantly reduced or stabilized behavioral problems in 90 percent of children served. Results have also demonstrated reduced cost of care within these programs when indirect cost offsets are considered, such as child welfare, juvenile justice, educational, and general health costs.

In addition, some of the current and past CMHS-funded sites have begun to evaluate the added effect of the integration of evidence-based psychotherapeutic interventions within the system-of-care model. Some system-of-care programs have begun to integrate evidence-based manualized therapies (such as parent–child interactive therapy) and community-based interventions (such as multisystemic therapy), demonstrating enhanced clinical outcomes. The Hawaii children's system of care has pursued the most ambitious integration of evidence-based interventions, creating a menu and an algorithm for the application of such interventions, with significant improved functional and clinical outcomes and decreased level of care intensity of services over time. However, there are major challenges in integrating evidence-based interventions into a community system of care, including maintenance of fidelity, need for added training resources, attitudinal changes by clinicians, and the overall complexity of the enterprise.

Services for Minority Youth

Services research literature with underserved minority youth has been sparse, and initially was focused on documenting racial differences in services provided. African American children tend to remain in foster care for longer periods of time and to have more foster care placements than white children. Studies have shown culturally diverse children to be underrepresented in mental health institutions and overrepresented in child welfare and juvenile justice settings and placements compared to nonminority youth, even when they are equally psychiatrically impaired. Ethnic and racial differences in the diagnoses of culturally diverse adolescents have been identified by some investigators, including overdiagnosis of conduct disorder and psychoses and underdiagnosis of affective, personality, and substance abuse disorders. Significantly lower rates for overall services utilization, and specifically for the treatment of depression among culturally diverse groups, have been documented. Some studies have found a significant relationship between race and the service

needs of racial ethnic minorities. Studies have also shown higher retention in treatment of minority youth if the clinician is of a similar ethnic/racial background.

Collaborative and Integrated Behavioral Health in Primary Care

Most of the research evaluations so far for collaborative and integrated behavioral health models have focused on their application to adult populations. There are a number of pilot collaborative care programs that have been developed which have demonstrated significant successes. For example, Massachusetts has successfully demonstrated the Massachusetts Child Psychiatry Access Project (MCPAP), a program that provides timely telephonic psychiatric and clinical guidance to primary care providers (PCPs) treating children with mental health problems. The program allows enrolled primary care physicians to get assistance for any child in their care. The program has enrolled most primary care practices, representing an estimated 95 percent of all youth in the state, and has high rates of PCP participation, with over 5,000 patients served from 2008 to 2009. Primary care physicians who use the program have reported significantly higher ratings of their ability to serve children with mental health problems. Similar statewide programs have been developed in New York State and Washington State, with similar results. A few studies have begun to demonstrate effectiveness of collaborative and integrated care models. For example, Kolko and colleagues studied children and their caregivers who participated from 8 pediatric practices and were cluster-randomized to Doctors Office Collaborative Care (DOCC; n = 160) or enhanced usual care (EUC; n = 161). In DOCC, a care manager delivered a personalized, evidence-based intervention. DOCC was associated with significantly higher rates of treatment initiation (99.4 percent vs. 54.2 percent) and completion (76.6 percent vs. 11.6 percent), improvement in behavioral problems and parental stress (P, 0.05–0.001), remission in behavior and internalizing problems, treatment response, consumer satisfaction, and greater perceived practice change and efficacy.

FUTURE RESEARCH NEEDS

There are still many areas of significant deficit in the evidence base for children's mental health services and systems of care. Areas in which further research is needed include the effectiveness of culturally competent services and culturally specific interventions, the effectiveness of school mental health services, the effectiveness of mental health services integrated within the juvenile justice and child welfare systems, the effect of different cost containment and reimbursement mechanisms, the effectiveness of a systems-of-care approach in combination with evidence-based interventions (both psychological and pharmacological), and the

integration of child mental health and primary care services. The application of population health and mental health services research findings in service system policy and planning are the ultimate objectives and value of such research.

▲ 54.9 The Treatment of Adolescents

STEVEN C. SCHLOZMAN, M.D., AND EUGENE V. BERESIN, M.D.

DEFINING ADOLESCENCE

Any discussion of the treatment of adolescents must begin with a definition of adolescence. Although most developmental theorists view adolescence as roughly coinciding with the onset of puberty, it is important to note that the exact criteria for both the onset and the conclusion of adolescent development are complex and multidetermined. Biological, psychological, social, and cultural paradigms all play a role in the conceptualization of what exactly constitutes adolescent development.

From a biological perspective, adolescence begins with the onset of puberty. It is important to note that puberty is not limited to the development of secondary sexual characteristics. In addition, neurodevelopment research suggests that during puberty the brain undergoes a number of important changes. These changes are most likely necessary for the emerging adolescent to move away from what Piaget characterized as a relatively rule-bound and concrete understanding of the world toward an increasing capacity for abstract thought. Neuron migration, changes in myelination, pruning of gray matter, and increases in white matter all lead to changes in frontal lobe activity and have been implicated as playing major roles in long-observed cognitive changes. However, there is also growing evidence for incomplete frontal lobe myelination leading to decreased capacities for complicated problem-solving activities in the presence of hotly affective environments. Thus, despite substantial development of brain regions responsible for executive function, the relatively poor myelination of these regions explains some of the classically observed lapses in judgment and some of the impulsivity that characterizes adolescent behavior. In this fashion, Piaget's observations have been validated and also challenged by a growing understanding of adolescent neurobiology.

Psychologically, adolescence has typically been viewed as a period of separation and individuation coupled with an increasing desire to form a coherent and consistent sense of self. These tasks, roughly characterized as *identity formation* by theorists such as Erik Erikson, Anna Freud, and Peter Blos, are central to the experience of the adolescent as he or she continues along the developmental trajectory. According to Erikson's epigenetic model, adolescence is determined by the quest for identity

formation at the risk of *role diffusion*. The onset of important advances such as the development of sexual and romantic attractions, the formation of political and ethical opinions, and the willingness to differ in opinion from both peers and adult caregivers are all key elements of these psychological changes.

In addition, G. Noam and others have proposed that during early adolescence, group identity and cohesion plays a much more important role than individual identity formation. Noting that belonging to a group and conforming to the norms of that group are important aspects of the early adolescent years, these scholars theorize that adolescents first experiment with separation and individuation by embracing the rules and regulations of their peer group. In "Eriksonian terms," this developmental challenge could be coined *inclusion at the risk of exclusion*. To this end, as they mature, healthy adolescents move away from all of the rules of any one peer group and instead choose those aspects of many different groups that best suit their developing sense of self. The normal early adolescent emphasis on popularity thus grows to also include the later emphasis on being comfortable that one can maintain a coherent identity without relying on the restrictions and rules of any single peer group.

Social norms and pressures contribute to adolescent development in many ways. Ideals of beauty, power, success, masculinity, and femininity are to a large extent socially determined. In modern industrial Western society, the adolescent's individual and group identities are significantly influenced by mobility and the increasing role of media as a means of information, entertainment, and communication. New technologies such as cellular telephones, broadband connections, and the Internet have expanded the adolescent's circle of relationships and generated instant access to groups of individuals, movies, music, news broadcasts, streaming video, and advertisements. Although group norms and role models previously were confined to relationships in real time, adolescents today are barraged with detailed and graphic information about the intimate lives of celebrities and other public figures in the news. Current events, often dramatic and traumatic events, are instantly available to the adolescent. The rapid transmission of information plays a major role in both defining the world for the adolescent and providing a constant stream of data through which the adolescent may become immersed and influenced in powerful ways. Although the media is no substitute for life experience in real time, the power of the media to create a social milieu with figures for identification, imitation, and role modeling has grown exponentially in recent years. For example, studies have demonstrated that the media has a powerful effect on adolescent body image and self-esteem and has complex manifestations across various ethnic, racial, and cultural groups. All of these factors have complicated the tasks of separation and identity formation in many ways that are only beginning to be understood, and

these social changes have led to worries regarding addictive Internet use, which seems to start most commonly during adolescence. These issues are addressed later in this section.

Finally, as for all developmental stages, adolescence exists within a specific cultural milieu. Although virtually every culture embraces rituals intended to recognize both the onset of adolescence and the transition to adulthood, the conceptualization of what characterizes adolescence varies in terms of cultural norms. What one culture might consider a normal development is often somewhat startling taken out of cultural context. As the world becomes increasingly multicultural, these considerations are especially important. For example, the Asian youth who begins to question his parents' values is often viewed very differently in Western versus Eastern contexts. Although someone with a Western outlook might view this as a healthy and normal emotional development, the youth's parents might see it as particularly pathological and dangerous. Cultural differences such as this are obviously generalizations, but keeping these potential differences in mind is extremely important to any clinical consideration of adolescent populations.

CONTROVERSIES IN CONCEPTUALIZING NORMALITY AND PATHOLOGY IN ADOLESCENCE

The adolescent's quests for identity and separation have led both clinicians and popular culture to view adolescence as a normally tumultuous period. Although most adolescents navigate the transition from childhood to adulthood without serious incident, there are times of upheaval that are experienced as real crises. These periods may be obvious sources of concern to significant figures in the teenager's life, such as parents, siblings, teachers, or other adults, or they may be concealed and go unnoticed. For most adolescents, the movement from complete dependence on family to independence is at once exhilarating and terrifying, and at other times it is filled with profound despair. Highly charged affect is quite typical of adolescents and is often intense and labile. In the separation process, the adolescent must in one way or another reject his or her parents and at other times seek parental approval and nurturing —even babying. It is not unusual, for example, to see an adolescent girl's bed covered with stuffed animals, and at the same time to overhear her talking about moving out of the house or fantasizing about sexual intrigues.

Although the normal adolescent is capable of understanding the consequences of his or her actions, teenagers typically live "in the moment" and are occasionally blind to risky behavior. Because normal myelination proceeds in a caudal-to-rostral pattern, emotionally charged moments may not enjoy efficient use of the more sophisticated regions of the brain until individuals are in their mid-20s. These neurobiological processes are compounded by cultural norms that create a sense of grandiosity and

invulnerability. However, at other times, the adolescent's omnipotence evaporates as the teenager fears a multitude of potential dangers, from physical illness to kidnapping. Finally, the quest for identity carries with it substantial self-consciousness, characterized by fear of public exposure and shame. These fears may result in reluctance to share feelings or discuss issues that are potentially humiliating.

In addition, all adolescent behavior is influenced by personal traits, such as temperament, and by the environment, including relationships with peers, siblings, and parents and the community in which the teenager lives. Consequently, there is a great deal of heterogeneity in adolescent behavior. To further complicate matters, developmental advances are never linear. Progress is punctuated by periods of regression to earlier stages. It takes considerable clinical acumen or a great deal of familiarity with a particular teenager to understand what is normal for one adolescent or pathological for another.

Some researchers feel that viewing adolescence as a tumultuous period creates a setting in which adolescent tribulations and "out-of-control" behavior are viewed as normative and therefore not deserving of clinical attention. Researchers such as Offer have instead suggested that whereas most adolescents are in fact well adjusted and not psychologically troubled, the tendency to view adolescence as "normally difficult" potentially risks missing the population of youth who are legitimately suffering. In fact, research suggests that approximately 20 percent of the adolescent population in Western settings is seriously in need of clinical intervention. Some of this attention is needed for managing particularly charged crisis points in normal development for youth at risk, whereas other attention is required to treat the onset of many psychiatric disorders that achieve greater prevalence during adolescence. Among these are mood and anxiety disorders, schizophrenia, eating disorders, and substance use disorders. The suicide rate increases tremendously throughout adolescence: Data from the Centers for Disease Control and Prevention (CDC) show that the suicide is the third leading cause of death in youth aged 10 to 24 years. In addition, data from the Youth Risk Behavior Survey (YRBS) published by the CDC show that 17 percent of teens "seriously considered" suicide during the 12-month period prior to September, 2012. There is also a continuing trend toward increasing numbers of Hispanic girls both considering and completing suicide. Thus, the psychiatric treatment of adolescents has significant public health repercussions.

Much of these challenges are driven by the paradoxical lack of careful thought among adolescents, who nevertheless clearly have the capacity to embrace rational and abstract problem-solving approaches. In short, often the overall judgment and risk assessment of adolescent thinking is markedly different from that of adults. For example, whereas adults would rarely accept a challenge to drive recklessly on the freeway, such a scenario

is not unheard of in late adolescent populations in spite of their growing capacity for sound judgment and abstract reasoning. Some researchers have suggested that the affectively charged environment of the adolescent leads to an increased willingness to take risks, sometimes called a “hot cognition” in the cognitive developmental literature. Again, this is best understood in the setting of the incomplete neurodevelopment outlined earlier. Thus, whereas adolescents might appear adult-like in their thinking during calmer moments, affectively volatile environments can pose a particular risk to his or her well-being. These observations serve to accentuate the need to view adolescent behavior as potentially in need of clinical attention.

Another area of controversy involves the interplay of media and popular culture in affecting adolescent behavior. Many researchers have suggested that violent or disturbing media increases the likelihood of psychosocial problems within adolescent populations. These studies have led to policy statements by a number of professional organizations, including the American Academy of Pediatrics and the American Psychological Association, in which suggestions for curtailing media impact are made clear. Other researchers have noted the potential use of the media in both understanding adolescent thinking and in allowing adolescents to explore difficult issues through displacement and projection. From a clinical perspective, therefore, the issue of media effects on adolescence is extremely important, and any discussion of the psychiatric treatment of adolescence must take into account this key controversy.

Among the major concerns surrounding digital media use in adolescence is the ways cell phones and social media are handled: 63 percent of teens exchange text messages daily, 22 percent log onto social media more than ten times daily, and 50 percent more than once a day. Over 90 percent of teens are online and 80 percent use social media such as Facebook, Twitter, Snapchat, or Instagram. There are considerable dangers of social media use in adolescents.

Though most teens think peers are nice, 88 percent witnessed others being cruel or mean. Considerable attention has been given to the serious impact of cyberbullying among adolescents. Cyberbullying increases dramatically from grade school through high school and may have significant psychiatric consequences, including depression, suicidal thoughts and behavior, anxiety and posttraumatic stress disorder, social isolation, low self-esteem, poor academic performance, and alcohol and substance use. Furthermore bullying has been shown to have lifelong psychiatric consequences, particularly anxiety and mood disorders. More than 90 percent of children use cell phones for going online and text messaging by Middle School.

Many teens reference their sexual behavior, substance use, and/or violence through digital media. Sexting is a particularly worrisome problem

in teens. Sexting is the use of text messaging or other means to post sexually explicit photos. Up to 20 percent of teens are found to engage in sexting, and while studies vary widely, probably 10 percent have sent an image, and as many as 20 percent have received images. The reasons for sexting are highly variable, but usually involve the desire to maintain or seek a relationship, peer pressure, boredom, joking around or showing off. While most teens feel the recipient would want to receive the photo and keep it to themselves, forwarding photos is a significant problem. Most teens are unaware that digital media affords recipients making a photo "go viral" and expand to a very wide audience. The consequences of such exposure may be profound and serious. Many teens who engage in sexting are deeply shamed, anxious, and depressed and few are aware that there could be potential legal problems including a risk of being charged with disseminating child pornography and placement on a sex-offenders registry if convicted.

While there may be dangerous consequences of social media, there are potential benefits. For many teens, the immediate contact affords nurturing social relationships, fostering separation from parents and increased autonomy, helping shy or anxious teenagers develop social interactions, and providing forums for discussing moral, social, or religious issues in concert with the adolescent's increased cognitive capacity. However, given the potential serious risks, it is imperative that clinicians know the media use of their patients. Media literacy is a critical and uncharted aspect of the care of adolescents, and one that should not be neglected.

Recently, there has been burgeoning concern regarding addictive Internet behavior among adolescents. Proponents of these concerns note that many people become enamored of Internet activity during adolescence at the expense of normal functioning. These adolescents are said to ignore more normal social behavior and spend increasing time engaged in Internet activity. Clinicians who are more skeptical of the concept of Internet addiction point to the lack of good prospective studies, confounding issues such as differing uses of the Internet among those who display worrisome Internet behavior, and poor understanding of molecular mechanisms such as dopamine reward systems that have been postulated in other addictive problems. In addition, what is considered socially normal increasingly involves the Internet. Thus, fundamental questions, such as how much time on the Internet is too much or whether activities such as Internet gaming and gambling hold the same risks as Internet pornography, need to be better explored.

Finally, in considering media effects on adolescents, one must consider the ongoing debate regarding massively increased use of video game activity among teens. Because many of these games adhere to increasingly realistic and complex narrative themes, there is concern that especially violent video games will desensitize adolescents to aggressive behavior.

However, there are investigations that suggest that video games offer opportunities for virtual displacement of aggression that might otherwise be acted out in the "real world." As with research concerning Internet use, data regarding video games are quite mixed, and much study is needed for a better understanding of the nuances of these activities.

WHEN DOES AN ADOLESCENT REQUIRE TREATMENT?

Psychiatric treatment is indicated for any individual when there is a disturbance in thought, affect, or behavior that affects normal functioning. For adolescents, this would include impairments in a teenager's biological functions, such as eating, sleeping, and other daily personal routines, as well as problems with relationships with family and peers, problems in school, and problems in occupational and recreational activities. Although it is true, as noted earlier, that normal adolescence involves a certain degree of emotional and/or behavioral volatility, most adolescents overall have a rather smooth course, punctuated by crisis points that usually resolve quickly.

The major issue for parents, caretakers, and clinicians is making the discrimination between a normative developmental crisis that will eventually self-correct and a behavioral change that indicates a deeper problem worthy of clinical attention. This distinction may not be easy for a number of reasons. First, there are often discrepancies between the way an adolescent looks and how he or she feels. For example, an adolescent with a depressive disorder who is contemplating suicide may appear no different than before the episode, somewhat quiet and contemplative, or mildly irritable. On the other hand, teenagers with profound insecurity and social phobia may present as arrogant and seemingly fearless. Second, although many adolescents are capable of effective communication, there is often a reluctance to share deeply troubling thoughts or feelings with friends, parents, or other adults. This may be due to developmental lags in expression, but more commonly it is due to the deep self-consciousness and feelings of vulnerability that are typical of normal adolescence. Consequently, many adolescents are misunderstood by parents and peers, which only compounds a sense of aloneness and personal distress. Third, there may be cultural taboos, stigma, or a sense of betraying family expectations that obstruct a teenager from expressing emotional or psychological problems. Despite these obstacles, there are important questions clinicians should keep in mind in determining whether an adolescent is in need of treatment:

- Has there been a developmental lapse, for example, a falloff from the trajectory with respect to functioning in school, home, friends, and recreational activities?
- What is the level of emotional distress?

- What is the meaning of the problem to the adolescent? Although a problem may seem minor for an adult, it may carry tremendous weight for the adolescent.
- How vulnerable is the adolescent to stress? Is there a range of effective coping skills, or is the adolescent limited in managing stress?
- What supports does the adolescent have with other adults at home or in the community?
- Does there appear to be a recent onset of a psychiatric disorder? Is there a past history of psychiatric disorder and/or treatment? Is there a positive family history of such disorders?
- How impulsive is the adolescent?
- Is there family psychopathology, such as mood disorders, substance use disorders, or severe conflict?
- Are there major changes in the family, such as divorce, unemployment, and so on, that might seriously disturb the adolescent?
- Are there concerns about physical or sexual abuse or neglect?
- Have there been recent losses in the family or in peer relationships, such as loss of a friend, romantic relationship, failure to make an athletic team, and so on? How vulnerable is the adolescent to loss?
- How capable is the adolescent in managing affect, such as anger or sadness?
- Are there other acute or chronic medical conditions in the adolescent or in the family?
- Are there cognitive limitations, such as mental retardation?
- Have there been any major media events, such as suicides, school shootings, terrorism, or copycat phenomena, that have a strong effect on the adolescent?
- Has there been a significant trauma to the adolescent outside of the family, for example, date rape, sexual harassment, bullying, scapegoating, and so on?

Answering these questions requires gathering data from multiple sources, including the adolescent, family members, teachers, pediatrician, medical record, or other members of the community. The research literature demonstrates that in children and adolescents there is a poor correlation between self-report and report from others regarding behavioral symptoms. Hence, data collection must include more than one informant.

MODALITY OF PSYCHIATRIC TREATMENT

The psychiatric treatment of adolescents can occur on a number of fronts. Treatment may focus on individual or group settings and may encompass interventions from pharmacological, psychosocial, and environmental

perspectives. Thus, the treatment of adolescents encompasses considerations of individual need, family and community resources, clinical impression, and biological history. Furthermore, treatment often brings together multiple aspects of the adolescent's world. Legal, academic, medical, and psychological issues all play potential roles in any clinical intervention.

Biological Interventions

Biological treatments primarily involve medication interventions. Agents such as antidepressants, conventional mood stabilizers, typical and atypical antipsychotics, anxiolytics, and psychostimulants all are used in adolescent populations. Obviously, choosing a pharmacological regimen is based on clinical and diagnostic impression, as well as the family's and the adolescent's willingness to embrace medication treatment. Furthermore, as for all medication treatments, both the patient and the family must have a sound understanding of the risks, benefits, and potential limitations of this particular modality. Finally, any consideration of medication treatment in the child population should include an understanding that randomized and controlled trials of specific medications are not always available and that many of the most commonly prescribed medications have not been approved by the U.S. Food and Drug Administration (FDA) for use in children. Nonetheless, the last 10 years have seen a dramatic increase in clinical investigation into the efficacy of pediatric psychopharmacology, and clinicians should understand that keeping abreast of these rapid developments is paramount in pursuing medication options for adolescents. In addition, the FDA black box warnings associated with the increased risk for suicide in antidepressant use in children and adolescents need to be taken into consideration when prescribing these agents. Families must be told of the FDA warnings and helped to understand the risks and benefits of these medications despite these concerns. The American Academy of Child and Adolescent Psychiatry website has instructions for how to discuss these complex issues with parents and teens. The risk posed by having these warnings includes the documented decline in the overall willingness to diagnose and treat psychiatric conditions in young people. Finally, as with pharmacological treatment of adults, treatment of adolescents may be most efficacious when medications are combined with psychosocial therapies.

A 15-year-old boy was noted by his parents to have a difficult time in leaving his computer in the morning. Although the problem was initially relatively well managed with gentle reminders that he was going to be late to school, over time, the boy showed a constant tendency to check his standing on an Internet social networking site. This behavior resulted in frequent school tardiness, eventual school refusal, and increasingly poor hygiene. He was referred by his pediatrician for treatment with a psychiatrist, with whom he endorsed concerns that if he did not constantly update his website, his "social score" would decrease, and that this decrease

would translate into worsening social standing at school. He did not enjoy the constant maintenance of his website but felt powerless to stop and was ashamed of his behavior. He was started on fluoxetine and received a course of cognitive-behavioral therapy for obsessive-compulsive disorder. Over the next few months, his behavior gradually improved, with decreased anxiety and greater social engagement.

Psychosocial Interventions

Individual and group interventions include psychoanalytic, psychodynamic, cognitive-behavioral, and interpersonal therapy approaches. All of these modalities, for both individual and group treatments, have been found to be effective for the treatment of a wide range of adolescent problems, including adolescent depression, anxiety disorders, substance abuse, and suicidality.

Psychoanalytic and Psychodynamic Therapies. Psychoanalytic and psychodynamic treatments seek to help the adolescent to come to terms with and thus better understand unconscious conflicts and maladaptive defense mechanisms. In addition, they may be useful in facilitating more-adaptive coping skills. These goals are accomplished by a close relationship between therapist and patient and the use of unconscious processes such as transference, countertransference, and resistance. The best candidates for psychodynamic and psychoanalytic psychotherapy are adolescents who have adequate cognitive and language functions to use insight, self-reflection, and an ability to communicate effectively with the therapist. They also must have sufficient ego strength to tolerate clarification, confrontation, and interpretation. Because psychodynamic therapy may precipitate some regression and will, at times, be stressful in uncovering conflicts, the adolescent should be able to tolerate affect and have sufficient impulse control to thwart acting out. Commonly used psychodynamic therapies include classical psychoanalytic psychotherapy, supportive psychotherapy and psychodynamic psychotherapies based on ego psychology, object relations theory, and self-psychology. As in the treatment of most adolescent disorders, psychodynamic psychotherapy is often conducted in conjunction with other modalities, such as pharmacotherapy, family therapy, and/or other psychosocial therapies. Although these forms of psychotherapeutic treatments are probably the most commonly applied interventions in the treatment of adolescents, the open-ended nature of these modalities has made randomized trials difficult. Many clinicians, however, feel strongly that a skilled psychodynamic treatment is immensely beneficial to suffering adolescents.

A 14-year-old girl gymnast began increasing her daily exercise and restricting her diet. She had never achieved menses, due to her low weight. She became fixated on the size of her thighs and belly and lost so much weight that her coach and pediatrician did not allow her to participate in athletics. She became increasingly terrified of getting fat, and she secretly exercised any chance she could. She was a perfectionist in academics, as well as in gymnastics. Because of excessive

weight loss, she was hospitalized, and the diagnosis of anorexia nervosa nonpurging type was established without comorbid disorders. Following hospitalization with modest weight gain, an outpatient plan was initiated including regular meetings with her pediatrician for monitoring of vital signs, weekly meetings with a nutritionist, weekly family therapy, and individual psychodynamic psychotherapy. In her psychotherapy, over the course of 2 years, she was able to understand that her perfectionism was a defense against low self-esteem, that she was very angry with her mother, who lived vicariously through her gymnastics and did not validate who she really was, and that she was, as an only child, the focus in her family, holding her parents' marriage together. Over time, she was able to understand the function of her anorexia as a way to avoid her maturation as a woman, as a dysfunctional means of developing some kind of identity, and as a passive-aggressive attack on her parents. With time, her weight increased, she was able to resume her athletics, and she developed close friends.

New research has focused on the process of mentalization and the theory of mind in the psychodynamic treatment of adolescents. Roughly speaking, mentalization can be considered the process by which individuals come to understand the thinking and emotional states of others. In a sense, the recursive thinking that becomes possible in adolescence is directly tied to this therapeutic skill. Thus, one attempts to build on the adolescent's capacity for empathy as his or her brain matures to the point at which empathy is more readily accessible.

Cognitive-Behavioral Therapy. Cognitive-behavioral therapy (CBT) has gained increasing popularity in recent years, and there are a number of studies suggesting its efficacy for problems such as adolescent depression, eating disorders, anxiety disorders, suicidality, and obsessive-compulsive disorder. CBT aims to help the adolescent to recognize cognitive distortions that lead to faulty interpretations and maladaptive behavior. Techniques such as relaxation and contingency reinforcement are used to help the teenager to tolerate affective charged environments. Treatment is often manual-driven, with a specific number of sessions and homework assignments between appointments. This form of treatment does not focus on aspects of unconscious motivations and conflicts. Instead it focuses on correcting distorted cognitions by modifying information processing.

A 13-year-old boy was noted by his parents to be extremely worried about contracting germs from his surroundings. He insisted on washing his hands more than 25 times a day and would often spend more than 1 hour a day making sure that his body and hands were clean and "free of contamination." After evaluation, the diagnosis of obsessive-compulsive disorder was made, and the boy and his parents opted for cognitive-behavioral therapy. The therapist started by helping the boy to rank his fears on a scale of 1 to 10, with 10 assigned to objects that he felt were most germ-laden and 1 assigned to those objects that were of little or no concern. The boy was then taught both relaxation techniques and how to engage in thought interruption, and he used these techniques in a stepwise fashion to overcome first the more benign elements on his list, then the most severe. Eventually, he was able to modify his behavior by combining his understanding of what worried him most with his capacity to master and eventually overcome his fears.

Behavioral Therapy. Behavioral therapy has been used for years in the

treatment of adolescent anxiety disorders, such as simple phobias, panic disorder, separation anxiety, and school refusal, as well as disorders of conduct and oppositionality. This modality is based on principles of operant conditioning and reinforcement and often uses important techniques such as systematic desensitization and contingency management. Behavioral therapy differs from CBT by focusing on behavior modification and not on issues such as faulty cognitions and distortions.

Interpersonal Therapy. Interpersonal therapy (IPT) was first developed in 1984 by Gerald Klerman and colleagues in an effort to provide a short, psychodynamically informed treatment of depressed adults. IPT is based on the central premise that depression occurs in the setting of interpersonal conflict and that therapy should focus in a time-limited fashion on specific interpersonal issues as a means of ameliorating depressed mood. Like CBT, IPT is manual driven and often includes homework between sessions. Although it has not been studied in the treatment of adolescents as much as CBT, IPT has been shown to be effective for the treatment of nonsuicidal, nonpsychotic adolescent patients.

Dialectical Behavioral Therapy. Dialectical behavioral therapy (DBT) was developed by Marcia Linehan, given the realization that patients with affective dysregulation, suicidal, and other self-destructive behavior did not respond adequately to CBT or psychodynamic psychotherapy. Her model involves replacing ineffective, maladaptive behavior in response to internal or external stimuli with skillful, adaptive behavior. In DBT, maladaptive responses are viewed as learned responses to painful affect. DBT for adolescents was developed by Drs. Alec Miller, Jill Rathus, and Marcia Linehan. It involves learning emotional regulation skills, developing strategies for stress tolerance, and enhancing interpersonal communication, and combines these modalities with mindfulness techniques. Typically, DBT involves utilization of an individual therapist and participation in a skills-based group, and requires that parents meet in groups, sometimes with their adolescents. One aspect of this form of therapy is the availability of a skills coach to help the adolescent "in the moment" to learn to utilize skills for mastery in real time.

DBT has been shown to be effective for adolescents with Borderline Personality Disorder, suicidal ideation and comorbid depression, bipolar disorder, eating disorders, and adolescent with impulsive and aggressive disorders.

Mindful Meditation. Mindful Meditation has become increasingly used as a treatment for a number of psychiatric and medical conditions in adolescents. While more research is needed, there is evidence for its

efficacy in treating anxiety, depression, pain syndromes, and use in modulating affective dysregulation, impulsivity and aggression. It is often a standard component of DBT for adolescents. Research has demonstrated that meditative techniques are helpful for general wellbeing and stress management.

Grouping psychosocial interventions into categories such as psychodynamic, CBT, IPT, and DBT formats potentially creates the false impression that practitioners practice distinct forms of each modality. Although most clinicians are most comfortable focusing on one or two of these therapeutic formats, almost all who treat children and adolescents use particular aspects of multiple treatments. Psychodynamic therapies can be aided by contingency management, and effective CBT is made possible with a strong and in some cases unconsciously motivated relationship. Indeed, Ablon and colleagues showed that the best indicator of success in all forms of treatment is less related to the therapeutic modality use than to universally important features such as the trust that the patient places in the clinician and the relationship that that the clinician has with the patient.

Environmental and Systemic Treatments

In addition to psychotherapeutic and biological interventions, the treatment of adolescents often includes therapeutic involvement in the adolescent's environment. *Family therapies,* for example, aim to help the adolescent to negotiate his or her changing role in the family dynamic. Because adolescence is characterized by a movement away from the family of origin, many families become potentially distressed and volatile as the adolescent asserts his or her opinions within the family environment. Family interventions help to clarify family responsibilities and responses as these changes take place.

Similarly, *school interventions* seek to help an adolescent's teachers and school to better understand the specific dynamics between an adolescent's behavior and the school's response to that behavior. School consultants can make huge changes in a teenager's ability to continue along the social and academic trajectory by helping teachers to better understand the adolescent's behavior, by recommending and in some cases providing outpatient evaluation, and by suggesting behavioral techniques within the classroom. Sometimes relatively small but psychologically informed interventions such as simply changing classrooms can be immensely beneficial for a troubled teenager.

Finally, there is a growing appreciation of the importance of bringing interventions to the environments in which adolescents are most troubled. *Multisystemic therapy (MST)* has gained increasing popularity for the treatment of conduct disorders among adolescent populations. MST is based on the premise that conduct-disordered teens need interventions in

schools, at home, in the office, and in the neighborhood. These interventions must be integrated and coordinated, and current studies document the efficacy of this multifaceted approach in reducing adolescent transgressions of conduct.

All forms of adolescent treatment are complicated by issues particular to adolescent development. Because much of the adolescent patient population is younger than 18 years old, parents must legally and ethically provide informed consent before allowing their children to be treated either with medications or psychotherapy. However, given the emphasis that healthy adolescents place on separation and autonomy, it is clinically paramount that this population understand the risks and benefits of psychiatric interventions and be willing participants in their treatment. Only in extremely rare circumstances, such as severe psychotic states or in the presence of dangerous suicidality, is it clinically useful to prescribe psychiatric medications and other treatments against an adolescent's will. In addition, adolescents may feel differently about their treatment when they are given the opportunity to discuss their feelings without their parents present. For example, side effects such as sexual dysfunction characteristic of many psychotropic agents need to be discussed with appropriate patients in the absence of their parents. In general, clinicians need to treat adolescents as much as possible like the adults they are striving to become, while at the same time keeping in mind all of the legal and ethical considerations that are paramount in the treatment of any underage patient.

Hospital and Residential Treatment

Most adolescents can be treated in the outpatient setting. However, at times, inpatient, residential, or day hospital care might be required. In recent years, largely due to third-party payers and the advent of managed care, access to these more restrictive environments has been quite limited. The primary indication for inpatient settings is typically danger to self or others. Adolescents might be admitted to short-term residential or day hospital programs, many of which are in unlocked settings, if there is an acute deterioration in behavior with an inability to function in the home and school environments. The most common diagnostic categories requiring hospitalization include severe depression, suicidal behavior, bipolar disorder, obsessive-compulsive disorder, psychosis, eating disorders, substance abuse, posttraumatic stress disorder, and conduct disorder. Inpatient, residential, and day hospitalizations offer the adolescent a therapeutic milieu for observation and multimodal treatment. The adolescent and family may use these services for medication management, behavioral containment, and the acquisition of better problem-solving skills. In many health care systems, a continuum of services has been established, with initial inpatient care leading to step-

down units, such as unlocked residential or day hospital programs that offer a less restrictive environment, and gradual re-entry into the community. A primary function of hospital-based care is to develop a comprehensive after-care program with coordination between outpatient services and utilization of school-based programs and other community services.

EFFECTIVE ADOLESCENT THERAPY

The treatment of adolescent patients is quite different from the treatment of latency-age or adult patients. Adolescents can seem both extremely childish and surprisingly mature. In addition, the same adolescent population may undergo rapid and unnerving developmental changes in a relatively short amount of time. These issues substantially complicate the clinician's task. Forming an effective alliance with an adolescent patient requires special attention to already important clinical considerations such as confidentiality and safety. For example, the patient who admits to using illegal drugs may not want his or her parents to know but may acknowledge a desire for help in understanding this growing drug problem. Although patient safety is always the most important clinical consideration, clinicians must view each situation on a case-by-case basis. Often, adolescents come to their treaters for guidance on issues that they are not able to discuss at length with their parents. A friendly, honest, flexible, and available clinician is absolutely essential for the adolescent to feel comfortable in coming forward with important and pressing issues.

Clinicians also need to be curious about their adolescent patients' worlds. Adolescents will express themselves wonderfully in displacement, finding voices in the music they listen to, in the television they watch, and in the stories and movies they embrace. Although it is neither reasonable nor possible for a clinician to stay abreast of the pantheon of popular culture, inviting adolescent patients to discuss aspects of their culture that excite them is a valuable means of building trust and of gaining insight.

FUTURE DIRECTIONS

The psychiatric treatment of adolescents is by definition a complex endeavor. Because adolescent behavior manifests as a function of biological, developmental, psychological, and cultural phenomena, the clinician must be prepared to take into account all aspects of the adolescent's world to effect change. Furthermore, no clear hierarchy exists among the various determinants of adolescent difficulties. The same behavioral problems among different adolescents can have strikingly different determinants. One irritable teen might have a biological predisposition to depression, whereas another might suffer primarily from a chaotic home life. A tendency to address only one aspect of an adolescent's presentation risks oversimplifying the extent to which

adolescents suffer and misses a valuable opportunity to be maximally effective. Indeed, it is this very complexity that makes the treatment of adolescents so rewarding and fulfilling.

55 Child Psychiatry: Special Areas of Interest

▲ 55.1 Adoption and Foster Care

SANDRA B. SEXSON, M.D., AND DALE AARON PEEPLES, M.D.

Adoption and foster care are social institutions that provide substitute care for children and adolescents who are unable to be cared for by their biological parents in their own homes. Foster care represents a temporary solution to out-of-home care, whereas adoption is aimed at a permanent assumption of parental responsibilities by parents other than the biological parent(s). Recent data suggest that more than 400,000 children are in formal foster care in the United States in a given year, with more than 640,000 being served by child welfare systems each year and close to 255,000 entering the system and slightly fewer exiting the system annually. All of these numbers represent a decrease from a decade ago. Informal fostering may also occur outside of the public system, adding to the numbers of children and adolescents affected. Statistics for adoption are even harder because adoptions occur in both the private arena and public child welfare system. It is estimated that approximately two and a half to three and a half percent of the US population is adopted. Child welfare data suggest that more than 50,000 children are adopted annually from the child welfare system. Best estimates suggest public adoptions account for 41 percent of all adoptions, with international adoptions accounting for 13 percent. The remaining 46 percent or so are adopted through adoption agencies and private lawyers. Child welfare statistics suggest that, although it has been trending down over the past decade, the number of children in the United States waiting in foster care for adoption at any one time remains well over 100,000.

The staggering statistics regarding foster care and adoption demand that psychiatrists and other mental health professionals address the complex needs of this vulnerable population of children and adolescents in the United States. Children in foster care frequently experience multiple placements, and many of those who are reunified with their families of origin subsequently are placed into care again. Children who are adopted

are less likely to have a disruption in placement. In recent years, parental neglect and parental inability to provide adequate care are the most common reasons that children are removed from their homes. Fifty years ago these reasons typically revolved around incapacitating parental illness or death or unstable financial situations. Today the reasons for parental incapacitation are heavily influenced by parental alcohol and drug abuse and all the iterations of poverty. Other, less common, reasons include physical abuse, abandonment, and sexual abuse. Although many children show resilience in the face of all of these stresses, the risk for mental and physical health problems in children in foster care and, to a lesser and somewhat more controversial extent, children in adoptive settings is well higher than that of the general population. Although it appears that many children enter placement situations with vulnerabilities in these areas, the consensus among professionals is that multiple disruptions in placements over time add to this vulnerability, increasing the risk for serious and prolonged mental health problems. This section reviews the history of adoption and foster care in the United States; identifies trends in the management of out-of-home placement, both foster and adoption, over recent years; and reviews the limited literature on outcomes, in an effort to inform the practicing psychiatrist how best to approach the care of this very vulnerable population.

FOSTER CARE

History of Foster Care

Throughout history there are accounts of children cared for by families or institutions other than their biological parents. Biblical accounts of Moses' rescue by the Pharaoh's daughter and biblical directives to men that they marry their brother's widow offer examples of nonrelated foster care and kinship care, respectively. For centuries, children have been abandoned by parents unwilling or unable to care for them. Early historical accounts suggest that churches and monasteries assumed responsibility for these children, who were often used as child labor, a practice that continued into the 19th century, when children were sent from cities, where they were seen as dangerous, to farm families, who took them in and used them as cheap labor. Older children, particularly, were placed in apprenticeships without supervision. These practices often removed children from their communities and families of origin permanently because of the distances involved in separation. In the 19th century, societies began to develop orphanages where children could be housed and cared for in groups, a practice that was found to be less financially expensive for the state. Pejorative attitudes toward abandoned children pictured them as coming from bad families and being at high risk of bad outcomes. Even during these earlier times, however, family reunification was a possibility. At the

beginning of the 19th century, mothers could reclaim their children by paying a fine and reimbursing the state for the costs incurred during the time the child was in the state's care.

In the United States in the middle of the 19th century, Charles Loring Brace developed a program to remove abandoned children from the streets of New York City and send them to families in which they often became child laborers and were permanently separated from their family of origin and their culture. However, his concept that these children were better served in family homes rather than institutions set the stage for foster care as it is known it today. Foster care, involving temporary out-of-home placement, became institutionalized in the United States around 1909. However, over the next decades children lived out their lives in foster placement with little attention being paid to permanency planning and with their situations frequently complicated by multiple placements, which often resulted in the children being lost in the system. In the early 1960s, the government instituted a plan (Aid to Dependent Children) to foster family preservation. *Permanency planning* to avoid the loss of children within the system became a goal, with reunification (return to the family of origin), adoption, or long-term foster placement as more permanent options. However, the emotional and developmental needs of children were not addressed until the Adoption Assistance and Child Welfare Act of 1980. This act was aimed at preventing unnecessary separation of children from their families by providing more services for the prevention of removal, as well as efforts toward reunification. It also sought to address the problem of the unstable and continuous cycle of children being in multiple foster homes over extended periods of time. It established mandated 6-month reviews of each child in foster care. Permanency planning was emphasized, with reunification the primary goal and adoption as the alternative. Over the years this act was expanded to provide adoption support for special needs children. Under Title IX of the Social Security Act, foster care children generally receive health care through Medicaid.

Many children who were removed from their homes were eventually returned to families of origin (up to 75 percent in earlier studies with around 50 percent as recent as 2013). A significant number of those reunited subsequently return to foster placement. The Adoption and Safe Families Act of 1997 sought to provide safeguards to protect children from neglect and abuse while promoting timely permanency plans and holding the child welfare system more accountable. Concerns that prolonged efforts toward reunification had been unsuccessful led to more stringent guidelines regarding permanency planning. States were required to move toward freeing a child for adoption when a child had been in foster care for 15 of the prior 22 months, with permanency hearings within 12 months after the child going into foster care. Kinship care in the form of permanent placement with a family member became a more popular option in lieu of

reunification. The limitations on the aggregate time in foster care also discouraged the prior practice of moving children from foster care back to the family of origin and then back into foster care again over and over, delaying decisions on other, more permanent options.

More recently child welfare legislation has attempted to address those foster children who "age out" of the system, that is, those who remain in the foster care system until transition into adulthood. Initial steps began in 1986 with the addition of an amendment to Title IV-E of the Social Security Act—the Independent Living Initiative. This provided states with funds for preparation for independent living as youth aged out of foster care. This was replaced in 1999 by the Foster Care Independence Act which increased funding to states to help with transition to independent living, and also provided the option for states to extend Medicaid coverage to the age of 20. In 2014, all youth aging out of foster care are eligible for Medicaid coverage until the age of 26 as a result of the Affordable Care Act of 2010. In addition to targeting access to health care, the federal government has also recognized the need of coordinating other services as children age out of foster care. The Fostering Connections to Success and Increasing Adoptions Act of 2008 requires the development of a transition plan at least 90 days prior to a youth aging out of foster care. Ideally this will help address housing issues, health insurance, education, mentoring, and employment services, as young adults exiting foster care have little or no "family-type" support. Each year more than 20,000 adolescents "age out" of foster care with limited connections or support systems.

Table 55.1–1.
Ethnic Representation of Children in Foster Care

Ethnic Group	Percentage of the Children in Foster Care	Percentage of the Children in General Population	Relative Risk of Foster Care Placement
Black non-Hispanic	26	13	About two times that of the general population
White non-Hispanic	42	63	About two-thirds that of the general population
Hispanic	21	17	Slightly above that in general population
Native American	2	1	About two times that of the general population
Biracial	6	2	About three times that of the general population

Who Is in Foster Care?

In the United States, there are currently more than 400,000 children in foster care. Although child abuse and neglect occur across all racial and ethnic groups, as a percentile, children of color are overrepresented in the

foster care system compared to the general population. Table 55.1–1 shows the comparisons relative to the percentiles in the general population, demonstrating a much greater risk for biracial, African-American, and Native American children than for white, and Hispanic children. Not only are there more African-American, non-Hispanic, and Native American children in foster care proportionately, but in addition, those in foster care are more likely to remain there for longer periods of time and are less likely to experience permanent reunification or adoption (Table 55.1–1).

It should be noted that there are some positive trends seen over the past decade regarding ethnicity and foster care. Although African-American children remain over represented in the foster care system, they have experienced the greatest reduction as a group of children receiving services in foster care, by over 47 percent. Almost all ethnicities of children have seen a drop in their numbers in foster care over the past decade. The one exception to this is biracial children, which had a 65 percent increase during that time. Additionally, Hispanic children experienced a marginal drop in true numbers (only 2.5 percent) but this is due to being members of a rapidly expanding demographic. These changes in the demographics of foster care are largely driven by local policies. Rates in large urban populations are responsible for much of the decline, as just 10 counties in the United States were responsible for half of the national decline. At a state level, 90 percent of the nation's decline is accounted for by changes in just 10 states. While California, New York, and Florida are responsible for the greatest decreases, the most growth in foster care placement was seen in Texas and Arizona.

Recently, a significant amount of media attention has been paid to unaccompanied minors crossing into the United States from the southern border. Children arrive in the United States from all over the world, and they are often fleeing desperate circumstances. At a bare minimum unaccompanied refugee minors experience the stress of adjusting to a new culture and separation from family. In addition, many have been exposed to war, rape, torture, and severe deprivation prompting their immigration to the United States. Subsequently PTSD, depression, and anxiety are common issues among refugee children. In 2002 Congress transferred the care of unaccompanied children from the Immigration and Naturalization service to the Department of Health and Human Services (HSS) in an effort to move away from an adult oriented detention model to a child welfare-based model. Unaccompanied children are defined as individuals under the age of 18 who have no lawful immigration status and who are without a parent or legal guardian. There are several options to house these children while finding more permanent placement-institutional shelters, group homes, independent living, and foster care. Placement in foster care is the most common of these, and the federal government has programs in 17 cities to arrange placement. Following that, placement with a sponsor,

family reunification, or return to country of origin are all possibilities. The benefits for these children as they enter foster care are the same as those for children born in the United States. State child welfare systems monitor their care while in the child welfare system. Additionally foster parents receive training for cultural sensitivity to help with the children's adjustment to life in a new country. All this is not without cost, and, in 2008, prior to the recent influx of children, approximately $127 million dollars a year was spent on the welfare of these children. Since then, the numbers of children entering the United States without an accompanying adult have skyrocketed. Historically, approximately 7,000 children a year were served, but beginning in 2012, the numbers almost doubled and estimates for 2014 number at over 57,000 children. Most of these children are males over the age of 14 who are found at the US border, primarily fleeing Guatemala, El Salvador, and Honduras. Eighty-five percent of youth served by HSS are placed with family members in the United States.

Native Americans have 565 federally recognized tribes. Among these there is a varying capacity of management of child welfare programs. Some Native American children are managed by state protective services. In the state system, they are over-represented relative to their portion of the population. Estimates about the number of children served by tribal organizations are unavailable, and therefore not included in national statistics. In 1978, the Indian Child Welfare Act was passed which reaffirmed and empowered Native American tribes to manage child welfare issues. It was put forth in response to the relatively high rates of Native American children in foster care, and the fact that they were often placed in homes away from their reservation and their culture. Specific plans for services vary from tribe to tribe, but federal funds are available and many tribes use supplemental funds as well. In addition to the challenge of operating a number of different models, services to children on reservations are also challenged by the rural nature of the setting, limited funding, and frequent turnover in local government, which can impact policy. Federal services are available to help Native American communities implement culturally sensitive practice model improvement projects.

Children of all ages are in foster care. Estimates in 2013 suggested that under 7 percent of those in care are less than 1 year of age, 33 percent are between 1 and 5 years of age, 22 percent are between 6 and 10 years of age, 22 percent are between 11 and 15 years of age, 16 percent are between 16 and 18 years of age, and close to 1 percent are older than 19 years of age. Many of the older children entered foster care younger than 1 year of age. Infants stay in care longer and are less likely to be reunited with their parents. Males continue to represent slightly over half of children in foster care at 52 percent.

As a group children entering foster care comprise a high-risk population for both physical and mental health problems. Studies suggest that one-

third of children in foster care have at least one chronic medical problem or disability and over 60 percent will have mental health problems during their lifetime. Estimates suggest that as many as 80 percent of children in foster care were exposed to drugs or alcohol in utero and 40 percent had low birth weight either from prematurity or in utero growth failure; both factors that increase the risk for many medical problems and developmental and mental health problems. It is not surprising that studies suggest that from 50 to 90 percent (compared to 10 to 20 percent in the general population and 35 percent or so in children living below the poverty level) of children who are placed in foster care have significant mental health problems necessitating mental health interventions. In addition, children involved in the child welfare system are at much higher risk for mental health problems than their socioeconomically matched counterparts. Of interest, those entering the foster care system are more likely to get mental health care than those who remain in their homes, regardless of clinical need, leading some to suggest that foster care is a gateway to mental health services for many children. Significant nonclinical predictors of the use of mental health services for children in foster care include older age and being white. In addition, children who have been sexually abused are more likely to access mental health services, as are children living in nonrelative foster care placements versus those in kinship care. Those placed for reasons of physical neglect are less likely to receive mental health services. Some studies also report decreased mental health services for younger children in foster care.

There is a growing body of literature illustrating the physiological changes children in foster care may experience due to early exposure to abuse and neglect. Neurodevelopmental impairment also results from early neglect. In addition to general growth delays, head circumference is decreased in children coming from institutional placements. The Bucharest Early Intervention Project (BEIP) is a longitudinal randomized controlled trial following children exposed to institutional care and comparing their growth and development to those who were able to find placement in foster care and a community control sample. In this study, when children were followed up at age 5, electroencephalography (EEG) patterns consistent with ADHD were present more often in institutionalized children than their peers, reflecting immature cortical development. In other adoption studies, both magnetic resonance imaging (MRI) and diffusion tensor imaging reveal decreased total brain volume in both white and gray matter. For children who found placement in foster care as opposed to an ongoing institutional setting, there was an increase in white matter volume suggesting some neural plasticity and the potential for some catch up once living arrangements improve. With respect to specific brain regions, studies are mixed regarding both the amygdala and the hippocampus, with some finding increased volume and others reporting decreased volume.

Despite undergoing similar experiences in terms of neglect and deprivation, outcomes for children do vary, suggesting that some individuals might inherit resistances to these stressors, while others might be more vulnerable to negative environmental effects. Polymorphisms in genetic sequences may offer some explanation for these different outcomes. Variation in the serotonin re-uptake transporter gene (5HTT) is associated with moderating the influence of early adverse experiences and the development of anxiety and depression. Studies in adopted children comparing groups adopted before and after the age of 6 months found that variation in the 5HTT allele did impact the development of emotional problems in children adopted after the age of 6 months. In the English and Romanian Adoptees (ERA) study, variation in dopamine reuptake receptors (DAT/DRD4) was associated with ongoing ADHD symptoms at the ages of 11 and 15, suggesting that children with the high-risk haplotype did not outgrow ADHD symptoms as rapidly as their peers. In the BEIP study, allele variation in the dopamine reuptake catechol-O-methyltransferase gene resulted in significantly lower rate of depressive symptoms in children with one of the variations.

Reviews of the literature consistently demonstrate that minority children, particularly African-American children, are less likely to receive services than their white counterparts are when both had high behavior dysfunction scores on behavioral screening instruments. This disparity suggests that caregiver, child welfare, and court official's attitudes regarding mental health service needs may be culturally biased, influencing which children in need get mental health services. Another concern in the mental health treatment of children in foster care has been the demonstrated increase in prescriptions of psychotropic medications to the foster care population, with probably less emphasis on psychosocial interventions. Given that the foster care population is very much at risk of mental health problems, it may not be surprising that this population receives psychotropic medications at rates of 37 percent compared to rates of 4 percent in the general population. The concern is whether evidence-based psychosocial interventions, which are often difficult to manage in unstable living environments or in homes with multiple foster children, are being employed when indicated. Certainly foster children are at higher risk for prenatal exposure to substances, malnutrition, and family history of mental illness, all of which could necessitate a pharmacological intervention. However, psychological factors such as grief, adjusting to a new environment, and attachment issues may manifest as internalizing and externalizing symptoms causing a psychiatrist to rush to medicate when a psychosocial intervention is in order. This is a particular risk when the history is frequently obtained from sources that only know a portion of the child's history.

Reasons Youth Enter Foster Care

The reasons that children and adolescents require placement outside their families of origin are complex, involving problems with the parents, child factors that contribute to failure of the nuclear family, and societal or environmental conditions. Biological parents' problems may place their children at risk of neglect or abuse. Substance abuse, mental illness, intellectual disability, domestic violence, and lack of social support systems (low socioeconomic status and being a single parent) all negatively affect the parents' ability to provide adequate care for their children. The child may also bring factors, such as temperament, into the situation that increases the risk of parental failure. Children with difficult temperaments and those with the inability to self-regulate effectively make parenting more difficult. However, even the child with an easy temperament may be at increased risk of neglect in a chaotic and demanding family. Children with cognitive and physical disabilities also may be more difficult to parent. Children who have temper tantrums and oppositional behavior bring more stress to the already vulnerable parent–child interaction. The more needs a child has, the more difficult it is for parents to provide care that is adequate. Finally, adverse environmental conditions may contribute to the failure of capable parenting. Examples that increase stress in families include poverty, unemployment, decreased or absent social supports, and poor nutritional resources. Effective interventions to prevent the need for foster placement, as well as interventions aimed at providing substitute care, must address all of these components if they are to be successful. Too frequently the child is moved to foster care, but many of the issues involved in the ongoing lack of fit for the child in the family are not aggressively addressed.

Outcomes

Outcomes for children and adolescents placed in foster care are hard to assess, but ongoing studies of youth aging out of foster care have provided some information about their transition into young adulthood. At age 26, they are still disadvantaged relative to their peers in many respects. Five percent are incarcerated. Thirty percent have had recent episodes of homelessness or unstable housing ("couch surfing" with friends). Less than half are employed (even excluding those who are incarcerated), and of those working, a third are employed part-time. Relative to peers, they earn approximately $18,000 less per year and 45 percent have experienced an economic hardship in the past year (lacking money for rent/utilities). Over half have health insurance, but two-thirds rely on a government program for this. Foster children face a number of academic challenges. Multiple placements lead to school absences and disruption. Foster children tend to miss twice the amount of school as their peers, and 34 percent had more

than five changes in their schools. At the age of 18 foster care youth are twice as likely to have had out of school suspensions, and three times as likely to have an expulsion. Preparing for graduation, the average youth in foster care reads at a seventh grade level, and only 50 percent graduate high school on time. Of those that graduate 20 percent go on to college, with less than 10 percent of those enrolling in college going on to graduate with a bachelor's degree. Outcomes during foster care look at issues related to the disruption of care, given that improving placement stability is perceived as a major goal in foster care placement. Over a 12-month period, as many as 50 percent of children in placement experience a disruption, resulting in movement to another home or a more restrictive environment. Child characteristics thought to increase the risk of placement disruption include older age, general health problems, a mental health diagnosis, family history of mental health issues, and presence of behavior problems, especially those related to conduct disorders. Studies assessing the impact of gender are mixed, but recent reviews suggest females may now be at greater risk of disruption. Children removed for physical and sexual abuse are also more likely to have trouble with a placement compared to those removed for neglect. In addition, the experience of stress in the foster family in 6 months prior to the child's placement has been associated with increased rates of disruption, while foster parents that are trained to deal with special needs are more likely to continue caring for challenging children. Emerging data that links the number of behavior problems reported by the foster parent per day with increased disruption of placement suggest the need to focus interventions on reducing the child's behavior problems and increasing the foster parents' ability to deal with them. Children in kinship placements seem less likely to be disruptive than those in nonkinship foster care. Reasons for this are unclear. Typically there are fewer children in kinship placements, which may affect a family's ability to manage a given child's behavioral problems. In addition, attachments in kinship placements may be easier to foster. Disruptions appear to be less likely when foster parents are warm and child centered and when foster children are open to fostering. There are well-established, evidence-based interventions focused primarily on teaching parents to intervene appropriately with the children in their care. However, few of these have been implemented with foster parents on a wide-scale basis. Policy and systems also play a role in placement stability for children. There are times when the state may mandate a move for a child to reunite siblings, switch to a long-term placement, or merely try to deal with the reality of funding issues. When children have a high level of turnover in caseworkers, they are at greater risk of changing placements. Subsidies for guardianship and adoption placement, as well as hiring graduate level social work staff, are associated with improved outcomes in placement. Without a doubt, multiple disruptions lead to increased problems for the

child and for the caregivers.

Since the 1980s, child welfare systems have focused more on reunification with the family of origin as a permanent placement option. However, over time some leaders in child welfare have questioned whether this goal is always appropriate because many children who are reunited go back into foster care. Lower rates of reunification occur when the child is very young, an adolescent, or African-American. When the child is removed because of neglect there is a lower likelihood for successful reunification. Family variables that decrease the rates of reunification include poverty and failure to visit when children are in foster care. Longer time in foster care, as well as kinship placement, also lowers the reunification rates. Still, over the years, child welfare has assumed that reunification is the best outcome for children in foster care based on the need for continued contact with the biological family and the fact that extended periods in foster care usually lead to less stability. However, recent data has accumulated suggesting that reunification may not always be the best option. Reunited children in several studies have had more behavioral problems, engaged in more risk behaviors, and had poorer life-course outcomes. Better outcomes for those who were not reunited included higher scores on intelligence testing, increased general well-being, and fewer problems with repeated criminal arrests. Some of the major parental issues that lead to foster placement—specifically substance abuse—are not easily remedied in the parent, limiting the likelihood of successful reunification. Intensive interventions to support families with mental illness, substance abuse, homelessness, and severe poverty are not readily available in most settings. Reunification in the right situation is still a laudable goal, but child welfare agencies should openly confront the pros and cons in each situation in an attempt to make a permanent decision in a timely manner that is best for the individual child.

Over the past three decades kinship care has become more popular as a formalized placement alternative to traditional foster care options. Federal laws such as the Personal Responsibility and Work Opportunity Reconciliation Act of 1996 and the Adoption and Safe Families Act of 1997 have given preference for child placement to kinship arrangements. Most states have options for reimbursing kinship care, although frequently at lower levels than nonkinship foster care. Theoretical advantages to kinship care include the preservation of the child's sense of family and cultural identity; increased access to relatives other than the kinship provider; greater stability in placement; maintenance of religious, ethnic, and racial values; and, potentially, the existence of previously established relationships with the children that may facilitate attachment relationships. Kinship care provides a way for the child's family to be preserved even when reunification with the family of origin is not possible. Children in kinship placements as compared to those in foster care also show greater

mental health stability and fewer behavioral issues. However, there are numerous concerns about kinship care. As a group, kinship caregivers are more likely to be single, older, with more health concerns, less education, higher rate of unemployment, and from lower socioeconomic status. Frequently, kinship caregivers are grandmothers who parented the foster child's parent, which causes some concern among child welfare agencies. Child welfare workers report having more difficulty supervising kinship placements, citing that kinship caregivers frequently do not adhere to parental visitation restrictions. Some of these negative differences may be alleviated with more equitable resources and support services and increased supervision commensurate with that provided to nonkinship foster parents. Continued research on kinship care is necessary to provide child welfare agencies with reliable data on the long-term outcomes of children reared in either kinship or nonkinship foster placements to inform future decisions.

Additionally, it is being recognized that the majority of kinship arrangements are informal, meaning the court and the public child welfare system have not helped broker the arrangement between the birth parent and the caregiver. Approximately 1.76 million children are in this type of living arrangement, six times as many when compared to families that have formalized the agreement. Unfortunately, this creates obstacles for both the caregiver and the child. Without a proof of legal rights, obtaining services ranging from health care to school enrollment may be impossible without assistance. Grandparents find themselves most commonly serving in the role of the informal kinship caregiver. Often they are reluctant to seek out legal action to terminate birthparents' legal rights. They retain hope that the social circumstances (often substance use) that led to the current living arrangement will correct itself, and the child will be able to live with the birth parent once more. Although this arrangement is often prompted out of compassion for the biological parent, it limits a child's access to social services, and places a child at risk in terms of permanency of placement, as they can be removed from the home at the whim of the birth parent. Policies vary state to state, but informal kinship caregivers have options beyond adoption that allow them to seek services for children. Unfortunately, these generally require some out of pocket expense for legal fees, which may be an obstacle to some families. Seeking guardianship will allow a caregiver to access services for a child, but in some states it would also require the termination of parental rights. Legal custody as opposed to guardianship is appointed by the family court instead of probate court, but otherwise quite similar in that it often requires the proposed custodian to provide proof of the birthparents' inadequacy, and in some instances parental rights will be terminated. Some states offer a de facto custody option. This is also managed by the family court and requires that the care provider prove that they provided for the child's needs for a period of time

(often 6 months to a year) without the involvement of the birth parent. Biological parental rights are not terminated, and no concerns about the birthparents' inability to raise the child need be discussed in court. However, once the ruling is made the birth parent is not allowed to remove the child from the de facto custodian without court approval.

Treatment Foster Care

Treatment foster care (TFC) refers to interventions focusing on at-risk children who are unlikely to otherwise be managed in the community and would thus find themselves in an institutional placement such as a mental health facility, juvenile corrections, or a secure residential facility. These are children who have experienced significant trauma, abuse, and neglect which have begun to manifest as major mental illness or budding antisocial behavior. TFC interventions are similar to a number of older services, such as "specialized foster care," "wraparound" foster care, and multidimensional TFC. All try to help at-risk children by developing strong community links, therapeutic training for foster parents, providing treatment directly in the home, limiting the number of children in the home, providing crisis intervention services, and treating the foster parent as a professional as well as providing additional payment to the foster family. Children show an improvement in social skills, a reduction in problem behaviors, and an increase in placement permanency. Such interventions may help reduce antisocial behavior, and subsequent incarcerations for youth in foster care. Additionally, children receiving such services have also shown improvements in school attendance, homework, and employment.

Mental Health Problems

Children in foster care struggle with many psychological issues because the reasons that they enter foster care have almost universally potential negative effects on psychological development and emotional adjustment. The events leading to the need for placement are adverse, often involving abuse, neglect, exposure to violence, and inconsistent parenting. Despite the fact that the foster placement may be a safer environment, it carries with it the loss of familiar surroundings and familiar caretakers, caretakers to whom the child usually has some attachment despite the abusive or neglectful relationship. In addition, foster placements typically are not planned but occur abruptly with little opportunity for preparation. How children handle these major stresses depends on the reasons for placement, the age and/or developmental level of the child, the old and new home environments, and the support systems available for the transitions. Each separation emphasizes the rejection and feelings of abandonment, compromising the ability of the child to develop effective emotional

attachments. Younger children are particularly vulnerable to attachment problems, which may affect their ability to relate effectively in the future. Their inability to trust their caregivers to provide them with consistent predictable care leads them to mistrust future relationships and exhibit behaviors of avoidance, anger, and/or oppositionality. These behaviors in turn make it hard for even the most nurturing of adults to continue to offer the child much-needed nurturance. Attachment to foster parents may also be complicated by complex and ambivalent feelings of being unfaithful to the biological parents when children open up to a relationship with a new caregiver. Typically children removed from their birth parents blame themselves, perceive themselves as unlovable, and feel guilty about the separation. When children cannot trust their caretakers, their psychological development is complicated by the use of primitive defense mechanisms, and they are at risk of developing pathological narcissism, which may lead to an inability to express empathy. Sometimes children have experienced care in their families of origin or in deprived placements that are so pathological that they may develop reactive attachment disorder or disinhibited social engagement disorder, which requires immediate and intensive intervention to avoid catastrophic outcomes.

Children who have experienced pathological care during their younger years also have difficulties regulating their behaviors, leading to problems with modulation of their emotions, aggression, and even attention and activity levels. Self-regulation is learned through a protective process with a predictable caretaker, an experience many foster children lack. In addition to the pathological care, there may be other risk factors for regulatory problems, including prematurity, low birth weight, and exposure to drugs and/or alcohol in utero. The world of the abused and/or neglected child is one of extreme unpredictability, which leads to high levels of anxiety and fear. They are unable to sleep, a problem that contributes even further to a pervasive inability to regulate behavior.

Not only have young children in foster care experienced loss of their primary caretakers, who, in many cases, were unpredictable and pathological in their caregiving, but many have also been traumatized overtly by physical and sexual abuse, as well as exposure to violence. Some may meet full criteria for acute or PTSDs, but many will have subthreshold symptoms that need to be addressed. The stress systems in the brain may be activated in such a way as to keep the child in a chronic state of arousal, an issue that more recent research suggests may impair the child's ability to manage stress in the future. Early and intensive interventions may remediate these problems at a neurobiological level.

Children in foster care also have much higher risks for developmental disabilities than children who are not in foster care. Risk factors that lead to foster care may affect development. These include such negative influences as direct effects of maltreatment (brain injury, spinal cord

injury, burns), as well as prenatal exposure to toxins such as alcohol and other drugs. Parental incapacities may have genetic components that affect the child as well, including intellectual impairments and language delays. Developmental disabilities also increase the risk that children will go into foster care and stay in out-of-home care longer, that foster placement will be less stable, and that other problems either within the child or the families involved will be exacerbated.

What about the Foster Parents?

Foster parents are asked to provide a nurturing and accepting environment for children who have had numerous negative and unpredictable experiences with adults in their environment, who come to a "temporary" relationship with ambivalence and difficulties with trust and attachment, and who then frequently test in numerous ways the foster parents' acceptance of them within their families. Foster families have to deal with frequent, occasionally less than helpful, intrusions into their lives by caseworkers and other supervisors of foster care while sometimes getting little if any support for this challenging and difficult task. Furthermore, they have to do this knowing that their attachment to the child is likely to be disrupted, often under situations that they do not support, such as sending a child back to parents who have a history of being abusive. Foster parents experience grief and loss as children enter and leave their care. They experience rejection and oppositionality from children under major stressful conditions. Although most placement agencies provide some education to prepare parents for the challenges of foster care, ongoing training specific to the individual child's needs and support systems to help the foster parent deal with their sense of loss and grief while continuing to provide nurturing support may improve outcomes for both the foster families and the children placed in their care. Professionals working with foster children and foster parents must address these important issues to facilitate optimum outcomes. The development of rituals for entering and leaving families and careful documentation through scrapbooks and photo albums may provide continuity in the life of the child moving across placements, as well as a historical record for the foster family.

The Psychiatrist's Role

The child and adolescent psychiatrist, along with the entire team of mental health professionals, is in a unique position to advocate for and provide effective interventions for the highly vulnerable population of foster children in the United States. In 2012, the American Academy of Child and Adolescent Psychiatry issued a guide outlining best practices in caring for children in foster care. Recent trends have led to increased use of psychotropic medications for children with Medicaid coverage. Due to a

combination of legitimate concern for safety issues surrounding some of these medications and state budgetary concerns, increasing attention is paid to prescribing practices of physicians treating children in child welfare services. Subsequently before considering a medication, it is imperative to conduct a comprehensive mental health assessment (including, whenever possible, reaching out to biological parents for history), and to identify any medical or developmental issues. Immediate intensive interventions are needed that address the breadth of the problem—not just prescribing medications, but also offering intensive parent training to foster parents specific to the child they must parent and implementing other psychosocial treatments along with psychopharmacological treatments that are evidence based for the disorders identified. Unfortunately evidence based nonpharmacological interventions are frequently unavailable or poorly reimbursed, including intensive parent training. Child and adolescent psychiatrists often struggle with little continuity of information about the child's functioning, therefore limiting appropriate decision making as well as few available resources for consistency in evidence-based psychosocial interventions.

When medication is indicated, educating all parties involved in the child's welfare is essential. Estimates of the number of children in foster care using these medications range from 13 to 37 percent depending on the study, compared to 4 percent of age matched peers. When it is determined that a child will benefit from a pharmacological intervention, consider a conservative approach. Avoid starting multiple medications or making multiple changes at once. Follow up with the patient in a timely manner when changes are made—ideally 2 weeks after an initial visit. If a medication does not appear beneficial, confirm that the dose and duration are appropriate, and then remove the medication by a gradual taper if it truly poses no benefit. When possible, use FDA-approved options and discuss "off label" use with all parties when such an approach is necessary. Whenever possible, become familiar with the preferred medications on the Medicaid formulary and use those. When polypharmacy is necessary, clearly explain the role of all medications to the child and the caregivers. In preschool age children, be very judicious about medication use.

It is necessary to keep the best interests of the individual child always at the forefront in assessment and intervention strategies and advocate for the child for permanency planning that considers the child's attachments, predictability, nurturance, support, and safety. Insisting that foster parents and families are involved in the treatment is also mandatory, avoiding the all-to-frequent custom of having a caseworker (or even a "transport" person with no information) brings the child to the psychiatric appointment without the involvement of the caregiver. Custody assignments should foster the child's sense of belonging within a system and should avoid disruption of strong psychological ties unless physical or emotional well-

being is compromised. Psychiatrists are uniquely qualified to evaluate these attachments and support systems and recommend and/or implement treatment interventions that are evidence based. In addition, as care providers, psychiatrists must advocate for the availability of effective services, which, while never readily available, may become even more limited as an effect of the expanding influence of Medicaid and managed care.

Looking to the Future

Although progress in understanding the problems and needs of children whose families of origin cannot successfully care for them continues, the field of foster care faces unanswered questions. Maltreatment and neglect have established negative effects on the growing child. Multiple placements with failure to provide consistent care over time definitely lead to negative outcomes. Nonetheless, many questions as to how best to intervene are often controversial and, more often, difficult to implement (even when evidence indicates an appropriate intervention) because of limited resources. Children and adolescents in foster care must have physical and mental health assessments and interventions beyond medication management from the very beginning of care. Foster parents need to be involved in these interventions. Agencies need to provide more education and individualized support to foster families who are providing the care for these challenging youth. Further research is needed to assess the viability of family preservation, early determination of the need for out-of-home permanency planning, and the advantages and disadvantages of kinship care over nonkinship care. Implementing more organized supports for adolescents who "age out" of foster care is a continuing challenge.

ADOPTION

History of Adoption

Adoption is a practice through which children whose parents are unable to provide for their care are supplied parents, often providing the adoptive parent(s) much-desired children. The practice is ancient, documented throughout history. Prior editions of this volume have summarized the history from ancient Babylonian times through today's practices. It was not until the 1850s that adoption was first recognized legally in the United States. Previously, informal adoptions often resulted in indentured servitude and child labor. In 1851, Massachusetts passed a law on adoption that integrated concepts that are still important. The law required judicial approval, biological parent or guardian consent, and the determination that the adoptive family was able to care for the child. Under these new laws, children were accorded legal membership in the family, although sometimes without access to inheritance. Children's needs became an

established priority.

Historically, adoption records, when available, were not confidential. Typically the birth certificate was not changed. In the early 20th century, social workers implemented the concept of the *closed adoption*, establishing secrecy among the triad of adoptee, birth family, and adoptive family. Social workers tried to match adoptees with adoptive parents based on race, religion, and physical and intellectual attributions. These efforts at secrecy were felt to protect the privacy of all involved, enhance permanency, and help the child avoid the social stigma of illegitimacy. Sometimes adoptees were not even told that they were adopted. Obviously many children were then, and still are, considered unadoptable. The practice of secrecy is controversial. Historically, concerns for all parties in the adoption process were made to argue in favor of secrecy. First, among these was the idea that the adopted child might experience confusion about their identity development and who their "real parents" were. Second, the adoptive parents might feel that they did not have the right to act as the child's "full parents." Finally, there was concern that the birth mother might not be able to move on from the loss of giving her child up for adoption due to the ongoing contact, thus prolonging her grieving process. Initial studies went on to refute such concerns. Additionally, as the face of adoption shifted in the United States, openness became unavoidable in many cases. Children adopted later in life through foster care are obviously aware of the family of origin. Similarly, children cared for by extended kin are often encouraged to maintain a relationship with the biological parents.

Open adoptions, in which records are open and adoptive children may actually have contact with biological parents, have become more common. The degree of openness varies from family to family, ranging from a one-time meeting between the biological mother and the adoptive parents to ongoing regular contact with the biological family. Although research is limited, recent studies eliciting feedback from adoptive parents have suggested that contact between the family of origin and the parents undertaking the adoption results in a higher comfort level with the adoption process for the adopting family, as well as instilling greater empathy in them toward the birth family. Adoptive parents have indicated that they are able to control boundaries with birth families, and generally note that they also feel they have a good level over control of communication. As this contact improved empathy toward the family of origin, it also may lead to more positive perceptions about the adopted child's behavior. Having an agreed upon and predictable structure for future contact is also seen as a positive to families. As contact continues, adoptive parents note fewer concerns that the biological parents may seek reunification, as trust between the two parties grows. Contact also reduces fears that adopted children have about their biological parents. They report less stress and worry about the safety and well-being of their family of

origin. Similarly, it is felt that some connection and openness can help them to better deal with mental health issues that the biological parent may be experiencing. This preliminary data are limited because the responses are almost totally from the adoptive parents, studies are small and nonstandardized, generally recruitment of subjects is through convenience samples, and most are focused on the adoption of white infants. Still the data offer some newer insights into the management of openness in adoption.

With societal changes, such as increased use of birth control, legalization of abortion, and the decreased stigma of single parenthood, the latter third of the 20th century saw fewer infants available for adoption, and both older children in foster care and children from other countries became potential adoptees for families in the United States. The goal for adoption of older children shifted from historical beginnings, when the benefit was for service to the adoptive family, to the psychological benefit of the child. Children from other countries began to be adopted in the United States after World War II and again after the Korean War, raising the controversy over transracial or transcultural adoptions, one that is not resolved. However, international adoptions have expanded rapidly over the last two decades, with Americans adopting children from many other countries, including China, Romania, Russia, India, Guatemala, and Colombia. In many cases, both with international adoptions and to a lesser extent with adoptions from foster care, the physical appearances of the child and the parent are obviously different, leading to the designation of "visible" adoptions.

Epidemiology of Adoption

Adoption is a well-established institution involving huge numbers of children and adults over the years. Although relevant statistics have not been routinely compiled, estimates suggest that between 2.5 and 3.5 percent of children in the United States are adopted, with more than 2 percent in nonrelative adoptive placements and another 1.5 percent in relative adoptions, including stepparents, who account for a significant number of "relative" adoptions. Foster care adoptions, although increasing somewhat with the push toward permanency planning, only represent about 15 percent of adoptions. Approximately 120,000 to 130,000 children are adopted each year, but this number has varied widely, with only about 50,000 annually in the 1940s and highs of 175,000 in the late 1960s and early 1970s.

Children are adopted in a number of different ways. Infants may be relinquished by their biological parents and adopted through private agencies or through attorneys, physicians, or clergy. These children are placed in adoptive homes either from the hospital or after a few weeks in "private" foster care. More and more of these adoptions are "open," with

contact initially with biological parents, particularly mothers, and in some cases, continued contact between the adoptive and biological parent(s) and in fewer cases ongoing contact. Although statistics on this group are not being collected, it is estimated that approximately 50,000 children per year are adopted in this manner. A second group comprises international adoption—the practice of adopting children from outside the United States. This group continued to increase over much of the last two decades often averaging close to 20,000 adoptions annually, until recent declines due to geopolitics. In 2013, there were just a little over 7,000 international adoptions. These adoptions typically are arranged through agencies, and total costs average a little under $30,000 and take 6 to 18 months to complete. The adopted children, although not newborns, are typically younger than those adopted from foster care, with almost 90 percent younger than 4 years of age and more than half of those under 1 year of age. These children may have had less than optimal care in orphanages prior to adoption. They were removed from their countries of origin and have little or no information about their biological families. Finally, children may be adopted from the foster care system. As many as 50,000 children or adolescents are adopted annually through the child welfare system. However, many more are waiting for adoption. These children typically have been in temporary placements, sometimes for a number of years. These adoptees are more likely to be from a racial or ethnic minority, and more than half are 6 years of age or older and may have experienced abuse and neglect, as well as multiple foster care placements.

Legislation continues to head in a progressive direction, gradually removing some of the barriers for adoption and opening the door for nontraditional adoptions, including single parent, gay, and transracial possibilities. As same sex marriages are still not recognized in all states, and it remains a relatively new phenomena in those states in which it exists, many gay and lesbian couples are unable to adopt children jointly. Fifty percent of gay and lesbian families that adopt go through the public system. Consequently, these families do a great service to many children remaining in foster care, and are generally also more willing to adopt transracial children. As openly gay families having the ability to adopt children is a relatively new phenomenon, longitudinal studies are just beginning to provide some outcome data. In early childhood, there appears to be no difference in internalizing or externalizing behavior by parent and teacher report in children raised in gay, lesbian, or heterosexual families. Further, there are no differences in gender role behavior in these children. Play preferences in young children appear less gender stereotyped in children reared by homosexual parents, particularly by lesbian mothers. Studies have also found that reduced parental stress is associated with better child adjustment. Consequently, state and federal policies that minimize discrimination against gay and lesbian parents can benefit their

children as well.

Approximately 40 percent of all adoptions are transracial, meaning that the race, ethnic or cultural origin of the child is different than that of one or both of the adoptive parents. This is most common in international adoptions, where 84 percent are transracial, but also seen in private adoptions (21 percent) and domestic adoptions (28 percent). Transracial adoptions in the United States initially involved only overseas adoptions, but in the 1960s, some transracial domestic adoptions began to occur. Parents were initially encouraged to de-emphasize the importance of racial differences to facilitate the child's integration into the new family. More recently, parents are encouraged to discuss race, and focus on the positives of cultural diversity, as well as acknowledging to their child that they are living in a racialized world to help validate any experiences with microaggression, or overt racism that may be directed at the child. Recently many studies have begun to focus on two issues- how to promote the development of a racial/ethnic/cultural identity for a child, and how to promote a child's awareness and ability to cope with racism. Contact with members of the child's racial community is helpful but occurs infrequently in transracial adoption. Having such connections may help children cope better with experiences of racism. Also of importance in the United States are the experiences of African-American children adopted into white families compared to African-American children adopted into African-American families. Researchers have described more identity issues in these populations, with African-American children reared in African-American families identifying themselves as African-American much more frequently than those reared in transracial settings. Findings are complicated because biracial children were included in the "African-American" population. Although highly contentious, both politically and socially, review articles conclude that transracial adoption leads to a majority of satisfactory outcomes, similar to other samples of adopted children after infancy.

Obviously adoptees enter the adoptive family with different life experiences. Those who are adopted as newborns experience family life and development much like children reared in biological families. However, the majority of others come from preadoption experiences of severe deprivation, traumatic life experiences, and multiple disruptions in caregivers before adoption.

Developmental Issues in Adoptive Families

Although most adopted children seem to progress along typical developmental trajectories, often even demonstrating developmental catch-up after adoption, there are some developmental challenges encountered in the adoptive family that are peculiar to the realities of the situation. Numerous authors suggest that there is an element of loss, embodied in the

process of relinquishment, in the psychological development of most adoptees, and that loss, particularly loss of the biological child that the adoptive parents were not able to have, may be an important psychological issue for the adoptive parents as well. These losses may affect the attachments of the child to the parents and vice versa, attachments that are necessary for typical development to progress. Benoit, Nickman, and Rosenfeld grouped these losses into three categories: *Overt* losses of environmental stability, including relationships; *covert* losses, which embody how the children think about the reasons for adoption and the effects that being "given up" may have on developing self-esteem; and finally *status* loss, which arises from feeling stigmatized by the fact of the adoption, a loss experienced generally but more commonly in transracial or international adoptees. These elements of loss may contribute to difficulties that the child may have in establishing strong attachments to the adoptive family. The parents may also have ambivalence regarding the adopted child, sometimes having failed to mourn the loss of their own fertility. This ambivalence, along with extended-family attitudes that may be unsupportive of adoption, can impair the adoptive parents' ability to attach wholeheartedly to the adopted child. Delays in finalization of the adoption may also cause adopted parents to have some reservations regarding attachment for fear of further disappointment and loss. Thus, one of the first major developmental tasks for the adoptive family is the facilitation of successful attachment. Attachment difficulties are more complicated when adoptions occur after multiple disruptions in care over extended periods of time or after prolonged periods of institutional care. In these cases immediate psychological interventions are imperative.

Adoptive parents have the additional responsibility of telling their adoptive children about the adoption and what they might know about the family of origin. Although in the past secrecy was frequently attempted, most professionals today recommend early disclosure and ongoing processing of the fact of adoption throughout the developmental years. Many feel that early disclosure, even before children can fully comprehend the information, is recommended. Addressing the reality of the adoption early and in an integrated manner allows children to develop healthy identities as adoptees as they progress developmentally, both cognitively and emotionally, over time and keeps the topic open as something easily talked about within the family. This may become very important when adopted children begin to wonder about their families of origin and begin to ask questions that the adoptive parents must answer as honestly and openly as possible. Anxieties about rejection may spill over into the adoptive family, causing children to worry about being removed from their adoptive homes. These issues are often heightened during adolescence, when children are normally struggling with issues of identity and separation from the nuclear family. Increased curiosity about families of

origin may be difficult for the adoptive families to address. Adolescents' typical desire to know more about their biological families, even to meet them, may feel like rejection to the adoptive families. When there is adolescent turmoil within families, adolescents may idealize the biological families as a way to exert independence within their adoptive families. It is unclear how more "open" adoptions, particularly those that foster open relationships with biological families, may affect these issues common in closed adoptions.

Over the developmental spectrum adoptive parents may find parenting challenges not experienced by biological parents. Frequently the adoptive parents enter the relationship with unresolved grief regarding their infertility, making them potentially less emotionally available to adopted children. Because of genetic differences as well as early experiences, the goodness of fit temperamentally and psychologically may not be optimal, making it more difficult for the adoptive parents to understand and respond empathically to the adopted children. Any problems the children have, any differences they may manifest, often tend to be viewed through the eyes of the adoption rather than as being normal variants within human development. Support for the adoption from extended families tends to decrease the effect of some of these challenges.

Risk for Mental Health Problems

It has long been established that adopted children are over-represented in both outpatient and inpatient mental health settings. Some of these findings predated the recent increase in numbers of children adopted from settings in which they had been neglected or abused prior to adoption. Some of this over-representation may result from evidence that suggests that adoptees are referred for problems of less severity than nonadoptees, leading researchers to hypothesize that adoptive families were more likely to seek interventions than nonadoptive families. Consistently, adoptees demonstrate more risk, however low, for externalizing behaviors, including substance abuse, conduct symptoms, aggression, and possible suicidal behavior, behaviors that are more distressing to parents and the community and more likely to lead to mental health referrals. Nonetheless, analyses controlling for the severity of the mental health problems demonstrated an increased risk in adoptees over that in nonadoptees. Researchers postulate that the reasons for this over-representation in clinical populations are complex and may represent an actual increase in risk for problems in this population along with a referral bias among parents who, for a multitude of reasons, including higher educational and socioeconomic levels, may be more willing to access mental health interventions for their children. Many of the studies suggesting increased risk fail to differentiate clinical from nonclinical samples, age of children when adopted, and the type of comparison group. Some suggest that the

over-representation statistics in clinical populations may be colored by a small group of very serious cases. Large nonclinical studies have yet to be completed, but the ones that have been done continue to show risk factors for the adopted population, albeit at lower levels. Drug use, antisocial behavior, and school adjustment are compromised, although adopted adolescents have fewer problems with withdrawn behavior and have increased prosocial behavior compared to nonadoptees.

Over the years it has been assumed that the older the child at the time of adoption, the higher is the risk for mental health problems. Studies in the 1990s suggested, however, that, although those children adopted as infants statistically demonstrated fewer behavioral and psychiatric problems, about 25 percent of them did have problems. Having a nonadopted sibling seemed to be a risk factor in these cases. In addition, studies have shown that deprivation in early childhood and later adoption resulted in the highest level of maladjustment. Yet, among these children, more than one fourth of them demonstrated no serious problems as adolescents. Other studies have suggested few problems in those children adopted as infants, and all tend to show increased difficulties in adjustment relative to the age of adoption, with infants showing the least problems and children adopted after the age of 10 years showing the most problems when compared to matched controls.

Comparison groups in adoption outcome research have been problematic as well. If the comparison group is that of nonadopted children from intact families, adopted children show more problems with adjustment. However, adopted children seem to have better adjustment than those raised in foster care or institutions and even those returned from temporary care to families where there is a history of and potentially ongoing impaired parenting. The complex nature of evaluating outcome demands addressing these issues, identifying risk factors that children bring to adoption, as well as risks within the adoptive family, and developing early interventions to help adoptive families and adoptees to address these risk factors early and intensively so as to improve outcome across the population.

Adopted children are frequently the source for research evaluating genetic versus environmental contributions to the development of mental illness. Researchers looking at schizophrenia have demonstrated that adoptees at high genetic risk for schizophrenia may be protected in optimal adoptive environments, whereas those who experience disordered parenting situations are more likely to develop schizophrenia, suggesting complex interactions between genetic and environmental contributions to the manifestation of the disorder.

International Adoptions

The practice of international adoptions has fluctuated over the last several

decades, with a gradual decline over the past 10 years. A recent high was in 2004, when 23,000 children were brought to the United States. More recent statistics place numbers closer around 7,000 to 9,000. Geopolitics play a strong role in the viability of international adoption, and if international relations sour, a large source of children available for adoption may suddenly become unavailable, as illustrated in Russia's ban of United States adoptions in 2013. The serious deprivation in the early lives of many of these children has focused attention on the importance of early childhood experiences. Developmental problems, particularly motor delays, as well as a broad spectrum of medical problems are commonly identified in children adopted internationally, particularly in those reared in orphanages. Approximately 12 percent of all adoptees have at least one chronic disability, twice the rate among all children in the same age range. Overall rates are similar among international and domestic adoptees. However, international adoptees who immigrated to the United States later in life, and consequently experienced longer periods of deprivation prior to adoption, have higher rates of impairment. The country of origin also influences disability status, as rates from children of Russian or Eastern European origin are much higher than those children hailing from China and Korea. Likely this is due to a greater reliance on institutional care in Eastern Europe as well as alcohol consumption rates that are twice as high in Russia as they are in China. All international adoptees should be given a full medical and developmental evaluation within the first 2 weeks after arrival in the United States, with interventions instituted immediately for infections, lack of immunizations, and early intervention for growth and developmental delays. International studies suggest that a large minority have increased mental health problems, particularly in the home setting. Preadoption conditions appear to be more predictive than age of adoption. The longer the child is in a deprived early environment, the greater is the risk for attachment difficulties. Interventions that foster attachment in these high-risk children should be implemented. Evidence suggests that children who are able to establish secure attachments with their adoptive mothers attain better developmental recovery, both cognitive and social, in middle childhood. Most studies show good outcomes for internationally adopted children. Factors that may increase the risk for developing mental health problems include male gender, older age at placement, preadoption care in an orphanage, and placement with a single parent or in a white collar family. The story of international adoption over the last several decades highlights the effect of extreme early deprivation and the possible recovery in developmentally supportive families. It has become apparent that adoptions after 24 months of age in these severely emotionally deprived children complicate recovery. Longer deprivation leads to more significant developmental delays and less complete recovery. In addition, recovery, when it occurs, typically does so within the first 2 years after

placement. The final chapter on long-term outcomes is yet to be written, but the evolving literature suggests that children severely deprived for long periods of time may continue to have problems with oppositional behaviors, attachment difficulties, odd or bizarre behaviors including social behaviors, and language delays. It is obvious that adoption improves the outcomes in many of these severely deprived children, many of whom are beginning to tell stories of the confusing move from their countries of origin, being placed frequently in families who do not speak a language they have ever heard, along with the abrupt discontinuation of any exposure to their language of origin. Those who have age-appropriate competence in their language of origin typically have better outcomes. Examination of the typical developmental process through which these young children adjust to English as a second language warns clinicians against diagnosing selective mutism in these children who are adjusting to a world totally dominated by a new language. Nonetheless, retrospectively these international adoptees seem to balance these confusing and benefit greatly from the more empathic and developmentally appropriate care in their adoptive families.

The Role of the Psychiatrist

Many child and adolescent psychiatrists work intensively in outpatient, inpatient, and residential treatment settings. Some are involved early in the adoption of high-risk children through consultation with schools, child welfare agencies, and juvenile court settings. Although there is little research in the area, case reports identify the need for empathy for both the adoptive parent and the adoptee. Psychiatrists working with adoptive families need to explore their countertransference issues related to adoption, including issues related to abandonment and rescue, which may impair their abilities to work with the dyadic issues in a balanced, empathic, and objective manner. It is imperative that psychiatrists educate themselves regarding the complicated research regarding outcomes to avoid presuming that adopted adolescents will have problems, a practice that may lead to self-fulfilling prophecies. Embarking on a psychotherapeutic process with an adoptee must fully include the parents to increase open communication within the family. At times adoptive parents harbor fears regarding the child's heredity, which may lead to the expectation for negative outcomes. Although without empirical evidence, group interventions for both adopted children and for their families may have potential as effective treatment methodologies. Issues that commonly arise in psychotherapy with adoptees involve problems with self-esteem and fears of additional losses or rejection. However, recent studies have demonstrated the development of good self-esteem in most adoptees. Issues related to curiosity about biological families are common concerns, sometimes leading to the opening of birth records without consent of the

birth parent. Another area of increasing focus relates to the common concern about treatment for attachment problems, which may be too frequently presumed in adoptive situations of early deprivation, causing clinicians to miss other treatable diagnoses. Controversial techniques such as holding have been discouraged by some national organizations. Newer interventions to foster attachment involving group educational programs on sensitive parenting coupled with focused feedback on the interactions between the parent and the child led to better infant outcomes, as well as enhanced parent–child attachments. Although the reality of adoption must enter into the psychotherapeutic equation, psychiatrists are cautioned to integrate issues related to adoption with an overall individualized assessment of the child in the family, avoiding the tendency to ascribe all psychopathology to issues related to adoption. Psychiatrists are obviously more likely to work with adoptive situations in which the children and families are not doing well. It is important to remember that, whereas adoptive status may influence the situation and negative experiences prior to the adoption exert great effect on the outcomes, each family needs to be evaluated thoroughly, and targeted interventions must be implemented in an effort to preserve the family because adoption disruptions in older adoptions are higher compared to adoptions in infancy. Data are difficult to come by regarding disruptions, but overall rates are around 10 percent.

Another consideration regarding treatment is that adolescence is the most challenging time for adopted children for both behavioral and emotional problems, regardless of the stage in life at which the child was adopted. This is partially due to the universal challenges of adolescence, but heightened due to the loss and trauma many adopted children experienced early in life. These experiences resurface during adolescence and can catch the adoptive parent off guard. Many adoptive parents envisioned a “happily ever after” scenario and believed that their love would be enough to help a child process issues related to grief, identity, and early childhood stressors. Consequently, adoptive families are four times as likely to seek counseling services and seven times as likely to seek residential treatment when compared to birth families. Problems may become so severe that a youth is at risk of re-entering foster care or the adoption is legally dissolved. From the limited data available, these outcomes are rare with approximately 10 percent of children who are adopted through the child welfare system finding themselves placed back into foster care. Of that 10 percent, approximately one-third may have the adoption terminated. Another 10 percent have extended disruptions to their living situation such as running away, living with another family member, or having an extended placement in a residential treatment facility or a juvenile corrections facility. As federal policy only began to encourage adoption from foster care in the 1980s and 1990s, postadoption services to families with special needs children are relatively new. They

tend to vary significantly from state to state, and it can prove a challenge to locate all services for families in need. Encouraging families to seek out services which improve their knowledge and skills is vital, as is reminding them that this is a sign of family strength, not parental inadequacy, as so many may believe. Education is where intervention begins and a discussion of the adopted child in light of the impact that early abuse and deprivation can cause will provide a greater understanding of the child, increase empathy, and help them look for ways to provide support and build on a child's strengths to promote resilience. It is also helpful to discuss realistic expectations of a child and to encourage parents to take care of their own well-being to promote better interactions with the child.

Psychiatrists may also work with the biological parents and families of children who have been given up for adoption or whose children have been removed because of abuse and neglect. These persons often have pre-existing psychopathology, which might become more complicated because of removal of their children. In addition, for those whose children are in foster care and for whom reunification is a goal, intensive psychiatric interventions and supports may be the most significant influence on ultimate outcome.

Future Directions

It is clear that for many children and families adoption meets a special need and facilitates a positive psychological outcome. For a minority, psychological adjustment is more challenging. Identifying more specifically the risk factors for less-than-optimum outcomes and developing evidence-based interventions to address critical issues like attachment, externalizing behaviors, and increasing empathic responses of adoptive families to high-risk children is the challenge for the future. Few current interventions take into account the complex nature of repeated trauma, attachment, and identity issues faced by adopted children. Policies that facilitate adoptions earlier when there is little hope for family reunification are imperative to interrupt the prolongation of temporary placements, which increase the risk of bad adoption outcomes. Additional work is also needed to provide adoptive families with post-adoption support to address the needs of the child as they are identified. Egregious policies that remain law in some states, which require adoptive parents to formally "abandon" children in order to obtain residential treatment, call for immediate correction. More needs to be learned about birth parents and optimal management of open adoptions or late reunions, which are becoming more frequent but about which very little is known. Finally, continued efforts are needed consistently to keep the best interests of the child at the forefront in all decisions regarding permanency planning, whether it is related to reunification, long-term foster care, or adoption.

▲ 55.2 Child Maltreatment

WILLIAM BERNET, M.D., AND BRADLEY W. FREEMAN, M.D.

Although the federal government and every state have programs to investigate allegations of abuse, prevent abuse, and educate caregivers, child maltreatment remains a terrible misfortune for millions of children and families. Child maltreatment affects young people of all ages—infants, children, and adolescents—and all social classes, ethnic groups, and religions. For centuries, the recognition of child maltreatment has been compromised by pervasive denial. That is, perpetrators typically deny they abused anybody. Maltreated children sometimes deny they were abused. Mandated reporters and otherwise concerned citizens, such as friends and relatives of the victim, may fail to notice and underreport abuse either purposefully or unwittingly. There are sociological phenomena through which entire communities deny the reality of child maltreatment because denial protects individuals from the awareness of a horrible aspect of life.

A diverse group of professionals—including law enforcement, school personnel, pediatricians, dentists, emergency department workers, pathologists, radiologists, mental health professionals, and attorneys—participate in the identification, protection, evaluation, and treatment of

child abuse victims. There are several roles for psychiatrists and other mental health professionals in these cases. As clinicians, for example, they may provide treatment of children who have behavioral or emotional problems caused by abuse. They may evaluate and treat perpetrators of abuse, many of whom were victims of abuse earlier in their lives. Aside from their role as clinicians, mental health professionals may evaluate children for a forensic or legal purpose. The forensic evaluation may assist the court in determining what happened to the child. In addition, child psychiatrists may be asked to evaluate the credibility of children who may have been abused and the competency of children to testify. In civil lawsuits pertaining to child maltreatment, psychiatrists and other mental health professionals may testify about the nature, extent, and cause of the child's psychological injuries. Finally, mental health professionals may address the problem of child maltreatment on the level of public policy by educating legislators and judges about the psychiatric aspects of abuse and the developmental needs of children.

DEFINITIONS

Fifth Edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5)

The somewhat terse classification system provided by the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) lists *child physical abuse*, *child sexual abuse*, *child psychological abuse,* and *child neglect*. The four mental conditions appear in the chapter "Other Conditions That May Be a Focus of Clinical Attention" and in the section "Abuse and Neglect." These categories should be used when the focus of clinical attention is severe mistreatment of one individual by another. The coding system of DSM-5 allows the evaluator to distinguish each type of maltreatment: confirmed abuse from suspected abuse; an initial encounter from a subsequent encounter; parental abuse from nonparental abuse; whether the abuse previously occurred during the person's childhood; and whether the mental health services are for the perpetrator of parental or nonparental abuse.

Federal Law

The Child Abuse Prevention and Treatment Act (CAPTA) was passed in 1974, and has been amended several times, most recently in December 2010. In federal law, *child abuse and neglect* mean, as a minimum, any recent act or failure to act on the part of a parent or caretaker, which results in death, serious physical or emotional harm, sexual abuse or exploitation, or an act or failure to act which presents an imminent risk of serious harm. In federal law, *sexual abuse* means the employment, use, persuasion, inducement, enticement, or coercion of any child to engage in or to assist

any other person to engage in any sexually explicit conduct or simulation of such conduct for the purpose of producing a visual depiction of such conduct. Sexual abuse also includes rape (and in cases of caretaker or familial relationships, statutory rape), molestation, prostitution, or other forms of sexual exploitation of children, or incest with children.

State Law

A large mass of legal definitions and guidelines exists at the state level. The legal definitions of terms related to the maltreatment of children vary from one jurisdiction to another, so clinicians should be aware of the definitions used in their locale. The following generic definitions are used in this section.

Neglect

The most prevalent form of child maltreatment, *neglect* is the failure to provide adequate care and protection for children. Children can be harmed by malicious or ignorant withholding of physical, emotional, and educational necessities. Neglect includes failure to feed children adequately and failure to protect them from danger. Physical neglect includes abandonment, expulsion from home, disruptive custodial care, inadequate supervision, and reckless disregard for a child's safety and welfare. Medical neglect includes refusal, delay, or failure to provide medical care. Educational neglect includes failure to enroll a child in school and allowing chronic truancy.

Physical Abuse

Physical abuse may be defined as any act that results in a nonaccidental physical injury, such as beating, punching, kicking, biting, burning, and poisoning. Some physical abuse is the result of unreasonably severe corporal punishment or unjustifiable punishment. Physical abuse can be organized by the site of injury: damage to skin and surface tissue, damage to the head, damage to internal organs, and skeletal damage.

Psychological Abuse

Psychological abuse occurs when a person conveys to a child that he or she is worthless, flawed, unloved, unwanted, or endangered. The perpetrator may spurn, terrorize, ignore, isolate, or berate the child. Psychological abuse includes verbal assaults (e.g., belittling, screaming, making threats, blaming, or expressing sarcasm), exposing the child to domestic violence, overpressuring through excessively advanced expectations, and encouraging or instructing the child to engage in antisocial activities. The severity of psychological abuse depends on (1) whether the perpetrator intends to inflict harm on the child and (2) whether the abusive behaviors

are likely to cause harm to the child. In contentious divorces, one of the parents may indoctrinate the child to fear or dislike the other parent, thus causing parental alienation between the child and the rejected parent. Depending on the circumstances, parental alienation may be identified by one or more of these DSM-5 terms: child psychological abuse, parent–child relational problem, or child affected by parental relationship distress.

Sexual Abuse

Sexual abuse of children refers to sexual behavior between a child and an adult or between two children when one of them is significantly older or uses coercion. The perpetrator and the victim may be of the same sex or the opposite sex. The sexual behaviors include touching breasts, buttocks, and genitals, whether the victim is dressed or undressed; exhibitionism; fellatio; cunnilingus; and penetration of the vagina or anus with sexual organs or objects. Sexual abuse may involve behavior over an extended time or a single incident. Developmental factors must be considered in assessing whether sexual activities between two children are abusive or normative. In addition to the forms of inappropriate sexual touching, *sexual abuse* also refers to sexual exploitation of children—for instance, conduct or activities related to pornography depicting minors and promoting or trafficking in prostitution of minors.

Ritual Abuse

Cult-based *ritual abuse*, which includes satanic ritual abuse, is physical, sexual, or psychological abuse that involves bizarre or ceremonial activity that is religiously or spiritually motivated. Typically, multiple perpetrators abuse multiple victims over an extended period of time. Ritual abuse is a controversial concept; some professionals believed in the 1990s that ritual abuse was a common phenomenon, whereas others were skeptical about most allegations and descriptions of ritual abuse.

Perpetrators of Abuse

There is some lack of consistency in who may be defined as an *abuse perpetrator*. Usually, a person must be a parent or designated caregiver to be charged with neglect, physical abuse, or psychological abuse. Another adult (e.g., a stranger) who injures a child would be charged with battery, not with child abuse. However, a caretaker or any other person could be charged with child sexual abuse. State laws vary in this regard.

HISTORY OF CHILD MALTREATMENT

Historical and literary sources have documented child maltreatment for thousands of years in cultures from all parts of the world. Although some forms of abuse were considered deviant or prohibited in particular cultures,

most often the abusive practices were accepted or even encouraged by the societies in which they occurred. The long-term trend in European and American history has been to move from blatant, socially acceptable child abuse to strong societal disapproval. According to Lloyd deMause, at least four historical periods can be identified.

Ancient Period

In the ancient period, adults seduced, violated, and murdered their children in an unashamed and socially acceptable manner. Human sacrifice, including children, was practiced by Greeks, Romans, Celts, Phoenicians, and others. The Hebrew Bible criticizes human sacrifice several times, so it apparently was practiced during that era. Greeks, Romans, and Egyptians commonly practiced heterosexual and homosexual pedophilia. The most notorious sadistic child abusers were the Roman emperors Tiberius, Caligula, Claudius, and Nero.

Medieval Period

In the medieval period, Christianity induced guilt, and parents could no longer abuse their children with impunity. When they did, they asserted they were following God's will. The notion of an incest taboo—a universal prohibition against incest that presumably transcends cultures—is an ironic manifestation of societal denial. Some authors think the opposite is true—that incest has been universal for most people in most places at most times.

Early Modern Period

In the 18th through early 20th centuries, the sense of guilt and shame increased to such a degree that incest and child abuse could no longer be considered acceptable. However, abusive practices continued in the underworld, out of sight of polite society. Infanticide through exposure or poisoning was a long-accepted way to dispose of an unwanted or defective child. Foundling hospitals were established to care for thousands of abandoned babies, but few children survived the dismal routine of institutions. Charles Dickens (*Oliver Twist*, 1837 to 1839) and Victor Hugo (*Les Miserables*, 1862) laced their story lines with social criticism and graphically portrayed man's inhumanity. Dickens, for instance, recorded the inhuman aspect of industrial society, including child battery, debasement of children for sensual or recreational purposes, and starvation and deprivation of the laboring child.

Toward the end of this period, societal awareness of child maltreatment increased. In the 1860s, a French forensic pathologist, Ambroise Tardieu, described severe child abuse after performing autopsies on children who had been beaten to death. Child abuse came to public attention in the United States through the case of Mary Ellen, an 8-year-old girl who was

severely maltreated. She was discovered by church workers in New York City in 1874, but they found the only agency available to help was the Society for the Prevention of Cruelty to Animals. Thus, they founded the Society for the Prevention of Cruelty to Children. In 1875, New York became the first state to adopt a child protection law, which became the model for other states.

Late Modern Period

In the latter half of the 20th century, child abuse became the subject of widespread clinical and governmental concern. Abusive practices were actively identified, rather than ignored and denied. Modern recognition of child abuse was signaled in 1946 by a pediatrician and radiologist, John Caffey, who noticed a syndrome of children with multiple skeletal injuries and chronic subdural hematomas. Until the 1960s, physical abuse of children was considered rare, partly because physical discipline of children was generally more acceptable and partly because of societal denial concerning violence toward children. In 1962, Henry Kempe and his colleagues brought child maltreatment to the attention of physicians and legislators in a historic article, "The Battered-Child Syndrome." Within 5 years, child abuse reporting laws were adopted by every state.

It took a separate societal realization during the 1970s to acknowledge the extent of sexual abuse. Incest was known to occur, but most people believed that it was unusual and happened primarily among deviant families. It is now known that incest and other forms of sexual abuse are not rare.

In 1974, the federal government passed the CAPTA, which established uniform national standards for the identification and management of child abuse cases. Child abuse legislation, originally directed toward case discovery and perpetrator punishment, now focuses on prevention, rehabilitation, and family reunification. Individual states independently define maltreatment, formulate investigative procedures, collect data, and organize service delivery systems.

COMPARATIVE NOSOLOGY

The first edition of the DSM (DSM-I) (1952) and the second edition of the DSM (DSM-II) (1968) made no mention of child maltreatment. The Group for the Advancement of Psychiatry (1974) mentioned child maltreatment among the pathogenic factors of childhood mental disorders: "The deleterious effects ... of open rejection or neglect, occasionally involving willful injury or inadequate feeding, are well documented." However, the Group for the Advancement of Psychiatry did not include child maltreatment in their proposed system of classification.

When the third edition of the DSM (DSM-III) (1980) was published, the

American Psychiatric Association Task Force on Nomenclature and Statistics introduced a chapter called "V Codes for Conditions Not Attributable to a Mental Disorder That Are a Focus of Attention or Treatment." The V Codes, which were modeled on the practice in the ninth edition, clinical modification, of the *International Classification of Diseases* (ICD-9-CM), did not include specific categories for child maltreatment. However, it was intended that child abuse would be coded as a *parent–child problem*, the category used "when a focus of attention or treatment is a parent–child problem that is apparently not due to a mental disorder of the individual (parent or child) who is being evaluated." The DSM-III specifically stated that "an example [of parent–child problem] is child abuse not attributable to a mental disorder of the parent." The emphasis of *parent–child problem* was apparently on identifying perpetrators of abuse, not the child victims of abuse.

The revised third edition of the DSM (DSM-III-R) (1987) provided a similar definition for *parent–child problem*: "This category can be used for either a parent or a child when the focus of attention or treatment is a parent–child problem that is apparently not due to a mental disorder of the person who is being evaluated." However, the example involving child abuse was replaced by "conflict between a mentally healthy adolescent and her parents about her choice of friends."

In the fourth edition of the DSM (DSM-IV) (1994), the title of the chapter changed to "Other Conditions That May Be a Focus of Clinical Attention." In addition, a specific section was introduced, "Problems Related to Abuse or Neglect," which included terms related to child maltreatment. The editors noted that this category was "included because of the clinical and public health significance of these conditions." For the first time, it was possible to diagnose clearly *physical abuse of child*, *sexual abuse of child*, and *neglect of child*. Furthermore, the DSM-IV made it possible to distinguish whether the person being evaluated was the perpetrator of abuse or the victim of abuse. The terminology regarding child maltreatment in the DSM-IV-TR (2000) was the same as that in the DSM-IV.

The fifth edition of the DSM (DSM-5) (2013) includes child maltreatment in the same chapter as in the previous edition, "Other Conditions That May Be a Focus of Clinical Attention." A new section was included titled "Abuse and Neglect." This section encompasses abuse of all persons, young and old. Diagnosing abuse with the current DSM nomenclature has become more specific. The child can be diagnosed as being a victim of *child physical abuse, child sexual abuse, child neglect*, and *child psychological abuse*. It remains possible to differentiate whether the clinical service was for the victim or the perpetrator of abuse. For adults, the provider can indicate if the abuse or neglect is from the individual's childhood history.

Additionally, the diagnoses of parent–child relational problem and child affected by parental relationship distress are also included in the same chapter but under the section titled "Relational Problems." That section includes the language, "In the extreme, these close relationships can be associated with maltreatment or neglect, which has significant medical and psychological consequences for the affected individual." The description of parent–child relational problem in DSM-5 indicates the child is affected in either the behavioral, cognitive, or affective domain.

The tenth edition of the ICD (ICD-10, Version 2007) has a slightly different way of organizing child maltreatment diagnoses. The ICD-10 has a chapter titled "Injury, Poisoning and Certain Other Consequences of External Causes" and a section titled "Other and Unspecified Effects of External Causes." Within that section is a heading for "Maltreatment Syndrome," which includes the following diagnoses: neglect or abandonment; physical abuse; sexual abuse; psychological abuse; other maltreatment syndromes; and maltreatment syndrome, unspecified. The ICD-10-CM (Clinical Modification) includes codes that enhance the specificity of the abuse or neglect diagnosis. For example, the abuse can be coded as either *suspected* or *confirmed* and the type of encounter can be denoted as either *initial* or *subsequent*.

EPIDEMIOLOGY

Each year, the Children's Bureau, an agency within the Department of Health and Human Services, collects data on child maltreatment. The results are published in an annual document called *Child Maltreatment*. The agency estimated that, in 2014, approximately 6.6 million alleged victims were reported to child protective services. Of those reports, 702,000 victims were identified. The substantiated cases were distributed as follows: 75 percent neglect, 17 percent physical abuse, 8.3 percent sexual abuse, and 6 percent emotional/psychological maltreatment. The Children's Bureau estimated 1,580 children died as a result of maltreatment in 2014. Approximately 70.7 percent of these deaths were children younger than 3 years of age. Additionally, 12.2 percent of fatalities had been identified as victims and received family preservation services in the prior 5 years, and 1.8 percent had been removed from foster care and reunited with their families in the prior 5 years.

The data were analyzed for patterns of maltreatment by the sex and age of victims. With regard to the age distribution of victims, the age group from 0 to 1 years of age had the highest victimization rate (24.4 per 1,000 children). The majority of identified child victims were either White (44.0%), Hispanic (22.7%), or African-American (21.4%). African-American children had the highest victimization rate, 15.3 per 1,000, and American-Indian or Alaska Native children had the second highest rate at 13.4 per 1,000 children. The rate of victimization declined with increasing

age of victims; adolescents aged 17 years were maltreated at a rate of 3.5 per 1,000 children.

All of these figures are approximations because the actual amount of abuse is unclear. The reporting of abuse and the annual victimization rate increased during the 1980s and reached a high in 1993 (when the victimization rate was 15.2 per 1,000 children in the population). This increase resulted from greater public awareness and willingness to report child abuse, improvement in data collection techniques by individual states, and local economic conditions that placed a larger number of families under stress. The victimization rate fell after 1993 and reached a low of 9.2 per 1,000 children in 2012.

ETIOLOGY

Physical Abuse

Although child abuse occurs at all socioeconomic levels, it is highly associated with poverty and psychosocial stress, especially financial stress. Child maltreatment is strongly correlated with less parental education, underemployment, poor housing, welfare reliance, and single parenting. Child abuse tends to occur in multiproblem families, that is, families characterized by domestic violence, social isolation, parental mental illness, and parental substance abuse, especially alcoholism. The probability of maltreatment may be increased by risk factors such as prematurity, mental retardation, and physical handicap. In addition, the risk of child abuse increases in families with a larger number of children.

Sexual Abuse

Social, cultural, physiological, and psychological factors all contribute to the breakdown of the incest taboo. Incestuous behavior has been associated with alcohol abuse, overcrowding, increased physical proximity, and rural isolation that prevent adequate extrafamilial contacts. Some communities may be more tolerant of incestuous behavior. Major mental disorders and intellectual deficiency have been described in some perpetrators of incest and sexual abuse.

DIAGNOSIS AND CLINICAL FEATURES

Abused children manifest a variety of emotional, behavioral, and somatic reactions. These psychological symptoms are neither specific nor pathognomonic: The same symptoms may occur without a history of abuse. The psychological symptoms manifested by abused children and the behaviors of abusive parents can be organized into clinical patterns. Although it may be helpful to note whether a particular case falls into one of these patterns, that in itself is not diagnostic of child abuse.

Physically Abused Children

In many cases, the physical examination and radiological evaluation show evidence of repeated suspicious injuries. Abused children display behaviors that should arouse the suspicions of the health professional. For example, these children may be unusually fearful, docile, distrustful, and guarded. However, they may be disruptive and aggressive. They may be wary of physical contact and show no expectation of being comforted by adults, they may be on the alert for danger and continually size up the environment, and they may be afraid to go home.

The literature regarding the psychological consequences of physical abuse and neglect indicates a wide range of effects: affect dysregulation, insecure and atypical attachment patterns, impaired peer relationships involving increased aggression or social withdrawal, and academic underachievement. Physically abused children exhibit a range of psychopathology, including depression, conduct disorder, attention-deficit/hyperactivity disorder (ADHD), oppositional defiant disorder, dissociation, and posttraumatic stress disorder (PTSD).

Physically Abusive Parents

Abusive parents typically delay seeking help for the injuries. The history given by the parents is implausible or incompatible with the physical findings. The parents may blame a sibling or claim the children injured themselves. The characteristics of abusive parents include a history of abuse in their early lives, a lack of empathy for the child, unrealistic expectations of the child, and an impaired parent–child attachment, especially to children who are defective in some way.

Carol, 4 years of age, had a change in her behavior at preschool approximately 3 months after the birth of her sister. Her teacher saw Carol push other children and hit a classmate with a wooden block, causing a laceration of the child's lip. When Carol's teacher took her aside to talk about her behavior, she noticed what seemed to be belt marks on Carol's abdomen and forehead. The teacher reported possible child abuse to protective services. In addition, the family was referred for psychiatric evaluation.

Carol's baby sister was colicky and slept only for short periods of time throughout the day and night. She stopped crying only when her mother held her. Her mother therefore had little time for Carol, and Carol's father took over her care on evenings after day care and on weekends. He began to drink more than usual and became increasingly irritable. The parents argued over the mother's attention to the infant and the requirement that the father take care of Carol. Carol, who was a bright, curious, and talkative child, constantly asked questions and often asked to carry the baby. When refused, she would lie on the floor and have a tantrum. She also began to have difficulty falling asleep and awoke repeatedly during the night. Carol's father was unable to cope with her requests for attention and often told her to "shut up" and slapped her when she continued her demands. On many occasions, he responded to her tantrums or repeated questions by hitting her with his belt.

While protective services monitored the situation, Carol and her parents began a family therapy program that included parenting training and behavioral therapy for Carol, which was coordinated with the preschool. Carol's father attended Alcoholics Anonymous (AA) meetings and stopped drinking. He was able to control his anger at his daughter. Six months later,

Carol's aggressive behavior ceased. She was doing well with peers, was sleeping through the night, and stopped having temper tantrums.

Sexually Abused Children

A variety of symptoms, behavioral changes, and diagnoses sometimes occur in sexually abused children: anxiety symptoms, dissociative reactions and hysterical symptoms, depression, disturbances in sexual behaviors, and somatic complaints.

Anxiety Symptoms. Anxiety symptoms include fearfulness, phobias, insomnia, nightmares that directly portray the abuse, somatic complaints, and PTSD.

Dissociative Reactions and Hysterical Symptoms. The child may exhibit periods of amnesia, daydreaming, trance-like states, hysterical seizures, and symptoms of dissociative identity disorder.

Depression. Depression may be manifested by low self-esteem and suicidal and self-mutilative behaviors.

Disturbances in Sexual Behaviors. Some sexual behaviors are particularly suggestive of abuse, such as masturbating with an object, imitating intercourse, and inserting objects into the vagina or anus. Sexually abused children may display sexually aggressive behavior toward others. Other sexual behaviors are less specific, such as showing genitals to other children and touching the genitals of others. A younger child may manifest age-inappropriate sexual knowledge. In contrast to these overly sexualized behaviors, the child may avoid sexual stimuli through phobias and inhibitions.

Somatic Complaints. Somatic complaints include enuresis, encopresis, anal and vaginal itching, anorexia, bulimia, obesity, headache, and stomachache.

These symptoms are not pathognomonic. Nonabused children may also exhibit these symptoms and behaviors. For example, normal, nonabused children commonly exhibit sexual behaviors such as masturbating, displaying their genitals, and trying to look at people who are undressing.

Approximately one-third of sexually abused children have no apparent symptoms. Most adults who were abused as children have no significant abuse-related symptoms. However, the following factors tend to be associated with more severe symptoms in the victims of sexual abuse: greater frequency and duration of abuse, sexual abuse that involved force or penetration, and sexual abuse perpetrated by the child's father or stepfather. Other factors associated with poorer prognosis are the child's

perception of being less believed, family dysfunction, and lack of maternal support. In addition, multiple investigatory interviews appear to increase symptoms.

Long-Term Consequences of Maltreatment

Many adults who were abused as children have no significant abuse-related symptoms. However, epidemiological studies—such as the Adverse Childhood Experiences (ACE) Study—have shown a link between childhood adversity and adult psychopathology in diverse populations. It is likely this vulnerability is mediated by persistent physical consequences of the maltreatment on the child's developing brain.

Intrafamilial Sexual Abuse

Incest may be defined strictly as sexual relationships between close blood relatives, that is, between a child and the father, uncle, or sibling. Because of increased reporting, sibling incest is an area of growing concern. In its broader sense, incest includes sexual intercourse between a child and a stepparent or stepsibling. Although father–daughter incest is the most common form, incest can also involve father and son, mother and daughter, and mother and son.

Intrafamilial sexual abuse and other sexual abuse that occur over a period of time are characterized by a particular pattern or sequence of steps. Victims of sexual abuse recount a gradual progression of boundary violations by the perpetrator, starting with tiny invasions and escalating to serious, overwhelming intrusions. Healthy, self-confident children rebuff the intrusions directly (via temper tantrums and verbal disagreements) or indirectly (through silence and distancing maneuvers) or by adopting a strategy that causes the offender to refrain.

Sexual abuse that occurs over a period of time evolves through five phases: engagement, sexual interaction, secrecy, disclosure, and suppression.

Engagement Phase. The perpetrator induces the child into a special relationship. The daughter in father–daughter incest has frequently had a close relationship with her father throughout her childhood and may be pleased at first when he approaches her sexually.

Sexual Interaction Phase. The sexual behaviors progress from less to more intrusive forms of abuse. As the behavior continues, the abused daughter becomes confused and frightened because she never knows whether her father will be parental or sexual. If the victim tells her mother about the abuse, the mother may not be supportive. The mother often refuses to believe her daughter's reports or refuses to confront her husband

with her suspicions. Because the father provides special attention to a particular daughter, her brothers and sisters may distance themselves from her.

Secrecy Phase. The perpetrator threatens the victim not to tell. The father, fearful of his daughter may expose their relationship and often jealously possessive of her, interferes with the girl's development of normal peer relationships.

Disclosure Phase. The abuse is discovered accidentally (when another person walks in the room and sees it), through the child's reporting it to a responsible adult, or when the child is brought for medical attention and an alert clinician asks the right questions.

Suppression Phase. The child often retracts the statements of the disclosure because of family pressure or because of the child's mental processes. That is, the child may perceive that violent or intrusive attention is synonymous with interest or affection. Many incest survivors rally around their perpetrators, seeking to capture any modicum of tenderness or interest. At times, affection for the perpetrator outweighs the facts of abuse, and children recant their statements about sexual assault, regardless of substantiated evidence of molestation.

A financially comfortable couple lived in a pleasant, clean house in a nice neighborhood, but they had no friends. Their four teenagers never had visitors. One day, the oldest girl, 17 years of age, went to the police and told them she had a baby at home and her father was the baby's father. The girl said her father had been having sexual relations with her for more than 4 years and he was now doing the same with her younger sisters. The mother admitted knowing about the situation for years, but she had not reported it to the authorities for fear of losing her husband.

Extrafamilial Sexual Abuse

Of course, sexual abuse is not limited to incest. Children may be abducted and sexually abused by strangers. A perpetrator may observe a playground and identify a child who is not closely supervised. A pedophile may molest this child and hundreds of other children before he or she is apprehended. For the child, this is usually a single, isolated experience.

However, children may be repeatedly abused by trusted adults, such as teachers, counselors, family friends, and clergy. In this scenario, the pedophilic perpetrator grooms the child over a period of time. He or she gains the friendship of children through enjoyable activities and gifts, introduces sexual activities that may seem innocent and even pleasurable, and progresses to more intrusive activities. The pedophile encourages secrecy.

A solo sex ring is a form of child sexual abuse that involves one adult

perpetrator and multiple child victims, who may know about each other's sexual activities with the perpetrator. A sex ring may also involve multiple perpetrators and multiple victims.

Neurobiological Aspects of Child Maltreatment

Genetics. Recent research has begun to elucidate the interaction between genetics and environmental factors (referred to as G × E interactions). Although G × E interactions have been studied for nearly a century in biology and general medicine, the mapping of the human genome has made it possible to study complex interactions among specific genes and between genes and the environment. For example, a G × E interaction appears to play an important role in the neurobiological response to childhood maltreatment. In several studies, maltreated male children with a genotype conferring high levels of monoamine oxidase A (MAOA) expression were less likely to develop antisocial behavior as adults. In other studies examining the role of genetics in modulating the response to stress, a functional polymorphism in the promoter region of the serotonin transporter gene (known as *5HTT* or *SLC6A4*) was found to affect the likelihood of developing depression and suicidality in response to stressful experiences. Individuals with one or two copies of the "short allele" were more likely to develop depressive symptoms than were individuals with two "long alleles."

Neuroimaging. Childhood maltreatment increases the person's risk of major depression, substance abuse, anxiety disorders, and PTSD, and maltreated individuals with those disorders tend to have an earlier age of onset, greater symptom severity, more comorbidity, a greater risk of suicide, and poorer treatment response than nonmaltreated individuals with the same conditions. It is noteworthy that imaging findings associated with these disorders—such as reduced hippocampal volume and amygdala hyperreactivity—are observed more consistently in individuals with a history of child maltreatment. Trauma victims who develop PTSD have changes in brain activation that are consistent with the individual's experienced symptoms. For example, individuals with PTSD who report reliving their traumatic events in the form of flashbacks have reduced activation in the medial prefrontal cortex and anterior cingulate cortex (observed on functional magnetic resonance imaging [fMRI]), which is consistent with less regulatory control over affective arousal states. However, individuals with PTSD who experience dissociation when exposed to trauma memories have increased activation in the medial prefrontal cortex and anterior cingulate cortex, which is consistent with robust inhibition of affective arousal states.

Chronic physical abuse and repeated sexual abuse cause changes in the child's developing brain that persist into adulthood. Chronic severe abuse

can lead to a syndrome known as complex PTSD or disorder of extreme stress not otherwise specified (DESNOS). This disorder, which was evaluated but rejected by the Posttraumatic and Dissociative Disorders Sub-Work Group for DSM-5, is characterized by alterations in the following: ability to modulate emotions; attention or consciousness; somatization; self-perception; perception of the perpetrator; relations with others; and systems of meaning. The core of this disorder is a breakdown in the ability to regulate internal states. Trauma exposure changes the way in which children perceive environmental stimuli, especially their perception of threats, and how they organize and process information. Specifically, individuals with a history of trauma are more vulnerable to reacting with subcortically initiated responses that are irrelevant or even harmful in the present situation.

EVALUATION PROCESS

The evaluation of a child or an adolescent who may have been physically or sexually abused depends on its circumstances and context. Practitioners must consider whether they are conducting a forensic evaluation, which has legal implications and may ultimately be used in court, or a clinical evaluation, which is done for a therapeutic purpose. A forensic evaluation emphasizes collecting accurate and complete data to determine—as objectively as possible—what happened to the child. Was the injury an accident, was it self-inflicted, or was it a result of parental abuse? Was the child sexually abused, or was he or she indoctrinated to believe that he or she was abused? The data collected in a forensic evaluation must be preserved in an audio and video recorded format. The results of the forensic evaluation are organized into a report that is read by attorneys, a judge, and others. However, the emphasis in a therapeutic evaluation is to assess psychological strengths and weaknesses, to make a clinical diagnosis, to develop a treatment plan, and to lay the foundation for continuing psychotherapy. The clinician may also be interested in determining what happened to the child, but it is not so essential to distinguish facts from fantasies. Compared with the forensic evaluation, the psychotherapist does not need to keep such detailed records and ordinarily does not prepare a report for court.

In addition to distinguishing a forensic examination from a therapy meeting, a number of factors may affect the evaluation of a child who was abused or may have been abused: whether one is a pediatrician in an emergency department or a child psychiatrist in an office, whether a parent or another person is suspected of the abuse, the severity of the abuse and the victim's relationship to the perpetrator, whether physical signs of abuse are obvious or absent, the age and gender of the child, and the degree of anxiety, defensiveness, anger, or mental disorganization the child exhibits. Often, the examiner must be creative and persistent.

From the psychiatric perspective, the interview is usually the primary source of information and the physical examination is secondary. In practice, children who may have been neglected or sexually abused are interviewed first and are later given a physical examination and other tests. A child who has been physically abused is more likely to have a physical examination that may be followed by a psychiatric interview.

Parent Interviews

The evaluator obtains a history from the parents (separately, in most cases) and other pertinent informants, as well as from the child. The emphasis of the interview depends on the circumstances.

Suspected Physical Abuse. The examiner should consider the possibility that the parents are not telling the truth. The physician becomes a detective because the parents who bring the injured child to the emergency department may also be perpetrators of the abuse. To obtain treatment, such caregivers lie about how the injury occurred.

When the child is brought to the emergency room, a detailed and spontaneous account of the injury should be obtained promptly from parents or other caregivers before secondary details and rationalizations cloud the information provided. The interviewer should allow the caregiver to explain, to expound, to derail, or to detour the story line. An abuser or codependent parent may claim to have happened on the injured child in a coma or bleeding from some unknown trauma or to have noticed significant bruising, burns, or a crooked extremity while bathing the child. Comparing the parents' histories can provide valuable insight into how power is wielded in the family unit.

A 30-day-old girl was transferred from a rural hospital to a university medical center because of supposed near sudden infant death syndrome (SIDS). The child was unresponsive and required mechanical ventilation. A brain scan revealed bilateral subdural hematomas, subarachnoid hemorrhage, and hemorrhage in the parenchyma of the brain. An x-ray skeletal survey showed two posterior rib fractures. An ophthalmologist observed extensive retinal hemorrhages. After the child was admitted to the Pediatric Intensive Care Unit, the child abuse consultant interviewed the parents separately. The mother, 28 years of age, said that she had recently started a new job. The baby had been perfectly fine when she had left her in the care of her live-in boyfriend, the child's biological father. The father, 24 years of age, said that when he checked on the baby, he found her to be not breathing, blue, and unresponsive. He ran to report this to a neighbor and then called 911. The child abuse consultant told the father the child must have been injured in some way and asked whether he had any explanation for this injury. The father said, "I shook the baby after I found her not breathing." The consultant concluded that severe child abuse had occurred and notified child protective services and the local police department so they could initiate and coordinate their investigation.

Suspected Sexual Abuse. In cases of suspected sexual abuse, the examiner should consider the possibility that the parents are not telling the truth. However, this situation is more complex than that of suspected

physical abuse. For example, the mother may wish to avoid the discovery of father–daughter incest by blaming the child's genital injury on another child or a stranger. In another scenario, the mother may concoct an allegation of incest when the child had never been abused at all. The first version protects a father who is guilty; the second version implicates a father who is innocent.

The examiner should determine how the allegation originally arose and what subsequent statements were made; determine the emotional tone of the first disclosure (e.g., whether the disclosure arose in the context of a high level of suspicion of abuse); determine the sequence of previous examinations, the techniques used, and what was reported; try to determine whether the previous interviews were likely to have distorted the child's recollections; review, if possible, transcripts, audiotapes, and videotapes of earlier interviews; seek a history of overstimulation, prior abuse, or other traumas; and consider other stressors that could account for the child's symptoms. The examiner should also ask about exposure to other possible male and female perpetrators.

In Either Case. Whether physical or sexual abuse is involved, a pertinent psychosocial history should be collected and organized, including the following:

1. Symptoms and behavioral changes that sometimes occur in abused children.
2. Confounding variables, such as psychiatric disorder or cognitive impairment, which may need to be considered.
3. Family attitude toward discipline, sex, and modesty.
4. Developmental history from birth through periods of possible trauma to the present.
5. Family history, such as earlier abuse of the parents, substance abuse by the parents, spouse abuse, and psychiatric disorder in the parents.
6. Underlying motivation and possible psychopathology of adults involved.

Collateral Information

The evaluator should consider requesting collateral information from the following, after obtaining authorizations: protective services, school personnel, other caregivers (e.g., babysitters), other family members (e.g., siblings), the pediatrician, and police reports.

Child Interview

Several structured and semistructured interview protocols have been introduced that were designed to maximize the amount of accurate information and to minimize mistaken or false information provided by children. These approaches include the Cognitive Interview, which

encourages witnesses to search their memories in various ways, such as recalling events forward and then backward. The Step-Wise Interview is a funnel approach that starts with open-ended questions and, if necessary, moves to more specific questions. The interview protocol developed at the National Institute of Child Health and Human Development (NICHD) includes a series of phases and uses detailed interview scripts. The Cornerhouse Forensic Interview Protocol known as RATAC (Rapport, Anatomy Identification, Touch Inquiry, Abuse Scenario, and Closure) is a semistructured, nondirective interview method for alleged victims of child sexual abuse.

Although these protocols may be particularly important in a forensic context, experienced clinicians endorse flexibility and consistent good-hearted behavior by the interviewer. As when seeing any patient, the evaluator must size up the situation and use techniques that are likely to help the youngster become comfortable and communicative. One victim might need a favorite object (e.g., a teddy bear or a toy truck); another might need to have a particular person included in the interview. Some children are comfortable talking; others prefer to draw pictures. An unrelated joke, a shared cookie, or the picture on the evaluator's wall may lead to a disclosure of abuse. Important comments might be made while chatting during the break time instead of during the structured interviews.

Interview Process. The interviewer of the child who may have been abused should remember the following principles:

1. Audio and video record the interview.
2. Use a minimum number of interviews (perhaps two or three), because multiple interviews may encourage confabulation.
3. Avoid repetitive questions, either–or questions, and multiple questions, and try to avoid leading and suggestive questions.
4. Use restatement, that is, repeat the child's account back to the child (which allows the interviewer to see whether the child is consistent and ensures that the interviewer understands the child's report).
5. Conduct the examination without the parent present (if the child is young, consider having a family member in the room).
6. Use an examination technique that is appropriate to the child's age and developmental level, such as drawings and play re-enactment.
7. Determine the child's terms for body parts and sexual acts; do not educate or provide new terms.

Interview Content. The interview should not take the form of an interrogation. The interviewer should note the child's affect while discussing these topics and be tactful in helping the child manage anxiety. Young children may not be able to report all of the relevant information. The examiner should explore the following:

1. Whether the child was told to report or not to report anything.
2. Who the alleged perpetrator was.
3. What the alleged perpetrator did.
4. Where it happened.
5. When it started and when it ended.
6. Number of times the abuse occurred.
7. How the child was initially engaged, and how the abuse progressed over time.
8. How the alleged perpetrator induced the child to maintain secrecy.
9. Whether the child is aware of specific injuries or physical symptoms associated with the abuse.
10. Whether photography or videotaping took place.

The Investigative Interview Protocol. The usual clinical interview may need some modification for evaluating a child who may have been abused. The Investigative Interview Protocol, which was developed at the NICHD, consists of the following components: introduction, rapport building, training in episodic memory, transition to substantive issues, investigating the incidents, eliciting information that has not been mentioned by the child, collecting information about the disclosure, closing the interview, and concluding with a neutral topic.

INTRODUCTION. The interviewer introduces himself or herself and explains in general terms the purpose of the meeting. The interviewer explains the importance of telling the truth. The child can say, "I don't understand your question" or "I don't know." The child can correct the interviewer if the interviewer makes a mistake.

RAPPORT BUILDING. The interviewer encourages the child to talk about the child's activities and interests but avoids focusing on television, videos, and fantasy.

TRAINING IN EPISODIC MEMORY. Asking the child to describe two specific past events assesses the child's memory and models the form of the interview for the child. Using nonleading, open-ended questions, the interviewer asks the child to tell everything that happened on two specific days. The interviewer trains the child to give a free narrative account, which is the pattern through the rest of the interview.

MAKING THE TRANSITION TO SUBSTANTIVE ISSUES. The interviewer asks the child to focus on the reason for the interview by making a nonleading statement such as, "I understand that something may have happened to you. Tell me everything that happened from the beginning to the end."

INVESTIGATING THE INCIDENTS. The interviewer starts with open-ended

questions, such as "Tell me everything about what happened." If the child describes a specific incident, elicit additional information in a nonleading manner by saying, for example, "You mentioned [a particular activity]. Tell me everything about that." After posing open-ended questions, the interviewer proceeds with focused questions that relate to information already mentioned by the child. For example, "You mentioned a friend was there. What was her name? What was she doing?" This process of investigating the incidents is repeated, which are typically "the last time," "the first time," and "another time that you remember well."

ELICITING INFORMATION THAT WAS NOT MENTIONED BY THE CHILD. The interviewer may proceed with direct questions only if he or she has tried other approaches and forensically important information is missing. For example, "When you told me about the time in the kitchen, you mentioned the man took off his pants. Did something happen to your clothes? Tell me all about that." The interviewer may need to formulate a direct question by making use of outside information. For example, "I heard you told your mother that something happened at school. Tell me everything about that."

OBTAINING INFORMATION ABOUT THE DISCLOSURE. The interviewer wants to know how the child came to disclose the alleged abuse. Using nonleading questions, the interviewer may say, "Tell me what happened after [the last incident]" and "Does anybody else know what happened?"

CONCLUDING THE INTERVIEW. At the end of the interview, the interviewer says, "You have told me lots of things today, and I want to thank you for helping me." The interviewer may also say, "Is there anything else you think I should know?" and "Are there any questions you want to ask me?" The interviewer should not compliment the child with comments such as, "You were very brave to talk about those things that happened." The interviewer may conclude with a discussion of a neutral topic, such as, "What are you going to do today after you leave here?"

Extended Forensic Interview. In typical child abuse investigations, a single-session forensic interview model is widely recommended by Child Advocacy Centers across the United States. Interview protocols, which try to define the ideal single-session interview, assume the child is a willing and able participant who can provide a significant account of the alleged abuse. If the single interview results in an equivocal account of abuse, the interview is flawed, or the details need further clarification, another interview following the same protocol may be required. These single-session interviews may not suffice for children who have difficulty relating to a stranger about emotional, traumatic information. Such children may benefit from a multisession interview process.

An extended forensic interview (EFI) model was investigated by the

National Child Advocacy Center to help determine if such a protocol would be superior to the single-session model for certain children. It was investigated for use in children who either (1) did not disclose but there was other compelling evidence for abuse such as medical findings, (2) the child was unable to provide a full disclosure during the single interview, and (3) the allegations remain unresolved (founded or unfounded) after the single interview. It was determined through field trials at multiple sites that a six-session EFI was the most efficient model. The results from the field testing showed the EFI had utility and had an equal rate of court outcomes as the single interview model. Thus, for single-session forensic interviews that may have initially been unfounded, the EFI helped to resolve the ambiguity surrounding the allegation in almost two-thirds of cases. Like other interviews, the EFI should be electronically recorded.

PHYSICAL EXAMINATION

A forensic medical examination is usually performed by a pediatrician, preferably one with special expertise in child abuse. No part of the human anatomy is unrelated to the question of possible child maltreatment. Fingernails, hair, oral cavity, eardrums, skin surfaces, clothing, and genitals must be assessed, and the results must be recorded. A comprehensive examination must direct attention to all aspects of the victim's health status, including maturity and developmental assessments, dental care, immunizations, and the review of systems.

Damage to the Skin and Surface Tissues

Bruises, burns, bite marks, abrasions, and lacerations should be noted. Harsh punishment of the child may produce bruised lower back and buttocks, slapped cheeks, pinched earlobes, and choke marks about the neck. Injuries resulting from abusive toilet training may include pinch bruises on the penis or scrotum and perineal burns. Feeding-related injuries generate lacerations to the oral cavity and labial frenulum tears. Choke marks may be attributed to attempts at cardiopulmonary resuscitation (CPR). Sharp-bordered, rectilinear bruises may reflect strap marks; these markings can cover an entire body surface and can leave buckle or eyelet impressions.

The human hand leaves various impression patterns. Grab and pinch marks are diagnosed by bruise-colored fingerprints. Negative imprints of fingers are slapping injuries, whereas oval-shaped bruises may result from grabbing during violent shaking. Human bites cause distinctive, paired, crescent-shaped bruises. The age of the biter can be determined by measuring the point-to-point distance between the center of the third tooth on each side (the canines). A distance of more than 3 cm suggests permanent teeth and, hence, an adult or a child older than 8 years of age.

Dating the onset and duration of bruises is problematic. As bruises age and resolve, the skin coloration passes through several hues, including red, blue, purple, green, yellow, and brown. The timing and coloration may be affected by variables such as the depth of the bruise and the amount of bleeding into the bruise. Although characteristic bruises indicate abuse, child abuse may occur without bruising. In particular, most children with fractured bones caused by inflicted injuries do not have an associated bruise.

Immersion burns generate a saved-and-scorched pattern, typically designated as *stocking/glove* or *donut distribution* burns. The skin pressed against a tub filled with scalding water is protected from the heat and remains unburned. Skin in direct contact with the water is scalded.

A 16-month-old boy was brought to the hospital emergency room because of burns from scalding water. The child had patches of erythema on his abdomen, down the sides of his legs, and on the medial aspect of his upper arms. The diapered area had been protected from the heat. While the emergency room staff proceeded with their assessment and treatment, the child abuse consultant interviewed the parents separately. The father reported that he had been trying to heat a baby bottle by placing it in the bathtub and running hot water on it. The father returned in a few minutes and found the toddler, who apparently had climbed into the tub, in approximately 2 in of hot water. The mother confirmed she had been busy and had asked the father to heat the bottle in the bathtub. The consultant thought the pattern of the burns was consistent with the story; the pattern did not look like that seen in forcible submersion. Although the parents' accounts were unusual, they corroborated each other and were consistent with the injuries. The consultant concluded that this was not likely to be child abuse but might constitute negligence. The consultant notified child protective services.

Damage to the Head

Damage to the head includes scalp hematomas, lacerations, brain injuries, and whiplash. Head trauma is a worrisome injury. Even minor insults to the head prompt most caregivers to seek immediate medical attention. More than 95 percent of serious intracranial injuries sustained in the first year of life result from physical abuse. The cause of injury, typically, is violent shaking, to-and-fro whiplash, or slamming. Retinal tearing and hemorrhage may be caused by shaking injuries. Subdural bleeding ranks among the most dangerous inflicted injuries, often resulting in death or serious crippling sequelae. Falls are often blamed for injuries, and a fall of from 1 to 3 feet can result in linear skull fracture and epidural hematoma. Such falls rarely result in subdural hematomas or clavicle or humerus fractures.

Inflicted black eyes are more common than serious eye injuries. Victims smacked about the eyes with an open or closed hand have both eyelids swollen with massive bruising. Generally, black eyes sustained from accidents involve trauma to one eye. Although other scenarios are possible, the onset of bilateral black eyes immediately after facial trauma generally indicates intentional injury.

Traumatic alopecia and subgaleal hematomas are caused by pulling the hair. Alopecia areata (noninflammatory hair loss) is characterized by loose hairs at the periphery of the bald area and is easily distinguished from inflammation or boggy swelling of the scalp caused by violent lifting of the child by the hair. Subgaleal hematomas may result when the aponeurosis connection between the occipital and frontalis muscles is wrenched off the calvaria, permitting rapid filling of the remaining space with blood.

Damage to Internal Organs

Rarely does a child sustain cranial and abdominal traumas from a single innocent fall. Significant abdominal blunt trauma should be suspected in an atypically still child because intra-abdominal injuries are the second-most-common cause of death in battered children. Damage to internal organs includes blunt trauma to the chest; bruised abdominal organs; occult liver lacerations; duodenal hematoma; pancreatic contusion or laceration; superior mesenteric artery laceration; and spleen, kidney, and bladder rupture.

Skeletal Damage

Skeletal damage is usually documented with x-rays taken immediately and also, if necessary for better definition, repeated approximately 2 weeks after the injury. The most distinctive radiological features of infant abuse are metaphyseal lesions, called *corner fractures* or *bucket-handle fractures*, depending on the perspective of the x-ray. In addition to metaphyseal lesions, the following are highly specific for child abuse because they are unlikely to occur accidentally: posterior rib fractures, scapular fractures, spinous process fractures, and sternal fractures. The following are considered moderately specific for child abuse: multiple fractures, especially when they are bilateral; fractures of different ages; epiphyseal separations; vertebral body fractures and subluxations; fractures of the fingers; and complex skull fractures. Radiologists are astute at locating evidence of trauma and can provide insight into causality and patterns of old, healing, or new fractures. A child may not report a fracture if more injuries are likely to result after disclosure.

Intoxication and Poisoning

Psychotropic and analgesic medication, alcohol, and illicit drugs have all been used by adult abusers to render a child or adolescent more susceptible to assault and less capable of offering accurate witness account. There have also been reports of administration of the following: salt; ipecac; laxatives; acetaminophen and aspirin, which are readily available; prescribed medications, including insulin; and water to the point of intoxication.

Physical Findings of Sexual Abuse

Labial and perineal tissues that are susceptible to friction-induced traumas manifest abrasions, contusions, lacerations, petechiae, and edema. Examination may reveal bloodied tissue, genitorectal tears, and infected secretions. The genital examination should be performed by practitioners with training and experience in interpreting and documenting findings.

Scarring after sexual abuse may be minimal or not evident if vaginal penetration has been gentle, consensual, or gradual. Vaginal and rectal tissues rapidly heal after injury, and abrasions can be repaired within several days. Thus, the lack of physical findings may indicate a return to normalcy after rapid healing of minor lesions or trauma perpetrated in a manner that left no material evidence. In other words, a normal genital examination does not mean the child was not sexually abused. Most victims of child sexual abuse have a normal or nonspecific genital examination.

Major insults to the penile head (scaldings, amputation) produce noticeable scars. Penile strangulation with a ligature may be inflicted as a response to enuresis. The more common traumas (e.g., hematomas, abrasions, and lacerations) are superficial injuries and heal rapidly without scarring.

Anal findings include dilation with loss of anal-rectal tone, flattened rectal rugae, lacerations, and wedge-shaped and linear scars. Acute trauma may result in swelling and spasm secondary to submucosal hemorrhage. Most rectal injuries, massive or minor, heal quickly and nearly completely, leaving little evidence of abuse. Minor but persistent irritants, such as pinworms, lichen sclerosis, atopic dermatitis, and rare hematological disorders, can be longer-standing rectal irritants and may confound examination outcomes.

SPECIAL TESTS AND LABORATORY EXAMINATION

An unconscious child or a child with a suspected head injury should have a computed tomography (CT) scan of the head. If the x-ray skeletal survey is negative but there is a high suspicion of abuse, the clinician may consider radionucleotide bone scan or bone scintigraphy. This technique is more sensitive than x-rays in detecting evidence of soft tissue trauma, as well as bone trauma, in child abuse.

When sexual abuse is suspected, the victim requires evaluation for sexually transmitted diseases (STDs). If the examination occurs within 72 hours of the alleged abuse, the clinician should consider cultures of the genital, anal, and oral mucosa. The following STDs are essentially diagnostic of child sexual abuse, unless they were acquired perinatally: gonorrhea, syphilis, and *Chlamydia trachomatis*. Positive serology for the human immunodeficiency virus (HIV) is diagnostic of child sexual abuse, unless it was acquired perinatally or by blood transfusion. The following

STDs raise suspicions of child sexual abuse and should ordinarily be reported to protective services: herpes simplex virus in a genital location, unless there is a clear history of autoinoculation; condylomata acuminata or anogenital warts, except that infants and young children may acquire anal and genital warts perinatally; and *Trichomonas vaginalis*.

Of course, pregnancy is diagnostic of child sexual abuse, as is the presence of semen or sperm acid phosphatase.

DIFFERENTIAL DIAGNOSIS

Physical Findings

Pediatricians who examine children who may have been abused must consider a wide range of congenital, infectious, toxic, and traumatic conditions in their differential diagnoses. The following examples are not meant to be exhaustive.

Conditions Manifested by Skin Lesions. A mongolian spot—a birthmark—may look like a bruise. Lichen sclerosis may look like sexual abuse. Chicken pox and impetigo may look like cigarette burns.

Conditions Manifested by Bone Abnormalities. Osteogenesis imperfecta, congenital syphilis, copper deficiency, and rickets must be considered. CPR sometimes causes rib fractures. However, the physical mechanics of CPR causes lateral rib fractures, whereas child abuse typically causes posterior rib fractures.

Conditions Manifested by Bruises. Vitamin K deficiency from liver disease, salicylate toxicity, bleeding disorders, and erythema multiforme must be considered.

Conditions Manifested by Eye Hemorrhages. Valsalva's maneuver causing increased intracranial pressure and hypertension must be considered.

Self-Inflicted Injuries. Scratches from itchy irritations, factitious illness, head banging, and Lesch–Nyhan syndrome must be considered.

Psychiatric Considerations

The psychiatric evaluation of youngsters who may have been abused may involve assessing the patient's credibility. Although children generally tell the truth when they talk about abuse, sometimes children make false denials (saying that they were not abused, when actually they were) or false allegations (saying they were abused, when actually they were not).

Possible Explanations of Denials of Abuse. A false denial or retraction may occur for several reasons. The child may have been pressured by the perpetrator or family members to recant the allegation. The pressure may consist of bribery, mockery, or threats of injury. The child may be protecting a parent or other family member, even without external coercion (i.e., the child takes on this responsibility through role reversal). The child might be frightened or distressed by the investigation and may decide to withdraw participation. For instance, an interviewer could induce a false denial by asking overly challenging questions. A child may be inhibited by shame or guilt; the child may mistakenly assume responsibility for what happened. Finally, the child may have accommodated to the abuse, consciously or unconsciously, instead of objecting to it.

Possible Explanations of Allegations of Abuse. A false allegation of abuse may occur for several reasons.

ALLEGATIONS ORIGINATING WITH ADULTS. Sometimes a false allegation arises in the mind of a parent or another adult and is imposed on the child.

Parental Misinterpretation and Suggestion. The parent may have misinterpreted an innocent remark, a neutral piece of behavior, or a benign physical condition as evidence of abuse and may have induced the child to endorse this interpretation. This happens in child custody disputes, as well as in other settings.

Parental Delusion. The parent and child may share a *folie à deux*, or the child may simply give in and agree with a delusional parent.

Parental Indoctrination. A parent may have fabricated the story and may have induced the child to collude in presenting it to the authorities.

Interviewer Suggestion. Previous interviewers may have asked leading or suggestive questions. An interviewer who believes abuse occurred may unwittingly shape a child's responses until the child validates the interviewer's assumptions.

Group Contagion. In epidemic hysteria, people modify what they have heard to meet their emotional needs. Thus, rumors may become more convincing as they are retold.

UNCONSCIOUS OR NONPURPOSEFUL MENTAL MECHANISMS IN THE CHILD

Fantasy. A younger child may confuse fantasy with reality.

Delusion. Although rare, older children and adolescents may experience delusions about sexual activities in the context of a psychotic illness.

Misinterpretation. Sometimes children misunderstand what happened and

later report it inaccurately.

Miscommunication. The child may misunderstand an adult's question, and the adult may later misinterpret or take the child's statement out of context.

Confabulation. Children fill gaps in their memory with whatever information makes sense to them and others at the time.

CONSCIOUS OR PURPOSEFUL MENTAL MECHANISMS IN THE CHILD

Pathological Lying. Also called pseudologia phantastica, this refers to children who tell stories with such zeal that they may become convinced of their truth.

Innocent Lying. Children may make false statements because that seems to be the best way to handle the situation. Developmentally, this is more likely to happen with younger children.

Deliberate Lying. Children may choose to avoid or to distort the truth for some personal advantage. This happens more with older children and adolescents.

PERPETRATOR SUBSTITUTION. The child may have been sexually abused and may exhibit symptoms consistent with abuse but may identify the wrong person as the perpetrator, resulting in a false allegation. The child may do this to protect the actual offender, or the child may displace the memories and accompanying affects onto another individual.

Possible Explanations of Allegations of Ritual Abuse. Other phenomena may be mistaken for cult-based ritual abuse, including pseudoritualistic abuse, psychopathological repetitive abuse, sexual abuse by pedophilic sex rings, false memories of abuse, and hoaxes.

The parents of a 9-year-old boy were divorced, and he spent the summers visiting his father. When he returned from visitation, the mother noticed injuries: A healing cut on the boy's right ear and a collection of superficial, vertical scratches from his umbilicus to his pubis. She had the boy disrobe and took digital images of his abdomen. Several days later, the mother took the boy and the images to the boy's regular psychotherapy appointment. She told the therapist that she was concerned the boy had been physically and sexually abused. The therapist interviewed the boy individually, who explained in a matter-of-fact manner his ear was cut accidentally when he had his hair cut and his abdomen was scratched when he went body surfing at a beach. The therapist concluded the boy had not been abused and reassured the mother. The therapist did not notify child protective services.

SPECIAL ISSUES

Fetal Abuse

Fetal abuse can be direct or indirect. A mother or a father may directly

attack their fetus through the abdominal wall or via the vagina. The risk is greatest during late pregnancy, when one of the parents becomes disenchanted with the prospect of a new baby. Indirect fetal abuse by failing to protect the fetus from alcohol, nicotine, or drugs is more common. Fetal alcohol syndrome is an important cause of mental retardation in the United States.

Neonatal abstinence syndrome (NAS) is another example of potential maltreatment to a fetus. Newborns who have been exposed to maternal drug use can undergo withdrawal after their birth. This can be due to illicit substance use by the mother or iatrogenic addiction (e.g., maternal treatment of a pain condition with opioid medication). The newborn's symptoms are reflected by the type of substance exposure. Symptoms of NAS encompass high-pitched cry, jitteriness, tremors, convulsions, sweating, fever, mottling, excessive sucking/rooting, poor feeding, vomiting, and diarrhea. A toxicology workup can be done in addition to thorough history taking, although the mother may be reluctant to disclose substance use. It is estimated that 3 percent of the 4.1 million women of child bearing age who abuse drugs will continue to use drugs during their pregnancy. From 2000 to 2009, the rate of infants born with NAS rose from 1.2 to 3.4 per 1,000 hospital births per year. Maternal substance use has both medical and developmental concerns for the newborn as well as legal, health, and economic impact for the mother.

Factitious Disorder Imposed on Another

In *factitious disorder imposed on another* (previously called factitious disorder by proxy and Munchausen syndrome by proxy), a parent, usually a mother, provides a history that fascinates and beguiles family physicians and expert consultants. The mother gives enough data to suggest a serious but poorly understood condition that requires extensive, painful testing. The child is often drawn into the improbable tale out of fear of contradicting the history given by the mother. Professionals become enmeshed in the apparent validity of the history, but no one can verify or witness the extraordinary symptoms that support the pathology of the child's alleged illness. Parents involved in the deception often have narcissistic, histrionic, or borderline personality disorder and thrive on the center-stage position they assume. In families in which factitious disorder by proxy is found, more than one child may be involved consecutively or simultaneously. In extreme cases, children can be killed, seriously injured, terrorized, and experience severe adverse effects from medications or other treatments.

A 12-year-old boy was referred for psychiatric evaluation because of oppositional behavior. The psychiatrist interviewed the youngster and his mother and learned they had an enmeshed relationship and their affect toward each other ranged from loving to embittered. An older

brother had finished school and worked full time but still lived at home. The patient's medical history was unusual, in that the mother claimed the boy had a long history of fainting spells that defied diagnosis. The mother, but no medical professional, had witnessed these spells. The mother was a secretary in a medical practice consisting of neurologists and neurosurgeons, and she had induced her employers to repeatedly work up the child with physical examinations, laboratory testing, and electroencephalograms (EEGs). In fact, one of the neurosurgeons did burr holes to place EEG electrodes directly on the surface of the child's brain. No neurological diagnosis was made, and factitious disorder by proxy was suspected. The child's neurologist said that no further testing would be done and encouraged psychiatric treatment. The psychiatrist helped the patient and his mother achieve age-appropriate psychological separation, and there were no more fainting spells.

Sex Trafficking

Sex trafficking has been likened to slavery by the Federal Bureau of Investigation. Children become involved in the sex trade for different reasons. Some youth are abandoned by their families and turn to prostitution as a means to survive on the street. Others are recruited into the sex trade through forced abduction, pressure from parents, or through connections the parents have with sex traffickers. These children are often taken far from their homes and become unable to develop relationships with peers or adults other than their abusers. It is estimated that almost 300,000 American youth are at risk of becoming victims of the commercial sex trade. The average age in which children enter the trade is between 12 and 14 years for girls and 11 and 13 years for boys.

The use of violence, drugs, coercion, and other methods of manipulation are commonplace among the traffickers. If a youth in the sex trade becomes addicted to drugs, the trafficker can use the addiction as a means of control. The National Center for Missing and Exploited Children created the Child Sex Trafficking Team in 2001 due to the need for specialized services in this area. Training of police officers, detectives, and emergency room staff can help to identify youth involved in trafficking.

Cultural Variations

Parenting practices in US society vary widely. They are partly determined by the cultural heritage of the family, and the cultural context of the alleged act should be considered in evaluating suspected neglect and abuse, including assessing whether the discipline of a child is abusive. Some unusual bruises result from cultural healing practices. Coining or cupping—techniques used in many European and Asian countries—are used to draw toxins from the skin surface and to remove feverish mucus from the system. In coining, a coin is heated in hot oil and massaged against the skin. In cupping, a heated glass cup is used to create suction against the skin. Skin scraping and moxibustion may also mimic physical abuse.

Female Genital Mutilation

Commonly called *female circumcision*, female genital mutilation is performed on an estimated 2 million girls worldwide each year. It is practiced across diverse socioeconomic classes and different ethnic, cultural, and religious groups. Commonly, girls are circumcised between 4 and 10 years of age, but the procedure may be performed on infants, may be postponed until just before marriage, or may be done after the birth of the first child. In some cultures, it is considered part of a ceremonial induction into adult society. Female circumcision, in the mildest form, consists of clitoridectomy—the anatomical equivalent of penile amputation. In its most severe form, total infibulation involves removal of the clitoris and labia minora plus incision of the labia majora to create raw surfaces that are then stitched together. This practice has been widely criticized, including opposition by the World Health Organization and other major health care groups. In the United States, female circumcision is generally considered child abuse. Efforts have been made to educate immigrant communities on the health risks and legal liabilities of the practice. Compromise may be possible by finding a way to satisfy the cultural requirements without using mutilation, such as adopting a nonmutilative ritual incision that results in only small scars on the labia.

Male genital mutilation (circumcision) is not usually considered child abuse, but it does have its critics. Although this simple procedure is one of the most common operations performed worldwide, complications may result such as hemorrhage and infection. Advocates of male circumcision cite research that it is somewhat protective against HIV infection, other STDs, and penile cancer.

Religious Practices

Certain religious practices may be construed as forms of abuse if they are likely to harm children. For example, adherents of Christian Science believe illness should be treated with prayer instead of medical care. As a result, children may sustain chronic illness, disability, or death. This is an area of flux: Some state laws and some courts have allowed parental discretion to withhold conventional medical treatment for legitimate religious reasons, whereas others have not.

Corporal Punishment

Within families, corporal punishment occurs often enough in the United States that it cannot easily be labeled deviant. Physical punishment by parents is permitted in 49 states by either statute or court ruling. Most child and adolescent psychiatrists discourage physical discipline but realize many capable and apparently nurturing parents spank their children. If physical discipline is used as a last resort, parental anger and frustration may exceed acceptable limits. In its most extreme form, a spanking turns

into a beating. After 10 to 20 minutes of such abuse, a child will bleed into the muscles and other tissues of the back, buttocks, and legs and may lose enough blood to die from hypovolemic shock.

Although professionals may disagree about the propriety of parental spanking of children, there is a consensus against the paddling of children by teachers. Professional organizations (e.g., the American Medical Association, the American Academy of Pediatrics, the Society for Adolescent Medicine, and the American Academy of Child and Adolescent Psychiatry) have gone on record favoring banning of corporal punishment as a disciplinary measure in schools. Although almost every developed country has banned corporal punishment in schools, it is still allowed in more than 20 states, especially in the southeastern United States. New Jersey and Iowa are the only two states that have banned physical punishment in both public and private schools. Within the welfare system, 49 states have prohibited physical punishment in foster care settings.

Teamwork

It is draining to establish rapport, to delve into hidden agendas, to uncover covertly presented data, to address multiple human needs, and to meet the legal obligations associated with child abuse cases. Clinicians are thus encouraged to participate in a multidisciplinary team. Team participation provides consultation and professional support essential for continued health, hope, and positive social interactions within the grim realities of case discovery.

In cases of suspected child abuse and neglect, the physician should make an assessment based on a history, a physical examination, a skeletal survey (when indicated), and photographs; should request appropriate surgical, medical, and psychiatric consultations; should diagnose the suspected maltreatment; and perhaps should secure the child's safety by admitting the child to a hospital. Usually, other members of the multidisciplinary team report the case to the appropriate child protection agency, provide skilled nursing, maintain security, arrange out-of-home placement, arrange a program of care for the child and the parents, and arrange for social service follow-up. These activities, taken together, should be a coordinated team effort. One feature of the team activity is regular meetings of the child abuse committee.

REPORTING LAWS AND PRACTICES

In every state, the District of Columbia, and all areas controlled by the federal government (e.g., military bases), physicians are required to report child abuse to the police or the appropriate child protection agency. The typical statute says a physician who has "reason to believe" or "reason to suspect" child abuse is required to report it. In most states, other

designated individuals, such as nurses, psychologists, school officials, police officers, district attorneys, and providers of child day care and foster care, are also required to report child abuse.

Underreporting

A significant factor in reporting errors is the failure of clinicians and other mandated reporters to consider child maltreatment in the differential diagnosis of child injuries. Frequently, mandated reporters fail to pursue the diagnosis of child maltreatment because of diverse cultural and socioeconomic factors. Lack of experience in dealing with the issues and the judicial quagmire that result when reporting many child maltreatment cases are also an important deterrent. Underreporting of abuse also occurs when well-meaning but misguided therapists attempt to monitor and to treat their abusive clients without involving the proper authorities. Some therapists think they are above the law; others simply have no idea what the law says about reporting child abuse. Perhaps the most important barrier to seeing and reporting abuse is denial. Reporters, both professionals and laypersons, are repulsed by the reality of child maltreatment and cannot accept the thought that abuse exists or is perpetrated by individuals like themselves, persons who in addition might not regret their harmful actions. The most obvious negative consequence of underreporting is the abused child and siblings are left in dangerous circumstances and are vulnerable to further abuse.

Overreporting

Although physicians are required to report abuse when they have reason to believe or to suspect (depending on the jurisdiction) it occurred, they are not required to report other people's beliefs or suspicions. Some clinicians have the mistaken idea that, if a mother expresses a concern that her child may have been abused, the suspected abuse must be reported, even when the clinician has investigated and has no suspicion that abuse occurred (e.g., an overly anxious mother who imagines her child was sexually abused at day care, even though an objective examiner found no indications abuse had occurred). The negative consequences of overreporting include increasing the load on an already overburdened child protective system and an unnecessary invasion into the lives of families, who are subjected to investigation, suspicion, and criticism.

TREATMENT

Child

The first part of the treatment of child abuse and neglect is ensuring the child's safety and well-being. The child may need to be removed from an abusive or neglectful family to ensure protection but emotionally may feel

even more vulnerable in an unfamiliar setting. Because of the high risk of psychiatric symptoms in abused and neglected children, a psychiatric evaluation is in order. Along with providing specific treatments for any mental disorders present, the therapist may have to deal with the immediate situation and the long-term implications of the abuse or neglect. Psychotherapeutic issues to be addressed with an abused child include dealing with the child's fears, anxieties, and self-esteem; building a trusting relationship with the therapist in which the child is not exploited or betrayed; and gaining a perspective, over time, of the factors that contributed to the child's victimization. These issues may be addressed in individual or group psychotherapy or both.

The intensity and duration of treatment depend on the severity of the symptoms. If an abused child has no posttrauma symptoms, it probably is adequate to provide a few counseling sessions that include psychoeducation and anticipatory strategies for recognizing problems in the future. For a child who has been minimally assaulted (e.g., a relatively innocuous single episode of fondling by a stranger), it may be adaptive for the child to forget the incident and to move on.

Abused children who have mild to moderate psychological symptoms have been treated with a form of cognitive-behavioral treatment that has four components: psychoeducation, anxiety management, exposure, and cognitive therapy. *Psychoeducation* includes teaching the child and the caregivers about the nature of maltreatment, offenders, and strategies to avoid future abuse. *Anxiety management* includes teaching children how to use relaxation and other coping strategies to reduce fearful responses to memories and reminders of abuse. *Exposure* refers to talking, drawing, or writing about the abuse experiences. It is usually helpful to have the child share the painful, ugly details of the abusive experiences with the therapist. This may take time and may require therapeutic creativity and flexibility. Although some children may be able to relate the bad things that happened through ordinary conversation, other children may need a variety of play, artistic, or other projective techniques. Some children avoid the painful memories through conscious (suppression) and unconscious (repression) mechanisms. *Cognitive therapy* techniques are used to help the child replace cognitive distortions about the event or negative feelings about himself or herself.

Abused children and adolescents with very severe symptoms (such as complex PTSD or DESNOS) require extensive treatment. These victims of abuse have been treated with a multimodal approach, including specific psychotherapies such as dialectical behavioral treatment (DBT), psychotropic medication, and perhaps hospitalization or residential treatment.

Parents

Developing an intervention plan for an abused or neglected child requires assessing the parents' behavior and functioning in several respects. The psychopathology and the prognosis for achieving adequate parenting skills of the abusive parent and the one who allowed the abuse to occur should be assessed. The evaluator should determine whether the parent's dysfunction is confined to this child or involves other children and whether the dysfunction is short term or long term (reflecting a lifelong pattern). The evaluator should assess the parent's willingness to participate in the intervention plan and the availability of personnel and physical resources to implement the various intervention strategies. One must consider the risk of additional physical or sexual abuse if the child remains in the home.

On the basis of the information obtained, several options can be selected to improve the parent's functioning: (1) eliminating or diminishing the social or environmental stresses; (2) lessening the adverse psychological effects of the social factors on the parents; (3) reducing the demands on the parent to a level that is within their capacity through day care utilization or provision of a housekeeper or babysitter; (4) providing emotional support, encouragement, sympathy, stimulation, instruction in parental care, and training in planning for, assessing, and meeting the needs of the child (supportive casework); and (5) resolving or diminishing the parent's inner psychic conflicts (psychotherapy). Some clinics provide group counseling for nonoffending parents.

Incestuous Behavior

The first step in the treatment of incestuous behavior is its disclosure, which means overcoming the denial and collusion of the family members. Usually, the perpetrator leaves the home, or the child is removed by protective services, so incest is not likely to recur. Often, the family does not reunite because the perpetrator is imprisoned or the parents' divorce. In those circumstances in which it is possible for the family to reunite, family therapy is useful to re-establish the group as a functioning unit and to develop healthier role definitions for each member. When the participants experience severe psychopathology, treatment must be directed toward the underlying illness. While the participants are learning to develop internal restraints and appropriate ways to gratify their needs, the external control provided by therapy helps to prevent further incestuous behavior. At times, legal agencies are involved to help enforce external controls.

PREVENTION

Primary Prevention

Measures that reduce the occurrence of child abuse—*primary prevention*—can be classified on the basis of their audience or intended recipient.

Universal interventions targeted to the general public include such strategies as a poster campaign admonishing parents not to shake their babies, warnings about consuming alcohol and drugs during pregnancy, and raising public awareness through the media, civic associations, church groups, and parent–teacher organizations. To some extent, children can be taught to avoid or to resist being abused. However, ultimately, the adults in a community must create safety and security for their children. *Selective interventions are targeted to populations at high risk of child abuse*. In general, for example, there should be less child abuse in a community with fewer single parents (use of birth control and greater involvement of fathers in families) and greater financial security (local jobs and social support systems). Governmental regulations may be helpful, such as the licensing of day care centers and regulations concerning the operation of residential programs for children. Finally, one can sometimes *intervene with specific persons or families that are at high risk*. Counseling and parenting classes may deter parents from being abusive, although this has not been substantiated. Treatment of parents who abuse substances and services for families with a history of spouse abuse may be helpful. Individuals can help friends and relatives who appear stressed and who are struggling with their parenting responsibilities.

Secondary Prevention

Early detection and prompt intervention when child abuse occurs comprise secondary prevention. Education of the medical profession, members of allied health fields, and all who come in contact with children aids early detection. Emergency department personnel, pediatricians, teachers, and counselors have many opportunities to identify abused children. It is hard to know how best to use the limited resources available to child protection agencies. Some critics think too much effort is put into assessing the millions of referred cases, with relatively little attention given to interventions. For instance, an agency might put many hours into collecting information, might arrive at a decision about whether a case is founded, and might engage in expensive legal measures but might offer little or no aid to help a marginal family function better. In general, child abuse and neglect prevention and treatment programs should try (1) to prevent the separation of parents and children if possible, (2) to prevent the placement of children in institutions, (3) to help the parents attain self-care status, and (4) to help the family become self-sufficient. As a last resort, to prevent further abuse and neglect, children may have to be removed from families who are unwilling or unable to profit from the treatment program.

FUTURE DIRECTIONS

When “The Battered Child Syndrome” was published in 1962, the concept

of child maltreatment had a rather narrow scope, that is, physical child abuse. During the half century since that landmark event, the understanding of child maltreatment has grown to include medical, educational, and other forms of neglect; child sexual abuse and the exploitation of children in child pornography; verbal or psychological abuse; observing family violence; the neglect of children in orphanages; and the abuse of adolescents in institutional settings such as residential treatment centers. In the future, the scope of child maltreatment will continue to enlarge and there will be descriptive research regarding less common forms of child abuse, such as factitious disorder by proxy; parental alienation, in which a child of divorced parents loses his or her relationship with one of the parents; and abusive corporal punishment in schools. The phenomenon and consequences of psychological abuse will be studied more thoroughly.

The sequelae of child maltreatment have been studied through retrospective and limited prospective research. The study of psychological abuse will be of particular interest to mental health professionals, especially since both *child psychological abuse* and *spouse or partner psychological abuse* were added to DSM-5. The definitions of these mental conditions refer to "nonaccidental verbal or symbolic acts . . . that result, or have reasonable potential to result, in significant psychological harm . . . ." The research project that addressed adverse childhood experiences (ACEs) took child psychological abuse into consideration, in that two of the ACEs directly reflected child psychological abuse: verbal abuse by a parent or other adult in the household and feeling threatened with physical injury. The ACE researchers found that an emotionally abusive family environment accentuated negative outcomes later in life. Authors from many countries have noted that causing parental alienation in a child—inducing the child to fear or hate a parent, resulting in psychological parentectomy—is a particularly pernicious contemporary form of child psychological abuse.

In the future, there will be systematic studies from an international perspective of child maltreatment, providing information on, for example, child soldiers in Africa, child suicide bombers in the Middle East, child labor in Asia, the trafficking of children and adolescents for prostitution, and the deaths of large numbers of children due to lack of food and medical care.

A major focus of research in the next few years will pertain to resilience. This research will address the question of why some maltreated children manifest very serious psychological and behavioral symptoms, whereas other abused children are free of symptoms both in the short and the long term. At least part of the answer to this question will involve genetic predispositions, specific life experiences, and the interaction between genetic and environmental factors.

In the more distant future, there will be greater understanding of the chain of events by which trauma damages young victims, starting with specific genetic and other congenital vulnerabilities and predispositions that interact with maltreatment and other forms of adverse childhood experiences. These predispositions and experiences lead to changes in cognitive and affective pathways in the brain, which will be observed through neuroimaging. Alterations in the brain will be shown to cause changes in behavioral and emotional functioning, which result in dysfunctional relationships and additional symptoms and disorders. Although society's goal is the primary prevention of child maltreatment, that objective will not be fully achieved. The research outlined here will inform the secondary prevention of the consequences of child abuse, as well as the biopsychosocial treatment of abused children.

▲ 55.3 Children's Reaction to Illness and Hospitalization

SUSAN BECKWITT TURKEL, M.D., JULIENNE JACOBSON, M.D., AND MARYLAND PAO, M.D.

HISTORY

Hospitalization of young children was a rare event before the mid-19th century, as most children were cared for at home, and hospitals were considered unsafe for them. When young children were admitted to early general hospitals their mothers typically remained with them to assist in providing their care. This was routine and met with little opposition. Some hospitals would only admit children on the condition their mothers were present. From the 1850s through the 1880s, hospitals encouraged regular visits from parents and siblings. These visits were viewed as important for the well-being of the sick children. Outbreaks of infectious diseases might temporarily restrict visits, but they were reinstated as soon as possible. Any restrictions on visits would be lifted for seriously ill or dying children. The goal was to create, at least in part, a "homeliness" where children could feel safe and comfortable.

The transformation of the hospital from poorhouse to headquarters for scientific medicine started in the period before the First World War, and had profound implications on medical care, research, and education. The exclusion of parents from the hospital began in the late 19th century, and hospitals gradually restricted parental access and removed toys, pictures, and pets from the wards. These changes reflected changing ideas about the spread of infectious diseases, the growing professionalism of nursing, the development of the specialty of pediatrics, and funding changes for health care. Visitors, including parents and siblings, were restricted or excluded from the children's wards because of the belief that the emotional upset the visits created would be detrimental to the child's recovery. Fear of infection led to banning personal contact between parents and their children, and glass panels were provided so parents could see their children on the ward. The practice of enabling mothers to remain with their hospitalized children never completely disappeared, but mainstream practitioners during this period were unconvinced of the importance of having the mother in the hospital with her sick child.

Nursing was highly regimented during this period, and children and parents often perceived the staff as uncaring. Although pediatric doctors and nurses cared about their patients' emotional well-being, they were taught to be disciplined, professional and scientific, and not to show affection or emotion. Children were traumatized by their illness, by separation from their parents and families, and also by the lack of warmth in the care they received.

Little changed until after the Second World War. At that time the prevailing practices were in conflict with emerging psychoanalytic and developmental theories of the social and emotional growth of children, and new thinking about the child's need for parental interaction and emotional care. John Bowlby, Deputy Director of the Tavistock Clinic in England, established a separation research unit in 1948, which led to his formulation of attachment theory. Bowlby warned that separation or denial of a warm, intimate and continuous relationship with the mother or mother substitute, or maternal deprivation, could have far-reaching effects on the child's character and mental development. Other psychoanalytic studies used hospitalization as an example of the first early separation from home. Psychoanalysts were aware of the lack of integration between the practice of child guidance, psychoanalysis, and pediatrics. The profound emotional reactions of children to physical illness were noted, as was the likelihood that mothers might be unable to make objective observations when they were emotionally upset by the stresses of their child's condition. The need to prevent the negative psychological impact of hospitalization on children was soon accepted by most psychiatrists and some pediatricians, but this did not yet change hospital practice.

James Robertson, a student working with John Bowlby, translated Bowlby's theories into film, starting with "A 2-year-old Goes to Hospital" in 1953. This film emphasized the detrimental effects of an admission that separated a young child from his family, friends, and mother's care. It demonstrated the phases of protest, despair, and detachment (or denial) through which small children pass when isolated from their mothers for a length of time. Robertson illustrated how children who had been left in the hospital exhibited greater behavioral problems when they returned home. His film was widely shown to both professional and lay groups and was instrumental in accelerating change in hospital practice.

Following the efforts of Robertson and others, public outcry led to the formation of a British parliamentary committee, chaired by Sir Harry Platt, which investigated the hospital care of children. The committee's report, "The Welfare of Sick Children in Hospital," published in Britain in 1959, led to the revolution in pediatric hospital care in Britain and other western countries. The committee found that children were expected to conform to ward routines, lie quietly in their cots, and were not allowed to play; their parents were allowed to visit only during restricted visiting hours. The Platt Report recommended unrestricted visiting and accommodation for parents, especially for children less than 5 years old. The committee sought to minimize potential damage caused by the separation of children and mothers and to encourage appropriate stimulation for the child in the hospital.

The recommendations of the Platt report took time to be implemented. Gradually the views of pediatricians and pediatric nurses changed from

those prevailing before the Second World War and became less discordant with the views of child psychiatrists. Pediatricians and child psychiatrists now agree about the significant impact of separation, illness, and hospitalization on children and their families.

The length of hospitalization and the reasons children and adolescents require hospitalization have changed considerably. Children used to be admitted to the hospital for much longer periods than they are today. Changes in morbidity and treatment modalities, along with alternatives to inpatient care such as day surgery, home intravenous antibiotics, ventilators and advances to maintain technologically dependent children at home, have led to shorter and less frequent hospitalizations. The average length of stay has been reduced by almost half and same day discharges have almost tripled in the past 20 years. The leading causes for hospitalization recently have been asthma, gastrointestinal disorders, pneumonia, and seizures; inpatient surgeries have declined as outpatient procedures have increased. Hospitalizations lasting more than 7 days now are likely to be for psychiatric reasons, chemotherapy and treatment of malignancies, or to address complications of procedures or prior treatment.

As survival rates have increased, at least 90 percent of children with chronic conditions now survive to young adulthood. Inpatient hospitalization for children with more common conditions has shifted to outpatient care, leaving proportionally more complicated, chronically ill children in inpatient settings.

Hospitalized children now are significantly medically complex. This small proportion of children account for most of health care expenditures: 20 percent of children with complex chronic illness and children with special health care need account for 80 percent of costs. The prototypical medically complex child has a multisystem disorder, is probably technologically dependent, has frequent inpatient admissions, requires multiple medications, multiple subspecialists, and optimal care coordination across inpatient and outpatient settings. Care is usually provided at tertiary care centers. These children have three times longer lengths of stay, over 10 times greater charges, significantly higher gastrostomy and tracheostomy placements, intensive resource use, and 15 times inpatient mortality. Seriously and chronically ill children are "growing up in the hospital," and the lives of these children and their families may differ considerably from their peers.

Table 55.3–1.
Estimated Prevalence of Chronic Diseases and Conditions in Children Ages 0–20 Years in the United States

	Prevalence Estimates Per 1,000	
Disorder	**1980**	**2007**

Asthma (ages 0–17 years)	20–53	52–127
Juvenile rheumatoid arthritis (ages 0–15 years)		0.1–0.2
Systemic lupus erythematosus (ages 1–12 years)		0.05–0.5
Cystic fibrosis (in Caucasians)	0.2	0.3125
Ulcerative colitis (estimated based on incidence)		0.4–0.5
Crohn disease (estimated based on incidence)		0.7–1.0
Type 1 diabetes	1.8	1.6–2.5
Congenital heart disease (based on data in newborns)	2.0–7.0	8.0–12.0
Pediatric malignancies		0.011–0.014

CONTEMPORARY PEDIATRIC HOSPITALS

Contemporary pediatric hospitals and wards are staffed and structured differently than adult units, and children's hospitals typically include features not found in most adult settings. The physical layout of a children's hospital or pediatric ward is usually designed to facilitate the child's primary caregiver staying with the child. Sleeping arrangements, showers, laundry, and other facilities are made available to increase individual patient and parent comfort and facilitate extended stays with children. Private rooms or conference rooms exist to allow doctors and parents to confer in privacy.

The last 50 years have seen significant changes in the approach to health care for children. Accommodations are now made to encourage visits even from large or extended families, placing the experiences of children and their families at the heart of health care. To decrease stress in waiting areas, toys and activities are available in brightly colored, child-friendly spaces. In order to provide maximum continuity of care, every child may be assigned a primary nurse who will continue to be the child's primary nurse in subsequent hospitalizations. While most large medical centers have hotels nearby for family members, children's hospitals often provide additional settings such as Ronald MacDonald House, where entire families may stay in small, subsidized apartments. Social workers, parent advocates, groups for parents and for siblings, and educational groups provide support to families. Disease-specific summer camps for patients and siblings and other recreational group activities for sick children are characteristically managed through children's hospitals or disease-specific charitable organizations. Parents, initially focused on potentially life-threatening physical concerns, often express deep gratitude for these services later and are grateful for additional support of their child's psychosocial development.

Child life programs have become standard at children's hospitals. They are available on most pediatric inpatient units and are found in some outpatient pediatric settings. Their purpose is to help minimize disruption in a child's development by hospitalization, surgery, or other potentially frightening or distressing medical experiences. Child life specialists provide

recreational activities, often in designated places where children can engage in therapeutic play. Child life specialists help provide information and preoperative preparation and can rehearse useful coping strategies for medical procedures with children. Preoperative surgical preparation programs have been shown to be effective in reducing anxiety, which may improve children's abilities to cope with the stress of a surgical procedure more effectively. The goal is to help children understand their feelings about their experiences in the hospital and facilitate better adjustment.

Emphasis has been placed on minimizing physically painful experiences. Regular assessment of pain in children using age-appropriate measures has been widely implemented, and the use of nonpharmacological and pharmacological techniques suitable for young patients are more standardized and better understood. These changes have been important in further decreasing the stress of hospitalization for children and adolescents.

Education is a major part of each child's life, and hospital schools and teachers are present in most pediatric settings. Some children's hospitals have arrangements with the local school system to provide teachers, and others employ their own. Either way, collaboration with the child's school is important in helping maintain academic progress as much as possible.

Principles of behavior management are typically incorporated into the culture of pediatric units, where staff can play an important role in modeling and encouraging age-appropriate behavioral management by parents. The absence of limits and consequences for misbehavior can be harmful for children, leading to acting out and difficulties in regulation of emotion and behavior. Although mental health professionals have limited opportunities to monitor behavior directly, and cannot substitute for parents and staff on the unit, frequent consultation with psychologists, social workers, and child psychiatrists can be helpful to the care team, to patients, and to families.

Helping children, adolescents, and their families adapt to hospitalization should involve the child, parents, family, and hospital staff. In current family focused models of care, a child's care is planned around the whole family with parents considered integral to the treatment process. Family-centered care has proven to be valuable in helping families and children cope with the stress, fear, and altered parenting roles that accompany a child's illness and hospitalization. While the creation of a nurturing and developmentally sensitive hospital environment is primarily the responsibility of staff, the assistance of family members is essential in establishing structure and maintaining stability for sick children. "Anticipatory guidance" about parenting struggles in and out of the hospital can be helpful. Parents of children with life-threatening illnesses often feel guilty and need support to maintain usual parenting practices. Parents of chronically ill children should be included in discussions with

hospital staff about realistic rules; this leads to increased compliance with daily schedules and consistent behavioral expectations.

Inpatient pediatric care requires constant review by nursing and medical staff as well as by patients and families to remain relevant and effective. While past initiatives have created the current environment of pediatric inpatient care, hospital staff should remain open to adopting additional practices as further studies identify better alternatives.

A CHILD'S UNDERSTANDING AND RESPONSE TO ILLNESS

Sick children are not a homogeneous group. They come to the hospital having had very different life experiences, irrespective of their medical condition. The presence of an acute, life-threatening, or chronic physical illness by itself is insufficient to produce psychiatric problems, but it may make the child more vulnerable to stresses such as conflict and confusion in the family, and may exacerbate any existing psychiatric illness or behavior problems. How a child will react to illness and hospitalization is a reflection of their age and understanding of their situation, their parents' response, and the nature of the illness and its treatment. There is little evidence that greater severity of the medical condition is itself associated with more negative emotional outcomes, but some observations of greater vulnerability for negative emotional response have been made.

Preschool children are hospitalized more than older, and children younger than 7 years are at risk of more frequent and potentially lasting emotional and behavioral problems after hospitalization than older children. The risk of later aggressive and hyperactive behaviors can usually be predicted by the mother's emotional state and the child's premorbid behavior. Baseline internalizing or externalizing behaviors may be the best predictor of increased behavior problems 3 to 6 months after hospitalization, and medically ill children with greater premorbid emotional and behavioral problems have more psychiatric disorders following their illness. When illness is experienced as an insurmountable obstacle or the cause of rejection by loved ones, the child may react with extreme emotional distress, and suicidal ideation and behavior may occur. Overall, 20 percent of children with chronic conditions have behavioral and emotional symptoms, double the rate of the general population.

Conditions that are less visible, have a remitting–relapsing course, or uncertain prognosis may be associated with greater emotional problems. Males with chronic conditions appear to have more emotional sequelae than females. Children with brain damage have poorer overall adaptation to illness, and adopted children and their parents also seem to have more problems with hospitalization. However, the personality characteristics of sociability, flexibility, and physical attractiveness appear to be protective, and may mitigate against more severe emotional problems. Children from families with clear boundaries, the capacity to balance competing family

needs, the ability to maintain flexibility, and the tendency to ascribe positive meanings to life events, fare best.

Chronic and serious physical illnesses involve recurrent separations and frequently upsetting events, which can be distressing to both parents and children. Surgery, medication side effects, procedures, and diagnostic tests can be frightening, confusing, unscheduled, disruptive to sleep, and painful. The burdens of chronic illness are pervasive and may produce chronically stressful situations, resulting in maladaptive behavior, emotional symptoms, and added financial burdens, all contributing to conflict, guilt, and anxiety in the family.

Medical illness and hospitalization can pose serious threats to the developmental process, and impact the physical and emotional environment, disciplinary context, schooling, family life, and the neurobiology of the chronically ill child, and thus profoundly affect cognitive, emotional, social and sexual developmental trajectories. Invasive procedures, separation from family, friends and school, lost opportunities to develop interests, and a diminished sense of self-mastery further complicate development. Environmental restrictions, such as isolation for infection control, and limited activities while in the hospital lead to fewer opportunities to discover personal strengths and weaknesses. Chronically ill children often have difficulty finding something to be "good at" and have trouble feeling confident and competent. Delayed growth and puberty are common in chronically ill children and adolescents, especially when malnutrition, prolonged corticosteroid treatment, or chronic inflammatory processes are prominent. These growth delays typically may have additional negative psychological implications.

Table 55.3–2.
Impact of Illness and Hospitalization

Age	Child's Response	Possible Effects of Hospitalization	Possible Effects of Chronic Illness
Infancy 0–18 months	Unable to understand Fear abandonment Perceive pain	Anxiety and confusion with separation	Decrease access to environment Parents guilt, anger, and grief may interfere with attachment Difficult to establish trust Greater helplessness
Toddler 18 months–3 years	Fear abandonment Little capacity for reasoning or understanding experience	Regression Negativism Restricted activities Important maintain routines Transitional objects help	Delay motor and language development Parental reluctance to set limits Problems with bladder and bowel function
Preschool	Fear mutilation	Fear abandonment	Parental overprotection

3–5 years	Magical thinking Attributes illness and pain to punishment for bad behavior	Fear mutilation Hospital play beneficial	Regression Limited initiative Compromised social skills
School age 6–12 years	Illness punishment for bad behavior or due to own ideas of cause Understand simple bodily structure and function Understand purpose of treatment	Fear pain Benefit from clear expectations and concrete explanations Important maintain roles	Alienation from peers Fewer social interactions Limited activities Parental overprotection
Adolescent 13–18 years	Abstract thinking Understand body processes and implications of illness Understand cause and effect and hypothetical reasoning Comprehend mind-body issues	Fear alienation from peers Value privacy Appearance important Want participate in treatment decisions	Concerned about appearing different from peers Concerned about medication side effects Risk-taking behavior Treatment noncompliance Immaturity and overly dependent on parents

One week after discharge from the hospital, a child often demonstrates increased anxiety about separation, may experience sleep problems, and may be more aggressive. These behavioral changes should quickly resolve as the child adjusts to the return home, but this may not always happen. Repeated admissions of children coming from dysfunctional or disadvantaged families are very likely to be associated with emotional and behavioral problems following hospitalization, but all children may be at risk. The most difficult period of adjustment to a hospitalization may be near the beginning, when new and painful experiences and separation are most distressing. Prolonged periods of hospitalization bring the risk of developing maladaptive behaviors. In a meta-analysis of studies of children's behavior after hospitalization, children hospitalized for 2 to 3 days showed more behavioral problems than those hospitalized for longer or shorter periods, and overall, briefer hospitalizations of older children were the least likely to have detrimental effects.

Posttraumatic stress disorder (PTSD) has been described following critical illness and surgery. Serious accidents and hospitalizations following acute physical trauma may be associated with PTSD, while the risk of PTSD in children and parents after simple planned surgery is almost nonexistent. Children and parents after newly diagnosed cancer and children and parents following solid organ transplantation may also be at risk of PTSD. Parental distress and characteristics of the family environment are more correlated with the development of PTSD symptoms in sick children than family composition, course of hospitalization, or the extent of a child's injuries. In contrast, commitment, help, support, and the open expression of feelings in the family can facilitate a child's better adjustment to newly diagnosed cancer and associated intensive medical treatment. Sometimes

the treatment of life-threatening medical illness may be experienced as repeated trauma, which might not impact during or immediately after treatment, but rather appear as long-term effects on affect modulation and interpersonal relationships.

Attempts have been made to mitigate the negative consequences of hospitalization, not only in the way hospitals are structured and function but also in provision of preventative educational or behavioral interventions. In a meta-analysis of a variety of interventions, psychoeducation was generally not effective with younger children, and any benefits from the experimental interventions disappeared by 4 weeks after discharge. Other programs, which focus on increasing parents' knowledge and understanding of the range of behaviors and emotions that young children typically display during and after hospitalization, and which support direct parent participation in their child's physical and emotional care are more effective, and help reduce the mother's emotional stress, depression and anxiety, reduce the child's negative behavioral symptoms, and increase the child's adaptability up to 12 months after hospitalization.

When psychiatric and behavioral symptoms are severe or persistent, a thorough psychiatric assessment, based on multiple brief examinations of the child and information gathered from parents, other family members, hospital staff, and teachers, is needed. A child's biological vulnerability to depression and anxiety may be inferred from a history of previous psychiatric symptoms or psychiatric treatment or from a family history of a mood, anxiety disorder, or other psychiatric disorder. Psychiatric syndromes of adjustment disorder, major depression, anxiety, delirium, and psychosis can be diagnosed in medically ill children and require intervention.

Behavioral and cognitive approaches, such as distraction, guided imagery, and relaxation for reducing procedural distress, are well established in the pediatric hospital setting. Supportive individual and family therapy and cognitive behavioral and family therapy may be useful in reducing anxiety and in providing patients and families with adaptive strategies to use in coping with illness and its treatment. Psychopharmacotherapy may be indicated based on severity and duration of psychiatric symptoms.

RESPONSES TO SPECIFIC ILLNESSES

Another way to evaluate the impact of illness and hospitalization on children and adolescents is to review reports of children's responses to specific disorders. As diagnosis and treatment become more effective, children are living longer and forced to cope with a variety of disorders. Several examples are described below.

Asthma

Asthma, a reversible reactive airway disease triggered by immunological and nonimmunological factors, is the most prevalent chronic illness of childhood, affecting more than 1 in 20 school aged children. While asthma can present at any age, 75 percent of patients present in the first 3 years of life. The sensation of chest tightness, respiratory distress, and anxiety may be particularly frightening to young children, while adolescents with new onset asthma seem to adapt more easily than expected. There is a high comorbidity in asthma with anxiety and depressive disorders, although this risk may be less when asthma is well controlled. Anxiety plays a greater role when a child's symptoms are mild, and it is more difficult to quantify symptoms when asthma is severe. Trouble breathing typically triggers anxiety, and proinflammatory cytokine release is found in both asthma and depression. Maximizing the child's ability to perceive symptoms and to comply with treatment can reduce the morbidity and mortality of asthma.

Rheumatological Disorders

Rheumatological disorders in pediatric patients are typically more severe clinically than the same disorders in adults and may have significant psychiatric and medical consequences. These conditions are treated with potent immunosuppressive medications, steroids, and immune modulators that themselves may be associated with psychiatric side effects. Psychiatric symptoms may also be a reflection of an autoimmune process or related underlying vasculitis, or the psychiatric disorder may be unrelated and coincident. In determining the long-term effects of psychiatric complications of pediatric rheumatological disorders, parental functioning may play a role, and parental distress and maternal depression have been associated with greater behavior problems in the child.

Juvenile idiopathic arthritis (JIA) can lead to social isolation, chronic pain, and skeletal deformities, which may lead to depression, anxiety, low self-esteem and lower quality of life. In studies of children and adolescents with JIA, those with less severe physical disabilities were often more affected psychologically, and more emotional and social problems and pain are noted in children whose parents feel stressed, pessimistic and guilty.

Systemic lupus erythematosus (SLE) in children and adolescents is associated anxiety, depression, and cognitive dysfunction. Pain, fatigue, and depression may be related to the effects of a chronic illness, medications, or to SLE itself. Central nervous system involvement, with both neurological and psychiatric symptoms, occurs in more than half of children and adolescents with SLE, usually early in the course of the disease. Neurocognitive impairment is common, and complaints of memory and concentration problems are frequent even when not documented on neuropsychological evaluation.

Cystic Fibrosis

Survival of patients with cystic fibrosis (CF) has been considerably extended by improved therapy of pulmonary infections, improved nutritional management, and an organized system of centralized care with physicians experienced in caring for the complications of CF. The psychological and social functioning of patients with CF is similar to that of healthy peers until their disease becomes severe and their physical and social activities become increasingly limited. Patients with CF are at increased risk of psychiatric problems, such as depression, and their ability to cope with their disease and comply with treatment are important for their quality of life. The psychological and social problems associated with CF may be intensified during adolescence, when more problems with independence, sexuality, relationships, and noncompliance emerge. It is difficult to develop independence when required daily care is complex and may require assistance, and it is difficult to develop self-esteem when chronic productive cough, physical limitations, and peer relationships are disrupted by recurrent hospitalizations. Boys and girls seem to respond differently: girls seem to have a better body image and to be more distressed coughing in public; and for boys, short stature and pubertal delay may have a greater impact on the quality of life than the issue of shortened survival.

CF is a common indication for lung transplantation. Most transplants are living donor lobar transplants, and are usually performed in adolescents. The mean survival is greater than 10 years posttransplant, which allows recipients to develop long-term goals and plan for independence.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is also often associated with depression and anxiety. Children with a good knowledge of their illness, an internal locus of control, a healthy family climate, and an open social network do well, and can maintain good mental health functioning despite severe illness. Disease severity appears to be a significant predictor of depressive symptoms in adolescents. The relationship between social support and adjustment observed with other conditions is also noted in children with IBD; those with high levels of social support from both family and peers show significantly better adjustment than those with limited support from either source. However, parental depression is associated with greater depressive severity in children more than adolescents with IBD. Cognitive behavior therapy and pharmacotherapy, with fluoxetine most studied, have been shown to be helpful in treating depression in children and adolescents with IBD.

Insulin-Dependent Diabetes Mellitus

Type 1 insulin-dependent diabetes mellitus (IDDM) affects many aspects of everyday living and requires a high degree of personal responsibility to manage effectively. Poor diabetic control in childhood is associated with greater risk of long-term complications and may lead to cognitive difficulties, making careful management more critical. Depression and anxiety are common in children and adolescents with IDDM, and risk is higher during the first year after diagnosis, in those with pre-existing anxiety, and in those whose mothers have psychiatric problems. Adolescence and associated physiological changes of puberty can lead to increased insulin resistance, at the same time peer relationships become more complex and parental supervision may be withdrawn, all leading to greater problems with compliance and glycemic control. There appears to be a direct relationship between the diabetic adolescent's emotional and physical well-being. Adolescent juvenile diabetics, who are considered well-controlled medically, tend also to be well-adjusted at home and with peers, are appropriately independent, and have good self-esteem and a sense of internal control.

Diabetes is associated with increased risk of eating disorders, which are associated with poorer glycemic control and increased risk of diabetic comorbidities. Intentional omission of insulin to lose weight or as form of suicidal behavior may occur with type 1. Similarly some patients with type 2 will intentionally omit oral hypoglycemic drugs to lose weight. Binge eating disorders are also common. Patients tend to deny their manipulation of their diet or insulin, but poor glycemic control, missed clinical appointments, and recurrent episodes of diabetic ketoacidosis or hypoglycemia should lead to suspicion of an eating disorder.

Heart Disease

Depression is common in patients with congenital heart disease, and can exacerbate the physical consequences of the disorder. Children with congenital heart disease may have more medical fear and fear of the unknown, more physiological anxiety, more depression, and more delinquent behavior than the general pediatric population. Those with cyanotic malformations may be at higher risk, which may be further exacerbated by maternal anxiety. Pain and separation from parents is more upsetting to younger children, while older children and adolescents are more focused on their physical status and the long-term implications of their condition. Accommodating to complete heart block and the implantation of a cardiac pacemaker often produces emotional distress; those children and adolescents without psychiatric symptoms who undergo the procedure demonstrate intellectualization, identification with medical personnel, and denial during the medical emergency. Problems in adjustment that occur following cardiac transplantation reflect the patient's previous level of emotional adjustment more than a specific response to the

procedure.

Ventricular assist devices (VADs) have become widely used in the management of end-stage heart failure in children particularly for cardiomyopathy or myocarditis patients. Although overall outcomes are favorable, medical complications are common, especially for children with complex congenital heart defects. VADs are most useful as a bridge to recovery or to eventual transplant.

Surgical Procedures

Some surgical procedures may be more disturbing than others, and children usually have more emotional problems after genitourinary surgery than after tonsillectomy. Although early psychoanalytic studies on the effect of tonsillectomy concluded that this operation was a stressful experience for every child, especially those with a history of previous trauma, currently the majority of children do well. Despite mild adverse behavioral changes in some younger children, more than 90 percent undergo the procedure without negative consequences.

Hemophilia

Hemophilia is an example of an inherited X-linked coagulation defect that serves as an illustration of individual and family response to a chronic and potentially lethal disorder. Most boys and their families adapt well and are able to maintain age-appropriate function at home and school despite their illness. The few who show poor adjustment tend to have over-protective, over-anxious, or guilt-ridden mothers, and the boys respond either with social withdrawal and fear, or with inappropriate recklessness.

Cancer

Cancer is the second leading cause of death for children ages 5 to 14 years and the fourth leading cause of death in adolescents ages 15 to 19 years. Progress in the treatment of pediatric malignancies has led to an increase in the number of children, adolescents and young adults surviving free of neoplastic disease, but this increased survival has come at a price. Survivors may suffer endocrinopathies, growth abnormalities, intellectual decline, neurocognitive and psychosocial dysfunction and increased rates of anxiety, depression, dementia, personality and behavioral disturbances. They also have an increased actuarial risk of developing a second malignant neoplasm. The prevalence rate of psychiatric disorders in children and adolescents with cancer is mixed; ranging from rare to as many as half of the patients with anxiety disorders, PTSD, and depression. Psychological interventions have shown promise in decreasing distress associated with diagnosis and treatment, but have not shown an effect on long-term clinical outcomes. Survivors of childhood malignancies may have impaired quality

of life, compromised social functioning and emotional well-being, including suicidal ideation, and diminished academic and occupational success as adults.

A CHILD'S RESPONSE TO ILLNESS AND HOSPITALIZATION AT DIFFERENT AGES

A child's behavioral response and concept of illness and its causes follow a sequence of developmental stages related to their perceptual ability and cognitive development. This section is specifically limited to a description of a child's response to illness and hospitalization at different ages.

Infants (Birth to 18 Months)

Serious illness and hospitalization separate infants from their parents and sets them in a strange, frightening, unpredictable environment. This can provoke anxiety and confusion putting them at risk of disruption in the development of basic trust. Infants younger than 7 months rarely protest separation from their mothers and seem to accept substitute caretakers in the hospital. They may then appear briefly but dramatically upset upon return home. Infants older than 7 months protest initially, appear uncooperative and subdued in the hospital, and then require a readjustment period upon return home. The more infants are provided with contact and comfort from parents when distressed by illness or hospitalization, the better basic trust can be protected. Infants subjected to unexpected medical procedures may have difficulty forming attachments and become anxious. Repeated exposure to pain and the absence of social stimulation in neonates may affect later pain sensitivity, brain volume, neuroendocrine functioning, behavior, and cognition. If parents are unable to hold and soothe their babies because of the nature of an injury or medical care, the babies are at risk of apathy and withdrawal, the attachment process may be disrupted, and separation anxiety may develop. Infants may then refuse to interact with parents, or become clingy, demanding, and difficult to soothe.

It is important to maintain consistent nursing staff and infant routines, preferably with parents or familiar caregivers in the baby's room. If they cannot stay attempts should focus on maintaining regular times for parental visits. Parents should be encouraged not to leave only after infants are asleep as this adds to an infant's anxiety and distrust. Normal stranger and separation anxiety may become exacerbated by frequent staff changes, so attention to providing familiar affectionate staff on a regular schedule may be helpful. Both parents and babies benefit from staff support.

Parents may need staff to model appropriate interactions and interventions with their baby.

Toddlers (18 Months to 3 Years)

Toddlers' primary developmental goal is to establish early autonomy and separation-individuation from their parents. These tasks require a secure base. They are difficult to accomplish without having first established basic trust, which may not have occurred effectively if the toddler was ill or hospitalized as an infant. Toddlers fear abandonment when separated from their parents or primary caregivers. Like infants, they benefit from maintenance of routines and stable relationships, which support early independence and efforts at developing competency. Transitional objects may be particularly helpful in this age group, so bringing toys, blankets or other familiar objects from home to the hospital or doctor's office may help calm an anxious toddler.

The requirements of medical care can be infantilizing and carry high risk of regression, increased dependence, and negativism. It is easy for parents to become over protective or overly permissive during a toddler's illness and behavior problems may result. If these parenting patterns persist after recovery, tantrums and oppositional behavior increase, which leads to parental anger and threat of rejection, followed by guilt and more permissiveness; a vicious cycle of behavior problems can develop. Providing anticipatory guidance to parents during a toddler's hospitalization and follow-up behavioral management and support after discharge can be helpful.

Preschool Age (3 to 5 Years)

Preschool age children seem to be more upset by hospitalization than older children or infants, but they are the most likely to benefit and respond positively when their environment is supportive. When the child is prepared for hospitalization, parental visits are consistent and parents participate in their child's care during hospitalization, the potential emotionally traumatic effects of hospitalization need not occur.

The preschool age is the period of "magical thinking" when children typically attribute illness and pain to punishment and hospitalization and separation to rejection. Limited understanding and concrete thinking contribute to fears and misconceptions, leading to feelings of guilt and distress. Children this age have a very rudimentary concept of the body and its parts. They fear mutilation, and all parts of the body are considered equally essential. This limited understanding, in association with fears of castration, may cause procedures such as phlebotomy and surgery to be especially terrifying. Children are often unable to articulate their fears. They may not understand adult attempts to describe bodily structures and functions, illness effects, or treatment plans. Children of this age often benefit from preparation for procedures through medical play. When material is presented in a manner congruent with cognitive function, comprehension improves and fear is reduced.

School Age Children (6 to 12 Years)

School age children are typically active and focused. Developmentally, they are working to become secure in their own abilities and accomplishments. During this period they acquire academic and social skills and begin to internalize parental and societal values. School age children, like younger children, often believe that their illness is a punishment for misbehavior. Their strong respect for authority and rules often leads school age children to feel illness or injury is the consequence of not following rules properly. Because their understanding of anatomy and physiology is more complete, children this age have less fear of mutilation than younger children. However, because their thinking remains concrete, they cannot comprehend hypothetical possibilities or complicated explanations. Adult attempts to explain illness, injury, or anticipated medical procedures may be confusing, especially when explanations are complex or abstract. Medical explanations can be easily misunderstood or misinterpreted, leading to confusion and increased fear which the child may be reluctant or unable to disclose. Drawings, photographs and clear explanations at an appropriate cognitive level will better help children understand and master their experiences. It is important to minimize physical pain whenever possible. Difficulty coping with pain, and anxiety about pain, may compromise a child's ability to understand and participate in care. Again, potentially painful or frightening experiences may be less stressful with adequate preparation and explanation. School age children should be encouraged to express their fears, ask questions, and talk about their feelings to engage them in the process and help increase their sense of mastery of their illness.

It is important to maintain routines and relationships for school age children during illness or hospitalization. Children should be supported to meet their responsibilities for school, maintain connections with peers, and participate in as many of their usual activities as possible, even when ill or hospitalized. These older children have an increasing awareness of the personal significance and implications of their illness. The ability to adapt to new, challenging experiences increases with age and expanding cognitive function. Coping with illness and hospitalization may increase children's resilience and teach skills useful in other settings.

Adolescents (13 to 18 Years)

Adolescence is a complex process of transition from childhood to adulthood and is a challenging time for most people. Adolescents' ability to understand their illness, their body and its functions, and the causes, nature, and treatment of their illness expands as cognitive skills increase. As formal operations develop in individuals of normal intelligence, adolescents are able to hypothesize cause and effect, understand

hypothetical suppositions and multifactorial explanations, and participate in decision making and assent/consent for treatment. Adolescents highly value their privacy and confidentiality, and are more skeptical of simplistic explanations or superficial reassurance.

Adolescents are usually aware of the implications of their illness. They may be concerned about its effects on their relationships, fertility and sexuality, and vocational possibilities. They fear the loss of independence and control, and of their sense of physical well-being and integrity. Younger adolescents especially do not want to be different from their peers. They are exquisitely sensitive to changes in their appearance and dread permanent disfigurement. They understand the permanence of death and fear it.

Issues of puberty, autonomy, personal identity, sexuality, education, and vocational choice are challenging to adolescents. They are more difficult for an adolescent who is also coping with an acute or chronic illness. Illness can be associated with medical setbacks, impaired physical or mental abilities, forced dependence, and perceived poor prognosis. When an illness is severe or disfiguring, an adolescent's identity, self-image, and ego-development can be negatively affected. Identity formation is especially challenging in the hospital setting, and adolescents may come to rely on their illness or disability as their identity, rather than setting goals or aspirations beyond the hospital environment. Biological, psychological, and social developments are highly interrelated. Delays in one area, such as body image or sexual development, lead to consequences in other domains. Delayed puberty in boys may lead to low self-esteem and apparent immaturity, which in turn can foster dependence on the family and eventual reduced educational qualifications and increased under employment or unemployment.

Not every young person with a chronic condition has significant psychopathology. Adolescents with a chronic illness are generally well adjusted and perceive their illness as less severe than their physicians assume they do. When adolescents perceive their illness to be severe, they are more likely to have symptoms of depression and low self-esteem. Many who live with chronic illness or disabilities are well adjusted socially and emotionally. Those adolescents with the greatest uncertainty of their outcome often have more difficulty accepting and discussing their condition, and may avoid disclosure to peers. In a study of chronically ill adolescents with a variety of disorders compared to matched controls, there were no differences in levels of anxiety or self-esteem between the two groups, and both held a similarly positive outlook on life. This finding may be related to the ability of adolescents to deny the worst aspects and consequences of their illness in order to function effectively, or it may be related to their experience coping with multiple minor stresses resulting in greater resilience and more successful coping strategies their healthy peers.

Compliance with treatment, rules, and authority may be problematic for

some medically ill adolescents, and they may be more likely to demonstrate risky behaviors than their healthy peers. Medically ill adolescents require the same anticipatory guidance and close supportive follow-up as any adolescent at risk.

It is important that adolescents participate in their own care and treatment decisions, although in most cases, diagnosis and treatment information is still directed to the parents. Hospitalized adolescents prefer to have medical information provided directly to them by health care professionals, but they often want their parents present for support. Adolescents would like to have discussions of diagnosis and prognosis as soon as possible after admission, even when their condition may be terminal. Adolescents often recognize the imminence of their death and want to discuss their feelings. They may request information that the parents are reluctant to disclose, and may be ready to discontinue treatment when their parents are not. In these situations, it is important that the health care team is ready to support both the adolescent and parents and to provide ways to bridge their differences. Advance care planning is encouraged by the Institute of Medicine and the American Academy of Pediatrics, and developmentally appropriate tools for discussing end-of-life care are available for adolescents and young adults.

FAMILY'S RESPONSE TO CHILD'S ILLNESS

The family of a seriously or chronically ill child is as affected by the illness and frequent hospitalizations as is the child, and the social impact of the illness is felt throughout the family system. Family systems are dynamic and can be sources of risk or protection for a child with a serious medical condition. Chronic conditions present the entire family with an additional set of tasks, responsibilities, and worries. There is personal impact on a parent, financial impact on the family, and implications for family and social relationships. Parents must deal with the day to day management of the illness, with the increased financial burden associated with medical bills and time lost from work, and with the uncertainty about treatment and their child's prognosis. This can place additional strain on a marriage and can significantly affect the parents' relationships with other children. Relatives, teachers, and friends may be available to provide support, but they also may be negatively impacted by the child's illness.

Nine aspects of a resilient family process have been identified: (1) balancing the chronic condition with other family needs, (2) maintaining clear family boundaries, (3) developing communication competence, (4) attributing positive meanings to the situation, (5) maintaining family flexibility, (6) maintaining a commitment to the family as a unit, (7) engaging in active coping efforts, (8) maintaining social integration, and (9) developing collaborative relationships with professionals. Family cohesion, open communication, and the ability to adapt to conflict are

indicative of healthy family function and psychological adjustment in families with chronically ill children.

Parental temperament and coping skills strongly influence how their child copes. Children take their cues for coping and adaptation to illness primarily from their parents, especially their mothers. Parents who are able to isolate their own fears and anxieties during crises are better able to enhance their child's understanding of the illness and to facilitate self-care and independence in their child. Parental anxiety can have a negative effect, and children with very anxious mothers often have less distress during procedures when their mothers are not present.

Parents tend to remain at the hospital during the initial diagnosis and early therapeutic interventions, and often return when illness worsens or complications arise. Once the first crisis passes, the mother is most likely to take on the day-to-day care of the child. She is often the parent who remains in the hospital with the child, accompanies the child to physician visits, provides support for procedures, and acts as advocate for the child with practitioners.

Studies of mothers of children with different chronic disorders have consistently found the mean level of reported adjustment problems to fall at about one standard deviation above the mean for the general population. Research on fathers' reactions is consistent with studies in mothers, although fathers are less well studied. Fathers traditionally take on additional financial burdens associated with a child's illness, have to endure separation from their spouse and child during hospitalizations, and deal with feelings of helplessness due to the inability to protect their child from harm. Differences in coping style may contribute to emerging family dysfunction. Parents, like children with a chronic disorder, are at risk of maladjustment, but there are considerable individual variations and many do well. Parents may experience marital distress and impaired sexual relationships, especially after their child's diagnosis of cancer. But parents of children with cancer may also experience their marriages as satisfactory and their partners as supportive, and higher divorce rates have not been found. While marital discord is associated with increased psychological problems in chronically ill children, a mutually supportive marriage can benefit the family's ability to cope with the stress of chronic illness. Parents may respond differently to traumatic brain injury in their children: fathers are more likely to use denial and report greater injury-related distress, while mothers are more likely to demonstrate acceptance and emotion-focused coping. Mothers may also be better able to adjust over time, while fathers' adjustment and marital satisfaction may not improve.

Siblings of a chronically ill child are in a very difficult position. Siblings often are asked to take increasingly adult roles to "help out," while receiving less attention and support from their parents. The sibling may love and worry about their sick brother or sister, and at the same time

resent them, causing feelings of guilt. Sibling rivalry and jealousy increase when the focus of both parents and the family's resources are directed toward the ill child. It is further exacerbated when mothers spend more time with their sick children than the healthy siblings. Siblings of chronically ill children are more likely to develop depression, anxiety, a negative self-image, and fewer quality peer activities. Younger siblings may be more resilient to these consequences, and life threatening or severe illnesses may exacerbate the risk.

Sibling adjustment typically parallels the family's adjustment, and finding ways to help the mother feel confident in managing her child's illness is integral to her ability to provide the optimal home environment for both the sick child and the healthy siblings. Parents of children with cancer, CF, and epilepsy rated the siblings' quality of life better than the siblings themselves did.

Siblings may be asked to donate hematopoietic stem cells for transplantation. Donor siblings often feel they "had no choice" about donating. Both donors and recipients may have post-traumatic stress symptoms following the transplant, and nondonor siblings may report more anxiety and lower self-esteem. Teachers have observed donors to have both more adaptive coping and more school problems and attention-seeking behaviors than nondonor siblings. Donors report the psychological aspects of donating outweigh any physical consequences, whether their sibling lives or dies. If the recipient dies, the donor sibling frequently feels guilty. They often use spirituality and religion as primary coping strategies. The donation process and having an ill sibling are associated with a range of positive and negative emotions. Siblings often feel isolated and that their family life interrupted. Siblings want to be included in decisions, be provided information, be given choices, have help sharing their feelings, be provided opportunities to meet with peers, and experience a supportive hospital environment.

Families who actively seek information and services, work to solve problems and express their feelings, and are able to balance personal, family, and illness needs show better adaptation to a child's illness and hospitalization. Maintaining supportive relationships with people in the community can also be an important protective factor. Informal support networks provide emotional and informational support and sometimes tangible aid, but when they are not enough, mental health services and formal support groups are needed.

When families are given a new devastating diagnosis, such as childhood cancer, the family may respond as though the event is a matter of chance beyond their control, and exhibit denial, detachment, intellectualization, or substance abuse. Optimally, the family views the illness as a challenge that is controllable and changeable, making long-term difficulties in psychological adjustment less likely.

Health care providers are very influential and play a powerful role in the lives of families with a sick child. Parents look to them for essential medical information and guidance. Pediatricians need to be aware that anything they say, whether well reasoned or not, can have an enormous impact on parents and their children, with potential effects that may be immediate or long lasting. Medical communication delivered in a thoughtful and sensitive manner can promote competent family functioning and resilience, despite life-threatening illness. However, when health information is not thought through before being given, it may be misconstrued, misinterpreted, or misunderstood, and may lead to a constellation of abnormal behaviors and altered parent-child interactions that are referred to as the vulnerable child syndrome (VCS), first described by Green and Solnit in 1964.

The cardinal features of VCS include (1) pathological separation difficulties, such as poor sleep in infants or recurrent unexplained abdominal pain or school phobia in older children; (2) infantilization with overprotective, overly indulgent, and overly solicitous parent, and an overly dependent, disobedient, irritable, argumentative, and uncooperative child; (3) bodily over concerns, when the child has many physical complaints and the parent (usually the mother) has difficulty differentiating between the child's discomfort and their own distress, and cannot distinguish mild, self-limited symptoms from potentially serious illness; and (4) separation anxiety, delay starting school and school underachievement. Predisposing factors to VCS include a history of infertility, miscarriage, illness during pregnancy; prematurity; a life-threatening illness; or a child with a chronic medical illness, especially if there was hospitalization during the first year. VCS is linked to more frequent ER visits and inpatient hospitalizations. Depending on how their parents perceive the event, even older children seen in an emergency department for minor head trauma or hospitalized for gastroenteritis or asthma may be at risk of VCS.

The prevalence of VCS in a community sample was estimated at 10 percent in 1995, but maybe higher today with improved survival of premature children and children with serious chronic illnesses. The degree of parental perception of vulnerability does not necessarily correlate with the severity of neonatal problems, birth weight, or current health. Rather, higher levels of maternal anxiety at neonatal discharge better predict parental perception of child's vulnerability and are associated with worse developmental outcomes. Affected parents often have difficulty with setting age-appropriate limits and demonstrate permissiveness alternating with excessive attempts to control their child's activities. They are also likely to seek higher levels of medical service and have more dissatisfaction with the medical care provided.

A child's perception of their own vulnerability does not necessarily correlate with their parents' perception. When children rate themselves as

vulnerable, most parents agree; when parents rate their children as vulnerable, only about half the children agreed.

Effective communication is at the heart of the preventing and managing VCS. If the child stays healthy and communication between parents and pediatricians is effective, VCS does not necessarily persist into school age. Persistent parental fear that a child remains vulnerable can be elicited by asking, "has your child ever been seriously ill?" VCS is likely when parents then respond by relating traumatic accounts of their child's perceived near death experiences. The physician's awareness of a parent with excessive anxiety or guilt, and of their own anxiety, can decrease the risk of unintentionally exacerbating parental anxiety and belief in their child's vulnerability when discussing diagnosis, prognosis, and anticipated treatment. The parents' frightening experience should be acknowledged, and parents should be provided a more accurate assessment of their child's health and told when time-limited medical problems are resolved and will not recur. The importance of encouraging appropriate autonomy in the child should be emphasized with discussion of potential adverse effects of excessive parental concern on a child's development and behavior. Reassurance and regular follow-up help to distinguish normal development and behavior from problems needing psychiatric consultation.

TRANSITION

As children with chronic and severe medical problems are living longer into adulthood, the previously unanticipated problem of transitioning a pediatric patient to adult care must be addressed. Adolescence describes the time from childhood to adulthood, when the teen must change from pediatrician to internist and move from shared responsibility to individual responsibility. At some time adolescence ends and adulthood begins, even for patients with special health care needs.

Adolescence can be a difficult time, especially for those with chronic illness who face unique challenges in developmental tasks. Effective transfer to adult care involves coordination and good communication with the patient, family, and adult physicians so that the anxieties of all, including the pediatrician, are adequately addressed.

There are two different approaches for transfer of adolescents with chronic medical problems to adult medical care. Patients may be directly transferred to internists. This is typical for patients with pediatric onset of adult disease. Alternatively, patients may be transferred to a specialized center focusing on pediatric disorders in adults. They will then be seen in pediatric clinics with separate areas for young adults.

Transition is not the same as transfer of care. Transition is a multifaceted process that addresses the psychosocial, educational, and vocational needs of adolescents as they move from child-oriented to adult-oriented care. It is predicated on effective communication between

pediatrician and internist and between the patient, parents, and providers. Transition implies a guided educational and therapeutic process rather than an administrative event.

Pediatric care is typically family centered. The pediatrician looks to the parent for information and to provide instructions. Adults speak to their physicians directly. It is useful for the adolescent preparing for transition to begin talking to the pediatrician directly, without their parents' assistance.

Transitions of care are periods of vulnerability and potential risk. Adult providers are often unfamiliar with the management of rare and often complex chronic childhood conditions. Young adults who have survived with pediatric care are at risk of deterioration after they move on to adult providers. Those with the less severe and visible conditions may have the greater problems moving from pediatric to adult care. They may experience no preparation, with minimal often last minute planning, and poor communication and coordination of transfer of care.

It is important that pediatric relationships are appropriately terminated as part of the transition process. The patient's level of developmental maturity and ownership of their own care is the most prominent determinant of transition outcomes. In order for the process of transition to be effective, the patient needs to have demonstrated adequate self-management skills, long-term social support, self-reliance, autonomy, and independence. Noncompliance with treatment is particularly prevalent in adolescents. Effective management requires attention to psychological and social issues as well as medical factors.

A positive sense of the future is associated with a greater sense of control in adolescents. Both in turn support their emotional well-being and growth, increasing the likelihood of a more successful transition. When accomplished effectively, transition can provide the young adult with a sense of the future and of future responsibilities that continued pediatric care fails to reinforce. A carefully planned transition to adult health care should improve self-reliance, enhance autonomy and independence, and support young people in attaining their maximum potential and having meaningful adult lives.

Table 55.3–3.
Recommended Approach to Transition in Adolescence

Period	Task
Early adolescence Ages 10–13 years	Introduce concept of separate and confidential visits with MD. Straightforward reward-oriented approach. Begin discussion of transfer of care. Need for privacy begins.
Mid adolescence Ages 14–16 years	Begin discussion of health living and risky behaviors in nonjudgmental approach. Expect increased introspection. Begin visits to new setting and meeting new providers.

Late adolescence Ages 17–21 years	Increased self-responsibility. Transition to adult providers. Future-oriented approach. Progression of personal identity and code of ethics. Physician seen alone. Evolving role of social supports.

SOCIAL MEDIA

The Internet and social media sites such as Facebook, Twitter, and YouTube are a few of the new online tools available that provide useful applications to foster information gathering, development of user-generated content, social interaction, and real-time collaboration. These technologies encompass blogs and patient experience journals, social networks, video-sharing and photo-sharing sites, wikis, and myriad other media, and are pervasive around the world. A growing majority of patients, including children and adolescents, particularly those with chronic conditions, are seeking out social media and other online sources to acquire health information, connect with others affected by similar conditions, and play a more active role in their health care decisions. Many patients and families can develop large support networks through sharing and disseminating information about their child's illness on specialized hospital sites such as CaringBridge or CarePages. Internet support groups and interactive peer video games can decrease some of the isolation patients and families feel with rare or unknown conditions or due to necessary hospital medical isolation practices. Applications that monitor and track symptoms (e.g., adherence, mood, nutritional intake, chemotherapy side effects, and blood cell count) may be very useful as well as applications that facilitate delivery of stress management and relaxation techniques (e.g., biofeedback, breathing exercises, mindfulness, and imagery) are available though not yet widely disseminated.

These tools are not a substitute for clear communication, clinical, psychological, and psychiatric assessment and treatment. Practitioners, patients, and families need to consider threats to confidentiality, privacy, and professional and therapeutic boundaries when communicating via social media.

▲ 55.4 Psychiatric Sequelae of HIV and AIDS

MARK DEANTONIO, M.D.

In June 1981, the first cases of what was later called acquired immunodeficiency syndrome (AIDS) in the United States were reported in *Morbidity and Mortality Weekly Report*. Since that time, this syndrome has become one of the greatest public health challenges. In 2012, an estimated 35.3 million people were living with human immunodeficiency virus (HIV) worldwide. HIV continues disproportionately to affect certain geographic regions (e.g., sub-Saharan Africa and the Caribbean) and subpopulations (e.g., women in sub-Saharan Africa, men who have sex with men, injection-drug users, and sex workers). In the last decade, there have been significant changes in the understanding, epidemiology, and treatment of this disease in children and adolescents, modifying psychiatric sequelae. In the United States, the prevention of vertical transmission and the surveillance of blood make it rare for a child or adolescent younger than

15 years of age to become infected with HIV. However, adolescent sexual behavior and drug use, especially when combined with psychiatric disturbance, put individuals at increasing risk of HIV infection in adolescence and young adulthood. Psychiatrists in the United States might never encounter an HIV-infected child but have a great opportunity to decrease the risk of infection when psychiatrically treating adolescents who are at risk. Gaining an understanding of psychiatric sequelae of HIV and AIDS and the dynamics of adolescent risk behavior will allow the physician to craft effective interventions to prevent transmission in youth.

EPIDEMIOLOGY

In 2014, the Centers for Disease Control and Prevention (CDC) published the HIV Surveillance Report documenting the incidence and rate of HIV infection in the United States from 2008 to 2012. The incident of HIV infection remained unchanged during this period being between 37,000 and 38,000 per year. Over this 5-year period, the rates for persons aged 13 to 14, 20 to 24 and 25 to 29 increased. The rate for persons aged 35 to 39, 40 to 44, 45 to 49, 50 to 54, 55 to 59, 60 to 64, and 65 and older decreased. The rates remained stable for individuals aged 15 to 19 and 30 to 34. Due to HIV infection surveillance during pregnancy, HIV infection remains low in children (under 13 years old) in the United States with an unchanged rate of 0.5/100,000 during this period. In 2012, the highest rates were for persons aged 20 to 24 years and 25 to 29 years with rates of 36/100,000. Though the rates of adolescents aged 15 to 19 were unchanged (10/100,000), it is notable that behavior leading to HIV infection often begins years before seroconversion to HIV positive occurs. Therefore, the high infection rates noted in the 20- to 29-year-old group can be due to risk behaviors which started in adolescence.

From 2008 through 2012, the rate for Asians increased from 5.8/100,000 to 6.1/100,000. The rates for Black/African Americans decreased from 63.5/100,000 to 58.3/100,000 as wells as for Hispanic/Latino from 20.6/100,000 to 18.5/100,000. The rates for whites remained the same from 6.8/100,000 to 6.7/100,000. It is difficult to interpret rate changes in Native Americans or Native Hawaiians as overall incidence is low (less than 250 per year in each group). Over this 5-year period the rate for females decreased; the rate for males remained stable. In 2012, males accounted for 80 percent of diagnoses of HIV infection among adults and adolescents.

From 2008 through 2012, the annual number of diagnosed HIV infections attributed to male-to-male sexual contact increased among adult and adolescent males. The numbers of infections due to injection drug use, male-to-male sexual contact and injection drug use, or heterosexual contact decreased. Among adult and adolescent females, the numbers of infections due to injection drug use or heterosexual contact decreased. In 2012,

among adult and adolescent males and females, the diagnosed infections attributed to male-to-male sexual contact (67 percent) including male-to-male sexual contact and injection drug use and those due to heterosexual contact (26 percent) accounted for approximately 93 percent of HIV infections in the United States.

Geographically, from 2008 through 2102, there were not significant changes by regions in the United States. The rates in the Northeast, the South, and the West decreased, while the rates in the Midwest slightly increased. In 2012, the rates were 20.7/100,000 in the South, 16.2/100,000 in the Northeast, 11.5/100,000 in the West, and 9.2/100,000 in the Midwest.

The changing US epidemiology shows relative control of HIV infection in children under 13, but a significant rise in rates of individuals in their twenties. Sexual behavior specifically male-to-male sexual contact is the primary cause of infection with injection drug use and heterosexual contact decreasing as a cause. The behaviors that caused infection for individuals in their twenties often begin in adolescence. These trends highlight the importance of interventions to change sexual behavior in adolescence.

There is another way in which HIV infection affects children and adolescents: When their parents or family members are infected. The number of US youth affected by HIV in a family member is growing because the majority of infected women are mothers; 60 percent have children younger than 18 years of age, and 45 percent live with their children. Living with chronically ill parents often with comorbid substance abuse has significant consequences for the affected family members, with potential psychiatric and social sequelae.

ETIOLOGY

Psychiatric sequelae of HIV infection in children and adolescents are due to multiple and interacting etiologies. These include direct and indirect effects of HIV infection on the brain, stresses of living in families often affected by substance abuse, psychiatric disorders, chronic illness, and death. Adolescents who contract HIV infection have a high likelihood of pre-existing psychiatric diagnosis, cognitive deficits, histories of sexual or physical abuse, ongoing substance abuse, homelessness, and chaotic family dynamics. The addition of HIV infection to these adolescents adds a profound stress and challenge to an already overwhelming existence.

HIV is transmitted through blood-to-blood or semen-to-blood contact. The virus can also be transmitted by penile–vaginal intercourse, especially if other sexually transmitted diseases (STDs) coexist. Receptive anal intercourse and the use of contaminated syringes are the most common causes of HIV infection in the United States. HIV-infected women can transmit the virus during pregnancy, delivery, or through breast milk. It also can be transmitted through untested blood products. There are four

identified types of human retroviruses, which belong to two distinct groups: the transforming human T cell lymphotropic virus (HTLV) types I and II, and cytopathic HIV-1, which is more common in the United States, and HIV-2. HIV-1 is further divided into groups, classes or subtypes, and circulating recombinant forms, all of which indicate geographic origin.

Testing to diagnose HIV infection has evolved to provide quicker, more accurate, and more cost-effective results. Current testing approaches directly detect the virus or demonstrate antibody to the virus or a component, which appears 2 to 12 weeks after acute infection. A definitive diagnosis among infants younger than 15 months old cannot be made because the antibody crosses the maternal–fetal blood barrier, so all infants of HIV-infected mothers will have maternal HIV antibodies whether infected or not. Once an individual is diagnosed as infected, the level of plasma HIV RNA (viral load) and the absolute numbers of peripheral CD4+ T cells are used to monitor clinical status.

In 1985, when HIV testing first became available, the main goal of such testing was to protect the blood supply. At that time, professional opinion was divided regarding the value of HIV testing for individuals and whether HIV testing should be encouraged because no consensus existed regarding whether a positive test predicted transmission of the HIV virus to sex partners or from mother to infant. No effective treatment existed. In 1987, the implications of positive HIV serology became evident. HIV testing and counseling was recommended for all persons in high-risk groups and all persons seeking treatment for STDs. In 1995, after perinatal transmission of HIV was demonstrated to be substantially reduced by the administration of zidovudine to HIV-infected pregnant women and their newborns, it was recommended that all pregnant women be counseled and offered testing for HIV. In 2001, the CDC recommended that all pregnant women should have HIV screening as a part of routine prenatal care. Although the woman needed to be aware of what they were being tested for, it was also felt that the previously recommended pretest counseling was a barrier to testing and should be simplified. At this time, the CDC recommended that HIV testing be offered routinely to all patients in high–HIV-prevalence health care settings, despite risk factors. In low-prevalence settings, targeted HIV testing on the basis of risk screening continues to be recommended.

In September 2006, the CDC again revised recommendations for HIV testing of adults, adolescents, and pregnant women. Due to the changes in demographic of the HIV/AIDS epidemic in the United States, increasing proportions of infected persons are younger than 20 years of age, women, members of racial or ethnic minority populations, persons who reside outside metropolitan areas, and heterosexual men and women who frequently are unaware that they are at risk of HIV infection. As a result, the effectiveness of using risk-based testing to identify HIV-infected persons has diminished. In addition, prevention strategies that incorporate

universal HIV screening have been highly effective (blood donors and pregnant women). Perinatal transmission rates have been reduced to less than 2 percent due to prophylactic administration of antiretroviral drugs, scheduled cesarean delivery, and avoidance of breast-feeding. Studies document that the majority of adults who are aware of their HIV infections substantially reduce sexual behaviors that might transmit HIV after they become aware that they are infected. Therefore, to increase the diagnosis of HIV infection, destigmatize the testing process, link clinical care with prevention, and ensure immediate access to clinical care for persons with newly identified HIV infection, the CDC now recommends the adoption of routine HIV testing in all health care settings for individuals from the age of 13 to 64 years. The testing should be undertaken only with the patient's knowledge and understanding that HIV testing is planned. Patients can refuse testing. Persons likely to be at high risk of HIV infection—injection drug users and their sex partners, sex workers, partners of HIV-infected persons, and persons who have had or whose sex partners have had more than one sex partner since their most recent HIV test—all should be tested annually. This significant change in testing recommendation reflects the ever-changing nature and better understanding of HIV/AIDS.

Pre-exposure prophylaxis or PrEP is a new tool in HIV prevention. It is a prevention option for individuals who are at high risk of getting HIV. It is a pill with two antiviral medications (tenofovir and emtricitabine) which are taken daily. While PrEP has been shown to be safe and efficacious for adults, the data on its safety and efficacy for adolescents are not clear. The CDC to date has not come out with a definitive recommendation, stating that the risks and benefits of PrEP for adolescents should be weighed carefully in the context of local laws and regulations about autonomy in health care decision making by minors.

Disclosure of a child's or adolescent's HIV status brings up complex issues requiring careful assessment of an individual's circumstance. Knowledge of one's HIV status is associated with emotional distress and increased rates of depression. The level of distress depends on how the disclosure occurs, under what circumstances, and the reaction of the people involved. Telling a child that he or she has HIV appears to be influenced by several factors, including older child age, higher child cognitive functioning, recent major life events, and higher family expressiveness. Many clinicians and caregivers are ambivalent about disclosing to children because of fears that the children will inappropriately disclose to the community at large and face stigmatization as a consequence. Current pediatric practice guidelines encourage disclosure by adolescence, but neurocognitive deterioration may complicate timing. Clearly it is critical that HIV status be disclosed to adolescents before they become sexually active. Simply telling adolescents that they are HIV positive may not reduce risky sexual behavior or disclosure of that status to their sexual partners.

This potential lack of disclosure underscores the importance of emphasizing safer sex practices, including condom use, for all adolescents regardless of HIV status.

Neurodevelopmental Sequelae of HIV Infection

HIV is found primarily in microglia and macrophages and not directly in neurons. The virus is thought to have neurotoxic components and to induce a variety of inflammatory factors that cause neuronal cell death. The clinical presentation of HIV neurological involvement can vary from mild neurocognitive impairment to static encephalopathy, progressive encephalopathy, and dementia. There has been more progress in understanding the effects of HIV on the brain in adults than in children, owing to the dramatic decrease in childhood infections. Studies of infected patients 13 to 18 years of age are limited to case reports. In the earliest asymptomatic stages, abnormalities may show up in cognitive abilities evaluated during neuropsychiatric testing but not necessarily as impairments in functioning. In children and adolescents, those infected also likely have cognitive deficits due to in utero drug and alcohol exposure, attention-deficit disorder, and learning disabilities, all of which increases maternal HIV infection risk and complicate neuropsychiatric testing. The clinical presentation of HIV central nervous system (CNS) involvement may vary with age of infection and mode of transmission. In children or adolescents infected through blood transfusion, encephalopathy generally presents later and follows a more indolent course. By contrast, in almost one-fourth of vertically HIV-infected children encephalopathy can present and contribute significant morality and mortality as an AIDS-defining illness even when the child is not severely immunocompromised. Early progressive encephalopathy is usually seen in young, untreated infants with high viral loads and rapid clinical deterioration. Vertically HIV-infected children who are labeled “slow progressors”—those with lower viral loads and higher CD4 counts—often exhibit no cognitive deficits throughout childhood and adolescence.

The most common computed tomographic findings associated with encephalopathy are basal ganglia calcifications, brain atrophy with enlarged ventricles, and enlarged cortical sulci. HIV-infected children have a higher incidence of ischemic strokes and cerebral artery aneurysms, which can rupture. Magnetic resonance imaging (MRI) has been recommended for infected children who present with a lack of neurocognitive progression or dysfunction even though they are otherwise asymptomatic.

In adolescents with advanced AIDS, a gradual progression into dementia is seen. It appears as a subcortical dementia process with motor impairment, cognitive disturbance, and a predominance of apathy over depression. Psychotic symptoms may be present. In addition, opportunistic

CNS infections such as toxoplasmosis, progressive multifocal leukoencephalopathy, and CNS lymphoma can complicate the CNS clinical picture. There is no specific treatment for HIV involvement of the CNS. When progressive encephalopathy is present in children and adolescents, increased doses of antiviral agents are used but there have not been studies documenting efficacy in children and adolescents.

CLINICAL FEATURES

Despite more than 30 years of studying HIV/AIDS in children and adolescents, there have been few studies of psychiatric diagnoses in these individuals. Although there is clearly defined neurological pathology due to HIV infection, psychiatric illness specifically due to HIV infection has not been quantified. Instead psychiatric diagnoses are related to inheritable psychiatric disorders and reactions to having a chronic illness in the context of often chaotic and traumatic environments.

Early studies of emotional and behavioral disorders in perinatally HIV-infected children showed high rates of anxiety, depression, adjustment problems, and attention-deficit/hyperactivity disorder. However, results among studies were inconsistent and failed to use appropriate control groups. Studies of behavioral disorder in HIV-infected children that included uninfected control groups of similar background generally reported high rates of emotional and behavioral disorder in both groups. One controlled study found elevated rates of attention-deficit/hyperactivity disorder in a sample of prenatally drug-exposed children, with no difference between HIV-infected and uninfected children. Another controlled study found elevated rates of internalizing and externalizing symptoms in HIV-infected children and demographically matched control. However, rates of symptomatology were actually higher in the control group. The Woman and Infant Transmission Study Group Study compared HIV-infected children with uninfected siblings born to HIV-positive mothers. Findings confirmed earlier data revealing high rates of hyperactivity and impulsivity in both the infected and uninfected children. The Pediatric AIDS Clinic Trials Group reported a higher frequency of psychiatric hospitalization among perinatally infected children than in the general pediatric population and HIV-uninfected members of the cohort. The majority of patients were admitted because of depression and a minority due to behavioral disorders. Studies of vertically infected adolescents and psychiatric illness are limited to case reports. The group whose AIDS progresses significantly in adolescence exhibits a dementia process, which may include psychosis and agitation. The group of vertically infected adolescents who are labeled “slow progressors” due to their mild degree of immune suppression appear to present with depression, anxiety, and chronic adjustment disorders related to chronic illness.

Adolescents who become infected as adolescents due to sexual or

injection substance abuse have not had their psychiatric diagnoses well studied. There is evidence that having psychiatric illness in adolescence, especially when coupled with substance abuse and cognitive and learning difficulties, increases the high-risk behaviors that can lead to HIV infection. This was most recently documented in a study in 2010. It has been documented that a significant number of HIV-infected adolescents have depressive disorders. Conduct disorder and substance abuse are also present to a significant degree. The majority of these disorders predated their HIV infection. There is evidence in the adult and adolescent literature that having depression while being HIV infected can alter the function of killer lymphocytes. This causes an increase in activated CD8 T lymphocytes and can increase viral load. Treatment with selective serotonin reuptake inhibitors and decrease in depressive symptoms reverse these changes. Clearly, more study needs to be made regarding psychiatric sequelae of adolescent-onset HIV infection.

TREATMENT

Psychiatrists play an important role in the treatment of children and adolescents who are HIV infected. HIV infection has changed over the years to a chronic illness in the United States, which requires multiple layers of care in a variety of settings over many years. Although pediatricians have expertise in managing developmental issues in chronic illness in youth, psychiatrists have a system-oriented approach arising from their work with patients who depend on the support systems provided by family, school, and community. Parents of HIV-infected children and adolescents have a high rate of psychiatric illness, substance abuse, and chaotic and dysfunctional family interactions. Psychiatry brings expertise to the treatment team in crafting interventions to promote family stability and family support of the patient's medical treatment. Finally, a significant number of children and adolescents who are HIV infected have pre-existing psychiatric illness, which requires psychiatric expertise to manage. In children and adolescents receiving antiretroviral treatment, lack of almost perfect adherence to daily regimes continues to be the greatest barrier to sustaining a clinically effective response. Lack of adherence can also lead to the development of HIV strains resistant to the available antiretrovirals. Although adherence issues are common with all chronic illnesses in children and adolescents, it is more of an issue in HIV-infected children and adolescents living in situations in which parents may be physically or mentally ill or with children and adolescents in a foster care or residential setting with inadequate supervision. The psychiatrist has a critical role in working with the treatment team, the child or adolescent, and caregivers to problem solve and intervene around issues of adherence.

The HIV epidemic adds to the challenges of psychiatric treatment of children and adolescents in inpatient and residential settings. The

American Academy of Child and Adolescent Psychiatry has the following recommendations concerning HIV and inpatient psychiatric treatment:

- HIV infection or risk of HIV infection is not a reason to deny a child admission to a psychiatric hospital.
- All patients admitted to a psychiatric hospital should be treated as if they were HIV infected. Even if all patients were tested on admission for antibodies to HIV, one is still not sure of infection status due to the potential latency period of antibody response documenting infection.
- Universal precautions should be employed for any secretions, including blood from any psychiatric inpatient. There is no need for a change in the management of an HIV-infected child if universal precautions are used for all inpatients.
- HIV positive or potentially positive patients do not require individual rooms or toilet facilities. HIV infected, or potentially infected, patients do not need to be isolated in regard to the milieu or peer groups. Such patients should participate in all aspects of the inpatient treatment program.
- The Academy agrees with the 2006 CDC recommendation of the adoption of routine HIV testing in all health care settings from the age of 13 to 64 years. The testing should be undertaken only with the patient's knowledge and understanding that HIV testing is planned. Patients can refuse testing. Persons likely to be at high risk of HIV infection, including injection drug users and their partners, sex workers, partners of HIV-infected persons, and persons who themselves or whose sex partners have had more than one sex partner since their most recent HIV test all should be tested annually. The Child and Adolescent Psychiatrist should balance the adolescent's request for privacy with the families wishes. There are specific laws regarding confidentiality of HIV antibody testing results and who authorizes consent in minors. These laws vary from state to state. Prior to testing, ensure the laws are understood.
- Results of patients' HIV antibody tests will be maintained in a confidential manner. A patient's HIV status should be shared only with those staff who need to know the status to appropriately care for the child while an inpatient. Sharing of HIV status should, of course, be in compliance with applicable state and federal law.

There is little published research on the psychopharmacological treatment of HIV-infected children and adolescents. The Pediatric AIDS Clinical Trials Group is beginning a study of treatment of attention-deficit/hyperactivity disorder in HIV-infected children, with no published results as of the time of this writing. All published studies are case reports, which are difficult to generalize. Interactions between psychotropic and antiretroviral medications are common in the HIV-infected child and adolescent. Most medications used in the treatment of psychiatric

disorders are metabolized by the cytochrome P450 (CYP) enzymes, especially the subgroups 3A4 and 2D6. Of the antiretrovirals, the protease inhibitors tend to pose the greatest risk of changes in drug levels that are significant in the HIV patient. Ritonavir is the most potent of the protease inhibitors, with the greatest effect on the inhibition of 3A4 and to a lesser extent 2D6. Enfuvirtide, a fusion inhibitor, is not an inhibitor of CYP enzymes and does not alter the metabolism of CYP 3A4, 2D6, 2C19, or 2EI substrates. Therefore, it has no significant effect on blood levels of psychiatric medications or other antiretrovirals. Efavirenz has been shown in vivo to induce CYP 3A4. Other compounds that are substrates of CYP 3A4 may have decreased plasma concentrations when coadministered with efavirenz. In vitro studies have demonstrated that efavirenz inhibits 2C9, 2C19, and 3A4 isozymes. Coadministration of efavirenz with drugs primarily metabolized by these isozymes may result in altered plasma concentrations of the coadministered drug. Drugs that induce CYP 3A4 activity would be expected to increase the clearance of efavirenz. Some antiretroviral drugs have been reported to cause psychiatric symptoms in HIV-infected youth, including mania with zidovudine and attention-deficit problems with efavirenz. It is important for psychiatrists to remain in contact with the other medical personnel providing treatment for the HIV-infected child or adolescent, maintain updated lists of all medication, and frequently consult updated web-based information sites regarding drug–drug interactions.

In terms of the strategy of psychopharmacological treatment, thoughtfulness is primary. The concern a physician has is that the psychiatric symptoms present are really due to the “organicity” of HIV infection and so should only be treated by maximizing antiretroviral treatment. Although this point of view needs to be considered, one can make psychiatric diagnoses and use psychopharmacology despite a possible underlying organicity caused by HIV. The most common disorders presenting in this population are attention-deficit/hyperactivity disorder, generalized anxiety disorder, major depressive disorder, bipolar affective disorder, psychotic disorder not otherwise specified, and schizophrenia. One should use the same medications with same dose titration as one would with an uninfected child or adolescent. The exception would be to start and maintain lower doses of medication in the patients with clear demented or encephalopathy. Stimulants in general have few drug–drug interactions, and lithium has none because it is excreted renally. In adults it has been reported that the HIV virus can target the destruction of cells in the basal ganglia, which can sensitize an individual to extrapyramidal side effects when he or she uses an antipsychotic medication. This observation has not been reported in children and adolescents, but because children and adolescents overall are more sensitive to extrapyramidal side effects, this should be of concern. Therefore, one should first use atypical

antipsychotics when treating children who have psychosis and adolescents who are HIV infected.

No specific psychotherapeutic interventions had been documented as being efficacious to treat psychiatric disorders in HIV-infected children and adolescents. However, there are studies showing efficacy of insight-oriented, cognitive behavioral, group therapies in HIV-infected adults with depression. Such treatments also document improved adherence to medication regimes. It is likely that adolescents would have a similar response to psychotherapies for depression. However, individual, family, and group interventions are an important adjunct to the successful treatment of HIV-infected youth. For infected adolescents, prevention programs emphasize reducing transmission acts, enhancing quality of life, increasing self-care behaviors, improving medical adherence, coping with medication side effects, dealing with appropriate disclosure of HIV status, and interacting with health care providers. Preventive interventions for youth living with HIV using therapeutic approaches based on cognitive behavioral principles have been studied. One intervention included two primary components: (1) increasing positive health behaviors, particularly around medication adherence and (2) enhancing altruistic motivation to reduce transmission acts. The intervention emphasized coping with being HIV positive, adopting healthy routines, partaking in health care decisions, reducing substance use and risky sexual behavior by identifying risk triggers, and increasing self-efficacy to use condoms and negotiate safe sex. The intervention sought to build skills and improve emotion regulation. These are similar to the strategies used to enhance psychological functioning for youth in psychiatric care. Adolescents who received the intervention reported more lifestyle changes, improved coping, fewer sexual partners, and a lower percentage of unprotected sexual acts than did youth who did not receive the intervention. Additional sessions emphasized increasing life satisfaction and emotional strength. The additional sessions reduced emotional distress and psychiatric symptoms among the infected youth, including somatization and anxiety. Programs have also been developed to help the adult caregivers' of children and adolescents with HIV infection. These programs teach effective parenting skills, parental monitoring of medication adherence, and increasing social support among family members and the community. Some of the more innovative interventions also address the caregivers' mental health and quality of life.

Despite potential long-term intergenerational consequences of HIV illness, few services are available to assist children and adolescents of HIV-infected family members. The few programs with published data have yielded positive effects for affected adolescents. These programs address coping with stigma, dealing with illness-related tasks, dealing with parental disclosure, increasing maternal well-being and social support, developing effective parenting skills, decreasing victimization, custody planning,

maintaining positive family routines, and handling emotional reactions to AIDS. Two- and 4-year follow-up studies of intervention effects have been both promising and disappointing. Two years after the intervention, treated adolescents reported significantly fewer conduct problems, less emotional distress, lower levels of family-related stress, and higher self-esteem than adolescents in the control group. Outcomes were comparable for youths who were bereaved and nonbereaved by parental AIDS and across ethnic and gender subgroups. Unfortunately, the positive effects eroded by the 4-year follow-up, underscoring the need for sustained support and treatment for these families. HIV prevention programs for affected children and adolescents must address intergenerational imitation of HIV risk behaviors and substance abuse and help them to cope with HIV-related psychosocial challenges such as bereavement. Unfortunately, psychosocial interventions for the affected have not been broadly implemented or prioritized.

CONCLUSION

Child and adolescent psychiatry, with its developmental and systems approach, has a unique position from which to manage the mental health sequelae of HIV infection in children and adolescents. Although this epidemic has created challenges, it has also given opportunities. The epidemic has forced a re-evaluation of child and adolescent sexual development and a more comprehensive understanding of the development of sexual orientation. It has prioritized the need for the assessment of sexual and drug-taking behavior as part of an adolescent psychiatric assessment. Finally, the AIDS epidemic demands that psychiatrists constantly monitor high-risk behaviors in adolescent patients and implement strategies to reduce these behaviors. Such interventions will improve the quality of life and prognosis of adolescent psychiatric patients regardless of HIV infection status.

▲ 55.5 Adolescent Substance Use Disorders

SEAN R. LENOUE, M.D., AND PAULA D. RIGGS, M.D.

INTRODUCTION

Substance use disorders (SUDs) account for about 6 percent of all deaths worldwide and cost an estimated $700 billion in the United States, alone. The vast majority of adults (approximately 80 percent) with chronic addiction started using drugs or alcohol as teenagers. Although the majority of adolescents in the United States report experimenting with drugs or alcohol before graduating from high school, most do not progress to a SUD. The estimated risk of developing an SUD by the age of 18 is 23.8 percent. Risk of progression to an SUD is increased in those who have pre-existing disruptive behavior disorders or other mental health problems, academic problems, and/or have experienced chronic adversities or maltreatment during childhood. Adolescent-onset SUDs are more likely to progress to chronic addiction in adulthood and also increase the risk of

developing mood and anxiety disorders as well as antisocial personality disorder.

At-risk youth can be identified in children as young as 3 to 5 years of age, often presenting with impulsivity, aggression, hyperactivity, inattention, poor persistence, and emotional lability. This constellation of symptoms, characterized as "behavioral dysregulation," is highly heritable and a strong family history of SUD is often present. Such children often continue to have poor self-control, develop disruptive behavioral disorders (oppositional defiant disorder [ODD], attention-deficit/hyperactivity disorder [ADHD], conduct disorder [CD]) in later childhood, and are at high risk of developing SUDs during adolescence. It is important for school personnel, pediatric primary care, and mental health clinicians to screen children for risk factors and refer for evaluation and interventions that may prevent or reduce their risk of early-onset SUD. It is also important to highlight that repeated use of drugs or alcohol can alter brain function in ways that reinforce or promote continued use and development of SUD even in youth without known risk factors. For example, youth with chronic painful medical conditions, acute or prolonged injuries, or multiple medical or dental surgical procedures may be at risk of developing addiction to prescription opioid pain medications even in the absence of pre-existing apparent genetic or environmental risk factors.

Research advances over the past two decades have led to the understanding that addiction as a neurobiologically based medical illness. Initial exposure to substances of abuse increases firing in the dopaminergic pathways of the ventral striatum, producing a subjective "high" that promotes further drug use. However, with prolonged and repeated drug use, dopaminergic neurotransmission gradually diminishes, producing less intense "highs," greater post-use dysphoria, and intense drug craving precipitated by substance-specific withdrawal symptoms. Drug craving can also be triggered by environmental "cues" (i.e., conditioned stimuli) that have frequently been paired with substance use (i.e., conditioned response). At this stage, neural circuitry in the dorsal striatum, rather than the ventral striatum, drives compelling mental preoccupation, decision making, and drug-seeking behaviors that promote habitual use making it much more difficult to consider reducing or discontinuing use.

Greater understanding of the neurobiology of addiction as well as genetic and environmental contributions to adolescent-onset SUD have informed the development of more effective substance prevention and treatment. This chapter focuses on specific aspects of the etiology, epidemiology, prevention, and treatment relevant to adolescent SUDs.

EPIDEMIOLOGY

Prevalence of Use

Substances that can be legally used by adults (e.g., tobacco and alcohol) have historically been those most accessible and commonly used by children and adolescents. For example, inhalants found in many household products (e.g., spray paint and gasoline) and over-the-counter "cold medications" containing dextromethorphan are most easily accessible and commonly abused by children and younger adolescents. Alcohol continues to be the most commonly abused substance by adolescents. However, both alcohol use and cigarette smoking have gradually declined over the past decade and were at the lowest levels in recorded history of the Monitoring the Future (MTF) Survey in 2014. While this is good news, it is important to recognize that despite the decline in alcohol use, almost a quarter of high school seniors reported at least one episode of binge drinking (5 or more drinks on one occasion) in the past 2 weeks in 2014. Binge drinking is especially risky behavior given the potential for serious negative consequences (e.g., motor vehicle accidents, and risky sexual behaviors). Similarly, the decline in cigarette smoking appears to be offset by a significant increase in the use of e-cigarettes among teenagers, the prevalence of which currently exceeds tobacco smoking. Also in 2014, the prevalence of marijuana use surpassed tobacco use among high school students, which is unprecedented in the history of the survey. Increased marijuana use among high school students is likely underpinned by growing national acceptance and the increasing number of states that have legalized medical and/or recreational marijuana use in the United States. Recent national surveys indicate that more than half of Americans (53 percent) favor marijuana legalization. Approximately half of Americans say that they have tried marijuana and, in 2014, more than 2 million reported using marijuana for the first time. Almost two-thirds (64 percent) of high school seniors believe that little harm comes from regularly using marijuana and both regular and daily marijuana use are at 30-year peak levels. This is particularly concerning from a public health standpoint in light of a growing body of research indicating that regular marijuana use during adolescence—a time of rapid brain development—increases the risk of psychosis and is associated with reduction in adult IQ and persistent neurocognitive deficits that may not be fully reversible even with abstinence. Regular use of marijuana before age 17 is also associated with poorer academic achievement, greater risk of high school dropout, as well as unemployment or underemployment in adulthood.

The prevalence of several other illicit drugs including cocaine, methamphetamine, and ecstasy decreased somewhat in 2014 (6 percent of 8th graders, 11 percent of 10th graders, and 16 percent of 12th graders). However, nonmedical use of prescription opiates and heroin use have become a national epidemic and public health crisis in the United States. According to the Centers for Disease Control and Prevention (CDC), deaths related to heroin overdose quadrupled between 2002 and 2013 in the

United States and more than doubled among young adults ages 18 to 25. Approximately 80 percent of young adult heroin users report addiction to prescription opiates before transitioning to injection heroin use. In 2013, almost 2 percent (1.7 percent) of adolescents ages 12 to 17 reported nonmedical use of prescription pain relievers. Between 2012 and 2014 the annual prevalence of heroin use for 8th, 10th, and 12th graders ranged from 0.2 to 0.5 percent. Taken together, these trends indicate the need for more effective substance screening, prevention, and earlier treatment interventions for adolescents.

CLINICAL EVALUATION

Screening

Primary care clinicians can play an important role in identifying youth who are likely to develop or have substance problems as well as motivating and encouraging behavioral changes. Fulfilling this potential requires effective screening and behavioral counseling interventions (BCIs) that are brief and feasible to implement in busy primary care practice settings. Screening, Brief Intervention, Referral and Treatment (SBIRT) initiatives and programs have been developed and adopted in many states to encourage primary care providers to utilize standardized screening procedures and assessment instruments. A number of research-based substance screening and assessment instrument tools have also been developed for use in primary care medical settings to assist clinicians in identifying high-risk youth and/or those who have started using or abusing substances (e.g., CRAFFT and Project ASSERT) A Rapid Teen Substance Use Screening Tool for Clinicians (S2BI). The S2BI tool may be administered by a pediatrician or filled out by the teen on a computer or tablet. Teens are asked to disclose any use of tobacco, alcohol, or marijuana during the past year, and any positive responders are then asked the same multiple choice questions about four additional categories of drugs (non-medical use of prescription drugs, illicit drugs, herbs/synthetic drugs, inhalants) and questions about frequency of use (e.g., “once or twice,” monthly, and weekly).

Most adolescent drug and alcohol screening assessments have been developed for use in primary care medical settings. Additional research is needed to evaluate the effectiveness of existing screening tools in other settings (e.g., mental health; school-based). Moreover, none of the existing drug or alcohol screening assessment instruments for children or adolescents meets sufficiently rigorous evidence-based criteria to be recommended by the United States Prevention Services Task Force (USPSTF). This is important and relevant because the Affordable Care Act (ACA) of 2010, recognizing the independence and methodological rigor of the Task Force, requires insurers to provide first dollar reimbursement only for screening or BCIs receiving a grade of “A” or “B” by the Task Force. Of

the 11 Task Force recommendations (to date) the following are related to substance screening and BCIs for children and adolescents: (1) the Task Force recommends that primary care clinicians provide education and/or brief counseling to prevent tobacco use in school-aged children and adolescents; (2) the Task Force determined that there is currently insufficient evidence to assess the balance of benefits and harms of screening and counseling for alcohol misuse, illicit drug, and nonmedical pharmaceutical use in youth less than 18 years of age in primary care medical settings. These recommendations apply to children and adolescents who have not already been diagnosed with an SUD.

Prevention

The Institute of Medicine (IOM) recognizes three categories of prevention interventions: (i) universal prevention targets the population as a whole; (ii) selective prevention targets high-risk groups of individuals; and (iii) indicated prevention targets individuals who manifest risk behaviors or early signs and symptoms of the illness. According to the most recent Cochrane review only the following three interventions were determined to have sufficient evidence to be deemed efficacious or effective: (i) The Unplugged Program (directed toward 12 to 14 years old), (ii) Life Skills Training Program (directed toward 13 to 17 years old), and (iii) Good Behavior Game (directed toward 6 to 7 years old). All are universal, school-based prevention interventions that are generally adopted school-wide and delivered by teachers trained in the intervention and delivered in the classroom setting. The Cochrane review did not identify any selective or indicated interventions or non–school-based/multi-component community-based prevention interventions meeting rigorous criteria for effectiveness. However, recent studies, not included in the Cochrane review, but meeting similarly rigorous criteria support the efficacy of at least one selective school-based prevention intervention known as the Project Toward No Drug Abuse (directed toward 14 to 17 years old), and one indicated school-based prevention intervention known as the Teen Marijuana Check-Up (TMCU).

Treatment

Most psychosocial substance treatment interventions address drug-taking in general. However, treatment of withdrawal syndromes or other medications used in substance treatment are generally substance-specific or used to treat co-occurring psychiatric disorders (e.g., ADHD and mood disorders). Compared to numerous studies in adults, relatively few randomized controlled trials have evaluated the safety and efficacy of medications for substance abuse or co-occurring psychiatric disorders in adolescents (shown in Tables 55.5–1 and 55.5–2).

Evidence-based psychosocial treatments of adolescents with SUDs supported by at least one randomized controlled trial include Motivational Enhancement Therapy/Cognitive Behavioral Therapy (MET/CBT) and MET/CBT + Contingency Management (CM) (both group and individual format) and family-based interventions (Multi-Systemic Therapy [MST], Functional Family Therapy [FFT], Multidimensional Family Therapy [MDFT], Brief Strategic Family Therapy [BSFT]), and Adolescent Community Reinforcement Approach (ACRA). Overall, these interventions show fairly comparable but modest treatment effect sizes on reductions in substance use but relatively low rates of abstinence ranging from less than 20 percent (most family-based and group MET/CBT interventions) to 30 percent (individual MET/CBT). At least two randomized controlled trials have reported that approximately 50 percent achieve abstinence during treatment when CM/abstinence-based incentives are added to individual MET/CBT compared to 30 percent abstinence with MET/CBT alone. This is consistent with results of numerous studies in adults. Moreover, individual MET/CBT has most consistently been associated with sustained or increasing posttreatment effect size in both adolescents and adults with SUD.

Table 55.5–1.
Medications Used for the Treatment of Substance Use Disorders in Adolescents

Medication	Trial	Targeted SUD	Main Outcomes
N-Acetyl-cysteine (NAC)	Gray et al., 2010	Cannabis use disorder	► Open-label trial, 24 participants (aged 18–21 years) received NAC 1200 mg twice per day. ► Significantly greater reductions in cannabis craving via the Marijuana Craving Questionnaire (MCQ) and cannabis use (via semi-quantitative urine drug screens).
Buprenorphine	Woody et al., 2008	Opiate use disorder	► Randomized 152 opioid dependent adolescents/young adults (aged 15–21 years) in this 12-week study. ► Participants either received a 2-week detoxification with Buprenorphine-Naloxone (Bup-Nal) or 9 weeks of Bup-Nal maintenance followed by a 3-week taper. ► Those maintained on Bup-Nal were significantly more likely to remain in the study at 12 weeks (70% vs. 21%) and had significantly less injection drug use and use of opioids or marijuana. ► However, the 6-, 9-, and 12-month follow-up groups were not significantly different in reported opioid use, cannabis use or injection drug use. ► Thus, 3 months Bup-Nal did not alter long-term course suggesting that even longer term

			maintenance may be indicated—additional research needed. ► Approved in United States for the treatment of opioid dependence in those 16 years and older.
Bupropion Nicotine replacement therapy (NRT)	Killen et al., 2004 Moolchan et al., 2005 Muramoto et al., 2007	Tobacco use disorder	► Bupropion and NRT alone and in combination have been shown to be well tolerated with a relatively good safety profile in adolescents. ► There is evidence of efficacy in adolescents for NRT delivered as patch and for Bupropion at 300 mg/day dose in at least short term.

Table 55.5–2.
Medications Targeting Co-Occurring Psychiatric Disorders in Adolescents with Substance Use Disorders

Medication	RCT	Targeted Disorder	Main Outcomes
Fluoxetine	Riggs et al., 2007	MDD	► Randomized 123 adolescents/young adults (aged 13–19 years) to fluoxetine (20 mg daily dose) or matching placebo. ► Participants in both groups received weekly individual MET/CBT as outpatient substance treatment during the 16-week trial. ► Compared to placebo, subjects treated with fluoxetine had significantly greater reductions in depression severity based on CDRS-R scores (primary depression outcome measure) and higher rates of depression remission (70% vs. 52%). ► Higher than expected depression remission in both groups suggests that the individual MET/CBT (targeting SUD) received by participants in both groups may have contributed to depression treatment response. ► Significant reductions in substance use were seen in both groups but no group difference. ► Regardless of treatment assignment, participants whose depressions remitted by the end of treatment showed significantly greater reductions in substance use compared to nonremitters, whose substance use did not significantly decline from baseline levels of use despite comparable treatment compliance and completion.
Lithium carbonate	Geller et al., 1998	Bipolar disorder	► Randomized 25 adolescents/young adults (aged 12–18 years) with dipolar disorder and co-occurring SUD to 6 weeks of treatment with lithium or matching placebo. ► Lithium treatment was efficacious for both bipolar disorder and comorbid substance use disorder in adolescence. ► Longer-term follow-up study needed.
Pemoline	Riggs et al., 2004	ADHD	► Randomized 69 adolescents/young adults (aged

			13–19 years) with ADHD and SUD recruited from the community to Pemoline titrated to a once daily 37.5-mg dose or matching placebo. ► Reductions in ADHD symptom severity were significantly greater in the Pemoline treatment group compared to placebo on 1 rating scale [Clinician Global Impression-Improvement (CGI-I)] but not both primary outcome measures (ADHD DSM-IV symptom checklist scores; adolescent report). ► Substance use did not decrease significantly in either group in the absence of specific psychosocial treatment for SUD.
Osmotic-release methylphenidate (OROS-MPH)	Riggs et al., 2011	ADHD	► Randomized 303 adolescents/young adults (aged 13–18 years) with ADHD and at least one nontobacco SUD to OROS-MPH (titrated to 72 mg daily dose) or matching placebo. ► Participants in both groups participated in weekly individual MET/CBT targeting SUD throughout the 16-week medication trial. ► Results showed significant reductions in ADHD symptom severity (ADHD-RS scores; primary outcome measure) and past-28-day substance use but no difference between groups. ► OROS-MPH was superior to placebo on some secondary outcome measures: (1) greater improvement in problem solving and coping skills related to their drug use and (2) greater number negative urine drug screens. ► Results suggest that adolescents in substance treatment (even if not yet abstinent) may benefit from concurrent treatment of co-occurring ADHD with OROS-MPH (which showed a relatively good safety profile and low abuse/diversion liability with regular monitoring in this setting).
Atomoxetine	Thurstone et al., 2010	ADHD	► Randomized 70 adolescents/young adults (aged 13–19 years) referred to outpatient substance treatment and meeting diagnostic criteria for ADHD and at least one nontobacco SUD to atomoxetine or matching placebo. ► Participants in both groups concurrently received individual MET/CBT targeting SUD throughout the trial. ► Results showed significant reductions in ADHD symptom severity (ADHD-RS) and substance use but no difference between groups on primary ADHD or substance outcome measures. ► Adverse events were consistent with those reported for atomoxetine in non–substance-involved adolescents with ADHD despite nonabstinence in most participants.

An important limitation of existing substance treatment interventions is that none of them specifically address or integrate or concurrently treat SUDs and co-occurring psychiatric disorders, despite the fact that the vast majority of adolescents referred for substance treatment have psychiatric comorbidity. In addition to long-standing systemic and economic barriers, relatively few studies have focused on development and testing of integrated treatment approaches. Only five randomized controlled trials, enrolling at least 60 subjects (≥30 subjects per group), have evaluated the safety and efficacy of medications for a co-occurring psychiatric disorder in adolescents with SUD (Table 55.5–2) with brief summaries of main outcomes.

DISCUSSION AND CONCLUSION

The past two decades of research have significantly increased the current understanding of risk factors and the neurobiology of addiction that often begins during adolescence. These advances have informed the development of more effective substance prevention and treatment interventions and greater recognition of addiction as a neurobiologically based medical illness. Health care reforms such as the ACA (2010) and the Mental Health and Addiction Parity Act (2008) have paved the way for more rapid integration of mental health and addiction treatment into the mainstream medical health care system in which addiction psychiatry/addiction medicine is likely to function and operate similarly to other medical subspecialties that provide treatment and long-term clinical management of patients with chronic medical conditions (e.g., diabetes, cardiovascular disease, and asthma). As such, medical clinician training programs (physicians, nurses, physician assistants) will need to significantly enhance clinical training in screening, diagnosis, treatment, and clinical management of addiction and chronic pain including medication-assisted treatment (MAT) to address rising number of individuals with opioid use disorders, which has become national public health crisis. Additional research is needed to develop more effective screening, earlier identification of at-risk youth, as well as earlier interventions for substance-involved adolescents to reduce the risk of progression to more severe and chronic addiction in adulthood.

▲ 55.6 Forensic Child and Adolescent Psychiatry

PETER ASH, M.D., AND ELISSA P. BENEDEK, M.D.

INTRODUCTION

Overview

Forensic psychiatry is a subspecialty of psychiatry that focuses on the interface between psychiatry and the law. It may involve consulting to courts, evaluation of individuals involved in the legal system, working in corrections, having involvement in legal issues related to practice, teaching, and performing research in forensic psychiatry. Psychiatrists seeking board certification in forensic psychiatry are now required to do a 1-year fellowship in an accredited forensic psychiatry training program. No such specialized training is available for child and adolescent forensic psychiatry, although, increasingly, trainees are getting more exposure to the area in residencies, and most forensic fellowships offer some additional experience in child and adolescent forensic psychiatry. Continued practice in this specialized area may involve certification, recertification, and maintenance of certification.

Forensic evaluations differ from clinical evaluations in that there is no doctor–patient relationship with an implicit duty of care, and confidentiality is limited inasmuch as most reports are being prepared for use in court. Forensic evaluations also differ in that evaluations are focused on answering a specific question. Often the question will have a specific legal definition, which may vary from jurisdiction to jurisdiction. For example, while most jurisdictions use a “best interests of the child” test in

determining custody in divorce proceedings, in many jurisdictions this test has a specific statutory definition that lists a variety of factors to be considered. It is important for evaluators to be clear on the relevant test in their jurisdictions. The forensic examiner approaches each case with a degree of skepticism beyond that used in most clinical settings. Malingering and secondary gain need to be considered in litigants and criminal defendants. To strive for objectivity, the forensic examiner seeks out a wide base of collateral information, known as "discovery" material, which typically includes legal, medical, psychiatric, and academic records, interviews with other family members, depositions, and police reports and arrest records, when relevant. As noted, confidentiality and patient advocacy do not exist in forensic evaluations; thus, guiding ethical principles are not the traditional *primum non nocere*—first do no harm—and beneficence. In fact, were the forensic psychiatrist striving to act in the examinee's best interests, it would skew objectivity. Appelbaum suggests that, in forensic psychiatry, primacy be given to the value of justice based on the ethical principles of truth telling and respect for persons. This primacy applies regardless of whether the forensic psychiatrist has been retained by an attorney for one side or is court appointed.

Dr. A was very concerned and sympathetic as she listened to Becky, a 12-year-old girl, discussing the emotional and physical abuse she claimed she had endured while visiting her father during an unsupervised visitation. Later, while interviewing Becky's mother, Dr. A listened to a verbatim account of the abuse. It was only upon later reflection that Dr. A recognized that Becky had been coached to parrot a word-for-word version of her mother's story, and that in her sympathy for this allegedly traumatized young woman she had lost objectivity.

Guidelines

Traditionally, child and adolescent forensic psychiatry has focused on issues of child abuse and neglect, custody, and delinquency. Beginning in the early 1980s, many child and adolescent psychiatrists were drawn into civil suits as expert witnesses in cases alleging child sexual abuse. Some experienced role confusion, in which they were trying to serve as both therapist and expert witness, seemingly unaware of this inherent conflict. Added difficulties were created by the lack of clear guidelines as to how one actually assessed children for suspected sexual abuse and the paucity of good research data regarding the long-term effects of child sexual abuse.

The American Academy of Child and Adolescent Psychiatry (AACAP) has issued practice parameters for forensic evaluations which include welcome principles of practice. Anyone undertaking forensic examinations of children or adolescents should become familiar with the American Academy of Psychiatry and the Law's *Ethical Guidelines of Forensic Psychiatry*.

Civil litigation involving children may involve other types of trauma,

malpractice, and class action suits against institutions for neglect or abuse. As more youths enter the juvenile justice system, there is a growing need for forensic psychiatrists who are willing to perform evaluations for the court or work within juvenile corrections providing evaluation and treatment for detainees and committed youths. There is a high prevalence of psychiatric disorders in this population, and many youth remain undiagnosed and untreated.

FORENSIC EVALUATIONS

Referrals

Most referrals for forensic evaluations come from attorneys, and some come directly from the court or from child protection agencies or parents. At the outset, it is important to clarify whom the attorney represents, whether the case is civil or criminal, and what the legal issue is. A useful practice is to ask the referring party to put these questions in writing in a cover letter. This also enables the attorneys to think more carefully about exactly what they want to learn from the forensic examination and refreshes the memory of the examiner doing the forensic exam. Conflicts of interest need to be ruled out in taking a case. These might include having treated a relative of the examinee, being on the faculty of a facility being sued, having social ties with the involved parties, or having a personal or work relationship with the physician defendant. Forensic psychiatrists need to consider whether they have sufficient expertise in the area in question. Lack of expertise in the topic being litigated does not necessarily preclude involvement as long as one notifies attorneys of this fact. Some attorneys may be willing to provide background materials on issues not often encountered, such as toxic buildings.

Ms. Smith, an attorney, called Dr. W. and informed him that she was representing a hospital that was being sued by the parents of a youth who committed suicide on an adolescent inpatient psychiatric unit. She had heard of Dr. W.'s fine reputation, both as a therapist of adolescents and as an expert witness, and she hoped that he would take the case. Dr. W. immediately recognized a conflict of interest, in that he did some of his training at this facility and believed that might compromise his objectivity. Furthermore, the defendant psychiatrist was someone with whom he had a collegial relationship. Finally, inasmuch as his practice was entirely outpatient, he informed Ms. Smith that he did not feel qualified to testify on issues involving the standard of care on an inpatient unit. Dr. W. declined to take the case. Dr. J., however, was an adjunct unpaid professor at the same university, had not practiced inpatient psychiatry for years but was not at all reluctant to become involved in the case and did not see a conflict of interest. Needless to say Dr. J. was cross-examined on just these issues.

Other factors to consider when deciding whether to accept a case are the extent of work anticipated; whether the referring attorney is asking just for record review or wants an evaluation as well; whether a written report is expected; the timeline of the case; and whether it is feasible to meet the case's discovery date—the time when attorneys must provide the other side

with their expert's name and opinions. Fees should be discussed and a retainer may be obtained up front. It is always unethical to accept a case on a contingency fee, in that it would compromise objectivity. Plaintiff's lawyers, in contrast, act as advocates for their clients, and so they often work on contingency fees in civil suits.

Dr. G, an inexperienced psychiatrist (not a forensic psychiatrist), agreed to participate in a civil case involving a potential traumatic brain injury that a child might have incurred in an automobile accident on a contingency fee basis and agree that his payment would be a percentage of the amount the child patient recovered. A more experienced forensic psychiatrist would have realized that this violated ethical principles.

Informed Consent

Unless a court order requires the evaluee's participation, prior to continuing the interview, informed consent should be obtained. Since in most cases minors are deemed legally incompetent to provide informed consent, consent is usually obtained from parents or guardians. However, respect for persons suggests that minors should be given information about the evaluation in a manner suitable for their developmental level, which includes explaining in age-appropriate language who has retained the expert, the purpose of the evaluation, that the evaluator is not there as a treating doctor, the lack of confidentiality, and that the expert may be called to testify. It is important to assist the juvenile in understanding the information presented. Assent to the evaluation should be requested. If the minor does not assent, the clinician needs to consider carefully whether it is appropriate to proceed with the evaluation.

Dorothy, an intellectually disabled 12-year-old, said that she understood that the evaluation would not be confidential but then could not explain what confidential meant. The evaluator then made a further effort to explain the concept in simpler language, and asked her again to explain it back.

In some cases in which an examination is court-ordered, informed consent need not be obtained, but the juvenile should still be informed of the nature of the evaluation. If a juvenile refuses to cooperate with a court-ordered examination, he or she should be informed of the possible legal ramifications of failure to comply with a court order. It is prudent to clarify that the forensic examination is not a treatment relationship, and examinees may need to be reminded of that in the course of the evaluation, particularly if they persist in viewing the examiner as being there to help them. If informed consent is required, a written release should be obtained for dissemination of the written report, and the examinee should be made aware of the limited confidentiality of the evaluation.

Written Report

The written report becomes the backbone of any forensic evaluation. Care needs to be taken to ensure that it addresses the relevant legal issues and contains the foundations for the expert's opinions. A thorough, well-written report often leads to an out-of-court settlement, avoiding the cost and trauma of going to trial. If the case proceeds to trial, the report becomes the basis of the expert's testimony. Reports should be free of any inflammatory or prejudicial statements, and parties should be treated with respect. A good check on one's possible bias is to ask, "How might my report have differed if written for the other side?" The expert must be aware that many people besides the judge may read the report, including plaintiffs, defendants, and their parents.

Dr. G. wrote in a report that the youngster "had the brain of a banana." Needless to say this was an inappropriate comment.

Dan, an adolescent whose parents were involved in a contentious child custody dispute, was concerned about the possible information that might be contained in the expert's report of his evaluation. He waited by the rural mailbox daily in an attempt to read the report before his parents and was successful in intercepting it. The examiner had made mention of his latent homosexuality. Dan was distressed about this report with just cause.

CUSTODY ISSUES

The Framework

Custody conflicts may arise between parents, parents and grandparents, parents and the state, gay, and lesbian parents, and cases involving surrogates. Child custody cases, particularly those involving abused or neglected children, often tug at the forensic psychiatrist's heart, and it is easy to become overly involved and engage in rescue fantasies. Empathy is admirable, but the forensic examiner also must be able to pull back and try to assess situations objectively. It is not easy when waging sides give divergent histories and attempt to sway the examiner to a polarized position. Custody battles often bring out the worst in parents and attorneys, leading the examiner to feel caught in the crossfire and repelled by the self-serving actions of some parents. Order often may be restored if forensic examiners set firm limits with involved parties and are clear about their roles. Examiners need to remember that the judge is the ultimate decision maker. Countertransference issues should be monitored and addressed continually. Parties should be treated with parity, and the examiner should keep an open mind and avoid making premature decisions.

Dr. H. regularly consults with colleagues about contested custody cases because of his concern that countertransference may be interfering with his decision making.

Legal Issues

The forensic examiner must be aware of statutory language regarding the basis for child custody decisions; these vary from state to state. When states have guidelines regarding factors to be considered in awarding custody, clinicians need to be aware of these. Since the early 1900s, custody decisions have been guided by the concept of the child's best interests, although critics have attacked this concept as vague and not always realistic and question the concept that there is only one psychological parent, particularly in the era of dual-career families. Custody issues are the only forensic situations in which the expert has an advocacy role in speaking for the child's best interests. In contrast, in most other forensic arenas, advocacy interferes with objectivity. Child and adolescent forensic psychiatrists may be asked to advise the courts on post-divorce issues of visitation, infant visitation, and parental relocation. They also may be called on to perform evaluations for the court or for protective services in cases of termination of parental rights and adoption. These involve complex issues and the thorny question of how long a child should be kept waiting for a permanent home.

Efforts should be made to meet with both parents in custody disputes and, when appropriate, observe the child interacting with each parent. Unilateral parental evaluations in divorce situations are of very limited utility, in that the examiner has only second-hand, and often biased, information about the parent not seen. Furthermore, the examiner cannot make comparisons between the parents if only one parent has been seen. However, custody situations arise when a child is in state custody and the evaluation is requested specifically in regard to one parent's mental health and parenting capacity, and a second parent may not be in the picture. Here, the question is not which parent should the child live with, but whether this parent is capable of caring for and meeting the particular developmental needs of the child. If not, is improvement likely within the near future in keeping with the child's developmental needs? In addition, there may be attachment problems that have interfered with bonding between the child and parent. Observations of supervised visits between parent and child may yield much useful information.

Ms. Smith was seen for an evaluation as to whether her parental rights should be terminated with her 5-year-old child after her 1-year-old son was murdered by her live-in boyfriend. Ms. Smith did not believe that her boyfriend had murdered her child as he had not yet been convicted. Her history was replete with past physical and emotional abuse by her boyfriend and others. She was compliant with all evaluation appointments and court-ordered psychiatric counseling until such time as her boyfriend was convicted. Even then she believed him—she protested his innocence and became less compliant with therapeutic sessions. The evaluator expressed concern about the safety of the 5-year-old child.

Joey, age 8, had been in a therapeutic foster home for 2 years, having been removed from his

home along with his younger sister (who was subsequently returned home) owing to profound neglect as well as abuse. He was receiving appropriate services; remained volatile, with extensive developmental problems; and typically became more aggressive and regressed after weekly supervised visits with his family. Joey's guardian *ad litem* (an attorney appointed by the court to represent the child) requested that Dr. J. perform a forensic evaluation in regard to whether visits should continue. Dr. J. reviewed extensive records, evaluated each parent, obtained history from them and the foster parent, and then observed a visit. Joey's little sister totally dominated the visit, and the parents were at a loss to control her aggressive and hyperactive behavior. Joey was passive and not very engaged with either parent. According to the visitation supervisor, this was a fairly typical visit. When Dr. J. met individually with Joey, Joey expressed concerns that his sister was still being abused at home, and his need to check on her seemed to be the only reason he wanted to continue the visits. Dr. J. told Joey that both parents were getting help and doing better with their parenting, but he remained unconvinced. Joey evidenced a positive relationship with his foster father and, in contrast, had little to say about his parents. Dr. J. recommended a psychiatric evaluation on the sister, but Joey's parents did not follow through with one. She further recommended cutting visits back to monthly, but Joey's anxiety and aggressive behavior persisted around these limited visits. It also became apparent that the parents were not up to the demands of caring for two special-needs children. Dr. J. recommended ceasing efforts at parental reunification but maintaining some contact between Joey and his sister.

Parental Capacity

Assessments of parental capacity must take into consideration the child's developmental needs, the fit between parent and child, and parental strengths and ability to protect, advocate, discipline, and provide emotional and cognitive support. In addition, the psychiatrist needs to assess the parents' cognitive capacities and social supports, as well as their histories and special issues, such as prior sexual abuse, substance abuse, domestic violence, and mental illness.

Making Recommendations

Recommendations to the court should address the legal issues at hand, be feasible, and be based on the child's developmental needs.

Dr. Q., in an effort to be fair to both parents, recommended that a school-age child alternate years between parents who lived three states apart. He apparently failed to consider the effect such an arrangement might have on the child's schooling and social life. The case was relitigated when the child began resisting transitions, and a more traditional shared-custody arrangement, with primary residence with one parent during the academic year, was arranged.

Forensic examiners need to remember that the court is the ultimate decision maker and not be offended if their recommendations are not followed. Sometimes this may occur because the court has become aware of new evidence or because of legal issues. However, a report that fails to demonstrate the basis for the expert's reasoning and opinions may also lead to recommendations not being followed.

CIVIL LITIGATION

Torts

A *tort* is a claim of wrong done to another person for which a legal remedy, most often a monetary award for the plaintiff, is sought. The plaintiff must demonstrate by a preponderance of evidence that there has been a breach of duty owed by the defendant to the plaintiff, as a result of which the plaintiff suffered an injury. Torts may be deliberate, as when an individual sets out to harm someone, or unintentional, as when the act results from negligence (as in malpractice and personal injury cases). The plaintiff may seek compensatory damages for pain and suffering, special damages for medical or psychiatric care, and, in intentional torts, punitive damages. In contrast to family law cases, a jury hears these cases, and a long period often elapses before the case goes to trial. The statute of limitations in each state limits the period during which an action may be brought and usually runs from the time when an injury is discovered. However, with juveniles, in most states, the statute does not begin to run until the child reaches the age of majority.

Susan, a 10-year-old girl, was severely bitten by a neighbor's dog and sustained a cosmetic injury to her lower lip. Her father instituted a suit against the neighbor in the role of her best friend. A forensic evaluation revealed the Susan had little concern about her injury. She was doing well in school, had many friends, and had future plans to become a teacher. Her concerns centered on her mentally ill mother who had been institutionalized and then ran away from the family. Susan wondered about her health and her whereabouts. Susan's father by contrast obsessed about her injury.

Posttraumatic Stress Disorder

A common claim is that posttraumatic stress disorder (PTSD) resulted from the negligent or intentional behavior on the part of a defendant. The forensic psychiatrist may be asked to examine the plaintiff by either side. Sometimes, the forensic psychiatrist's role is limited to record review and critiquing the forensic report of the other side. Evaluating a child or adolescent for alleged PTSD and commenting on issues of causality and future damages is a complex and challenging task. Very young children may have difficulty verbalizing the subjective symptoms of PTSD, and it may manifest itself differently in children than adults. Re-enactment of a trauma may be common, but flashbacks are less likely than with adults. Parents may not be the best observers of their children's behavior and may veer toward minimizing or exaggerating psychopathology. Heightened arousal in PTSD may be confused with attention-deficit/hyperactivity disorder (ADHD) or coexist with it. Children, especially those living in inner cities or war zones or those exposed to domestic violence, may experience cumulative and chronic PTSD that clouds issues of causality. Prior trauma may sensitize them, thereby heightening their vulnerability to subsequent trauma and the development of PTSD. Age at time of trauma

may affect which symptoms develop but not necessarily symptom severity. The course of PTSD is often affected by parental responses to trauma—hence the need to explore family dynamics and other environmental mediating factors. In addition, the forensic psychiatrist should be aware of studies on the longitudinal course of PTSD in childhood.

Key Points

Key points in the forensic assessment of children involve getting thorough developmental and family histories, including whether the child has experienced prior victimization or witnessed violence or sexuality and, if so, how he or she has dealt with it. In addition, it is important to note from other sources the exact onset of symptoms. For example, pediatric records may indicate that a child's sleep disturbance and bedwetting preceded a trauma, contrary to the history given by parents. The forensic psychiatrist should be aware of the salient literature on memory in children and the suggestibility of child witnesses. The child who has been through multiple interrogations may feel that he or she has not been believed and start to embellish his or her responses or try to please the interviewer by giving the desired responses. Leading questions and either–or questions that give forced choices can be hazardous.

Questions should be put to the child in an unbiased way that encourages the use of narrative recall. It is important to elicit the child's recall of traumatic events both verbally and through the use of spontaneous play and drawings, which may reveal traumatic themes. The child may evidence behavioral signs of trauma within the interview, such as heightened startle response or, in the case of the sexually abused child, undue familiarity. Although young children are not likely to malinger, statements made by interviewers or parents can readily influence them. Source misattribution, in which children confuse something they have read or been told about with something that actually happened to them, may also lead to erroneous allegations. In research settings, children who were repeatedly urged to think about nonevents eventually came to believe they really happened.

Eddie, a 4-year-old nursery school child, claimed that she had been repeatedly sexually abused by her nursery school teacher. In addition, she reported the she had accompanied her classmates to a secret location in a nearby park where there were sacrifices of animals that they were forced to observe. After a transcript of the initial evaluator's interview of Eddie was obtained it was possible to conclusively opine that she had been asked leading questions repeatedly and then complimented when she gave the desired answers. In addition she had been told that other classmates had told the interviewer about their horrific experiences with the nursery school teacher.

Pitfalls

Common pitfalls in the forensic evaluation of damages in civil litigation include attributing all of a child's symptoms to the trauma being litigated,

failure to get an adequate prior history, bias that leads to selective interviewing, the failure to pursue disconfirming data, and the need to give attorneys the opinions they seek. Some examiners immediately equate trauma with PTSD and fail to consider other diagnoses, or even whether the trauma in question meets the threshold of trauma necessary to meet the diagnostic criteria of the latest diagnostic manual (DSM-5). Similar problems may be encountered with plaintiffs alleging trauma-related depression or other psychiatric disorders.

Dr. A. was called by a defense attorney to review discovery material in a case that alleged permanent harm and suffering in 6-year-old Tony, who was alleged to have been sexually abused at age 3 years in his day care center. Dr. G., the forensic expert for the plaintiff, had evaluated the child and performed psychological testing on him and concluded that the boy's conduct problems were all related to the alleged abuse, which the child had difficulty recalling. However, his early history on the boy was cursory, and he had little information about the mother, who was a single parent, and did not review medical records. In her thorough review of discovery material, Dr. A. learned that Tony had witnessed extensive domestic violence and his mother's rape, shown signs of hyperactivity since age 2 years, and exhibited much anxiety related to his mother's safety and several separations from her at times when she was unable to care for him owing to depression. Tony also had delayed language development. Dr. G, at the time of his deposition, was asked why he had not asked about these matters. He said he considered the mother's personal life a private matter and did not see its relevance to the litigation. Dr. A, when deposed, pointed out that many other factors beside the alleged abuse might account for Tony's behavioral problems.

JUVENILE JUSTICE CASES

Overview

The US juvenile justice system, which is more than 100 years old, is in a state of rapid change. The founding premise that wayward youths could be rehabilitated through education, special services, treatment, and redirection has been challenged as more hard-core and violent youths enter a juvenile justice system that lacks sufficient dispositions and funding. Until fairly recently, there have been few data on effective treatments and a paucity of adequate dispositions and funding for this population. In response to the upsurge of adolescent violence which peaked in the early 1990s, out of a concern for public safety many states passed mandatory waiver statutes which typically specified that any juvenile in a certain age range who was charged with certain specified crimes would automatically be waived to adult jurisdiction. Other forms of waiver to adult court include judicial waiver, in which a juvenile is waived after a hearing, and discretionary waiver, in which the district attorney by statute is allowed discretion to prosecute certain classes of juvenile defendants in either juvenile or adult court. Juvenile crime has actually decreased dramatically in the last two decades, and in response there is a trend to loosen some of the broad waiver statutes. Studies suggest that adolescent defendants waived to adult jurisdiction are more likely to recidivate once released than

are youths who committed comparable crimes and remained in the juvenile justice system.

The Juvenile Court

The juvenile court remains a civil court in which judges have wide discretion, procedures remain more informal than in adult court, and records may remain sealed. However, in actuality there are many loopholes and exceptions to the concept of the sealed juvenile record. If a juvenile is waived to the adult court, his or her records go along. Juvenile records may also be released to insurers, the military, and employers and for purposes of licensing and national security.

It was not until the 1960s that juveniles were afforded any due process rights. In a seminal 1967 case, *In re Gault,* Justice Fortas charged that "in most juvenile courts the child receives the worst of both worlds: That he gets neither the protections accorded to adults nor the solicitous care and regenerative treatment postulated for children." As a result of this case, juveniles were afforded the rights to notification, counsel, confrontation and cross-examination, and the privilege against self-incrimination. They do not, however, have the right to jury trials or transcripts of proceedings. In 1970, *In re Winship* held that the standard of evidence in juvenile hearings must be beyond a reasonable doubt, the same standard used in the adult criminal court.

Preadjudicatory Examinations

Courts often request psychiatrists to perform preadjudication examinations on juveniles. These are designed to help the judge to make appropriate dispositions. These examinations are similar to diagnostic evaluations but go further in that they also consider mitigating factors, risk factors for continued delinquency and the risk the youth may pose to the community. In addition, an assessment of amenability to rehabilitation and recommendations as to what sort of treatment the youth needs may have bearing on the type of facility to which the youth is committed.

Waiver Evaluations

Waiver, or *bindover,* as it is known in some jurisdictions, refers to the transfer of a juvenile from the juvenile court to the adult court, in which proceedings are criminal, not civil, and public, not closed, and sentences may be harsher and extend into adulthood. Most adolescent defendants who now enter the adult criminal system do so as the result of mandatory waivers or as a result of prosecutorial discretion. With judicial waivers, evaluations are used for determining which court should have jurisdiction of the youth, not for disposition as in a preadjudicatory examination. Thus, the focus is on helping the judge weigh factors that have a bearing on the

decision of whether to waive a youth. In addition to developmental and psychosocial history and diagnostic issues, the examiner considers whether the youth has benefited from any interventions, be they therapeutic or within the juvenile justice system, thus far. Amenability to treatment that can be provided within the juvenile system and ability to contain the youth within the juvenile justice system are also considerations. Special needs that the adult correctional system might not be able to meet need to be identified, and consideration also may be given to age, size, and maturity of the youth. Risk of future violence must be assessed, and short-term prognoses may be made based on known risk factors.

Competency Examinations

Competency is a term that may be used in reference to many legal issues, such as competency to stand trial, waive *Miranda* rights, plead guilty, and waive the right to counsel. The court may also request an evaluation in regard to competency to stand trial if waiver seems likely. An adolescent must be competent to stand trial in adult court. Until the mid-1990s, very few states required that a youth be competent to stand trial in juvenile court, under the theory that many youth were immature and so incompetent, and that the role of the juvenile court was to promote rehabilitation. Since the mid-1990s, an increasing number of states have required that a youth be competent to stand trial in juvenile court, as well. Competency examinations focus on the individual's current ability to understand the charges against him or her and their severity and potential consequences, understand the trial process, be able to work with his or her attorney in developing a defense, and be able to participate in courtroom proceedings. While in many respects, the evaluation of competency to stand trial of a youth is similar to that of an adult, issues of developmental immaturity are much more likely to render a youth incompetent. Juvenile defendants who are found incompetent to stand trial pose a challenge for the courts, in that a major component of restoration is simply to let the minor mature. However, prosecuting a youth several years later who is now in a different developmental stage from how he was when the crime was committed is problematic.

Criminal Responsibility Assessments

In contrast to competency evaluations, which assess present state of mind, assessments regarding criminal responsibility attempt to reconstruct the defendant's state of mind at the time of the crime. Retrospective assessments of state of mind are always more difficult and rely on not just the defendant's version of events but also a great deal of discovery material. *Insanity* is a legal term that is used as a defense to relieve defendants of responsibility for the crime. States have different legal definitions of

insanity, and a few states allow no insanity defense. Legal definitions of insanity typically include a cognitive prong that gets at whether the defendant, at the time of the crime, as a result of mental disease or defect, lacked substantial capacity to appreciate the wrongfulness of his or her conduct. *Substantial* implies serious mental disorders and does not cover Axis II diagnoses or, usually, PTSD. The exact wording of the insanity defense varies from state to state. Some states have an additional volitional prong that refers to the inability of the defendant to restrain himself or herself as a result of an abnormal state of mind. In addition, the law requires that the defendant possessed a guilty state of mind (*mens rea*)—that is, intention at the time of the crime. Mental abnormalities may affect the ability to form intent or lead to diminished responsibility for the act. Thus, a murder charge might be reduced to manslaughter if the defendant was not capable of premeditation. A few states now permit a guilty but mentally ill plea, which results in the same sentence as if found guilty, but supposedly promotes more treatment while incarcerated. While youth waived to adult criminal court can potentially make use of their state's insanity defense, only a minority of states allow the use of an insanity defense in juvenile court.

Sentencing Evaluations

In juvenile court, if the court has already obtained a preadjudicatory evaluation covering the youth's developmental status, treatment needs, and amenability to rehabilitation, that report will often be used in sentencing. Courts or attorneys may utilize similar reports in the sentencing phase if a prior evaluation has not been done or if a supplemental evaluation is deemed useful.

For youth tried as adults, forensic evaluations are increasingly utilized in sentencing decisions. For serious crimes, a series of US Supreme Court cases have changed the landscape with regard to the sentencing of adolescents. In 2005, in *Roper v. Simmons,* the Court held that "evolving standards of decency that mark the progress of a maturing society" had changed to the extent that the death penalty for youth under 18 years of age was "cruel and unusual punishment" and thus unconstitutional. The Court cited three factors regarding adolescents that made them less culpable as a class, and thus not deserving of death: (1) that adolescents were developmentally immature, and thus more impulsive and more prone to respond to peer pressure, (2) that their behavior was often affected by adverse environmental circumstances over which they had no control (such as where they lived and the circumstances of their families), and (3) that their personalities were still in flux and so their actions could not be seen as reflecting enduring character traits. Five years later, in the case of *Graham v. Florida,* using similar reasoning about adolescent culpability, and also noting that neuroscience evidence about the development of the adolescent

brain supported an understanding of why adolescents thought differently from adults, the Court held that a sentence of life without parole (LWOP) was unconstitutional for all nonhomicide offenders. The *Graham* court also said that "A State is not required to guarantee eventual freedom to such an offender, but must impose a sentence that provides some meaningful opportunity for release based on demonstrated maturity and rehabilitation," leaving it somewhat unclear whether this imposed a duty on the state to foster rehabilitation, or just left to the defendant who has received a life sentence an opportunity to demonstrate rehabilitation at a subsequent parole hearing. Two years after *Graham,* in 2012, the Supreme Court, again using the *Roper* analysis of adolescent culpability, ruled that even for murder, a mandatory LWOP sentence for adolescents was unconstitutional, although a state could still give an LWOP sentence following a sentencing hearing. Since adolescent culpability turns on psychological factors, forensic evaluations of these defendants have an important part to play in sentencing hearings where life and LWOP sentences are being considered. Although the Court holdings pertain directly to issues of death and LWOP sentences, the factors of reduced culpability of adolescents have been used in sentencing hearings of adolescents facing lesser sentences and in sentencing hearings of young adults who are slightly older than 18 years of age but who arguably, in many developmental respects, resemble adolescents under age 18.

Blended Sentences

Some courts, such as New Mexico's, have started using criminal sanctions within the juvenile court, and others such as Michigan are experimenting with blended sentences by which the youth, on reaching the age of majority, is automatically transferred from a juvenile correctional facility to an adult one. In Minnesota, judges may impose extended juvenile dispositions with stayed criminal sanctions. Courts also are using mandatory minimum sentences for certain crimes. A very promising development has been that of youth drug courts for first-time offenders charged with drug-related offenses. Close court supervision is combined with outpatient drug treatment and a team approach, which appears to be cutting down on recidivism.

Interventions

The last decade has seen many changes in the juvenile justice system. There has been much more attention to the prevalence of mental illness in this population and the implementation of evidence-based treatments for conduct disorders, substance abuse problems, and comorbid psychiatric disorders. However, many facilities and programs continue to rely on outdated interventions in which juveniles are treated in groups with their

deviant peers. Numerous studies attest to the lack of efficacy of many programs for this population, and research has documented the negative effect that delinquent youth have on one another. Innovative community-based treatment programs, such as intensive probation, are proving effective in helping youth on probation cut down on reoffending. Another effective approach is multisystemic therapy, which was designed to target and influence the known correlates of antisocial behavior in youth. This may occur with youth living either at home or in foster placement. It uses intensive services that focus on problems within the child and his or her family and environment and promotes prosocial behavior. It is a cost-effective treatment that provides an alternative to out-of-home placement and has shown to be effective with delinquents. Collaborative problem solving is another intervention that is being used effectively in many juvenile facilities. Therapeutic foster care also has been shown to cut down on recidivism in some studies. A number of school-based programs now have good evidence of efficacy in reducing violence. In addition, diversion programs and mental health and drug courts are showing promise in keeping youth out of correctional facilities.

EVIDENTIARY STANDARDS

Prior to 1993, the standard for admissibility of expert scientific testimony was whether the opinion was based on theories generally accepted in the scientific community, the so-called *Frye* standard. Judges did not have to decide themselves on the scientific merit of a theory; they only needed to ascertain if it was generally accepted. In 1993, in a case interpreting the federal rules of evidence, *Daubert v. Merrill Dow,* the Supreme Court adopted stricter evidentiary standards requiring that expert testimony be based on scientific knowledge. Federal judges now had the job of deciding whether a theory was actually scientific, not whether it was generally accepted. Under the reliability prong of *Daubert,* the Court listed four nonexclusive factors to be considered when considering the reliability of theory or techniques as cited in Federal Rule 702. These included (1) testability, (2) subjection to peer review, (3) potential rate of error or standards regarding operation, and (4) acceptability in the scientific community, the remnant of the earlier standard set forth in *Frye*. Under the relevance prong, the Court asked the following: (1) Does the testimony logically advance a material aspect of the case? (2) Is there a valid connection to disputed aspects of the case? (3) Is the testimony sufficiently reliable? And (4) Does it rise to the level of intellectual rigor of an expert in the relevant field? *Daubert* is binding in federal courts and is followed by most but not all state courts. It has affected testimony in cases of alleged child sexual abuse and has limited admissibility of hearsay testimony in child custody cases.

FUTURE DIRECTIONS

This is an exciting time to be working in the field of child and adolescent forensic psychiatry because expanding research allows for opinions that are based on research data in addition to specialized knowledge of child and adolescent development, which will aid the courts in their deliberations. This subspecialty is gaining recognition and a body of literature along with clinical guidelines. Child and adolescent psychiatrists also have an important role in conducting research in the areas of prevention, intervention, and understanding the effect of trauma on the developing brain.

The juvenile justice system is in need of further reform. Many programs are inordinately expensive, and their efficacy had not been documented. In fact, in some programs, interventions have led to more reoffending or violent behavior. In many jurisdictions, juvenile offenders receive poor legal representation due to excessively large caseloads assigned to juvenile defenders and inadequate compensation rates. The recognition by the courts of the decreased culpability of adolescents, and the rapidly expanding knowledge of the underlying neurobiology of the developing brain, gives hope that public policy will continue to move in the direction of taking account of developmental information in rehabilitating adolescent offenders. Standards for determining child custody also need to be reviewed in light of changing family structures and the vagueness of "the best interest of the child" standard. Finally, it is hoped that forensic psychiatry fellowships will offer more flexible and diverse programs for those trainees wanting to specialize in child and adolescent forensic psychiatry.

ACKNOWLEDGMENT

The authors would like to acknowledge Dr. Schetky for her contribution to previous versions of this chapter.

▲ 55.7 Ethical Issues in Child and Adolescent Psychiatry

ADRIAN NATAN SONDHEIMER, M.D., AND ARDEN D. DINGLE, M.D.

Ongoing scientific developments and discoveries continue to advance and enhance the practice of medicine, often in areas relevant to the care of children and adolescents. The medical profession is no stranger to such continued accrual of new knowledge and to the potential benefits and risks associated with these advances, especially those that at times suggest quantum leaps ahead. In past centuries, the pace of change in the "knowledge base" was slower, but societies still needed medical personnel, designated "healers," whose responsibility was to diagnose ailments, provide treatments, care for the sick, give advice to the afflicted and their families, and develop new understandings of maladies. Since time immemorial, society's healers have encountered and considered conflicting theoretical stances, goals, and approaches. Steady advances in knowledge in the pursuit of providing optimal care have always led to comparisons of consequent risks versus benefits, and practitioners often had to confront the reality that proposed new solutions to problems can induce harmful effects.

These age-old conflicts among and between competing views and goals in the pursuit of "doing good" are ethical ones, and physicians—today's "healers"—exemplify their professional roles when giving these conflicts their due consideration. Situations in which such conflicts, or ethical dilemmas, arise include the degree to which physicians impose their wills on a patient when the patient's wishes oppose the physician's; the potential for physicians' personal aggrandizement or hubris to influence medical decision making; and the recommendation of treatment options that would benefit an individual patient but might conflict with the needs or desires of the family, community, and/or society.

Ethics is the discipline that focuses on moral principles or values that guide attitudes and behaviors while examining notions of right and wrong in relation to these human activities. Acting in an ethical and professional manner has been a fundamental tenet of medical practice throughout its history and remains an essential aspect of medical practice. The ethics of medicine has always intended to concern itself with the pursuit of patients' best interests and the societal good while respecting individual patient's personal rights. The codifications of musings about these considerations serve to advise, admonish, or assist people to behave in desirable ways, and these written compilations reflect the philosophical worldview and religious, spiritual, political, cultural and economic circumstances of their societies.

CODES OF MEDICAL ETHICS'HISTORICAL, NATIONAL, AND INTERNATIONAL

Medical ethics is the application of the ethical discipline to medicine. The individuals designated to treat the somatic and psychological ills of the community's members—today's physicians—are commonly accorded privileges and respect for their specialized knowledge and abilities. To promote this trust and protect the public, the healers and their communities have produced formalized written codes, or guidelines, governing the behaviors and conduct expected of physicians. These codes of medical ethics focus substantially on the treatment obligations of the healers to the individuals residing within these communities.

Several themes and exhortations are commonly found in medical codes of ethics that date back many hundreds of years and emerge in myriad cultures. These include primacy of respect for human life; physician responsibility for the patient; emphasis on virtue and duties; provision of help; avoidance of harm; equality of care for rich and poor; setting of fees; methods used to establish diagnoses, with the expected employment of clinical observation and reasoning; use of appropriate therapies; confidential nature of patient–physician communications; prohibition of physician–patient sexual relationships; and provisions for punishment or sanctions in the event of poor technical performance, code violations, or both.

In the United States, the formation of the American Medical Association (AMA) in 1847 was accompanied by the creation of a code of ethics. A society organized in 1844 by 13 medical administrator superintendents of "American Institutions for the Insane" became the foundation for the creation of the American Psychiatric Association (APA) in 1921. In 1973, the APA produced its first code of ethics, which was annotated and revised in subsequent years.

Considerations of children's needs were largely absent in the formative years of these professional organizations. The dawn of the 20th century saw the beginnings of professional reflections concerning children's health needs as separate from those of adults. The American Academy of Pediatrics was founded in 1930, and in 2007 that body adopted for the first time a document focusing on the mission, values, and professionalism distinctive to its practitioners. APA members, independent psychiatrists, pediatricians, psychoanalysts, and other medical practitioners with a primary interest in children's mental health founded the American Academy of Child (and Adolescent) Psychiatry (AAC[A]P) in 1953. The AACAP introduced its code of ethics in 1980; it was expanded, with accompanying annotations, in 1995, revised in 2007, and substantially rewritten in 2009. In 2014, the code was further revised and enhanced by the inclusion of discussions related to social media, expansion of research matters to include scholarly activities, and a focus on the explicit natures of potential boundary crossings. The AACAP code covers ethical issues

relevant to clinical, administrative, and scholarly practice in child and adolescent psychiatry. Its narrative is organized around principles and major specified areas of concern inclusive of: Developmental Perspective, Promoting the Welfare of Children and Adolescents (Beneficence), Minimizing Harmful Efforts (Nonmaleficence), Assent and Consent (Autonomy), Confidentiality (Autonomy/Fidelity), Third Party Influence (Fidelity), Scholarly and Research Activities, Advocacy and Equity (Justice), Professional Rewards, and Legal Considerations.

This code uniquely introduces a developmental perspective, thus covering an essential aspect of caring for children, adolescents, and their families. It affirms that abiding by these ethical principles is considered an essential aspect of being a competent and capable child and adolescent psychiatrist (CAP). Further, continued learning and maintenance of the ability to identify, analyze, and make decisions about ethical dilemmas are considered a key skill set for all medical students, residents, and physicians. Ethical CAPs should possess the knowledge of ethical principles and their use but, even more fundamentally, understand that this knowledge and skill set are an essential aspect of their professional demeanors and should be reflected in their behaviors. The code advises that a key aspect of the ethical practice of CAP is a developed awareness of one's personal beliefs and the impact of these beliefs on the clinical and professional choices made by the practitioner.

Ethical thought is universalizable, that is, ethical principles and reasoning apply in all situations, nationally and internationally. However, when ethical reasoning is utilized, attention must always be paid to situational context and culture. Thus, while emphases on, for example, competence, honesty, avoidance of exploitation, confidentiality, boundaries, and protection of research participants transcend individual nation-states, their examination and potential resolutions are partially contingent on geographic location. Many ethical and related codes have been produced by international bodies, including those of the World Medical Association (originated 1949), World Psychiatric Association (originated 1996), and the United Nations Convention on the Rights of the Child (1989). This last document established the rights of children to survival, development, protection, and participation in society and, by implication, their health care. In 2006, the International Association for Child and Adolescent Psychiatry and Allied Professions (IACAPAP) produced the document Ethics in Child and Adolescent Mental Health, which created principles addressing the rights of children and behavioral guidelines for the professionals who treat them worldwide.

While children and families in developed countries can struggle to access services, the resources available to developed versus resource-poor countries, as well as the natures of their governance and cultures, serve as the greatest differentiators in mental health approaches to children living

in dissimilar locales. In the former, for example, the practitioner frequently is concerned with the ethics surrounding recommendation of brand versus generic medications in comparison to the practitioner whose pharmacological armamentarium often is empty. Similarly, a locale's culture often determines whether a child's protests are welcomed as a sign of developing autonomy versus being viewed as a violation of elders' decision making for the group, the culturally sanctioned norm. At the worst, displaced refugees, homelessness, immigration, sex-trafficking, and the production of orphans (secondary to war, capture and disease) account for huge numbers of children in predominantly resource-poor countries. A paucity of mental health professionals in these locations further ensures that little attention will be paid to children's psychiatric needs. The ethical imperative to improve children's life circumstances and to provide appropriate care, however, remains unaffected by the surround.

MEDICINE AND MENTAL DISTURBANCE

From a historical perspective, within the context of medically influenced writings, mental illness was first formally addressed by the Greek physician Hippocrates and, several centuries later, by Galen in Rome. The ancient Romans dealt with the definition of mental disturbance, the nature of caregivers, guardianship, approaches to care, and legal competence. Thus, Roman society and numerous others that followed, by recommending approaches that they considered to be correct and beneficial medical and judicial professional behaviors, were instrumental in contributing to the creation of modern codes of behaviors expected of healers. Focusing on medical illness, inclusive of those who suffered from mental disturbance, the codes and laws forged by the ancient Romans and reconsidered and expanded in subsequent eras explicitly addressed the ethical conflicts that daily confront medical practitioners without separating the somatic and psychological spheres.

CHILDREN AND ETHICAL CONSIDERATIONS

When and how did children come into the picture? Some historians have posited that prior to the 17th century, in the Western world, children generally were not viewed as developmentally distinct from adults. Pediatrics was first established as a unique specialty in the late 1800s. Over the last few centuries, children and adolescents have been recognized as distinct groups engaged in ongoing growth, as well as knowledge and skill acquisition, in emotional, physical, intellectual, language, moral, and interpersonal spheres. In the last decades, increasing recognition and support has accrued to the perspective that children have inalienable rights to development and participation in society, as described in the UN Convention on the Rights of the Child. The substages of child and adolescent development imply that children's maturation in developmental

spheres correlate with chronological age and, therefore, that expectations of children's capacities for comprehension, reasoning, and sound making of decisions will vary with the individual child's degree of attainment. From an ethical perspective, insofar as these capacities remain immature during development, children generally are not granted decision-making rights; rather, these responsibilities remain with their guardians. When the goals of the guardians and their children conflict, however, problems may ensue. Furthermore, children are commonly cared for by individuals or agencies concerned with their welfare, such as schools, individual health practitioners and institutional providers, governmental welfare and protective services, and juvenile justice systems. Information exchange among these parties is necessary for the provision of care, but the transmission of data among them can occur without a child's knowledge, leaving affected children vulnerable to the potential misuse of confidential information. Thus, the factors of continuous developmental maturation, potentials for children–guardian conflicts, and numerous avenues of and needs for information transmission frequently lead to ethical dilemmas concerning children.

Ethical Dilemmas and Reasoning

Practitioners might recognize the presence of a child-related ethical dilemma when experiencing internal conflict about potential divergent approaches to the provision of clinical care. For example, CAPs consulting to a pediatric clinic, with 15 minutes available to see a 6-year-old distressed patient, must consider whether to spend this limited time with the patient and guardian or with the guardian alone. If psychiatrists choose the latter, then they can anticipate obtaining a coherent history without needing to "manage" the individual patient, an approach that could rapidly and succinctly provide the needed medical input. However, direct observation and interaction with the child might prove crucial to an adequate database. How to provide the best care—an ethical imperative?

Ethically problematic situations like this one are commonly ambiguous —they involve gray areas. In the face of such a conflict, given the pressure of time and clinical demands, harried clinicians might not register the ethical dilemmas related to the principles of *beneficence* (promotion of well-being) and *nonmaleficence* (avoidance of causing harm). Therefore, it is most advisable for clinicians to resist an immediate response, consider the alternatives, engage in a reasoning process—largely a risk–benefit analysis—and ultimately make their choice based on a resolution that is least damaging and ideally most helpful to the patient.

Ethical Principles and Forensics

Medical ethics is a field of inquiry based on principles that are considered

universal, inclusive of the obligations to pursue *beneficence, nonmaleficence, autonomy* (promotion of individual freedom of action and choice), *fidelity* (faithfulness, loyalty, and respect for the rights of others), and *justice* (treatment of individuals with fairness and equality). Parenthetically, within this last category, consideration may also be given to the concept of *social justice,* that is, the treatment of groups of individuals with fairness and equality. These principles often serve as the foundations for derivations of legal precepts and administrative decisions. For example, the legal concepts of the individual's right to privacy and informed consent for medical procedures largely derive from the principles of autonomy and fidelity. Additional concerns include the possibly conflicting rights of individuals and society, as in the case of proposed quarantine for contagious infectious disease which pits conflicting concepts of individual autonomy against those of communal social justice. Ethical dilemmas in medical practice often involve the operation of several of these principles simultaneously, and the principles may conflict and compete.

The consideration of multiple principles in a reasoning process, however, allows for leeway in decision making. The law, by contrast, although generally based on ethical deliberations, defines acceptable choices and behaviors more narrowly. Not uncommonly, the discussion of ethical considerations segues into an examination of legal ones, conflating the two distinct disciplines. At times, the legal response can be at odds with powerful ethical arguments. For example, in custody disputes that include significantly involved nonbiologically related foster parents, certain jurisdictions adhere to laws that mandate awarding custody to the closest biological relative, even to one not involved in the child's current care. Such compulsory rulings might conflict with evidence of the establishment of close and long-standing emotional ties between children and their nonrelative foster parents. In such instances, implementation of the law could appear to cause harmful, in contrast to beneficial, effects.

Although several distinct ethical concerns may exist simultaneously, over time one approach to the dilemmas usually takes form as the most beneficial, or least harmful. The CAP clinician, administrator, researcher, or teacher, dealing with a problematic case, must strive to arrive at the least damaging resolution, commonly using a risk–benefit analysis. Awareness of relevant laws is necessary to this reasoning process, but the law is not necessarily the deciding factor.

CHILD-RELATED CONCERNS

Areas of ethical concern common to child and adolescent psychiatry practice include confidentiality, parent–child conflicts in desires and rights, assent to or refusal of treatment or research, physician responsibility for continuation or termination of care, child advocacy and protection, agentry, boundaries, and professional responsibilities.

Dilemmas arise in many contexts, including inpatient and outpatient facilities, private offices, and institutional settings; in the course of obtaining histories and providing treatments; abuse and neglect; divorce and custody; and forensic settings (e.g., court). Participation in administrative and research/scholarly activities often raises ethical issues. Conflicts arise owing to increased physician awareness of, and sensitivity to, issues of culture and religion, changes in health care delivery and economics, heightened understanding of the scientific basis underlying disease etiology and expression, the influence of various institutions involved in health care, and the presence of electronic methods of communication, used both professionally and socially. Consequently, new dilemmas, or old dilemmas in new garb, confront CAP practitioners, administrators, researchers, and educators on a daily basis.

Multiple Agentry

Angela, a pregnant 15-year-old, was informed that her 16-week-old fetus was anencephalic. Obstetrics personnel urged termination of the pregnancy, but Angela refused to abort. One day later, she became acutely suicidal. In the emergency department, a psychiatric evaluation found her imminently dangerous to self. Angela refused to agree to psychiatric hospitalization and an involuntary commitment process was begun. Subsequently, the receiving psychiatric hospital refused to admit Angela without a prior termination of pregnancy. Angela's history indicated that the state child protective services agency, which had functioned as Angela's legal guardian for 5 years, had 1 year earlier removed Angela's then 7-month-old child from her care after a finding of neglect.

CAPs are obliged to recommend and pursue optimal care for their patients. In this case, doing so would require a guarantee of the patient's safety, and, therefore, in Angela's case, hospitalization is indicated. The practitioner, however, must also take into account other influences, such as, in this case, obstetric and pediatric personnel who strongly argue for the termination of the pregnancy to spare anticipated future suffering of the patient and fetus. Other positions requiring consideration include those of the receiving psychiatric hospital that refuses to admit Angela without prior termination of the pregnancy; Angela's foster parent, who refuses to countenance abortion as an option for a child living in her house; the child protective services agency, Angela's guardian, which refuses to take a decision-making role, arguing that the patient is competent to make decisions; and the patient, who refuses to assent to either psychiatric hospitalization and termination of the pregnancy. While Angela's right to make the decision about her hospitalization varies depending on the state in which she lives, she retains the right to decide about her pregnancy throughout the entire United States. The CAP has the obligation to be Angela's advocate in order to ensure that her best interests are protected and she does not experience harm. Thus, working with Angela to better understand her views and helping her to make good decisions, while

utilizing appropriate strategies to manage her distress, is essential.

CAPs commonly face issues of multiple agentry—the need to be responsive to a case's interested parties, who often are pursuing conflicting agendas. As above, it is fundamental that the CAP protect and advocate for the individual patient. That is, CAPs must act as agents for the minor patient while not permitting themselves to be swayed by the goals of the other parties, their own personal biases, the sources of income that pay for the physicians' efforts, or their allegiances to fellow professionals. CAPs have the obligation to act as the agents for their minor patients, despite the engagement in the care of these patients by parents or guardians with whom the CAP may spend more time than with the child and who often are paying the physician's fees.

"I want you to treat my daughter. She's been misbehaving at home and at school. This has nothing to do with my recent separation from her mom, and the fact that my new girlfriend is living in our home. I'm not going to say another word about this—concentrate your efforts on my daughter!"

"I am the only normal one in my family. You've heard what happens at home—my parents are crazy. Who behaves like this? I'll tell you, people who have problems. They should be in treatment, not me."

Who is the patient? When dealing with children and adolescents, it is often useful to use a family systems perspective that focuses on the dynamics between and among the various parties in the nuclear household. This stance can be viewed as a beneficial approach for all the involved parties because it permits CAPs to function as agents for both the family as a unit and its individual members. When the guardians refuse such an approach, however, practitioners face at least two ethical dilemmas. CAPs need to provide optimal care to the child while not alienating the parents and must avoid inappropriately labeling the child with psychopathology when the primary disturbance may reside with the parents. Such an approach requires clinical dexterity and due regard for the autonomy of all the interested parties while maintaining as primary the needs of the child.

Effects of Culture and Religion

As the intermingling of differing, multiple cultures continues to be the ever-growing norm in the United States, CAPs are frequently called on to deal with conflicting notions of expectable behaviors and deviations from them.

"I brought my 13-year-old daughter to the emergency department because she's hitting me. She's sinful, and she's crazy. We've always gone to church together, 5 days a week, and now she refuses to go. She has to go, because otherwise the Devil will take hold of her, as He did to me in my teens, when I had her. Her hitting me, her mother, is just the beginning of His hold on her, and through her the Devil will infect my younger children."

> "I don't know why my parents are bothering you with this. They want me to be more observant of our rituals, participate more in our culture, and continue with my education. Both of my parents didn't finish high school and most people my age back home are working at a job. I'm trying to do what they want, but now I found a job and they have no reason to be mad that I'm quitting school."

Varied culturally and religiously defined misbehaviors are found within an array of ethnicities and denominations. CAPs must rely on the profession's scientific knowledge base to evaluate case data in order to arrive at psychiatric diagnoses rather than using the belief systems and mores preferred by a culture or religion. However, CAPs should also be aware of, acknowledge, and have respect for the importance of cultural and religious perspectives to patients and their families. Treatment plans and dispositions should be approached in a similar manner, using resources peculiar to the belief system to the extent possible, without jeopardizing the care of the child. In addition, CAPs should note that separation-individuation phenomena manifest and provoke consternation in many, perhaps all, cultures. In the interest of providing good care, CAPs are ethically bound to pay attention to both culture-specific and developmentally normative behaviors. Not infrequently, education concerning normal child and adolescent development, conveyed in a caring manner, is much appreciated by the parent living in an otherwise self-contained culture.

Countertransference

The five aforementioned scenarios likely engendered, in the evaluating and treating psychiatrists, affective responses toward the protagonists. *Countertransference,* the term colloquially used to describe these phenomena, is closely related to CAPs' affective responses to the raised issues. What are the psychiatrists' attitudes toward abortion, teenagers who engage in sexual activity and become parents, parents reluctant to acknowledge the effect of their behaviors on their children, assaultive youths, individuals for whom religious and cultural beliefs and mores are paramount, and youngsters striving for autonomy? It is important for CAPs to engage in self-inquiry and determine the reasons for their countertransferential responses to these factors so as to ensure that these phenomena do not negatively affect optimal care for the children (and adults) under their care. Overidentification by CAPs with the child or adult is dangerous, as are rescue fantasies that focus on children who seem to live with little in the way of adequate adult protection, advocates, or both. CAPs in earlier stages of their training may tend to ally themselves with their patients, whereas older ones, many of whom have become parents, may tend to express greater empathy with the guardians. Ultimately, CAPs must

focus on the needs of the child and avoid choices that are more reflective of the individual psychiatrist's intrapsychic dynamics.

PROVISION OF CARE

From a clinical perspective, ethical considerations should begin with the first patient contact and extend past the final meetings.

Assent and Consent

> "Hello, doctor. I would like to make an appointment for my 9-year-old boy who probably has ADHD (attention deficit hyperactivity disorder), and I know he has lots of behavior problems."

> "Oh, I'm not telling him that we're coming to see the doctor. He gets so upset and I figured you could explain it better."

Questions that should follow immediately on such a seemingly innocent and sensible inquiry about an appointment ought to address whether the involved child agrees to a medical procedure (i.e., the psychiatric evaluation and interview). Will the child assent to this procedure, is he averse to it, and/or is he being coerced by the parent to attend? To what extent should children's objections to the initiation of an evaluation, or to treatment that might be recommended at its conclusion, be respected—that is, to what extent is children's *autonomy* considered? Have the children been reasonably well apprised by the guardians of the reasons for the proposed evaluation, and, if not, by the practitioners in the course of this first meeting—in other words, has the assent been informed?

Insofar as children ordinarily are legally considered minors until age 18 years, children are generally unable to give legal *consent* to proposed medical procedures, but they may *assent* to them. It is the children's guardians who provide consent. Further complications can arise when disagreements exist between children's legal guardians regarding proposed care, as may occur in the context of divorced parents. Often one of the parties is legally designated the guardian ordinarily responsible for obtaining medical care for their children. In any case, in emergencies, the urgent need for provision of care becomes the physician's paramount consideration, irrespective of parental guardianship. In situations short of emergencies, however, lack of consent or opposition by one of the guardians raises ethical and legal dilemmas. The parental disagreement might be exacerbated by psychiatrists' actions favoring the stance of one of the parents, which could negatively affect or harm the child by aggravating the parental conflict. Standing in contrast, psychiatrists must also consider the children's rights to an evaluation and their need for care.

> "I'm pregnant, my parents don't know, I'm not sure who the father is, and I'm not sure what to

do about it. I'm 15 years old, I can think for myself and make my own decisions, I have the money to pay your fee, and I want to discuss this with you without my parents knowing about it."

"I don't see why you want to talk to my parents. Yes, I live with them but they really don't know anything about me and I'll be leaving soon when I graduate from high school."

These adolescents are not simply assenting to treatment, but are requesting care from psychiatrists. A 15-year-old pregnant girl, in some states' jurisdictions, is automatically considered an adult or "emancipated minor" by dint of her pregnant state, whereas in others she remains legally a minor. "Mature" or "emancipated" minors can legally access care for themselves. Ordinarily, however, care only can be provided, except in emergency situations, with the consent of an adult. At what age does the adolescent develop the cognitive and emotional maturity to be able to give consent? Is that decision based on chronological age (e.g., attainment of age 18 years), or is it situation or case dependent? Given that adolescence is a stage of rapid physical and cognitive maturation and change, this fluidity in growth renders ethical questions regarding autonomous decision-making more complex and less certain than when dealing with similar issues in younger children. As adolescents advance toward cognitive maturity, respect for their desires and opinions should progressively be factored in to professional decisions in the interests of respecting the youths' entitlement to *autonomy*.

Confidentiality

It is the physician's responsibility to protect, and not convey to others, information about a patient, unless the patient has given permission for this transmission. The patient has a right to expect adherence by the physician to this obligation, which serves as a basis for a trusting physician–patient relationship. The principle of confidentiality is often subject to limitations in work with children, in that guardians, patients, and agencies want and require information about child patients, and children often are unable to comprehend the risks and benefits involved in the waiver of their rights to confidentiality. In addition, electronic medical records and other electronic methods of communication can mean that, without adequate built in safeguards, multiple individuals and institutions may potentially access confidential patient information.

"It's simple, doc. You've known my kid for a while. She's seriously disabled, she's 10-years-old, and we need the state benefits to which she's entitled. Just fill out this ten-page form—it asks for all kinds of information about her—nooooo problem!"

"Doc, can you give me a copy of her chart? The school needs the records to start their evaluation process and it'll be faster if I just deliver them the information."

A signed release from guardians permitting transmission of information about children might satisfy legal concerns, but ethical issues remain that warrant exploration. To what extent do children's disabilities affect their capacity to provide assent? Would state/school involvement foster a child's development or hinder it? Is all, some, or none of the requested information pertinent to the child's condition? Is the information requested legally protected, or might it be accessible or transmitted to parties in the future without the patient's or guardian's knowledge? Psychiatrists must evaluate these issues by simultaneously playing the role of child advocates and attempting to protect children from current and possible future misuse of the information that the practitioners might provide. Such questions should be addressed with both guardians and, to the extent possible, patients, because families need to be aware of the ways in which information provided to third parties might subsequently be used. They also should be educated about the potential risks of information disclosure when various forms of electronic communication, such as e-mail, social websites and cell phone texting, are employed.

"About those emails I've sent you about my daughter. You know, asking whether she talks to you and tells you the truth or she lies? Please don't tell her about those messages or about any of the info I've given you about her."

Adolescent patient to psychiatrist: *"I don't really talk on the phone. Can you text? I'll definitely get any messages then. And that way I can let you know what's happening; it would be great to talk between sessions."*

Commonly, parents or guardians are eager to know details concerning information the CAP has obtained in the course of treatment of their minor. The use of a family therapy approach at the onset of treatment, with an explicit message emphasizing free but judicious exchange of information, can circumvent many confidentiality concerns. Informing the family members at that time that information requested or supplied outside of treatment sessions would likely be shared with all obviates otherwise sequestered communications. As well, it is warranted to notify all participants at the outset that potential self-harmful or externally directed aggressive acts do not fall under the confidentiality obligation. In forensic contexts, minors and their guardians need to be informed from the outset of the lack of confidentiality concerning personal information (i.e., that the information included in forensic reports will be made available to all the interested parties and be part of the public record). Ultimately, practitioners should always exercise tact and restraint in the provision of information to all concerned parties, and all the more so when the transmitted information is likely to be reviewed by non-mental health professionals.

Separately, the advent of commonly used digital media and electronic communications, while positively facilitating information exchange of all kinds, does not in any way eliminate the need for alertness to the existence of ethical considerations and legal concerns in these spheres. The considerations that govern face-to-face care apply equally to electronic communications with patients and their families, despite their apparent ease of use. Thus, potentials for boundary violations, confidentiality and privacy transgressions, negligence, and defamatory messages are abundant and sometimes not obvious. Further, the seductive simplicity of seeking and finding information about patients and their families, easily obtainable via the Internet, could result in ethical violations when performed without the patients' and families' knowledge and, similarly, if not necessary for the patients' care. All of these concerns and behaviors involve potential violations of the patients' rights to expect respect by physicians for their *autonomy* and avoidance of breaches of *fidelity*.

Fidelity and Mutual Trust

Fidelity, honesty, and *integrity* are three cardinal qualities expected of physicians that contribute to the measure of a physician's professionalism. Patients are entitled to expect physicians to deal with them openly, stay with and not abandon them through the course of their illnesses or disturbances, and make attention to their needs primary before a physician focuses on possible self-interests. These expectations, however, may come under pressure when a physician feels threatened or hemmed in.

> "You've seen my 16-year-old son for a month. He's angry and unhappy, fighting with me, and failing school. I think he's using drugs. I want you to tell his pediatrician to order a tox[icology] screen and have it performed without his knowledge when he sees the doctor next week. My son would refuse if asked directly. If it turns out negative, he won't know I suspected him of drug use; if positive, I'll keep the results to myself and decide later what I want to do about it."

The patient's guardian requests of the psychiatrist to deal with the patient in a nonstraightforward manner to obtain important information. This request is ethically problematic because the creation of mutual trust between physician and patient is a fundamental tenet for the establishment of a sound treatment relationship. A physician–patient relationship in which neither side could expect honest exchange would be doomed from the outset, even if the knowledge sought in a clandestine manner were significant. The means to ends should be discussed in a candid exchange, even if some of the desired ends are, in the short run, thus rendered more difficult to achieve. Short of emergencies, there is no place for a paternalistic approach that would justify withholding vital information from a patient. It is crucial to the establishment and maintenance of successful therapeutic relationships that all family members understand

this principle.

CAPs and others involved in the care of children are periodically faced with behaviors that adults experience as repugnant, threatening, or both.

An inpatient pediatric attending addresses the consulting CAP: "The nursing staff on my unit have been telling my patient, a 15-year-old boy with hepatic failure, that they wish he would die. He developed severe hepatitis as a child and became a 'darling' of the unit during his stays there, while receiving and then rejecting two liver transplants. He is back here now being evaluated for a third transplant, but 2 weeks ago he was charged with sexual abuse of a child, and the staff has completely turned on him."

CAPs tend to have considerably more experience with victims of abuse than with (alleged) perpetrators. Physicians' efforts, therefore, are mostly devoted to the repair of those individuals who have experienced emotional injury. Children who are accused of doing (or who do) bad things, however, also require care. Nondiscrimination is a fundamental ethical imperative. Provision of the physicians' care is dependent on a patient's needs and not on the whims, preferences, or biases of the practitioners. Thus, it is incumbent on CAPs to act as advocates for the abusing, malfeasant, and nasty child as much as for the victim deserving of sympathy. In other words, despite possibly harboring negative feelings toward patients, physicians must maintain *fidelity* to them and continue loyally to provide the distasteful children with professional service.

Despite such exhortations, situations arise in which CAPs' negative feelings toward children may interfere with the provision of good care, in particular when CAPs feel threatened by the children.

A 15-year-old male teenager in a detention facility, adjudicated for murder, calmly says to the examining CAP: *"I know where you live. I don't like you. You stay in my face and I'll kill you. That's not a threat—that's a promise."*

Psychiatrists, like all human beings, are entitled to self-preservation and considerations of self-interest. To the extent possible, CAPs should avoid allowing these concerns to jeopardize the health of their patients. Termination of care may be appropriate in the event CAPs believe themselves to be in danger, but only if provisions are made beforehand for care to be provided by other practitioners.

Boundaries

Physician behavior toward patients should always be initiated and maintained with the patient's best interests in mind. Medicine's professional ethos emphasizes strict physician adherence to the value of integrity. In the context of the physician–patient relationship, the concept of boundaries refers to limits within the relationship that ought not be breached. Maintenance of such boundaries helps preserve the integrity of

the relationship. Although some physician behaviors clearly violate the physician–patient boundary and are impermissible (e.g., sexual relations between physician and patient; physician use of confidential patient-derived information for the physician's gain), other behaviors reside in gray areas. Physicians who divulge personal information to patients, or overlook timely payment for services from patients reporting financial difficulties, may be engaging in good, compassionate practice or in enticing and exploitative behaviors that service the physicians' needs, or both.

> "I saw you eating dinner at a good restaurant a few weeks ago, so I figured you liked it. You've helped our family so much that I wanted to say thank you with a gift card to that place. Don't worry, it isn't a big deal."

> "Can you come to my graduation? I couldn't have made it without you."

> "Can you lend me fifty cents? I'm really hungry and don't have enough money for the potato chips."

> "The case is a great example of what I am presenting on, and I need to send in my talk tomorrow. It would be too difficult to find the patient and ask her permission to use her information. I'll change the details so no one will know who the patient is."

Work with children and adolescents can lend itself to the potential for boundary infringements. CAPs who passively enjoy the spectacle of a child's oppositional or adolescent's seductive behaviors and therefore neglect to set appropriate and timely limits, agree to treat children despite knowing the family socially, accept significant presents, prolong children's care owing to an attraction to a parent, or discuss with colleagues or write for publication about a patient for the purpose of self-aggrandizement are, in all these instances, potentially violating the patient's boundaries.

Patients justifiably expect not to be exploited by their physicians and to feel secure in the treatment setting. Despite best intentions to engage in self-monitoring, physicians' positive countertransferences toward patients could result in behaviors that end in a special or favored status for particular patients. In those instances, it is highly recommended that physicians recognize these types of behaviors and their potential for leading toward more frank violations. Rapid consultation with respected colleagues is the preferred antidote to strengthen and secure physicians' self-control and provide patients with sound and unimpaired care.

CURRENT AND FUTURE ISSUES

Although the ethical principles of beneficence, nonmaleficence, autonomy, fidelity, and justice remain immutable, their consideration must be applied to constantly changing contexts that include advances in scientific

knowledge, innovations in means and modalities of communication, changes in financial structures, shifts in societal priorities, newly created treatment approaches, and novel research foci with patients. These arenas continually evolve, with further developments undoubtedly to come. The implications for child and adolescent psychiatry practice have been and will be considerable, leaving physicians struggling to keep pace with these rapid changes and the freshly minted ethical dilemmas they pose. The following subsections focus on eight relevant areas.

Genomics

In 2000, the Human Genome Project concluded a successful effort to decode the DNA sequence of an individual's 23 paired cellular chromosomes. The consequences of this achievement, as well as the ongoing knowledge accumulated from continued research in this area that includes DNA-based tests concerning specific genetic disorders, focus on chromosomal changes, and gene products, have profound implications for illness prognostication, treatment, and counseling; the relative importance of environment and genetics in the transmission of psychiatric disorders; and payments for the treatment of these disorders.

For example, current capabilities include the potential use of gene chip technologies to determine the optimal pharmacological treatment of children resistant to specific medications. Future CAPs will no doubt be in a position to consider genetic information, unique to their patients, as a basis for deciding whether to treat an illness preventively that has not emerged or has barely been expressed. The proposed treatments might be applied with currently available psychotropic medications or with yet-to-be-developed gene therapies. Informed *assent* or *consent,* or both, and the weighing of the numerous risks versus benefits of these postulated interventions, need to be mandated as ethical components of the process. Similarly, CAPs' notations in the medical records of genetic information and related considerations could lead, without strong adherence to the principle of *confidentiality,* to inadequate safeguards for the protection of patients' genetic data. This breach, in turn, could lead to the stigmatization of patients and possible discrimination against them by potential employers or agencies responsible for hiring and the provision of health and life insurance coverage.

There appears to be a consensus that children ought not to be genetically tested for precursors to adult-onset psychiatric disorders, such as Huntington and Alzheimer diseases. However, technologies might soon become available that would be capable of screening children for childhood-onset psychiatric disorders, and a strong argument could be made that not to do so would put the child at undue risk. As knowledge expands, the enhanced ability to predict children's development of behavioral, cognitive, and affective traits and disorders is likely to become a

factor that CAPs will consider. It is probable, therefore, that the CAPs of the future will be concerned with the principles of doing good and avoiding harm in the context of working to a considerably greater extent in tandem with medical geneticists and counselors.

Treatment of Psychiatric Prodromes

Clinical researchers have postulated that the appearance of specific behavioral signs and symptoms in childhood or adolescence may be pathognomonic (i.e., currently prodromal) of the later development of full-blown severe psychiatric disorders, such as schizophrenia. Several institutions chose, therefore, to investigate this contention by considering the combination of the appearance of these early-onset behaviors together with a positive family history for the illness as predictive of the likelihood of its later development in the identified youths. Because of the debilitating nature of the full-blown illness, it was the investigator's intentions to provide treatment—for example, neuroleptic medications—to these youths and subsequently to monitor outcomes. Relevant ethical concerns were and are many. Aside from the complicated matters of informed consent and assent, dilemmas include accuracy of the identifications and intrinsic difficulties in monitoring outcomes. Specifically, it is at best difficult to determine whether it was preventive pharmacological treatment that forestalls later full expression of the illness, given that the expression might not have occurred under any circumstances. Similarly, the development of adult-onset schizophrenia in a prodromal individual not exposed to preventive treatment might occur despite earlier exposure to neuroleptic medications. And, complicating the situation, the data on treating prodromal individuals has at best been equivocal, resulting in the discontinuation of these programs at several of the experimenting institutions. Furthermore, recent work suggests that psychosocial, family-based interventions may be more effective for prodromal individuals than antipsychotic drugs. In sum, the theoretical prodrome is not definitively predictive; it simply postulates vulnerabilities and increasing possibilities of the later emergence of full-blown adult-onset illness.

Within this paradigm, later development of the illness in a previously untreated youth would imply that there was an earlier withholding of a potentially beneficial intervention. Further complicating the picture, a proposed treatment—for example, neuroleptic medication—might be known to have the potential for producing severe deleterious effects. Finally, knowledge of genetic factors that might more accurately predict the future development of the illness is a promising anticipated advance in molecular biology, but one that remains as yet to be achieved. Of course, the theoretical basis for the treatment of childhood psychiatric prodromes is not limited to schizophrenia, and similar ethical considerations, involving uncertainty of outcomes, potential dangers and benefits of

interventions, and the effects of withholding interventions, would apply to many of the biologically based disorders.

Information Technologies

Substantial advances in electronic data collection, reporting, storage, retrieval, and communication are continuing to revolutionize medical practice, thus enhancing the possibilities for sustained continuity of care while raising novel ethical issues for child and adolescent psychiatry practice. The advent of the electronic medical record increases the possibility of transmission of confidential information concerning minors, without a guardian's consent, over the time period that the information is electronically stored (theoretically forever). The child, who owing to age lacks control over personal information transmission one day becomes an adult. At that time, potential employers', health insurers', and public agencies' electronically facilitated access to this information could negatively affect the individual, owing both to the stigma that continues to attach to mental disturbance and the effect of pre-existent illness on employer hiring practices and employee acquisition of health benefits. Will an adult have control over personal health data entered into information banks when that individual was a minor? Who owns this information, who is empowered to make these decisions, and what standards are to be used?

The Health Insurance Portability and Accountability Act of 1996 was established to create transaction standards and privacy rules overseeing the electronic transmission of personal medical information. Although the Act, which became effective in 2003, was intended to provide federally mandated privacy protections for this information, critics contend that loopholes exist. In the interest of advocacy for patients, it has become the CAP's professional responsibility to alert children's guardians, as well as the adolescent who may have arrived at a cognitive maturity enabling comprehension of the implications, to these privacy concerns.

In a related phenomenon, individuals of all ages, in huge numbers, are increasingly using the Internet and other electronic platforms to store information and communicate. Simultaneously, electronic systems are increasingly used to provide treatment, as in telemedicine, and many websites exist to complement traditional therapies. In-place security protections of these systems vary. Patients' medical information could be accessed by strangers. Many people fail to appreciate the implications of putting out information electronically on social media, e-mail and via texting. Children and adolescents, in particular, due to their developmental immaturity, often lack the capacity to truly understand the immediate and long term implications of sharing personal data via these mechanisms. Use of these systems by professionals creates potentially significant additional complications, for providers as private citizens as well as in their roles as health care personnel. In addition to the challenges of keeping patient

information secure, maintenance of boundaries in the therapeutic relationship, while providing effective treatment interventions, may frequently be threatened. These communication methods can be effective, personally and professionally, but their use requires caution, vigilance and self-monitoring.

Funding and Provision of Patient Care

In the United States, health care costs have been a major expenditure for the past four decades for individuals, employers and the government. At the same time, many have voiced concerns about the quality of provided care. Various administrative interventions have been implemented in the attempt to improve care as well as to contain costs. The Affordable Care Act, enacted in 2010, the most recent major health reform, aims to improve access to affordable health insurance for more Americans, enhance the quality of health care, regulate the health insurance industry, and decrease health care spending. It is too early to determine the impact of this legislation on the practice of child and adolescent psychiatry though the law, increasing the number of individuals having coverage for mental health care, in turn highlights the shortage of CAPs and other mental health providers in most areas of the country. An earlier reform enacted during the 1980s, colloquially termed managed care, had a clear effect on child and adolescent psychiatry practice. Managed care's primary goal was cost containment, which often complicated and compromised the delivery of effective psychiatric care for children and adolescents. Its innovations included gatekeeper requirements, prior approval for treatment—even in emergencies, and limitations on treatment length and access to providers. Then and now, many of the institutions providing insurance payments for mental health care are for-profit companies with obligations to their shareholders, suggesting possible conflicts of interest negatively affecting their customers and patients.

Sixteen-year-old Julie was psychiatrically hospitalized for expressing suicidal thoughts after having been physically assaulted by her father. Julie's parents had divorced 5 years previously, and Julie since lived with each parent at different times. Six months before the hospitalization Julie became pregnant, was "kicked out" of her mother's home, and obtained an abortion while living with her father. The recent assault was the father's response to Julie's demand to spend time "chilling" with her drug-dealing boyfriend. During the admission Julie exhibited symptoms of a major depressive disorder, although her suicidal ideations had diminished in frequency and intensity. Hospital utilization review informed the attending CAP that the patient's insurance coverage provided a maximum 5-day stay and demanded that the patient be discharged on the 5th day. The parents stipulated "impossible" expectations of Julie in the event that she might come to live with them; Julie demanded both discharge from the hospital and the right to live with her boyfriend; and a state child protective services investigation found no need for its further involvement in the case.

One of the raisons d'être of the current versions of managed care is the

pursuit of the ethical principle of *distributive justice*. In the case of health care provision, that translates into the funding of basic care for the largest number of people by controlling costs expended on the care of individual patients. Furthermore, the fact that many managed care and health insurance companies are for-profit concerns, that is, their primary goal is to benefit their shareholders, is an obvious additional consideration when examining the motivations contributing to administrative stances and decisions. Nevertheless, the CAP, despite awareness of these "macro" concerns, continues to be bound by the professional obligation to provide beneficial care for each individual patient, independent of funding. Although, in the previous case, Julie's hospitalization coverage is about to expire (in theory so that there will be coverage available for other individuals in need), Julie continues to require care—for her depression, protection, and sustenance. The attending CAP remains ethically and legally responsible for attempting to make the best, or least damaging, decisions regarding Julie's needs for care in the immediate future. If the CAP deemed that further hospital stay was indicated, it would be incumbent on the CAP to request additional funding from the insurance company, appeal the company's refusal of funding in writing, or arrange for hospitalization elsewhere. If comfortable with the discharge option but not with the current dispositional choices, the CAP would be obligated to pursue the state child protective services agency to re-examine the case, given that it is this agency's responsibility to provide alternative placement possibilities. Although funding mechanisms may change, the CAP's ethical constraint to provide beneficial care is immutable.

Dr. Green, a CAP, had been providing a combined treatment approach of psychotropic medication and psychotherapy to Ben, an 11-year-old boy who had developed posttraumatic stress disorder (PTSD) 6 months earlier after exposure to a stressful event. Ben's mother informed Dr. Green that her health insurance benefits, obtained via her employment, had changed. The new insurer limited coverage by CAPs to brief medication checks, and benefit payments for psychotherapy were available exclusively for nonmedical mental health personnel. Dr. Green believed that the psychotherapists recommended by the insurer had inadequate training to handle Ben's case.

While frustrating and time consuming, CAPs have the obligation to advocate with insurance companies in their attempts to obtain what they consider optimal care for their patients. It is notable that in some parts of the United States, most commonly in large, urban areas, some CAPs have managed the dilemmas and conflicts arising from dealings with insurance companies by choosing to not participate with them and, instead, engage in fee-for-service practices. While this approach does allow these psychiatrists to provide treatments as they deem appropriate, it raises major ethical issues related to access to care and larger considerations of social injustices. *Split treatment,* defined as the CAP providing psychiatric

evaluations and medication management while nonmedical mental health practitioners provide verbal therapies, has become the norm in numerous health care settings. Consequently, many psychiatrists have far less knowledge of their patients than do their peers who provide combined treatments, while they yet retain an ethical responsibility for their patients' optimal care. In addition, these CAPs often have little contact with the nonmedical mental health practitioner providing verbal treatment. Reduced knowledge of patients, and self- and externally-induced pressures to treat more patients in less time, raise the possibilities of poorer attention to patients' needs despite the ethical constraints to provide beneficial care, not do harm, and make the patient's interests the primary concern.

Advocacy

The impetus to contain health costs, with an emphasis on fiscal restrictions, has significantly highlighted the imperative for child advocacy in both public and private systems caring for youth. Children lack the autonomy and power that cognitive maturity, access to employment, and voting rights provide. Their guardians, insurers, or both, inadvertently or deliberately, may make decisions that are not in the children's best interests. Therefore, proper treatment and placement venues, possible needs for evaluation and treatment, the foci and choices of treatments and the need for their continuation, the value of extended physician–patient relationships, and recommendations for adjunctive investigations and care are all matters that may require advocacy by the CAP for a child.

A 10-year-old boy with a history of assaultive behaviors was brought to a hospital emergency department after having attempted to stab a peer with a knife 1 hour before. The patient was still agitated, expressing rage at this peer, and possessed negligible insight and responsibility for his behavior. Nevertheless, the boy's father insisted on discharge of the patient to his supervision in order that they keep their long-established plans to fly the following day to a distant city. Independent of the family plan, the patient did not want to be hospitalized. The father assured the evaluating CAP that he would immediately obtain psychiatric care for his son in the new location. The patient's insurer expressed ambivalence about hospitalization, especially after learning of the father's wishes, but reluctantly agreed to cover the costs in the event the CAP chose this course of care.

The guardian's concerns are legitimate, and his intentions may be well meaning. The insurer's concerns are legitimate as well, although considerably influenced by financial considerations. Owing to safety considerations, however, the CAP must opt for psychiatric hospitalization of the child. The practitioner is obligated to advocate for the child's immediate well-being, even in the face of opposition from the guardian, child, and insurer. *Advocacy* implies choosing the least damaging or most beneficial course for the child in dealings with parents, guardians, agencies, insurers, and the patients themselves. Individuals, agencies, or insurers may attempt to dissuade CAPs from their chosen course because the

interests of the payment providers may conflict with the immediate needs of the child. As the child's potential advocates of last resort, however, CAPs should provide to the interested parties the reasons underlying their position as well as the maintenance of their medically indicated stance, despite possible resistance or antagonism.

Administration

CAPs serve as administrators in a variety of institutional settings and wear multiple hats. Common to CAP administrators are responsibilities for the provision of clinical mental health services to child and adolescent populations, responses to ever-increasing budgetary pressures, and, in that context, maintenance of staff morale and cohesion. Common administrative maneuvers during times of budgetary constraints include attempts at financial savings via personnel layoffs and cutbacks, reduction in services to patients and their families, and shifting of clinical priorities and foci. For example, the CAP administrator may consider whether funds formerly intended for adolescent inpatient care should be shifted to child day-hospital services or vice versa; whether a child outpatient clinic should be maintained or scuttled if expenses exceed income; and whether a child and adolescent psychiatry employee should be assigned an increase in caseload without a corresponding increase in salary or time availability. These considerations, maneuvers, and decisions cause distress to the administrators, patients, and professional staff.

The CAP administrator is constrained by the ethical injunctions to not do harm and to maintain fidelity to patients. Fiscal realities also necessitate considerations of *distributive justice,* translated into the attempt to provide reasonable care to the greatest number. Considerations of these fiscal concerns can come at the expense of patients currently receiving treatment. The administrator must seek to ensure that care remains available to them —if necessary, via referral.

Administrators are also responsible for the behaviors of those who report to them.

Mrs. Smith complained to the CAP director of a mental health clinic: "My 8-year-old has a diagnosis of oppositional defiant disorder and, with him present, Dr. Jones accused me at length of being the cause of his troubles. Since then, my son doesn't listen to anything that I tell him to do. You better get rid of that Dr. Jones."

The mental health administrator has the reasonable expectation that child and adolescent psychiatry personnel will perform competently and professionally, which includes according patients and their guardians appropriate respect. Administrators must also investigate patients' complaints. When allegations have foundation, the administrator must determine whether a professional's misbehavior or poorly chosen words

reflect a momentary aberration or are one in a series of inappropriate actions. Psychiatric work with children and adolescents has the potential for stimulating poorly restrained countertransferential responses that arise primarily from a professional's unresolved conflicts, possibly stemming from the physician's childhood, in contrast to behaviors reflecting an objective response to the clinical presentation. It is the CAP administrator's responsibility to ensure appropriate professional behavior among the caregivers under his or her supervision. The administrator must also distinguish between a single untoward incident that may be responsive to personal counseling in contrast to the consistent expression of ingrained unprofessional behaviors that would require a significantly stronger response. In both situations, the administrator must endeavor to ensure, as much as possible, that the behaviors do not recur and that professionalism is maintained.

Effect of Pharmaceutical Industry

For a number of years concerns have been voiced about the complicated relationships between medicine and the pharmaceutical industry. Pressure has been brought to make public traditionally private information detailing the financial relationships between individual physicians and pharmaceutical companies. As well, drug companies are now required to make all data derived from their studies publicly available, including negative results. Further, more and better data has been collected on the number of children and adolescents prescribed multiple psychotropic medications, often with unclear indications, while progressively younger children are affected by this phenomenon. These and related concerns are promoting continued discussion of the ethical dimensions of industry–physician and industry–psychiatrist relationships and stimulating ongoing advocacy for transparency and change. Medical schools have implemented policies regarding these relationships, imposing restrictions on interactions and exchanges between industry representatives and physician trainees and practitioners. Professional organizations have re-evaluated their relationships with pharmacological companies and instituted new and more stringent policies that govern their dealings with each other.

The industry, "Pharma," produces the medications prescribed by physicians. It also funds the bulk of CAP research, directly and indirectly funds the work of academic researchers, and underwrites and provides financial support for professional journals, conferences, and lectures. In response to negative publicity concerning Pharma's contributions to individual prescribers, subtly designed to influence prescribing practices, presentations by "opinion leaders" and "freebies" supplied to clinicians in the forms of small gifts, dinners, and pharmaceutical samples continue, though not to the same degree as was true in recent years. The industry engages in these practices, in largest part, because the component

companies are for-profit concerns, beholden to their shareholders, and their primary goal is to maximize purchase of their products. The results of Pharma's largesse to CAP professionals can result in increased discovery and dissemination of new knowledge, expanded evidence-based understandings, and improved patient care. However, given the potential for unconscious biases that are the consequences of funding sources for research as well as donation of "presents" to prescribers, practitioners need to remain intelligent consumers of the professional literature in order to judge the purported value of research results and their interpretations against possible sources of external influence.

Because gifts and samples tend to promote reciprocally positive responses from recipients, clinician CAPs might unwittingly be induced to prescribe more expensive, in contrast to less expensive, medications, or brand in contrast to equally effective generic drugs, thus unnecessarily increasing costs for their patient's families. The current influence of Pharma on clinical practice has the potential for leading to an increased emphasis on drug studies in professional journals, at the possible expense of studies devoted to the nonpharmacological components of the CAP's treatment arsenal. This possibility, coupled with a changed health care indemnification environment, in turn can lead to excessive CAP dependence on drug prescription and, on occasion, to its excessive use. In addition, the expansion of criteria to include youngsters in diagnostic categories from which they had been formerly essentially excluded, as in the case of bipolar disorder, could be perceived by some observers as a consequence of the insidious effect of the influence of Pharma as easily as it would be viewed by others as a real and considerable psychiatric advance.

Thus, the relationships between Pharma and child and adolescent psychiatry as a profession, as well as with individual CAPs, raise numerous potential and actual conflicts of interest. Can these conflicts be managed, or should they be eliminated, by sundering all but indirect contacts and contributions between the industry and CAPs? As illustrated, the ethical dilemmas are many and profound, and the choices made by individual practitioners and professional organizations are likely to significantly affect future patient care, research funding, basic science knowledge, and professional education.

Research, Neuroethics, and Psychopharmacology

Arguably, the major recent advances in CAP knowledge and treatment have resulted from quantum leaps in knowledge of neural function, particularly at the brain receptor and molecular levels. This knowledge has correlated with a considerable expansion in the knowledge base of neuropsychopharmacology, accompanied by the continued development of new products available for the treatment of disabling conditions.

As is true for all treatment techniques, the decision of whether to

intervene pharmacologically requires a risk–benefit analysis. The potential dangers of acute or chronic side effects must be weighed against the long-term effects of unhindered chronic psychopathology. There remains a dearth of knowledge concerning the effects of psychotropic medications, either short or long term, on possibly vulnerable developing brains. Although some negative effects have correlated with medication treatments (e.g., aspirin with Reye syndrome and central nervous system stimulants possibly with growth retardation), studies have not, by and large, followed psychotropic-taking children for years into adulthood. Many psychiatric disorders first manifesting in childhood or adolescence (e.g., autism spectrum, bipolar, Tourette syndrome, and obsessive-compulsive disorders) are likely to remain manifest as chronic conditions in the ensuing decades, whereas the long-term effects of the psychotropic medications prescribed for their treatment are uncertain.

In a related concern, psychotropic medications are commonly prescribed by physicians for "off-label" use. For example, many medications prescribed by CAPs for child psychiatric disorders (e.g., schizophrenia and bipolar disorder) have FDA approval of prescription only for adults. Thus, medications that target severe behavioral and cognitively disruptive behaviors of childhood, which include antipsychotic, mood-stabilizing, antidepressant, and cardiovascular agents, often do not have FDA approval for their prescription to children. In addition, prescriptions of these medications for newly defined psychiatric conditions, such as disruptive mood dysregulation disorder, have as yet to obtain FDA approval for this purpose, and their use in these circumstances would again be termed "off-label." Although considered clinical judgment can result in the conclusion that these medications in fact might be indicated and beneficial, a rigorous evidence base for that opinion could be weak or nonexistent. Because many childhood behavioral disorders contain elements of various disease entities without, however, fully satisfying the established diagnostic criteria, pharmacological management is often attempted based on coupling the overt behaviors with hints or suggestions of other signs or symptoms. Also, practitioners attempt to treat with medications because adequate and appropriate psychotherapeutic and environmental interventions often are not accessible or available. These diagnostic uncertainties and absences of full ranges of care, coupled with inadequate evidence bases, always pose the ethical conflict between the desire to provide good care—for example, by using what are thought to be appropriate and indicated psychopharmacological agents—and the possible iatrogenic precipitation of harm.

The lack of knowledge concerning long-term outcome indicates the continued need for research to expand the child psychiatric scientific database. Political jockeying around the creation of a mandate to study the effects in children of medications prescribed to adults continues to be an

ongoing process. Such a directive has not occurred. Rather, the pharmaceutical industry has been encouraged to expand drug trials to include children via the use of incentives, for example, by increasing the time period allotted for exclusive patents. In any event, until an increase occurs in the number of drug trials focusing on children, prescribing new medications to youngsters without advance knowledge of potential ill effects could put them at risk. Thus, informed consent is crucial in these circumstances. A description of the treatment protocol, risks, and benefits that might accrue consequent to the provision or withholding of the novel treatment, and avoidance of coercion with respect to patient participation, should be expected by the prospective participants in what are essentially experiments whose predictable outcome is indeterminate. Although consent to a child's participation in a research protocol must come from fully informed guardians, the child should be advised of all the pertinent factors to the extent of his or her capacity to understand, and noncoerced assent obtained for participation to occur.

The phenomenal increases in knowledge of molecular biology have widened the spectra of innovative drug treatments, not only for diseases of the brain but also for the enhancement of what until now has been considered cognitive or affective functioning, or both, within that broad range called "normal." Stimulant medications, for example, are known to be effective in increasing attention and concentration not only for children diagnosed with ADHD but also in normal populations. Novel antidepressant medications, effective for the treatment of major depressive disorders, in coming years might also prove useful in forestalling the "downs" in the ups and downs of ordinary life. Might the drugs of the future enhance the sociability of the nondisabled shy younger child or, conversely, reduce the boisterousness of the mildly annoying exuberant child? One needs only to look at controversies regarding possible steroid augmentation of athletic performance to comprehend that similar improvement or magnification of abilities could equally be applied to brain function. It is an open question whether the popular response to steroid-related athletic enhancement might be similar to, or differ from, the responses to medication-induced brain enhancement. In any case, these and related concerns are subject to musings by neuroethicists, those bioethicists who discern such futuristic scenarios as imminent.

A similarly relevant matter concerns the significant increase in the number of psychotropic medications prescribed for children in the United States and elsewhere in the world over the last few decades. Potential explanations for this numerical explosion are many, including a gain in sophistication of professional knowledge of indications for interventions with medications in children, the number of studies indicating medication efficacy (coupled, unfortunately, with earlier withholding from publication of studies productive of negative findings), the range of medication choices

among chemical classes of psychotropic medications, access to medical and psychiatric care by larger numbers of children, dollars devoted to the advertising of pharmaceuticals that target physicians (including CAPs), and CAP professional education that might increasingly emphasize "biological" interventions at the expense of time devoted to training in the verbal therapies. Publicly aired concerns about this increase, in concert with suggestions that the administration of SSRIs to depressed youngsters increased the risk of suicidality in the children, led to FDA health advisories that culminated in "black box" warnings about this danger. The factors of a significant illness (depression) associated with a potentially fatal outcome (suicide), occurring in a high-risk population (adolescents) whose treatment (SSRI antidepressants) might slightly and inconclusively exacerbate the incidence of the self-harmful behavior, all occurring in the context of a pharmaceutical industry that has significant interests in the marketing of its products, has left CAPs on uncertain ground as they attempt to weigh the risks versus the benefits of their therapeutic choices and do what is most beneficial for their patients.

Following the FDA advisories, later studies revealed that the rate of SSRI prescriptions for this population dropped sharply, a development followed in turn by a seemingly significant increase in suicidal behaviors in the target population. This is a fine example of the ethical dilemmas CAPs face as they grapple with an enlarging psychotropic armamentarium, broadening clinical presentations for which medications are prescribed, and increasing economic pressures on and inducements for the practitioners to write prescriptions. In the end, it is incumbent on CAPs to adopt the ethical stance of weighing the objective evidence, while distancing themselves from personal considerations and biases, and making choices that foster the best interests of the child.

TEACHING ETHICS AND REPORTING VIOLATIONS

The American Council of Graduate Medical Education mandates the teaching of ethics in child and adolescent psychiatry training programs in order that future CAPs be aware of the potential emergence of ethical conflicts during their careers. Topics deserving didactic exposure during training commonly include matters generic to all physicians, such as confidentiality, boundaries, professional responsibilities, and relationships with health care providers, companies, and industries, as well as topics focused more specifically on child and adolescent psychiatry practice. The latter would likely include the topics of child advocacy and protection, informed consent and assent, refusal of treatment, child–guardian conflicting rights, agentry, compensation source, autonomy and paternalism, and research-related risks and benefits. In addition, closer attention likely would be paid to the pitfalls potentially accruing to communications via electronic transmissions, and the ethical responsibility

for the practitioner to be aware of federal, state and local laws governing medical and child and adolescent psychiatry practice. Clearly, ethical concerns regarding children arise from the youngsters' needs for adult protection and nurturance, given their physical and cognitive immaturities. Related training in and knowledge of psychodynamics, the origins of motivations, and systems theory would augment, and can easily be incorporated into, the CAP trainee's ethics education.

During this training, CAP trainees should become informed about the AACAP *Code of Ethics*. The document addresses the needs and rights of children and their guardians, as well as the CAP's responsibilities to both. On occasion, trainees and/or experienced practitioners may experience uncertainty regarding an ethical dilemma concerning a child, and referral to the *Code* may help to guide the response.

The AACAP Ethics Committee also serves as a potential resource for advice concerning ethical dilemmas. After deliberations by the committee, inquiries receive suggestions for approaches to resolution. The potential value to be derived from requesting consultation from colleagues, when faced with ethical dilemmas in general and from the committee in particular, cannot be overstressed. In recent years, inquiries presented to the AACAP ethics committee have included concerns about administrative orders to withhold information from families; "double booking" of patient appointments; inadequate research supervision; noninclusive and/or biased custodial evaluations; the use of agencies and credit bureaus to collect fees; potential breaches of patient confidentiality; poor or potentially harmful patient care; organizationally blocked access to professional consultation coupled with inadequate supervision; video monitoring on CAP inpatient units; disclosure of case details in, and obtaining patient consents for, publications; abandonment of children by professionals in the context of threatening parents; potential supply of sexual paraphernalia to patients; practice of child psychiatry without formal training; the impact of television and other media on children younger than the age of 3 years; requests of families for funding of research; treatment by a CAP parent of that psychiatrist's child; reporting alleged abuse/neglect to state child protection agencies; and potential adoption of former patients. In addition, the AACAP Ethics Committee has developed a range of educational materials, disseminated in various forums and maintained on the AACAP ethics website, related to child and adolescent psychiatric practice. Of note, in 2010, the AACAP implemented a mandate requiring all AACAP members to obtain attested to ethics education credit every 2 years.

Periodically, fulfilling a different function, the committee receives complaints concerning practitioners alleged to have engaged in unethical practices in matters concerning children and adolescents. When further investigation is indicated, complainants are referred to appropriate

organizations and agencies, such as the APA and AMA district branches and state medical licensing boards. Investigations by these entities could result in "no findings" or recommendations for sanctions, which may include reprimand, suspension, or loss of licensure. Abrogation of licensure by a state medical licensing board, consequent to findings of an ethics violation, automatically results in loss of membership in the AACAP, the guild representing the profession's ethos.

The role of the healer in society has a long history, and society's designated medical personnel have always been faced with ethical dilemmas. With the rapid increase in relevant scientific knowledge and related technological achievements, the dilemmas have grown more complex and complicated. The basic understandings, however, remain the same and undiluted, that is, the challenge of doing good and not engaging in harmful behaviors, equally for all patients. CAPs have the additional burden of caring for the immature child, as well as maintaining good relations with his or her guardians and caretakers. Whether the CAP is wrestling with the age-old conflicts surrounding privacy and confidentiality or dealing with the newest developments in genetics and transmission technologies, ethical responsibilities represent a never-ending challenge for all practitioners and for the subspecialty as a profession. In the face of unceasing change, therefore, teaching of ethics, discussions of current dilemmas, revisions of ethical codes, and monitoring of practitioners and practices are a must for maintenance of the profession's integrity.

▲ 55.8 School Consultation

JEFF Q. BOSTIC, M.D., ED.D., SHARON HOOVER STEPHAN, PH.D., AND ALEXA BAGNELL, M.D.

INTRODUCTION

Approximately 55 million youth attend the 130,000 public and charter elementary and secondary schools across the United States. This positions schools and psychiatry to be vital partners in both responding to emerging student psychopathology and configuring a positive environment for children to develop lifelong coping skills and resilience. For most children, school is the one natural setting where professionals are consistently available to monitor how they are functioning and learning, and to intervene when necessary. School psychiatry increasingly assists schools in early recognition of youth with difficulties to prevent future worsening of problems. Psychiatrists' roles within schools vary and range from the traditional clinician developing and advocating a treatment plan for a patient, to systemic, mental health promotion, early intervention and prevention programming for the school itself.

HISTORY AND LEGISLATION INFLUENCING MENTAL HEALTH IN SCHOOLS

Mental health clinicians have collaborated with school personnel for over 100 years. Sigmund Freud advocated that psychoanalysis had educational as well as clinical benefits for society, and Anna Freud, trained first as a teacher and later as a child psychoanalyst, consulted with educators to help them better understand student behaviors and classroom dynamics. In the latter half of the 20th century, mental health consultation to schools underwent expansion stimulated by broad sociocultural events. First, Gerald Caplan used school-based interventions to assist teachers working with refugee students displaced after World War II. Second, the civil rights movement in the 1960s led to the passage of federal educational rights legislation. This legislation initiated systematic identification of students with emotional and behavioral disabilities, and created a need for clinical advice about assessing and treating these students in the least restrictive school settings. Third, the increased recognition since the late 1960s of problem behaviors among students, such as substance abuse, unprotected sexual intercourse, and more recently, bullying and school violence, caused schools to turn to mental health clinicians for advice. Fourth, the decrease in the 1990s in psychiatric hospitalizations and residential placements, coupled with the lack of access to mental health care among those most in need, resulted in proliferation of school-based mental health treatment, and delivery of psychiatric services within schools, as well as "transition" programs, to assist students coming from inpatient units back into school life. Technological improvements, including telepsychiatry access in schools, and monitoring "apps" to support students have provided additional mental health access, and have facilitated home-school-community coordination and delivery of care. Fifth, federal legislation, such as the No Child Left Behind Act of 2001, mandated the education system to meet the needs of all children and youth in providing appropriate supports for academic success. The President's New Freedom Commission report of 2003, *Achieving the Promise: Transforming Mental Health Care in America,* recognized the importance of mental health in learning and social/emotional development and outlined recommendations for addressing gaps in the provision of mental health services to youth, including a specific recommendation to expand school mental health programs. In 2004, the Garrett Lee Smith Memorial Act (P.L. 108–355, October 2004) became the first federal legislation in the United States to provide specific funding for youth suicide prevention and early intervention programs, to intervene, treat, and prevent mental and behavioral health problems that can lead to suicide in young people. Sixth, psychiatrists have been enlisted more recently in responding to traumatic events impacting or occurring at schools, such as natural disasters (e.g., surrounding hurricanes or tornados), or catastrophic human events such as murders or war. Finally, increased proactive, resilience-building for students, facing seemingly ever-increasing stress loads, have expanded the range of mental

health efforts at school, including social–emotional learning curricula, mindfulness, and executive skill coaching.

MENTAL HEALTH PROBLEMS AND SCHOOL OUTCOMES

Approximately 20 percent of students aged 6 to 17 years currently suffer from significantly impairing psychopathology. Less than one-fifth of these students receive any treatment for these disorders and only 1 in 10 with substance abuse. Minority groups and the uninsured are less likely to receive mental health services. One-quarter of public schools have no counselors, and over half do not have a social worker, yet schools are being asked to deal with more of the mental health needs of their students. Of those youth receiving services, 70 percent report school as a primary source.

Youth mental health has significant impact on school outcome. First, mental health impacts all students in a school. Most notably, Hattie's exhaustive meta-analysis of variables associated with academic achievement revealed that disruptive behaviors at school and emotional distress are among largest impediments to all students' academic achievement in a school setting. School dropout rates continue to approximate 10 percent and are significantly higher in youth with mental health problems. The cause of not completing school is attributable to an underlying psychiatric disorder in half the cases. Reports of increased bullying, including cyberbullying, and school shootings accent the importance of recognizing and responding to the mental health needs of students.

School psychiatry has expanded beyond individual mental health problems to address school wide and community issues including mental health promotion, school violence, bullying, substance abuse, and discipline. Psychiatrists and other mental health professionals continue to refine child psychiatry's role in schools incorporating business and educational principles in effecting change and improving system functioning. Modern school consultation focuses more on early identification and intervention at the individual and system level to help attain short-term educational and behavioral goals and to prevent later long-term negative outcomes. Mental health literacy has emerged as a focus for children to learn how to optimize and maintain good mental health, to understand mental disorders and treatment, to decrease stigma, and to enhance help-seeking when needed, and is being developed actively in Canada (http://teenmentalhealth.org/curriculum and http://www.myhealthmagazine.net).

Schools today face significant demands to inculcate ever-increasing knowledge, to prepare students with more complex vocational skills, to socialize children, amidst increasingly virtual communities, to interact with others appropriately and increasingly, and to maintain their health and

safety. These varied, often competing agendas impact every intervention proposed by the school consultant. Moreover, public, private, parochial, and charter schools may not only vary widely in their priorities but also in their system hierarchy and their accountability to the community. Familiarity with each individual school, its priorities, and its staff is a prerequisite to any meaningful consultation. Accordingly, evaluating the "school" itself often helps clarify what unique school strengths or weaknesses should be factored in to recommendations, as well as resources that may expand or limit options for interventions. This is summarized in Table 55.8–1.

Roles of School Personnel

As the demands on schools have intensified, staff roles have changed such that consultants must have realistic expectations about who can perform specific interventions with students as recommendations are provided. The consultee may be anyone within the school hierarchy, and the consultant must address needs while being mindful of how the consultation will impact everyone else within the system. The consultant must also consider who is in a position to implement recommendations when providing consultation.

Teachers remain the front-line staff most involved with students. Elementary teachers usually have approximately 25 students for 6 hours each day. By middle school, teachers usually teach in a specific content area, providing instruction to approximately 150 different students each day. *Aides* or Paraprofessionals ("Paras") often do not possess a 4-year college degree or teacher certification, but may work under a classroom teacher, or work with a specific student who has different teachers. *Special education teachers* are credentialed to provide alternative instruction to smaller groups of students with learning disabilities such as dyslexia, nonverbal learning disorders, or emotional disorders interfering with learning. For students to receive instruction from special education teachers, they must have an Individualized Education Program (IEP).

School counselors are often the primary mental health support within a school and sometimes provide psychotherapy and crisis support to students, although often their primary role in secondary school is to assist students in academic or vocational planning and class selection. *School psychologists* are either employed by the school district or have a contract with the school to test and help construct IEPs for students to address their specific learning difficulties. They may also provide individual and group therapy to students, but are often working with many schools. *School adjustment counselors and/or social workers* have been added to school staff in many locations, where their primary role is to provide psychosocial interventions to students, and sometimes their families. *School nurses and nurse practitioners* address acute health care needs of students, provide

health education and administer medications to students; school nurses usually travel between several schools, and approximately one-third of their service in schools is mental health care. *Occupational therapists* work with students individually or in small groups to help students with basic activities of daily living, and alternative strategies for students who have sensory integration issues to help them learn to cope with various stimuli. *Speech-language therapists* meet with students who have communication and social skills difficulties individually and in small groups.

Table 55.8–1.
Framework for Evaluating a School

School Component	What to Observe	Potential Questions for Staff
School Building	Safety/Security: Does the building appear safe? Is the building comfortable (temperature, chairs/desks, lighting, noisy)? Does the building prize students (student art on the walls, recognition of student achievements, evidence of student-parent-teacher alliance)? Is this a place a child would want to be?	How does one enter/exit the building? Where do students go if they are having a hard time? Where are students' classwork or projects kept or displayed? What happens after school is over? Do students stay in the building before or after school?
Classrooms	What do classrooms look like? What size are classrooms? How many students are in classrooms, and how many adults? How many learning areas are there, and are they separated so children can be in a quiet place within classrooms? How stimulating (visual, auditory, tactile) are classrooms, and do the students appear over/understimulated?	What's the average number of students in each classroom? How are teachers encouraged to set up their classroom? If a student is having a hard time in the classroom, where does he/she go? How did you (teacher) decide what to put up in your classroom?
School Atmosphere	How is a stranger greeted? Does the school seem organized for students or for staff? Do most students appear engaged (alert, attentive, answering/asking questions) with instruction? How do students and staff interact (smiling, directives, calm, tense)? Do children thrive here?	Who should I meet when I enter the building? How do students move between classes/to lunch/recess? What do students do when they've finished classroom assignments? What do staff expect from students here? What do staff most worry about here regarding students?
School Staff Administrators	Are administrators present/accessible? What kind of tone/impression does the administrator convey? Do staff appear comfortable around the administrator? Who does this administrator best serve (students, teachers, parents, other	What kind of interactions does the administrator have with students (discipline, earned reward time, common interests discussed in halls/lunch)? What is the administrator's priority in this building?

	administrators)? What led to this administrator being selected for this building (student needs, up/down move for this administrator)?	What do staff seek from the administrator (support, camaraderie, ideas, discipline, avoidance)?
Teachers	Do teachers want to be in this school (eager to be with students or staff)? Do teachers stay in this building? How do teachers engage students (time to work, demonstrate content, model enthusiasm, surprise students)? How often do teachers alter the instructional approach (every 10 minutes, something different [lecture, student reading, class discussion], different modalities [visual, auditory, tactile] employed) during instruction?	How many teachers left this building last year? Average over the last several (5) years? What is the student: teacher ratio? What's the average length of time teachers have been in this district/building? How many teachers here have advanced (masters, doctoral) degrees? What kind of teachers do best in this school (independent, orderly, collaborative, creative)?
Special Staff	Are other school staff present? How do teachers and other school staff interact (take student out, co-teach, friendly/tense)?	What kind of special educational staff work here? How often are they in this building (always, weekly)? How do teachers describe other staff (particularly contributions of special educators)? What kind of other teachers are in the classroom (parent aides, "paraprofessional" aides)? Do they work with particular students, with everyone in the classroom?
Support Staff	Are support staff friendly? Do they appear open about discussing the school and students? Do support staff work well with other staff?	What kind of support staff are in this building? How long have most of them been here? How are support staff paired up with other staff?

School administrators coordinate between and within the school and the community. *Principals* and *vice-principals* manage all services (teaching, discipline, custodial) within their school building and report to the *superintendent*. The superintendent guides educational activities among all the schools within a school district and reports to an elected school board in public schools, or an appointed board in private, parochial, or charter schools.

Role of Psychiatrist in Consultation

The contact for the school will depend on the consultee, the question, and the goals of the consultation. Systemic and school-wide issues require the support and involvement of the school administrators, as well as school staff. Individual student issues may only require the teacher and/or

guidance counselor becoming involved, though may involve administrators and other support staff depending on the nature of the consultation. The consultant should approach communication as bidirectional, with the goals of gaining important expertise from the school in terms of academic, social and behavioral observations, as well as sharing of mental health expertise and evidence-based practices and treatment within the limits of confidentiality and taking into account relevant legal and ethical factors.

SCHOOL CONSULTATION FRAMEWORK

The psychiatric school consultant should consider how *micro problems can lead to macro solutions,* that is, how individual student problems can be addressed to improve circumstances for all subsequent students and staff. Five components should be considered in every consultation:

1. Who is the actual **Consultee,** and what are the *confidentiality* parameters?
2. What is the Consultation **Question,** and what is the consultee seeking and wishing will happen?
3. How is the larger **System** experiencing this problem?
4. What **Legal or Ethical Factors** should be considered?
5. How does the consultant understand this problem **Biopsychosocially**?

The Consultee and Confidentiality Parameters

The consultant must establish procedures to clarify who is appropriate to contact or to evaluate. When requested to meet with students, the consultant must obtain parental permission before interviewing any student. If parents refuse for the consultant to evaluate their child, the consultant may still observe, unobtrusively, the student, and consult to staff about their questions on how best to work with this student. Clarification of confidentiality should occur, sometimes recurrently, with staff, students, and parents. Anyone meeting with the consultant should understand how information is shared and whether written clinical information is placed in the student or personnel records.

Clarification of the Consultation Question and Needs/Wishes of the Consultee

Consultants help others define the problem and envision solutions. While consultees may ask for interventions to assist a student, sometimes they actually wish that the consultant will address administrators or recommend the student be removed from this consultee's classroom. Consultants must "read between the lines" to clarify both the consultee's overt request and underlying desires. The success of every consultation depends on the consultant understanding the consultee's concerns and wishes, such that both agree on the problem and on realistic goals for any intervention.

The System Reaction to the Problem

The problem will affect various school staff members differently, and each may have different goals for this consultation. Consultants should clarify who requested a consultation, who knows about the consultation, who has consented to the consultation, and who should be informed about the findings for this consultation. The more that differing goals can be aligned, the higher the probability that participants will invest in a proposed solution.

Legal and Ethical Factors

Special educational laws may provide the student different opportunities, yet families or schools may not see the applicability of such laws in a particular case. Parents may decline psychiatric consultation offered by the school, or may refuse to give consent for a psychiatrist to consult with school staff about their child. Attuning to parental concerns, wishes, and fears often helps diminish resistance to consultation, although consultants may still address teacher questions without seeing the child if a parent refuses for consultants to meet with their children. If abuse is suspected, the consultant may help staff articulate concerns to the appropriate agency, or in acutely dangerous situations such as suicidality or homicidality, the consultant can assist consultees in facilitating emergency treatment or warning others who may be at risk. In the case of consultation regarding an individual student, and particularly if a student will be interviewed or evaluated by the child psychiatrist, a written consent form is generally required, signed by the parent and/or guardian outlining permission for release of medical information to the school. Parents cannot, however, prevent a clinician from observing a student and consulting directly with school staff. Legal and ethical ramifications should always be considered for every proposed intervention. Accordingly, unusual or paradoxical interventions, such as recommending students avoid particular teachers or encouraging parents to not help their child with assignments, are not appropriate; rather, the consultant should support collaborative, transparent efforts by the student, family, and school to improve difficult situations.

Biopsychosocial Understanding of the Problem

Child psychiatrists integrate people's biological vulnerabilities to psychopathology, their past experiences, and current family, peer, school, or other social stressors which might contribute to dysfunctional behaviors. Social, interpersonal, or family problems are the most commonly reported mental health problems in most schools. Considering these different influences may provide multiple intervention targets for a particular problem and may call for employment of diverse existing services in the

school and community. For example, a disruptive, hyperactive student may need referral for a medication evaluation, a behavioral plan at school and home, and connection to social groups such as sports teams, choir or band, and summer camps. The resources and skills available will differ between districts, schools, and classrooms and plans need to work within existing resource capabilities and commitments in order to have best chance of success.

SCHOOL CONSULTING TECHNIQUES

Ally

1. *Validate consultees' perceptions before proposing any solutions.* Validating perceptions cultivates consultee trust that the consultant understands their predicament. If in doubt, ask questions or pose solutions as questions ("What would likely happen if we . . . ?").
2. *Bind anxiety.* Everything the consultant does either increases or decreases anxiety within the system. The more people who share the problem, the less anxious each individual will be. While consultants may not know the answer to various problems, thinking through how they would find an answer can diminish consultee's anxiety ("Hmmm, while we don't know everything we need at this point, wonder if we attempt _____, that will at least provide us clarity, or "data" about an approach so that we can figure out what's more (and less" likely to work with this student.").
3. *Create respect for everyone involved.* Minimizing splitting of staff, students, and parents decreases the probability that individuals will oppose an intervention. The consultant can attempt to separate personalities from the problem by focusing on terms used, by identifying the common goals between parties, and by identifying the circumstances each party uniquely faces ("So . . . it seems where we all agree, and can start, is _____.") Similarly, giving credit for ideas to various staff can increase their investment and also demonstrate how diverse perspectives can be integrated.

Align

4. *Find the good intent gone awry.* When students or staff act inappropriately, the consultant can back up to the good intention that motivated the person's (mis)behavior so that self-esteem, and thus willingness to attempt different behaviors, is maximized. For example, if a teacher "yells" at students, the consultant can "backtrack" to the diligent efforts by the teacher to get the student's attention and to feel responsible that the student learns the material. Then the consultant is positioned to examine alternatives (visually signal the child, use a very soft voice, etc.), which will seem less critical of the teacher's yelling.

5. *Help others to see the child (or staff member) differently*. Maladaptive behaviors may be used to solve problems when no other solution is available (e.g., talking in class may be the only way a student "knows" to slow down instruction or to obtain positive attention from others since the student cannot garner positive attention by doing the academic task) ("It sounds like [student] remaining at home allows [student] to monitor the parent's sobriety; suspect we'll need to find another way for the student to be reassured the parent is stable, or the student will continue to report somatic symptoms to check up on the parent, since that seems more a priority for the student right now than school participation.")
6. *Connect others*. Opportunities for various staff to be empowered and to collaborate may optimize benefits to the staff and the student, by utilizing existing services in the school and community. Staff who frequently see the student, and who understand or have compassion for the student, often have most impact on the student, as well as the staff and even the culture of the school. ("It sounds like [staff member] can check in with the student on Mondays and Thursdays, while [different staff member] can check in Tuesdays and Wednesdays—when will these staff members have an opportunity to compare their findings?").
7. *Appeal to shared values by giving people options they cannot argue with*. Explore and identify appropriate desires of students and staff so that interventions can be provided to realize those appropriate goals. For example, identifying that a student seeks to attend college, or hold a particular job, provides a "frame" for posed interventions ("You've indicated you want to attend/work at _____, and they require you show up on time, so we have to practice going to sleep at 10 PM so that you can be ready the next morning.").

Mobilize

8. *At every opportunity, expand the consultee's skills*. Whenever possible, the consultant attempts to assist the consultee in selecting and implementing skills helpful for that situation. The consultant aspires to provide the consultee facility with multiple skills that the consultee can use subsequently independently.
9. *Use the consultee's own words to frame interventions*. Framing interventions with terms used by the consultee, by staff, and by students, increases each person feeling heard and improves the probability of each investing in proposed solutions.
10. *Identify one step up from the current situation*. Consultees may need help seeing the steps in a sequence toward appropriate behavior (e.g., cursing may be "a step up" from physically assaulting others). Even small positive changes generate momentum to achieve greater changes.
11. *Move toward anticipating problems rather than reacting to them*.

Efforts to help consultees see how problems arise, and how they might be prevented in the future can empower consultees to find and face problems early. More importantly, initial reactions may not represent optimal solutions, but instead create additional conflicts or problems.

TIERED RESPONSE TO CHILDREN WITH EMOTIONAL DISABILITIES

The categorization of children into "eligible or not" for special education is undergoing significant revision, as the importance of early detection and timely response has become clear. To enhance school planning for all students, and to accelerate interventions for students who show difficulties accessing the curriculum, including because of emotional or behavioral issues, schools have been encouraged to initiate "Response to Intervention" (RTI) plans for such students. RTI has also been called a "multi-tiered" approach, as RTI is not "part of" special education, but instead a mechanism for addressing students, whether identified as special education or not, who struggle at school. This tiered system recognizes the value of both school and community interventions for students at these various tiers, as summarized in Figure 55.8–1.

Screening

RTI relies on screening to clarify targets for intervention for students. This begins with universal screening for all students, both for academic and for emotional issues that impede learning. If students screen "positive" and require more specialized interventions, then increasingly specific mental health assessments are employed, and for students having significant specific difficulties (e.g., clinical depression, anxiety, ADHD), these students may receive specific assessment tools to clarify targeted needs and to monitor progress. Example assessment tools across these tiers are provided in Table 55.8–2.

In the academic arena, the first tier of RTI emphasizes "scientific" instruction for all students, so that approximately 80 percent of all students would receive solid, effective instruction and make progress, and thus not need any further educational interventions. Tier 2 (and Tier 3) includes students more likely to be identified for special education. Tier 2 includes "pull-out" or small group instruction for approximately 15 percent of students usually having mild difficulties. Tier 3 is for those 3 to 6 percent of students who require much more specialized programming to make progress at school, and these students are often identified also as qualifying for special education. The parallel emotional and behavioral RTI model assumes a similar distribution of students, with approximately 80 percent of students demonstrating successful emotional and behavioral skills with universal mental health promotion and prevention programming, and the remaining students benefiting from varying intensity levels of mental

health intervention.

Interventions

While RTI is not a specific component of special education, it allows immediate response without significant evaluations or team meetings to address more quickly emerging student problems. RTI is not designed to delay provision of services for students requiring special education, but rather as an augmentation to regular education to address individual differences rapidly with scientifically supported techniques. RTI plans are required to be "evidence-based," meaning that interventions shown/proven effective can be implemented, and not just anything the school or parent might devise. A number of tiered programs have such empirical support, have been employed in diverse schools, and are shown in Table 55.8–3.

FIGURE 55.8–1. Multitiered system of support. (From Stephan SH, Sugai G, Lever N, Connors E. Strategies for integrating mental health into schools via a multitiered system of support. *Child Adolesc Psychiatric Clin North Am.* 2015;24(2):211–231.)

Accommodations and Modifications for Specific Disabilities

Psychiatrists are most frequently called on to evaluate students in tiers 2 or 3, to determine whether a disability (e.g., emotional, developmental, or medical ["other health impaired"]) is present, and to recommend relevant services, behavior management strategies, or placement needs appropriate for the student. Any child, who is not progressing appropriately in school, has the right to an evaluation to assess whether they have a disability. This can be requested by the teacher, clinician and/or parents, but requires parental consent. Psychiatrists should be aware of the laws protecting students with special education needs, and updates for these in the United

States can usually be found at http://idea.ed.gov.

Students who do not progress through the standard curriculum may qualify for special educational services. Legal protections have evolved to provide every student in the United States with an appropriate education. Although the Fourteenth Amendment to the United States Constitution prohibits discrimination through its equal protection clause, more recent legislation has guaranteed the educational rights of disabled students. *Section 504 of the Rehabilitation Act* (1973) ensures that all disabled children receive a "free and appropriate" public education (**FAPE**) in the "least restrictive environment" (**LRE**). Students qualifying for a 504 Plan may receive special *accommodations* to help them meet educational requirements. Theoretically, *accommodations* refer to classroom changes that help the student meet requirements, without "lowering" academic standards.

Table 55.8–2.
Example Screening Tools for Universal, Selected, and Indicated Student Needs

Tiers	Instrument	Comments
1	Systematic Screening for Behavior Disorders (SSBD) http://store.cambiumlearning.com	Well-validated, efficient, preferred instrument for internalizing issues; inexpensive; normed for grades 1–6 (elementary)
1	Student Risk Screening Scale (SRSS)	Technically adequate, free, quick (15 minutes for entire class), easy to interpret; for grades K-12
1, 2	Strengths and Difficulties Questionnaire (SDQ) www.sdqinfo.org	Well-validated, better for externalizing issues; free, can be scored online to decrease administrative time; for ages 3–17
1, 2	Behavior and Emotion Screening System (BESS) www.pearsonassessments.com	Well-validated, wide range of problem behaviors; can be done online; can be expensive and timely to score; for grades PreK-12
2	Adaptive Behavior Assessment System	Assesses adaptive skills across lifetime; software-based scoring and reporting
2	Behavior Assessment System for Children (BASC-2)	Measures behaviors associated with internalizing and externalizing problem behaviors and academic competence; rules out response bias; web-based screening capacity available
2	Child Behavior Checklist (CBCL)	Well-validated, several subscales (including school subscale) that factor into internalizing and externalizing domains
2, 3	Disruptive Behavior Disorders Scale (DBD)	Assesses the presence and severity of symptoms of inattention, hyperactivity/impulsivity, conduct disorder, and ODD; parent and teacher versions; helpful for diagnostic purposes or evaluating medication effects
3	Revised Child Anxiety and Depression Scale (RCADS)	Subscales for distinct anxiety/depression disorders; can be repeated; for grades 3–12
3	Screen for Child Anxiety Related Disorders (SCARED)	Can be repeated as needed; may need to read to children <11 years

3	UCLA PTSD Index	Part can be repeated to monitor progress; for ages 7–18 years

A more complete list (and copies of the instruments) of free assessment tools is available at http://csmh.umaryland.edu/Resources/ClinicianTools/index.html.

Table 55.8–3. Example Tiered Interventions for School Mental Health

Tier	Program	Goal
1	**Good Behavior Game**	Classroom intervention with a set of evidence-based strategies and a classroom game to increase self-regulation and cooperation and decrease unwanted behaviors
1	**Life Skills Training**	Group or classroom intervention to promote general social skills, self-management, drug resistance, and violence prevention
1	**Project Achieve**	Group or classroom intervention to prevent alcohol, tobacco, and marijuana use and violence
1	**Project Alert**	Group or classroom intervention to prevent alcohol, tobacco, and marijuana use and violence
1	**Second Step**	Classroom curriculum that teaches socioemotional skills to decrease impulsive and aggressive behavior and increase social competence
2	**Check and Connect**	Individualized intervention for students showing warning signs of disengagement and at risk of dropping out. The program monitors school performance and provides mentoring, case management, and other supports
2	**Coping Power**	Group intervention for children at risk of aggressive behaviors, drug use, and delinquency. Uses cognitive-behavioral techniques to teach children how to cope with anger, anxiety, decrease impulsivity, and develop and improve social, academic, and problem-solving skills
2	**Strengthening Families Program (SFP)**	Increases resilience, reduces risk factors to improve social competencies and school performance, and to reduce problem behaviors, delinquency, and alcohol and drug abuse in high-risk children
3	**Aggression Replacement Training**	CBT-based intervention to help children and adolescents improve social skill competence and moral reasoning, better manage anger, and reduce aggressive behavior
3	**Coping Cat**	CBT-based intervention to help children recognize and clarify anxious thoughts and feelings, develop plans for effective coping, and self-evaluate and reinforce positive coping skills
3	**Cognitive Behavioral Intervention for Traumatized Students (CBITS)**	CBT-based group intervention to reduce symptoms of PTSD, depression, and behavioral problems; improve peer and parent support; and enhance coping skills
3	**Interpersonal Psychotherapy for Depressed Adolescents (IPT-A)**	Short-term manualized intervention focusing on developmental and interpersonal needs of adolescents (12–18 years old); builds communication and social problem solving skills
3	**Stark School-Based**	CBT-based intervention for children with depression that teaches self-control techniques, social skills, assertiveness, and relaxation training, imagery,

Additional safeguards have been provided by Public Law 94–142 (1975), revised as the *Individual with Disabilities Education Act* (**IDEA,** PL 101–476, 1990), enacted to provide a free appropriate public education (FAPE) which emphasizes "special education and related services designed to meet their unique needs . . . " The IDEA now provides for educational services to include disabled children under the age of 6, and up to, when necessary, age 21. It ensures that all disabled children receive an Individualized Education Plan with parental input and consent, and includes due-process guarantees if parents disagree with this plan or with the student's placement in an alternative setting or school. The IDEA prevented "troublesome" children from being refused admittance, or from being ejected because the school contended that it did not offer an appropriate program. It goes beyond Section 504 by allowing *modifications,* so the student does not necessarily have to meet the same academic requirements as students in regular education. For example, a wheelchair-bound student would not be required to meet physical education requirements applicable to students without a disability.

The *Americans with Disabilities Act* (**ADA,** 1990) provides additional legal protections for disabled children. The ADA prohibits the denial of educational services, programs, or activities to students with disabilities and prohibits discrimination against all such students once enrolled. Students with suspected disabilities can be identified through observations by their parents, teachers, other professionals, or through school-based screening (e.g., vision/hearing tests and group achievement tests). If parents suspect their child has a disability, they may request an evaluation to determine if a disability is present and interferes with educational progress. This is usually provided in writing to the school's principal. A child with a suspected disability is usually referred to a child study team at the school to provide accommodations. If this proves insufficient, a multidisciplinary team of school-based professionals may conduct a comprehensive individual analysis of all suspected areas of disability. Classroom evaluation/observation, educational and/or psychological testing, medical examinations (including those of psychiatrists), and parental interviews or visits are usually performed to determine eligibility for special educational services. If the parent feels the evaluation is inaccurate, an independent evaluation may be requested, although the school is not "bound" to follow recommendations from an outside evaluator. A framework commonly employed by school districts for determining eligibility is presented in the following section.

Determining Special Education Eligibility

1. Does the child have *one or more of the following types of disability* (documented by the medical evaluation/diagnosis, educational/psychological testing, etc.)?
   Autism
   Developmental Delay
   Intellectual Disability
   Sensory-Hearing, Vision, Deafness, Blindness
   Neurological
   Emotional
   Communication
   Specific Learning
   Other Health
2. If one or more of these disabilities is present, is the child *making effective progress in school*? If the student is being *re-evaluated* to determine if a disability is still impacting the child, would the child continue to make progress in school without the currently provided special education services?
3. Is the lack of progress a *result of the child's disability*?
4. Does the child *require specially designed instruction in order to make effective progress in school* or does the child require related services in order to access the general curriculum?

If the child requires specialized instruction because he or she is *not* making effective progress in school because of a documented disability (includes social and interpersonal progress–not just academic progress), the student is eligible for an Individualized Education Program (IEP) under IDEA. If any of the above conditions are *not* met, the child is *not* eligible for IDEA services, but may be eligible for a 504 Plan or for other services. Section 504 services apply to any person who has a "physical or mental impairment which substantially limits a major life activity" and extends to a wider group of students than those under IDEA. Initially, schools often attempt a 504 plan for students with disabilities minimally impacting educational progress, and then perform IEP evaluations with modifications if the 504 Plan appears insufficient. A child who qualifies for special educational services under IDEA must have a written IEP developed by a team of educators. The IEP specifies in what setting the special services will be provided and this setting must be appropriate to the child's needs and least restrictive of his/her interactions with nondisabled peers. A behavior management plan can be written into their IEP, with the goal of preventing suspensions or expulsions for disruptive behavior. School districts usually attempt to provide special education services on-site or within their district, but when appropriate services are unavailable the school must arrange for an alternative placement out-of-district. Psychiatrists are expected to recommend *services* to address the student's disability, rather

than specific settings or schools. This process is summarized in the example case below. See Table 55.8–4 for specific interventions.

Table 55.8–4.
School Service Plans for Students with Psychiatric Disorders

Type of School Service Plan	Response to Intervention (RTI)	504 Plan	Individualized Educational Plan (IEP)
Purpose	To respond quickly to data that suggests student not making sufficient academic progress	To ensure that all students have equal opportunity to learn, even if have a disability; focus is student's opportunities as compared to other students in that school	To remediate symptoms of a student's disability; student's unique needs are the focus
Criteria to receive this plan	Data (either from universal screening, or from progress monitoring) suggests insufficient academic progress	Student has an impairment that limits a major life activity, but may not require specialized instruction	Student has a disability which interferes with educational progress, and which requires specialized instruction
Who develops this plan	Support staff, teacher and administrator, usually with parental input	Teacher, administrator (often the school's designated "504 Coordinator," school counselor and usually parent, student (if appropriate)	Educational team, including staff certified in special education; may include evaluations by school psychologist, social worker; parent may bring friends, advocates, own evaluators to be part of team
What is usually provided	Changes within classroom (Tier 1) or mental health supports (Tiers 2 and 3) to enable student to perform better based on "evidence-based" supported interventions	Changes within classroom or school building to enable student to complete curriculum expectations	Changes within classroom setting(s) to provide student different instruction, and may substantially alter what is required of student
Example of what is provided	Student is allowed to sit closer to teacher during instruction; student is met arriving at school by familiar staff to decrease anxiety	Student is allowed more time to complete tests; student may be provided device to hear better	Student may leave regular language arts class and receive specialized reading program; student may be exempted from course requirements
Which staff deliver	Usually regular education staff,	Usually regular education staff	Staff with specialized training (special education

services	though support staff may deliver services to students at Tiers 2 and 3		teachers, speech therapists, occupational therapists, etc.)
Where the student receives services	Regular classroom, small group or individual support depending on response to interventions at each Tier	Regular classroom with regular peers "to the maximum extent appropriate"	Wide ranging, from regular education classrooms (inclusion) to pullout for special education classrooms, to off-site day school programs, to 24 hours/day residential schools
Review of the plan	As frequent intervals using ongoing progress monitoring data	Plan reviewed at least every year	At least every year plan is reviewed, and every 3 years the student is retested to see if still qualifies
Disciplinary actions	Usually not applicable	If "manifestation hearing" indicates student's impairment or disability caused misbehavior, then student cannot be suspended/expelled; school is not required to provide free, appropriate education for suspended or expelled students	If "manifestation hearing" indicates student's disability caused misbehavior, then student cannot be suspended/expelled; if student is suspended or expelled, school must still provide free, appropriate education
Appeal recourses	None provided	School may alter 504 Plan immediately should circumstances indicate need; "notice" may be provided verbally; family may appeal to the Office for Civil Rights if perceive school is discriminating against child because of a disability	School must provide "prior written notice" before changes in educational plan or placement are made; family may appeal decisions or plan to local then state departments of education

DT, a 12-year-old 6th grader, struggled at middle school, not keeping up with assignments, losing materials and homework, and making inappropriate comments to other students and teachers. The student performed well on cognitive testing, with verbal skills at the 80th percentile, nonverbal skills 77th percentile, working memory 50th percentile, and processing speed at 37th percentile. There were no traumatic events described, and the student was typically happy, although inconsistent in class, and other peers were distancing from DT because she was talking at the wrong time and not picking up on social cues. The family reported the student had done well in elementary school, but was now overwhelmed and needed a specialized school placement. These symptoms and difficulties in working memory alerted the child psychiatrist to ADHD, which usually evolves by elementary school. In this case, the child had been able to manage effectively enough at elementary school. As the social, academic, and organizational demands increased markedly at middle school, the child was now experiencing greater impairments. The school worked with the family to encourage the family to discuss with their primary care clinician evaluating DT for ADHD (and possible treatments), while the school enacted accommodations for DT's inattention, disorganization, and social skills.

SCHOOL ACCOMMODATIONS FOR MENTAL HEALTH PROBLEMS

Accommodations and Modifications for Students with Selected Psychiatric Disorders

According to the National Comorbidity Survey, an estimated 7.2 million Americans prematurely terminated their education because of early onset psychiatric disorders. The failure to complete educational milestones has negative implications from an individual and societal perspective. It is associated with an increased risk of behavioral and legal problems, peer and social difficulties, psychiatric disorders including substance abuse and depression, and effects on later-life opportunities including occupational achievement, financial security and health and well-being lifestyle behaviors. Conversely, children who do well in school appear to develop factors protective against such negative outcomes.

Psychiatrists may be asked for specific classroom and school environment modifications by the school, the legal system, and/or the parents. The sample interventions in Table 55.8–5, derived from www.schoolpsychiatry.org, may be appropriate for particular students having various psychiatric disorders, depending on the needs of the child and the resources of the school. Such interventions should always be paired with the individual needs of each student rather than categorically applied to every student with that disorder, so interventions addressing several comorbid conditions are often required. Interventions may be adapted to a student's individual service plan, as modifications/accommodations, or more informally implemented in regular classroom settings. Success or failure of these interventions often helps clarify whether a child can remain in the current school environment or requires a different, usually more restrictive, educational setting. While students are entitled to an education in the least restrictive environment, this parameter may necessitate a student receive instruction in a regular classroom, receive some instruction outside the regular classroom, receive all instruction in a self-contained special education classroom, go to a program at another site, or attend an off-site 24 hour/day residential school. The psychiatrist's report will be most helpful if it provides the child's diagnoses ("rule-out" diagnoses are not helpful to schools), appropriate accommodations for symptoms that impair school progress, recommendations for services (e.g., social pragmatics training through speech therapy), and program recommendations (e.g., staff trained to work with students with autism spectrum disorders). From these recommendations, the student's educational team can collaborate with other providers and staff to construct an individualized plan, and then to identify a specific placement to address the student's unique needs. Table 55.8–5 provides examples of these interventions.

Delivery Models of Mental Health in Schools

Direct service models typically reflect a partnership between communities and schools to support an array of mental health services in the school, and/or linked to the community. School-based health centers (SBHCs) and comprehensive school mental health systems (CSMHSs) are two models that reflect such partnerships, providing mental health care to students via a collaboration with community providers.

School-Based Health Centers (SBHCs). School-based health care is a health care service model that is designed for children and adolescents and is responsive to challenges such as inadequate or inconsistent access to primary care, restricted access to mental and oral health services, cultural and linguistic isolation from the mainstream health care delivery system, and lack of insurance or underinsurance. SBHCs provide children and adolescents with access to high-quality, comprehensive clinical and preventive health care that is culturally and developmentally appropriate and delivered in a setting that is trusted, familiar, and immediately available—their school. SBHCs integrate into schools, building an interdisciplinary team of providers who deliver prevention and integrated care that effectively meets the complex medical, behavioral, and social health needs of children and adolescents. Currently, SBHCs serve approximately 1 percent of schools in the nation, though the Department of Health and Human Services has called for a marked increase in their numbers (30 percent increase in the next 3 years). SBHCs are found now in most States, within rural, urban and suburban communities, and across elementary, middle, and high school settings. Public and private resources have been targeted to their establishment in low-income and underserved communities where health disparities are more likely to exist and families have limited access to health and mental health services. Evaluations to date indicate that SBHCs significantly improve children and adolescents' access to and utilization of medical, mental health, and substance abuse services, particularly among disadvantaged populations. While SBHCs provide primary care, approximately 75 percent include mental health as a component of service delivery, and psychiatric consultants often serve students in a treatment capacity, as well as system consultation and care management.

Comprehensive School Mental Health Programs (CSMHPs). Comprehensive school mental health programs (CSMHPs) provide a full array of tiered services, including universal mental health promotion activities, selective prevention, and indicated early intervention services such as clinical assessment and treatment. CSMHPs rely on collaborative partnerships between school systems and community programs so that school-employed mental health professionals are meaningfully supported

by community mental health programs. Increasingly, community mental health staff partner with school-employed mental health staff and educators to provide this more comprehensive integrated model. From a national sample of 1,064 school districts, around 50 percent reported contractual/formal agreements with community-based agencies to augment service provision. Community mental health program partners may include community mental health centers, hospitals, and universities. The shared goals of these partnerships emphasize improving student behavior, addressing barriers to learning, increasing access to mental health care, and improving student attendance and academic achievement.

Table 55.8–5.
School-Based Accommodations/Modifications

Target Symptoms	Interventions To be Implemented by Teacher/School Staff	Examples Specific Tactics for Staff to Employ
ANXIETY		
Worry	Forewarn the student of transitions, and have "tasks" for the student to focus on during transitions	If the student is worried about a school trip, provide tasks that distract from anxiety, such as checking attendance, or holding the door at the site.
	Devise a desensitization approach agreeable to the student	If the student fears speaking in front of the class, allow the student to: have the speech read by a peer; read the speech into a recorder outside class; do the speech with a peer reading some part.
	Help the student examine other perspectives	The student says "I can't go to the school assembly because everyone will notice that I'm nervous." Ask the student: "how would your best friend/someone you admire handle a situation like this? What does your friend think you should do?"
	Provide the student with competing responses to negative thoughts or behaviors	The student says "I'm afraid I'll start crying in class." Ask the student: "if you start to feel sad, what can you do before you start to cry? Can you distract yourself by doodling?"
Emotionality	Provide specific steps the student can take to relax or provide a relaxation ritual	Take three deep breaths; tense fingers or toes for five seconds, then relax.
	Provide alternative foci to distract the student from somatic symptoms	Provide the student a phrase to think of or an activity (doing three problems then standing up, 10 problems then walking to the fountain).
Separation Difficulty	Provide desirable activity/responsibility for the student upon entering school	Before school begins, allow the student to feed fish, clean boards, play with peers, or discuss music/sports with another student who shares interests.
	Provide times during	Have a brief script/message the student can phone to

	the school day for the student to convey brief (30 seconds) messages to his/her family	a parent ("Hi Mom, made it through Science–now we're going to make penguins in art class. I love you.); prepare the parent not to over-react to tearful messages.
	Have a parent send notes to the student to read as a reward for staying at school for increasing intervals	Have a parent place a brief note to the student in his/her lunchbox that the student can read at lunchtime ("Dear [name], I know you're at lunch now–enjoy the cupcake. Have a great afternoon, and when I pick you up today we'll get to play soccer. Love, Dad").
Social Fears	Allow the student to observe several other students before attempting a task	If the student resists speaking in class, allow the student to observe others, focusing on how they start, how long they speak, where they look, and how they stop.
	Have the student rehearse social skills in a smaller or more relaxed setting	In a small group facilitated by a counselor, have students review and role play how to make and keep friends. Give students homework to practice skills in other settings (classroom, playground, home play date, etc.).
Obsessive Thoughts	Establish acceptable teacher comments to "unstick" the student when he/she is obsessing	With the student and parents, identify useful statements to break an obsessive cycle ("Move to your seat on 3 – 1, 2, 3." "Now think about your coach – what would he/she say to your "rut," "stuck moments?").
	Allow the student to dictate or tape record if he/she cannot touch the pencil or paper	Teacher or voice dictation software can "transcribe" the student's ideas to avoid touching/erasing the paper.
Compulsions	Allow the student to alter the work sequence	If the student gets stuck doing problems in a certain way, allow the student to start with even numbers, or start from the end and work backwards to #1.
	Have the student identify and substitute less disruptive compulsive behaviors	Allow the student to touch underneath the desk, flex fingers, or do versions of compulsions that are not disruptive to others.
MOOD SYMPTOMS		
Sad Mood	Check in with the student to quantify his/her mood status each day	Allow the student to complete a mood scale (10 = very happy to 1 = very sad) at first check-in time each morning.
	Help the student identify "all the evidence" surrounding his/her negative perceptions of self or events	Examine specific events that led to the student's conclusion that "I'm no good." What happened that led to this conclusion? Did anything happen that disputes your conclusion? What else happened in your other classes that day?
	Help the student	The student says "I'm no fun. No one wants to be

	identify automatic negative thoughts	around/play with me." Ask the student: "What happened that made you think this?" or "what evidence leads you to reach this conclusion?"
	Acknowledge the student's feelings (rather than dispute/argue with feelings)	"It's sad when . . . .," "discouraging," "frustrating" rather than "it's not so bad," or "aw, come on, things will be better soon."
Irritable Mood	Model appropriate responses to replace irritable responses	Provide an alternative, appropriate comment: "I know you have something important to say, and I want to hear it, but I can't hear your point when you use sarcasm. It sounds like your point (without sarcasm) is _____." Could you please say your point again without relying on sarcasm?"
	Allow the student to take him/herself out of a situation (self-timeout) when irritability is starting to disrupt others	Provide specific steps for the student to remove him/herself from situations ("I [student)] feel myself getting frustrated, so I am going to leave this kickball game and swing on the swings for five minutes. After I watch others, and think I understand what I'm supposed to do, I'll try kickball again.").
	Provide opportunities for the student to "fix" problems or inappropriate classroom behaviors	Allow the student a chance to "redo" with an appropriate comment or behavior; if the student tears up paper, allow him/her to tape it together.
Manic Mood	Allow the student to complete schoolwork or tests in a less stimulating environment	Identify a calm, comfortable area (with limited distractions, noise, and sensory stimuli) where the student can complete work/tests.
	Allow the student alternative modes of expression if he/she cannot verbalize in a useful way or is speaking too rapidly	Provide the student with an opportunity to write, dictate, or draw ideas.
	Allow the student to have homebound instruction during manic periods	Determine the conditions that warrant homebound instruction (e.g., the student is sleeping during the school day while awake at night; the student's fears or delusions are causing conflicts in the classroom). Home instruction may need to be provided by specialized (therapeutically trained) staff.
Appetite Changes	Encourage the student to use snacks and/or physical activity to enhance functioning	Provide snack breaks when the student finishes tasks. Encourage the student to be physically active at appropriate times by taking attendance to the office, standing and moving books, etc.
	Change food reinforcers to nonedibles	Instead of chips or candy, reinforce the student with stickers, computer time, or points to earn a lunch date with a preferred peer (if increased appetite/weight).
Fatigue; Energy Loss	Augment classroom	Tape-record or videotape lectures and provide

	instruction with recordings of instruction	recordings to the student.
	Identify study partners who can support and assist with assignments	Allow a peer to study with the student and to assist in academic assignments.
	Introduce physical activity throughout the day	Provide the student physical responsibilities (taking attendance to the office, emptying trash, putting up class materials) throughout the day to encourage physical activity.
	Grade the student based on work completed or attempted (rather than work assigned)	Grade items completed (e.g., even numbers only), and do not count the items the student does not get to (odd items).
Suicidal or Self-Harm Thoughts	Identify appropriate methods for expressing feelings of hopelessness or self-destruction	Encourage the student to draw pictures, write songs or poems, or use sculpting to depict feelings of sadness, anger or despair.
	Establish a hierarchy of people for the student and staff to contact if the student has suicidal thoughts	Specify multiple staff and treatment providers, and the order or circumstances for contacting them, when the student is feeling or appearing unsafe.
Psychosis Symptoms		
Hallucinations Delusions	Identify and avoid the student's exposure to known distressing stimuli	Clarify with the student or family the items, places, or topics that trigger delusional thinking and find alternatives, particularly when the student is stressed or currently experiencing psychosis symptoms.
	Allow the student alternative schoolwork or activities to avoid provoking delusions	If the student cannot proceed with a task, provide an alternative, "grounding" task which requires little creativity, such as reading, moving items, or doing rote tasks.
	Devise steps to employ when the student is delusional or hallucinating	Employ a series of steps to de-escalate the student when he/she is becoming more delusional (first: change topic, second: change activity, third: change setting, fourth: change staff).
ATTENTION-DEFICIT/HYPERACTIVITY SYMPTOMS		
Inattention	Define classroom expectations in positive terms	"Please sit down, get our your pencils and paper, and let's look at the board to find our first task."
	Give the student duplicate materials	Keep a set of classroom materials in the student's desk and another set at home in case essential items are forgotten.
	Affix materials to the student's desk	Keep regularly needed materials such as pencils attached to the student's desk where they cannot be misplaced.

	Provide organizational devices in the classroom	Use colored folders to distinguish math vs. reading vs. social studies work; use a clipboard to hold papers or current activities.
	Keep a sample model of a correctly formatted paper for the student to refer to	Keep formatted (even laminated) paper showing where name, date, etc., should appear on the student's assignments.
	Have the student repeat directions back to the teacher	After giving directions, have the student repeat back the sequence
	Provide check-in points during lessons	"Raise your hand when you finish the first three problems, and we'll come by to check them."
	Provide untimed or extended time for tests or assignments	Allow the student to work at his/her own pace, even "rest," so he/she can demonstrate all that he/she has learned.
	Diminish external distractions	Minimize noise in the classroom by using headphones, tennis balls on chair legs, or rugs.
	Use a daily progress book or email between school and parents	Send a small book or email between school and home to keep parents and teacher aware of the student's daily progress, and of any events that might influence the student's attention.
Hyperactivity	Clarify volume and movement expectations of the student before unstructured activities	"As we go through the hall, we'll only use our whispering voices if we have to speak, then in the lunchroom we'll remember to use our 'inside' voices."
	Specify acceptable personal space	Clarify space boundaries with visuals such as "each person has the space of four tiles." Put tape on the floor to demonstrate that others stand outside this distance.
Impulsivity	Establish a waiting routine	Develop with the student a multistep plan for waiting, such as "count to five then raise your hand and look the teacher in the eyes."
	When behavior is inappropriate, first remind the student what he/she is expected to do, then reinforce efforts closer to classroom expectations	During misbehavior, clarify what you want the student to do rather than describing the misbehavior ("next time you turn in a paper, make sure your name is at the top" instead of "don't turn in a paper without your name at the top").
AUTISM SPECTRUM SYMPTOMS		
Communication Difficulties	Create situations to motivate language use	Structure situations so that language becomes helpful (choose the flavor of ice cream from a list).
	Allow the student time to process information and respond	Provide sufficient time for the student to understand direction and to respond (wait 10 seconds for student response).
	Ensure that the teacher is positioned strategically to	Align at the student's eye level. Touch the student's desk or chair while quietly saying something like, "Look at the——(checklist or material) and listen. I

	engage the student's attention	need you to know . . . . . ." Pause to give the student time to shift attention.
	Provide choice boards for the student to communicate preferred activities	Show the student different options for tasks (picture of a book [for reading], food [for snack], counting cubes [for math]).
	Develop visual cues to reduce sensory overload	Devise visual cues such as hand signals or use of pictures to diminish reliance on verbal and physical prompts.
	Use scaffolding techniques to promote spontaneous language	Add "parts" (sentence starters, transition statements to connect ideas) to facilitate conversation with the student.
Difficulties with Social Interaction	Pair the student with a "typical" peer/buddy to help carry out social interactions in structured settings	Team the student with a "typical" peer during a structured recess kickball game to show the student how to kick, run, and catch.
	Divide social skills into successive steps and teach the steps incrementally	Break down social encounters and teach multiple ways to accomplish each part (you can introduce yourself by saying your name, by asking what the other person is doing, by showing the other person an interesting object, by just saying "hi," or by having a friend who already knows someone introduce that person).
	Provide explicit teaching about how to start conversations, respond to comments, and end conversations	Describe specific phrases and behaviors to create conversations ("stand this far from a person, look at their eyes, say 'hi', ask if they want to play four square with you," "say 'maybe another time' if they say 'no.')
Restrictive Routines/Interests	Provide alternative tasks, particularly when the student is sensory overloaded	Allow the student several choices within his/her daily tasks. The student can choose the order of tasks, or when/where to take a break.
	Specify the student's routine for asking questions or describing topics when the student seeks or presents information	Explain that the procedure for asking questions is to limit him/herself to two questions, then allow others to ask ("You can ask the two most important questions to begin work.")
Sensory Issues Include extreme over-sensitivity or under-responsiveness to sound, light, or other sources of stimulation	To control sensory inputs, allow the student to be first or last in line or to leave class early	Allow the student to change classes five minutes before the other students, or have him/her hold the door open for other students and then join the end of the line as the "caboose."
	Teach students who use distracting vocalizations or other self-stimulating	Practice humming loudly and softly and have the student role-play appropriate times to hum loudly and appropriate times to hum softly.

	behaviors to employ other intrusive vocalizations or behaviors

Additional specific interventions are available at www.schoolpsychiatry.org.

http://smhp.psych.ucla.edu: clearinghouse of important mental health, school, and education materials.

http://ies.ed.gov/ncee/wwc/: information on broad categories of findings of "what works" in schools including academics and mental health.

http://www.ldonline.org: information on classroom changes for students with learning disabilities, including ADHD.

http://www.ideapartnership.org: up-to-date information on changes in the IDEA parameters.

http://www.wrightslaw.com: information about legal aspects of education, including IDEA 504 Plans.

http://www.r14success.org: Response To Intervention school programming across academic and emotional areas.

Many schools have mental health supports less comprehensive than in SBHCs or CSMHPs, yet provide important components of student mental health. Examples include school system consultation, prevention and intervention programs, early identification screening programs; web-based mental health resources, and on-site or video consultation with off-site mental health clinicians. The model adopted by a school often depends on resources, state law, and student and school needs and priorities.

Selection of Evidence-Based Intervention and Prevention Programs

There are many prevention and early intervention models targeting both high-risk and all children in schools. Successful school models integrate the school, family, and community in coordinating services and instituting reform. Common elements in successful intervention and prevention programs include: youth being connected to a trusted adult, access and coordination of appropriate programs and services with ongoing evaluation, program continuity with school support, and emphasis on early identification and intervention. Psychiatrists can help schools identify and implement appropriate programs depending on the needs and resources of the school system. Universal prevention programs address the school system as a whole and aim to better the overall educational climate and

learning environment by coordinating community and outside resources. Specific intervention/prevention models target a wide range of risk behaviors including anxiety, depression, substance abuse, and bullying/violence. Several repositories of evidence-based and promising practices have been developed to assist practitioners and agencies (including school districts and schools) select scientifically supported interventions based on designated criteria (e.g., age, setting, and target outcome). The following sites include several evidence-based school interventions for students with mental health needs.

Websites for Evidence-Based Student Interventions

DELINQUENCY/VIOLENCE/AT-RISK BEHAVIORS:

1. **FindYouthInfo.gov:** This program/site features evidence-based programs that prevent and reduce delinquency or other youth problem behaviors (e.g., drug and alcohol use). Programs focus on one of the following problem behaviors: delinquency; violence; youth gang involvement; alcohol, tobacco, and drug use; family functioning; trauma exposure; or sexual activity/exploitation.
2. Promising Practices Network (PPN) on Children, Families and Communities (http://www.promisingpractices.net/programs.asp): The PPN site features summaries of programs and practices that improve outcomes for children.
3. Blueprints for Violence Prevention Model Programs Selection Criteria (http://www.colorado.edu/cspv/blueprints/model/criteria.html): Blueprints programs have the highest standards by showing evidence of a *deterrent* effect with a strong research design, *sustained* effect, and multiple site *replication*.

SOCIAL-EMOTIONAL LEARNING (SEL):

4. The Collaborative for Academic, Social, and Emotional Learning (CASEL) (http://www.casel.org/programs/selecting.php): "CASEL Select" programs provide outstanding coverage in five essential SEL skill areas, have at least one well-designed evaluation study demonstrating their effectiveness, and offer professional development supports beyond the initial training.

MULTITIERED SYSTEMS OF BEHAVIORAL SUPPORT:

5. Positive Behavioral Intervention System (PBIS): https://www.pbis.org/school/school-mental-health/ interconnected-systems: PBIS provides a school-wide program to enhance positive behavior in the school system.

MENTAL HEALTH AND SUBSTANCE ABUSE:

6. The National Registry of Evidence-based Programs & Practices (NREPP)

(http://www.nrepp.samhsa.gov): Intervention summaries are provided to help determine whether a particular intervention may meet identified needs.

SUICIDALITY:

7. Suicide Prevention Resource Center: Best Practices Registry (BPR) For Suicide Prevention (http://www.sprc.org/featured_resources/bpr/index.asp).

School Violence. The awareness of violence occurring at school (greatest in middle schools) has gained increased attention, and psychiatrists are often contacted to assist in the management of such events. Initial efforts emphasize supporting and empowering the staff and identifying and responding to those in distress, both staff and students. While initially efforts have been to provide universal responses to all students in the school, increasingly, efforts emphasize working with those students and staff most troubled by the event or at-risk. Psychological First Aid for Schools (http://www.nctsn.org/content/psychological-first-aid-schoolspfa), for example, is an evidence-informed intervention designed to assist school staff, students, and their families in the aftermath of a school crisis, disaster, or other violent or traumatic event. The intervention empowers school administrators, educators, and support staff to promote safety and comfort, stabilization, information gathering about current needs and concerns, practical assistance to students and families (including connection with social supports), information about coping and linkages to other community resources.

Psychiatrists are also asked increasingly to evaluate the potential "risk" of students acting violently toward others. A collaborative effort by the U.S. Dept. of Education and the U.S. Secret Service examined 37 instances of targeted school violence and the characteristics of 41 perpetrators. This Safe Schools Initiative (SSI) concluded that the most effective way to prevent an attack at school is to enhance the positive relationship between students and staff. In addition, the SSI clarified the circumstances of school violence: (1) attacks at school are rarely sudden, impulsive acts; (2) other people knew, before the attack, of the attacker's ideas or plans to attack; (3) no "profile" exists to accurately identify which students will attack a school, and any screening approach would both identify an unacceptable and excessive number of potential assailants as well as fail to accurately detect violent perpetrators; (4) most attackers had access to weapons, had felt themselves bullied or mistreated, had struggled with losses or failures and suicidality, and had indicated needs for health; despite prompt response by law enforcement, most events were stopped by other means/entities. For psychiatrists evaluating students at risk of school violence, important topics have been identified to better gauge risk, and are summarized below:

Determining If a Student Poses a Threat

1. What are the student's **motives** surrounding the threat (e.g., retaliate against others, be famous, and have others fear or respect)?
2. Have there been any **communications** suggesting ideas or intent to attack (e.g., disclosures by others, writings, drawings, and social media comments)?
3. Has the student shown **inappropriate interest** in:
   a. *School attacks or attackers*?
   b. *Incidents of mass violence*?
   c. *Weapons* (including recent acquisition of weapons)?
4. Has the student engaged in **attack-related behaviors** (e.g., attempted to make weapons/bombs and harmed animals or others)?
5. Does the student have the **capacity** to carry out an act of targeted violence (e.g., the means to obtain weaponry and confederates to assist)?
6. Is the student experiencing hopelessness, desperation, and/or **despair**?
7. Does the student have a **trusting** relationship with responsible adult(s)?
8. Does the student see violence as **acceptable** or desirable, or the only way to solve problems?
9. Is the student's "story" **consistent** with his/her actions?
10. Are other people **concerned** about the student's potential for violence (e.g., have others alerted school staff, law enforcement, or students about this student?)
11. What **circumstances** might affect the likelihood of an attack (e.g., if some event occurs, or doesn't, holidays/anniversaries of related events [Hitler's birthday], other school assaults)?

▲ 55.9 Prevention of Psychiatric Disorders in Children and Adolescents

WILLIAM R. BEARDSLEE, M.D., DAVID A. MRAZEK, M.D., AND PATRICIA J. MRAZEK, PH.D.

INTRODUCTION

Over the last two decades, there has been significant expansion of empirical research that demonstrates it is possible, in some instances, to prevent mental illness and problem behaviors, particularly in children and youth. In 2009, the Institute of Medicine issued a report focused on children, youth, and families entitled, "Preventing Mental, Emotional, and Behavioral Disorders Among Young People." This report chronicled several major advances since the last IOM report in 1994, including an increased number of efficacy and effectiveness trials, a deeper understanding of risk and protective factors for mental illness, and advances in understanding the neuroscience that underlies preventive intervention. In addition, this report highlighted the fact that the major mental illnesses of adulthood have their onsets in childhood and adolescence, with the onset of symptoms preceding the onset of full-blown disorders, in most cases, by several years.

Such advances in preventive intervention research suggest that it is now possible to set public health goals designed to decrease the incidence of behavioral problems and psychiatric disorders within a given population. Practical strategies for correcting problematic developmental trajectories have been identified, and the salient characteristics of target populations have been defined. Rigorous preventive interventions have been implemented across diverse populations and been shown to be effective. Finally, informative longitudinal studies have followed children into adulthood and demonstrated differential outcomes and the important influences of risk and protective factors at multiple levels. The study of the prevention of psychiatric disorders offers an unusual opportunity to study mechanisms by which disorder is either expressed or prevented and, as such, must be an important part of overall research on development. Preventive intervention research also highlights the influence of broader forces on children's development such as neighborhood characteristics, wealth disparities, and lack of access to resources. Yet, although psychiatrists and other mental health professionals are in key positions to identify those children who are at the highest risk for the development of psychiatric disorders and to institute appropriate interventions, to date, many psychiatrists have been reluctant to embrace developments in preventive intervention. As a reflection of democratic principles and also an emphasis of the Affordable Care Act, it is important that the same quality of

treatment and prevention services be available to all children and families. This requires being able to implement and disseminate evidence-based preventions and treatment widely. A major emphasis of both IOM reports of 2009 was the need to study implementation and dissemination much more fully. This is a focus of a current IOM forum.

Part of the reluctance of psychiatrists and other mental health professionals to engage in advocacy and practice for preventive interventions is that accepting the idea of prevention requires a major paradigm shift from a traditional concentration on the diagnosis and treatment of those seriously ill, in which the focus is on what can be done for the child or adolescent immediately. Prevention requires asking a different question: what does the child, the family, and even perhaps the broader community need 1, 3, and 5 years down the line in order to ensure the best possible trajectories of healthy development for the child and the family? In addition, as the field of prevention has incorporated an increased understanding of genomic variations in the onset of illness, and of the biological, as well as the psychosocial, context of risk and protective factors for illness, preventive interventions are increasingly conceptualized as including both biological and environmental components. The acceptance of preventive interventions has been slow because many of the investigators and clinicians who have been involved with the interdisciplinary development of preventive interventions are not familiar with molecular genetics.

In fact, focusing on prevention requires mental health professionals to recognize that mental health and physical health are inseparable and, hence, preventive interventions in one realm often exert a positive effect in another. Successful preventive interventions are inherently interdisciplinary, drawing on findings and insights from psychology, sociology, medicine, adult and child psychiatry, social work, many medical disciplines, and the field of developmental neuroscience multiple approaches to genetics. Mental, emotional, and behavioral disorders are developmental. That is, they have their onsets at different points across the lifespan, requiring a series of interventions that can be positioned at different points across the lifespan.

The development of a new domain of science can be facilitated by the introduction of new knowledge from related fields that require major reassessment of previous beliefs. This reassessment can subsequently lead to integration of these new insights into the traditional core knowledge base of the science.

Every medical specialty is being challenged to consider how genomic variations influence the onset of illnesses as well as the selection of treatments that can be tailored to be maximally effective for each patient. This new orientation provides an opportunity to begin to practice "individualized personalized medicine." This approach to diagnostic

evaluation focuses on biological vulnerabilities that can be identified in each individual patient. Consequently, preventive interventions, in the same way as therapeutic interventions, will increasingly be conceptualized to include both biological and environmental components. Consideration of molecular genetics is essential in this regard.

This chapter focuses on preventions for children, youth, and families. The current understanding of prevention research is guided by four key principles. First, because improving the health of a population is an essential goal, preventive interventions must eventually be able to be delivered to entire populations. Second, health disparities remain a growing and profound problem, and preventive interventions can help in addressing health disparities. Third, awareness of cultural and linguistic competence and the need for cultural humility must guide the adaptation and delivery of preventive interventions. Finally, given the implementation of the Affordable Care Act with its strong focus on prevention and its emphasis on mental health services as one of the ten essential services, a focus on prevention is timely and necessary.

Definitions

In an attempt to clarify the research evidence and advance the science of prevention, the 1994 IOM Committee on the Prevention of Mental Disorders recommended the adoption of an alternative definitional taxonomy for mental health interventions: prevention, treatment, and maintenance. The use of the term "preventive intervention" in this classification system was restricted to interventions provided prior to a patient receiving a psychiatric diagnosis. The term "treatment" was reserved for interventions targeted at patients with a diagnosis. The term "maintenance" referred to the care provided to patients with chronic illnesses who had not had a remission as a consequence of their primary treatment.

The IOM Committee recommended that preventive interventions, which were previously referred to as primary prevention, be subdivided into three categories, which were designed to be administered to populations prior to the initial onset of a psychiatric diagnosis. These categories were referred to as universal, selective, and indicated preventive interventions, and were differentiated from each other based on their targeted populations. In consideration of the interdisciplinary nature of prevention, this fundamental categorization was continued in the 2009 report.

Universal preventive interventions are targeted to the general public or to a specified group. By definition, universal interventions are provided to individuals who have all levels of risk, including no risk factors at all. A common example of a universal preventive intervention is fluoridation of a water supply to improve the dental health of a community. *Selective*

preventive interventions are targeted to individuals whose risk of developing mental disorders has been demonstrated to be increased. These identified risk factors may be associated with imminent onset or with risk at a later point in development. Biological markers that indicate predisposition for mental disorder but are detected in individuals that are free of symptoms represent an example of medical criteria that can be used to initiate a selective preventive intervention. *Indicated preventive interventions* are targeted to high-risk individuals identified as having detectable signs or symptoms associated with the ultimate development of a mental disorder. Symptoms or signals, which are early warning signs of future development of a psychiatric illness, may arise years before a patient develops a sufficient number of symptoms to meet the full diagnostic criteria that are required to establish the occurrence of the psychiatric disorder. Indicated preventive interventions can be initiated early in the natural course of a mental disorder when the first signs and symptoms appear.

Sufficient evidence has accumulated to include mental health promotion as a fourth major category of preventive intervention (see Fig. 55.9–1). Mental health promotion aims to enhance an individual's ability to achieve age-appropriate developmental tasks or developmental competence and to have a positive sense of mastery and well-being, as well as to strengthen an individual's ability to cope with adversity.

The term *risk factor* is used in both prevention and treatment, but the implications of risk for these two concepts are different. In prevention, a risk factor must predate the onset of the illness and can be the characteristic that is used to identify a target population. The reduction of risk factors that are both causal and malleable is a goal of preventive interventions. Once the diagnosis of an illness has been made, risk factors that are subsequently identified may be used to guide treatment decisions and to provide insight into prognosis. One well-studied example of a risk factor is parental mental illness. Another is undergoing severe loss, such as a family member.

FIGURE 55.9–1. The mental health intervention spectrum for mental disorders. (Reprinted with permission from Mrazek PJ, Haggerty RJ, eds. *Reducing Risks for Mental Disorders: Frontiers for Preventive Intervention Research*. Washington, DC: National Academy Press; 1994.)

Protective factors decrease the risk of the onset of mental illness. An individual with one or more protective factors is at a lower risk for the development of a specific psychiatric illness than an individual without the protective factor. Most protective factors are nonspecific and have been perceived to be universally beneficial. Common examples of protective factors include a supportive family environment, adequate family financial resources, and access to high-quality education.

Increasingly, research has highlighted the ways in which biological and environmental risk and protective factors interact. The study of epigenetics has emphasized the important ways in which environmental influences can profoundly affect gene expression across generations. Exploration of gene-environment correlations and gene-environment interactions offer important ways to study mechanisms.

Examples of Research on the Prevention of Mental Health Problems in Youth

Figure 55.9–2 presents a schematic representation of the different interventions that are likely to be effective across the span of childhood. Early in life, interventions for high-risk families (e.g., home visitation, center-based care) have been shown to be valuable. As children enter school, both academic enrichment activities and social skills training are valuable, as are various kinds of parent training. As youngsters enter adolescence, there is evidence that some programs can cut the incidence of major depression and substantially reduce substance abuse.

Across the bottom of the diagram, three types of factors that occur across the span of childhood and adolescence are emphasized: the

importance of addressing families in adversity; the importance of interventions that strengthen the fabric of schools and communities; and policy interventions such as those that provide ready access to preventive and treatment services, and that support families. A central theme in the 2009 report is that preventive interventions can reduce or minimize toxic biological and psychological processes, richly reinforce self-regulatory prosocial behavior, teach prosocial skills and values, and foster acceptance. The overall conclusion of the report was, "The scientific foundation has been created for the nation to begin to create a society in which young people arrive at adulthood with the skills, interests, assets, and health habits needed to live healthy, happy, and productive lives in caring relationships with others."

In what follows, rather than trying to comprehensively review all prevention approaches, the focus is on preventive interventions that are particularly relevant to psychiatric practice, and that illustrate more general points about prevention approaches. Specifically, this chapter reviews key interventions targeting family adversity, externalizing behaviors, depression, psychosis, and substance abuse.

Preventions Targeting Family Adversity. Examples of effective parenting programs in risk situations are the effective programs designed and implemented by Wolchik, Sandler, and colleagues at the University of Arizona: The New Beginnings Program (NBP) for families facing divorce, and the Family Bereavement Program (FBP) for families facing bereavement.

Using a randomized, controlled clinical trial design, two well-described preventive approaches were tested in the NBP. The first targeted mothers and consisted of 11 group sessions and two individual sessions; the second provided this same program for the mothers, as well as 11 sessions for the children. Both interventions were compared to a control group where the mother and child received three books on how children adjust after a divorce. In follow-up studies, researchers found very few differences between the mother-only and mother and child interventions, but argue that this was the result of focusing primarily on the outcome of coping. Wolchik and colleagues suggest that the lack of benefit of the child program may be due to little opportunity for the children to practice more adaptive coping strategies and a presentation that may have been too didactic for the young children. The results of a 15-year follow-up demonstrated that the young adults who received the preventive intervention (NBP) were less likely to develop an internalizing disorder than were young adults in the control group during the time period since the 6-year follow-up, and young adults who developed a disorder had a slower rate of onset. Also, between the 6- and 15-year follow-up assessments, males in the NBP group displayed a lower rate of substance-related disorders and reduced

substance use in the past year.

FIGURE 55.9–2. Interventions and their targeted developmental stages.

For families struggling with the loss of a parent, Sandler and colleagues developed the FBP. With a similar structure to the NBP, FBP provides caregivers and children with 12 group sessions, 4 of which include shared activities for both the caregiver and the child or adolescent. Caregivers also participate in two individual sessions. The control group received 3 books, discussing child, adolescent, and adult grief, over the course of 3 months. A 6-year follow-up indicated that effective parenting, operationally defined as caregiver warmth, acceptance, and consistent discipline, had increased in families receiving the FBP. An examination of mediating effects showed that improved parenting at postintervention and at an 11-month follow-up mediated the effect of intervention on the outcome of effective parenting 6 years after the completion of FBP. Although not directly measured in this study, a similar intervention that increased effective parenting had a depression prevention effect on parents, such that parents who participated in the active intervention had fewer cases of depression. These results demonstrate that relatively brief interventions have the potential for long-term sustained effects in families that have experienced a major stressor, such as divorce or the death of a parent. More generally, interventions that are highly specific and increase capacity of parents to parent effectively have a strong knowledge base.

Preventions Targeting Youth Externalizing Behaviors. Webster-Stratton originally developed a treatment intervention for young children with conduct disorder and their families. This intervention, The Incredible Years

Parenting Series, includes therapist-led group discussion that emphasizes parent training. Parents view standardized videotapes that present parents and their children engaging in both desirable and problematic interactions. Findings demonstrate that this program improved parent and child interactions and significantly reduced the children's conduct problems and increased cooperation, compared to a control group. This treatment was later modified to become an indicated preventive intervention for children with early symptoms of conduct disorder but who did not meet diagnostic criteria. More recently, this intervention was modified further to allow it to be used as a selective intervention for children enrolled in Head Start programs who were all considered to be at high risk but were not symptomatic at the time of the intervention. Teachers in the active intervention group used more positive classroom management techniques, and their students had fewer conduct problems and more emotion regulation than control students. Since then, this program has been widely disseminated.

Poduska, Kellam, and colleagues document the long-term effects of a universal classroom–based intervention with children during their first and second grade years. Their intervention, the "Good Behavior Game" (GBG), is directed at improving the classroom management skills of teachers, socializing children to become better students, and reducing aggressive and disruptive behavior. A randomized, controlled trial was carried out in 40 first grade classrooms in 18 elementary schools in Baltimore, Maryland. Significant positive results were found, but these outcomes varied by gender, baseline level of risk, and cohort. Generally, the children with the highest level of risk from the fall of the first grade through the seventh grade benefited more than other children who were assessed to be at lower risk. The most aggressive boys in first grade who received the GBG were the children who demonstrated the greatest reduction in aggressive behavior over the course of first through seventh grades. These boys were less likely to develop an antisocial personality disorder as an adult and had a 50 percent reduction in lifetime illicit drug use. These results point to the benefit of early behavioral interventions.

Preventions Targeting Depressive Disorders. Quite fruitful work has been done in the area of the prevention of depression. There are both specific risk factors for depression, such as having a parent with depression, a depressogenic cognitive style, or a prior depressive episode, and nonspecific risk factors, such as poverty, exposure to violence, and social isolation. Research suggests that children who have either specific or nonspecific risk factors are at increased risk for disorder, and that interventions targeting these risk factors may prevent the onset of depressive symptoms and disorders. Recent meta-analyses support the value of preventive intervention approaches targeting depression and show

that it is possible to actually prevent episodes of major depression in both adults and youth.

An example of a strong depression prevention program is the Coping with Depression Course (CWD), developed by Lewinsohn in the mid-1970s. After finding much success in the reduction of depressive symptoms in adults who received this prevention and treatment course, Clarke and colleagues adapted the CWD for use with an indicated sample of adolescents and demonstrated the prevention of unipolar depressive disorder. Later, Clarke and colleagues used the CWD course with adolescents of depressed parents who themselves had subsyndromal symptoms of depression. Only 9.3 percent of these adolescents went on to develop a major depressive disorder, compared to 28 percent of adolescents who were at similar risk but did not receive the preventive intervention. Garber and colleagues undertook a four site replication of this study, again using adolescents at double risk, because their parents had experienced major depression and they themselves either had prior depression and/or symptoms of depression. This study demonstrated a strong and sustained effect from the prevention program. At a 33-month follow-up, adolescents in the group cognitive behavioral prevention program had significantly fewer onsets of depressive episodes, compared to those in the comparison group; however, for adolescents whose parents were currently depressed at the time of enrollment, the average rate of onset did not differ statistically between the intervention and nonintervention groups.

A second example of a preventive intervention targeting youth depression was developed by Compas and colleagues, who explored preventive interventions for children with depressed parents using a family group cognitive behavioral (FGCB) strategy. Children between the ages of 9 and 15 who had a parent with a history of Major Depressive Disorder participated, along with their parents, in either the 12-session FGCB intervention, or they received 3 sets of written materials about depression in the mail every 8 weeks. Eighteen and 24-month follow-ups demonstrated that the FGCB preventive intervention significantly reduced the onset of the children's depressive episodes for up to 2 years after the intervention ended compared to the control group. Additionally, this preventive intervention reduced the children's internalizing and externalizing symptoms. In another randomized control trial of this intervention, Compas and colleagues found a mediating role of parental behavior, more specifically parental guilt induction. Similar to Sandler and colleagues' FBP, it was found that a reduction in negative parental behaviors improved family functioning; 1 year after the end of the intervention, reductions in parental guilt induction were associated with significantly lower internalizing symptoms and lower levels of negative cognitive style in the youth participating in the FGCB program.

An illustration of a preventive intervention that reduces the risk associated with depression is the Preventive Intervention Project, which targets relatively healthy children, aged between 8 and 15 years, who have a biological parent with a clinical mood disorder. Two manual-based programs were tested. The first intervention consisted of a two-session group lecture format for the depressed parents; the second intervention used a clinician-facilitated format consisting of 6 to 11 sessions, including separate meetings with parents and children, as well as a family meeting. In both formats, psychoeducational information about mood disorders was provided, and parents were helped to better support the initiatives of their children. In the clinician-facilitated format, efforts were made to link information about mood disorders to the depressive illness experiences of the parents in the intervention. At the 4.5-year follow-up, parents who received either the lecture format or the clinician-facilitated intervention reported improvements in their behaviors and attitudes regarding their children, and the internalizing symptom scores of the children who had received either of the interventions improved when they were assessed at follow-up. Moreover, there was a significant relation between the number of positive changes that the parents reported in their behaviors and attitudes regarding their children and the improved understanding of course and treatment of mood disorders that was achieved by their children. This family-based approach is particularly applicable to implementation in a clinical setting, which could be accomplished by adding a relatively small number of additional sessions to the standard treatment of those adult patients with mood disorder who have children in the therapeutic range. Beardslee's family-based depression prevention approach has been adapted successfully for use in different ethnic and cultural groups, both in the United States and around the world.

Prevention of Early-Onset Psychosis. Several investigators have focused on children and youth at high risk for the development of schizophrenia and the prodromal symptoms of psychosis. The goal of much of this work has been to identify risk factors or biological markers that could inform studies designed to prevent the onset of an initial episode of psychosis, or to optimally treat a patient at the very earliest point in the initial onset of the illness. Although these intervention strategies all have been multidimensional, one critical aspect of these interventions is the prudent use of antipsychotic medications. For example, McGorry and colleagues gave young first-episode psychosis patients a low dose of risperidone therapy to treat their early symptoms; results revealed that risperidone was very effective in reducing psychotic symptoms and improved the individual's quality of life, treatment experience, and adherence.

In the United States, with efforts to reduce the duration of untreated psychosis (DUP) from early symptoms to engaging in treatment, Srihari,

McGlashan, and colleagues have developed the Specialized Treatment Early in Psychosis: Early Detection (STEP-ED) program, an adaptation of McGlashan and Johannessen's Early Treatment and Intervention in Psychosis (TIPS) study. The TIPS Early Detection in Psychosis Study, conducted in Norway and Denmark, provided the general public, schools, and Early Detection teams with information about prodromal, first-episode schizophrenia symptoms. This program shortened the DUP by an average of 1.5 years. In the upcoming Specialized Treatment Early in Psychosis project, the researchers seek to adapt the TIPS model for Americans, and hope to improve presentation, engagement, and early outcomes through the reduction of DUP. STEP-ED will employ a public education campaign by utilizing social marketing techniques, including interactive websites, posters on buses, advertisements on social media sites, television, and radio, professional outreach at primary care sites, religious, and educational settings, to promote help-seeking behavior. Srihari, McGlashan, and colleagues will compare the effects of the STEP-ED program to a usual detection program.

Another way to prevent the onset of psychosis, other than reducing the DUP, is to focus directly on the programs designed to detect symptoms early and intervene to prevent psychosis. McFarlane and colleagues created and implemented the Family-aided Assertive Community Treatment (FACT) program and conducted a 2-year follow-up study. Adolescents were assigned to one of three groups, clinically low-risk (CLR), clinically high-risk (CHR), or very early first-episode psychosis (EFEP), based on their score on the Positive Symptom Scale of the Prodromal Symptom Scale. Individuals designated to the CHR and EFEP groups received FACT, which incorporates a variety of interventions, including psychoeducational multifamily group (PMFG) therapy, elements of assertive community treatment, supported education and employment, and psychotropic medication. Those in the CLR group received community care, which consisted of monthly monitoring through phone assessments. Results demonstrated that 2 years after treatment, FACT was effective in reducing symptoms, whether positive, negative, disorganized, or general symptoms. Participants in the FACT condition, who were at risk or experiencing very early psychosis, also had improved Global Assessment of Functioning scores, work and school participation, and overall global outcomes. The findings suggest that preventive interventions can be effective in preventing the onset or progression of psychosis, and that family interventions are extremely important in the treatment and prevention of psychotic symptoms. Given consistent evidence that demonstrates that subsequent episodes of psychosis are associated with a less optimistic prognosis and probable neurodegenerative cerebral changes, the development of preventive interventions for schizophrenia and bipolar disorder is a high public health priority. The identification of children who are at risk as a

result of carrying susceptibility genes for these disorders is a research strategy that has not yet been systematically implemented.

Prevention of Substance Abuse Disorders. Many researchers have developed preventive intervention programs for substance abuse in children and in adolescents. Botvin and Eng developed a universal prevention program, Life Skills Training (LST), which has been shown to be quite successful in reducing substance abuse in middle and high school students. During 30 lessons over the course of 3 years, students participating in LST were taught skills, information, and attitudes to resist temptations to use substances in adolescence. In dozens of efficacy trials, LST has reduced cigarette smoking, alcohol consumption, methamphetamine usage, and marijuana use as much as 80 percent compared to control groups. Similar results have been found with minority group students. Some LST trials have discovered that elementary school programs have positive long-term effects. The LST intervention's effects have been maintained up to 12 years after the completion of the program. Booster program designed for the LST program have demonstrated maintenance of and even bolstered the original intervention's effects.

Likewise, Kumpfer, and colleagues developed the Strengthening Families Program: for Parents of Youth 10 to 14 (SFP). This 14-week, family-focused substance abuse prevention program has demonstrated significantly greater reduction rates of substance use in high school students, compared to school-based alcohol prevention programs. SFP also has generated many significant positive effects in family functioning and parent-child relationships. SFP has been successfully adapted for many cultural groups, such as Hispanic, African American, Native American, and Asian Pacific Islander families, and has been widely adapted internationally.

Now that children and adolescents have greater access to mobile devices and computers, Internet-based prevention programs have become increasingly popular. In a meta-analysis by Champion and colleagues, seven school-based substance abuse prevention programs delivered through either the Internet or CD-ROMs, including Consider This, ASPIRE, CLIMATE, Head On, and several other programs, were assessed for their effectiveness in preventing alcohol, tobacco, and cannabis use in adolescents. Five of the seven programs were found to reduce drug and alcohol consumption in the follow-ups, which were completed between 6 and 34 months after the cessation of the program. Although the reviewers discuss how the effect sizes were modest, the reduction of substance use after the implementation of Internet and computer prevention programs provides evidence for how these new methods for disseminating interventions have the potential to be very effective and can be used by individuals in a variety of urban and rural settings.

Issues in the Prevention of Mental Illness

Barriers to Providing Clinical Preventive Interventions. Despite the very strong scientific evidence about the benefits of preventive interventions, there are relatively few psychiatrists who are involved in the administration of evidence-based preventive interventions. There appear to be three major barriers to the adoption of these interventions. First, there is no clinical infrastructure for delivering preventive and early intervention services. Provision of services to large numbers of children requires the coordination of multiple agencies, disciplines, and service delivery systems. Without a well-developed and accessible clinical infrastructure, most families are unable to receive preventive services even where treatment services exist. A second barrier to the provision of early clinical intervention is that there are insufficient resources to pay for these services. The lack of reimbursement through either public payment plans such as Medicaid or by private insurers prevents most psychiatrists and other mental health clinicians from providing preventive services. A third barrier to initiating early interventions is the absence of an academic curriculum designed to train general and child psychiatrists in the assessment of children who demonstrate very early symptoms of psychiatric disorders. Information and training in available evidence-based, early-intervention, manual-based protocols are not routinely provided to psychiatry residents.

There is a significant and growing public health awareness of the disparity between the recognition of the need for both prevention and early intervention services and the absence of a plan for developing an efficient and effective systematic delivery of such services. An immediate goal should be the development of new clinical initiatives that would begin to provide appropriate services to the highest-risk populations. The Affordable Care Act has a strong emphasis on prevention, and it may well be possible to increase reimbursement for psychiatric services, using mechanisms such as medical homes, collaborative care models, and braided funding.

Economic Issues. Ideally, psychiatric administrators should take responsibility for the management and funding of preventive interventions. However, to achieve this goal, new mechanisms to reimburse the provision of preventive services within the mental health field must be created. One issue will be a revision of diagnostic and billing codes to define specific evidence-based prevention services and to ensure payment for the delivery of these services. The standard medical reference for procedures that will be paid for by insurance companies is the Current Procedural Terminology (CPT) codes of the American Medical Association. CPT codes have been designed to define virtually all clinical procedures that have been accepted as legitimate services. Unfortunately, payment for many of the current CPT

codes that could be used to support services designed to prevent psychiatric illness have not been classified as traditional psychiatric interventions that are covered by medical insurance. Furthermore, even if insurance policies were to change and begin to make payments for preventive interventions that were authorized, many of the available CPT codes that are related to prevention-related services have been assigned very low relative value units (RVUs). When a CPT code is given a low RVU assignment, payment for the service will be quite low. Although a common compendium of CPT codes are established for all medical subspecialties, virtually no mental health specialists are able to use available codes for risk reduction and anticipatory guidance because of the difficulties that exist in receiving adequate payment. This needs to change and appropriate provision for payment needs to be made.

Another administrative problem is that payment for psychiatric services has traditionally required that a psychiatric diagnosis be identified for the patient prior to the clinician receiving payment. By definition, children who are receiving preventive services do not have a psychiatric diagnosis that would be included in the 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) at the time of the provision of a preventive intervention. Instead, these children may have problems that could be classified using a "V code." Unfortunately, many insurance companies make the argument that the services provided to deal with problems that are categorized using V codes are not medically necessary. Therefore, these services are not eligible for medical insurance, and these payers deny payment to any psychiatric patients that have not been assigned a traditional Axis I diagnosis.

Training Issues. The next generation of psychiatric clinicians must be better trained in the science of the prevention of mental disorders. Much needs to be done to achieve this goal. For evidence-based prevention programs to be implemented on a national scale, it is absolutely necessary that clinicians be appropriately trained to provide these specified interventions. Supervised training experiences to provide trainees with appropriate skills will have to be incorporated into the traditional residency curriculum as one of the "core competencies" that must be developed during residency training. The ability to identify children at risk and deliver evidence-based preventive interventions must become an academic expectation of training. However, for this goal to be achieved, the importance of preventive interventions will need to become more explicitly stated in the residency training requirements that are available to provide guidance to the design of clinical training programs. Ultimately, board certification and recertification must require the demonstration of clinically relevant applications of preventive interventions as part of the core knowledge base that is examined.

Research Issues. Continuing a strong research program in prevention is essential. As noted, it provides one of the best ways of understanding the mechanisms by which either disorders are expressed or the balance of risk and protective factors is altered and disorders are prevented. Research investigators should be encouraged to assess multiple risk factors and multiple outcomes crossing the domains of mental health, substance abuse, physical health, and learning disorders. Priority should be given to sequential preventive interventions that can strategically target high-risk children prenatally, in infancy, in early childhood, in elementary school, during the teenage years, and finally in young adulthood. In addition, research efforts must consider and track high-risk youth and the different interventions they need at different stages (e.g., high-quality child care, daycare, and early education followed by access to high-quality schools). Finally, preventive intervention studies must aim to access the mechanisms by which such interventions work. Greater attention to genetics, epigenesis, and gene environment interactions is clearly warranted as this work goes forward.

The following case example illustrates how newer pharmacogenomic approaches offer great promise. George was 16 years old when he started experiencing depressive symptoms after his girlfriend decided to end their relationship. George had a family history of bipolar disorder and, by using pharmacogenomic testing, a clinician familiar with preventive approaches to mental illness was able to treat him safely.

When George presented to the clinician, he reported sleeping for more than 10 hours a night, rarely leaving his home, and having little interaction with his friends. His maternal uncle had struggled with bipolar disorder for many years. Although his parents had no history of mania or hypomania, both his mother and his father had been successfully treated with selective serotonin reuptake inhibitors for episodes of major depressive disorder.

A series of eight outpatient cognitive-behavior therapy sessions targeting his depressive symptoms proved to be minimally effective. Subsequently, George was placed on a dose of 20 mg of fluoxetine per day while being followed closely for the possible emergence of suicidal ideation. Within 2 weeks, he reported that he needed to sleep for only 1 or 2 hours each night and was experiencing marked surges of energy.

His psychiatrist became concerned that George was becoming hypomanic and was at risk for developing bipolar disorder. Prior to selecting another medication to manage these new symptoms, he ordered pharmacogenomic testing of a panel of genes with the goal of minimizing additional adverse reactions. George was determined to have a normal genotype of his cytochrome P450 2C19 gene, indicating that he could effectively metabolize 2C19 substrate medications. However, his cytochrome P450 2D6 and 2C9 genotypes documented that he was a poor metabolizer of both 2D6 and 2C9 substrate medications. In addition, his serotonin transporter genotype was associated with an increased risk for the onset of depression, and his GRIK3 genotype indicated that he was at an increased risk for the development of bipolar disorder.

George was started on a low dose of lithium, and the fluoxetine that he had been receiving was discontinued. After 2 months of outpatient treatment on lithium, he complained of having less energy and had become very discouraged about his ability to complete his planned applications to attend college. Given the results of his pharmacogenomic genotype testing, he was placed on a dose of 10 mg of escitalopram per day in addition to the lithium. After 4 weeks, he reported feeling much better and had not experienced a recurrence of hypomanic symptoms. He was subsequently able to complete his college applications without further difficulty.

George was maintained on lithium and escitalopram throughout his first year at college.

During the summer before the beginning of his second year away at school, both medications were discontinued and he remained euthymic.

Although fluoxetine is an effective and economical treatment for major depressive disorder in adolescents, fluoxetine is primarily a 2D6 substrate medication. Of note, the cytochrome P450 2C9 enzyme plays a secondary role in the metabolism of fluoxetine. Patients with both of these pathways compromised are at very high risk of developing side effects while taking standard doses of fluoxetine.

The clinical observation that manic activation may occur in depressed adolescents when treated with selective serotonin reuptake inhibitors has been frequently reported. However, clinicians have concluded that the benefits of treating many depressed adolescent patients with antidepressant medications have outweighed the risks of activating bipolar symptoms in the relatively few adolescent patients who develop manic symptoms when treated with these medications. Fortunately, it is now possible to identify genetic risk factors for activation and offer alternative medications. Managing the treatment of depression in a manner that minimizes activation can be conceptualized as an example of an indicated preventive intervention designed to prevent the onset of a first full episode of bipolar disorder. More generally, this case illustrates a way of thinking that is likely to be more useful in both treatment and prevention going forward.

Looking Forward to the Future. There is a debate in the prevention field regarding the cost–benefit ratio for universal interventions. Some universal prevention studies have been shown to provide the most benefits to the children who are at highest risk. In contrast, many children who are at minimal risk do not benefit at all. This pattern of response supports the view that early screening and interventions targeted to help populations with specific high risks, including early prodromal symptoms, could be considered for some disorders. Integrating the new, rapidly evolving personalized medicine approaches will become increasingly important in the future as well understanding how to effectively disseminate widely those prevention approaches that are strongly supported empirically.

Inasmuch as there are potent risk factors for multiple disorders (poverty or exposure to violence), more attention also needs to be devoted to addressing these public health drivers. The IOM recognized this in emphasizing the role of poverty: “One factor lurks in the background of every discussion of the risks for mental, emotional, and behavioral disorders, and antisocial behavior: poverty [. . .] Although not the focus of this report, there is evidence that changes in social policy that reduce exposure to these risks are at least as important for preventing mental, emotional, and behavioral disorders in young people as other preventive

interventions. We are persuaded that the future mental health of the nation depends crucially on how, collectively, the costly legacy of poverty is dealt with."

It is now possible to implement evidence-based selective and indicated preventive interventions to minimize risk factors associated with the onset of mental disorders. Broader implementation of these interventions for children and adolescents at risk for depression, conduct disorder, and psychosis will require continued political commitment. Given that these evidence-based interventions are predicted to have an ultimate cost savings effect on public health expenditures, there is real reason to be optimistic about their expansion and to recognize the need to ensure that such approaches are widely implemented.

ACKNOWLEDGMENT

This chapter is dedicated to the extraordinary work and life of Dr. David Mrazek who passed on May 6, 2013.

▲ 55.10 Child Mental Health Services Research

BONNIE T. ZIMA, M.D., AND REGINA BUSSING, M.D.

Child mental health services research integrates advances in child psychiatric assessment and treatment in examining unmet need for services, service use across care sectors (e.g., specialty mental health, primary care, schools, child welfare, juvenile justice, informal care), and the quality of care along its continuum (e.g., prevention, early detection, assessment, treatment, follow-up). It is a specialty area within the larger context of health services research in which the overarching goal is to improve the alignment between clinical need, delivery of recommended care, and health policies to sustain quality care.

Conceptually, it can be viewed as the second arm of translational research that translates scientific advances from "bedside to community." Westfall and colleagues expanded this model by inserting a third translational step, "practice-based research," which translates research findings to patients (e.g., treatment guideline development) and real world practice settings (e.g., dissemination and implementation research). This area of research is in contrast to the first translational arm which translates scientific advances in basic science to clinical research, shifting the generation of knowledge from "laboratory to bedside." To meet this challenge, health services research uses a compendium of quantitative and qualitative research methodologies that brings together expertise from multiple medical specialties and disciplines (i.e., social sciences, biostatistics, economics, health policy, administration), community partners, and consumers. For child mental health services research, the breadth of expertise also includes the perspectives of primary caregivers, teachers, social workers, case managers, probation officers, and child advocates.

Early stages of child mental health services research typically describe access to care and its predictors, extent of unmet need for services among children identified as clinically meriting treatment, and the delivery of care (e.g., service use, filled medication prescriptions) in usual care settings. Findings at this stage are typically a wake-up call alerting others of the potential magnitude of a problem in child mental health care, such as rising prescription rates of atypical antipsychotic medication among very young children. Some studies may also explore how mutable factors at several levels (i.e., system, community, family, child) independently predict who

receives care while adjusting for clinical need, to identify target areas for reducing disparities in access to or quality of care. Examples of questions driving such research are: Among children with a psychiatric disorder and impairment, who is more likely to access care? What are the potential mechanisms underlying disparities in child mental health care? How can technology (e.g., telepsychiatry) improve access and continuity of care?

With the development of treatment guidelines and quality measures, the scope of child mental health services research has expanded to describe the gap between recommended and usual care, and the predictors of greater adherence to recommended care processes. Improving the quality of child mental health care is of public health significance because child psychiatric disorders are prevalent, disabling, and costly. Use of treatments with established efficacy in community settings is typically low, and underuse of recommended treatment for mental health problems during childhood may negatively impact a child's developmental trajectory. Examples of questions common to quality of care research are: What proportion of children receives guideline-concordant care? What organizational, provider, family, or child factors are predictive of acceptable care? How should evidence-based practices (EBPs) be modified for use in community-based settings while preserving their effectiveness? Does provision of nationally recommended care processes relate to improved outcomes for children and their families? And if so, for whom and at what cost? How should care for child mental health problems be integrated into primary care settings in such a way that provision of care is seamless across care sectors and tailored to the changing needs of the child and family? What is the role of emerging technologies and how can they be applied to improve the quality of care? How does the extent of community partnership in developing new models of care improve engagement, uptake, and sustainability? Such information is necessary to inform the development and dissemination of quality improvement interventions delivered to children with mental health problems and their families.

As an introduction to child mental health services research, this section briefly describes the historical context and summarizes findings from select landmark studies and health policies. Access to care is described as a separate component of quality, following Avedis Donabedian's conceptualization of quality that argues that accessibility is a separate yet influential component of quality. This is followed by an overview of a well-established model of quality of care, examples of quality of care research and national quality measures. Because the study of the quality of care for children with psychiatric disorders and their families spans the care continuum, the reader is encouraged to read cross-referenced sections and chapters to stimulate further inquiry about how to close the gap between recommended and actual care.

HISTORICAL CONTEXT

As outlined in Table 55.10–1 advances in clinical, epidemiology and health services research as well as health policy initiatives shape the historical context from which child mental health services research has emerged. The first half of the twentieth century was characterized by increasing federal initiatives that raised public awareness of the need to improve the quality of life for children, such as a child's right to preventive health care, safe working conditions, and a free public education, particularly for those identified as seriously emotionally disturbed or handicapped. After the mid-century mark, child psychiatry was identified as a relatively new medical subspecialty, with its first national professional organization established in 1953 and board certification in 1959. During the next three decades, landmark epidemiological studies provided some of the first prevalence estimates of child mental health problems in community-based populations and their correlates. These studies were significant because the findings raised awareness of the substantial proportion of children who met criteria for a psychiatric disorder and the need to improve early detection and access to child mental health services.

During the 1980s the pediatric community identified psychosocial conditions, such as poverty, family dysfunction, and child exposure to traumatic events, as part of the new morbidity of child health that included learning and behavioral disorders. The conceptualization of child health was further broadened the following decade to include attention-deficit/hyperactivity disorder (ADHD) within the definition of chronic conditions among children with special health care needs. Within this same time period, a philosophy for a system of care for children was operationalized. The two core values were that care should be child centered and community based. These values were later echoed a decade later in the guiding principles underlying the pediatric medical home. Remarkably, these principles share similar dimensions of "quality" as identified in the "articles of faith" underlying good medical care by R. I. Lee and L. W. Jones more than 50 years earlier. Nevertheless, sustained articulation of these values and principles is important because it provides a relatively consistent framework from which programs serving children with mental health problems can plan and implement new models of care for children with mental health problems. Table 55.10–2 summarizes the guiding principles of these two conceptual models.

During the 1990s, federal initiatives increasingly focused on improving child mental health care and promoting basic science, clinical, and health services research for childhood psychiatric disorders. In preparation for a national epidemiological study to estimate the prevalence of childhood mental disorders and service use, the Methods for the Epidemiology of Child and Adolescent Mental Disorders (MECA) Study was conducted. The MECA Study was a multisite, community-based study that further refined

standardized assessment methods of psychiatric diagnosis, impairment, mental health service use, and risk factors and also provided prevalence estimates of childhood psychiatric disorders and mental health service use among four diverse geographic areas. Despite these advances and others, to date, only one study, the National Health and Nutrition Examination Study, used standardized diagnostic interviews among a nationally representative sample of children ages 8 to 15 years to estimate the prevalence of ADHD among US children.

Table 55.10–1.
Brief Historical Context from Which Child Mental Health Services Research Is Developing

	Event(s)	Significance
1909	White House Conference on Dependent Children	Raised public awareness of poor living conditions and high cost of homes for emotionally disturbed children. National recommendations for improved child programs stimulated the development of child welfare and foster care system.
1912	Federal Children's Bureau created	Establishment of the oldest federal agency for children. Located in the U.S. Department of Health and Human Services' Administration for Children and Families, the agency is responsible for assisting states in the delivery of child welfare services; providing grants to states, Native American tribes, and communities to operate a range of child welfare services (e.g., child protective services, family preservation and support, foster care, adoption, and independent living); and making major investments in staff training, technology, and innovative programs for children.
1919	The Child Welfare League of America chartered	Establishment of the oldest and largest national nonprofit organization dedicated to developing and promoting policies and programs to protect US children and strengthen US families.
1920	The Dawson Report published in England	Considered to be one of the founding documents in the history of epidemiology by introducing the concept of primary care. Lord Dawson believed health care in a given district should be based on "primary health centres," which he termed "institutions equipped for services of curative and preventive medicine to be conducted by the general practitioners of that district." Difficult cases requiring special treatment would be referred to "secondary health centers." In addition, "secondary services" would be equipped for the care of infectious diseases and chronic ailments such as epilepsy or mental illness. "Teaching hospitals," with medical schools, would treat the most difficult illnesses and provide physician training.
1922	Pediatric Section of AMA approves the Sheppard-Towner Act while the AMA House of Delegates condemns it.	The Sheppard-Towner Act supported federal funding to states for health services for mothers and children. The AMA opposed it, calling it "an imported socialist scheme." Following this disagreement, AMA leadership promptly ruled that no section could independently adopt a resolution. This ruling was described as, "sterilizing the Pediatric Section [that] made the

		American Academy of Pediatrics inevitable."
1930	White House Conference on Child Health and Protection	Children's Charter established, outlining a set of 19 principles in the areas of education, child labor, vocational training, recreation, family welfare, health, growth and development, disabled children, and related areas, including the Bill of Rights for the Handicapped Child.
1930	American Academy of Pediatrics established	On June 23–24, 1930 at Detroit's Harper Hospital, 35 pediatricians drew up the constitution and by-laws for AAP. The purposes of the AAP were: 1. To create reciprocal and friendly relations with all professional and lay organizations that are interested in the health and protection of children. 2. To foster and encourage pediatric investigation, both clinically and in the laboratory, by individuals and groups.
1933	Roger I. Lee, Lewis Webster Jones, and Barbara Jones, *The Fundamentals of Good Medical Care,* a publication of the Committee on the Costs of Medical Care	Defined quality of care as follows: "Good medical care is the kind of medicine practiced and taught by the recognized leaders of the medical profession at a given time or period of social, cultural, and professional development in a community or population group." Identified eight articles of faith underlining the concept of good care: 1. Good medical care is limited to the practice of rational medicine based on the medical sciences. 2. Good medical care emphasizes prevention. 3. Good medical care requires intelligent cooperation between the lay public and the practitioners of scientific medicine. 4. Good medical care treats the individual as a whole. 5. Good medical care maintains a close and continuing personal relationship between physician and patient. 6. Good medical care is coordinated with social welfare work. 7. Good medical care coordinates all types of medical services. 8. Good medical care implies the application of all the necessary services of modern scientific medicine to the needs of all the people.
1935	L. Kanner, *Child Psychiatry*	First English-language textbook on child psychiatry.
1938	Fair Labor Standards Act signed into law by President Franklin Delano Roosevelt	Prohibited interstate shipment of goods made in firms that employ children younger than age 16 years or children younger than age 18 years in hazardous occupations.
1950	Mid-Century Conference on Children and Youth held	Prepared the Pledge to Children, which summarizes commitments by adults to children to promote education, strengthen family life, safeguard civil equality, improve workplace conditions, enhance democratic citizenship and institutions, and advocate for the development of the child's individual talents and potential.
1953	American Academy of Child and Adolescent Psychiatry established	The leading national professional medical association, currently composed of more than 6,500 child and adolescent psychiatrists and other interested physicians dedicated to treating and improving the quality of life for children, adolescents, and families affected by these disorders.
1958	Community-based	First wide-scale epidemiological study of problem behaviors

	epidemiological survey of mental health problems among those living in a northeastern US community	among a US community-based sample. Using systematic assessment methods for problem behaviors, investigators identified high rates of fear and worries among children aged 6–12 years in a general population sample, suggesting that symptoms are in part developmental. Established the feasibility of child self-report of emotional and behavioral symptoms. Used multiple-informant data and reported discrepancies in mother and child reports for some symptoms.
1959	Board certification in child and adolescent psychiatry offered for the first time by the American Board of Psychiatry and Neurology	National application of standards for clinical knowledge and skills in child and adolescent psychiatry.
1961	Kerr White and colleagues, "The Ecology of Medical Care," published in *New England Journal of Medicine*	Seminal article that promoted the development of health services research. The authors "observed that traditional indexes of public health—including mortality and morbidity—do not adequately describe the actions of individual patients and doctors." They argued that doctors should combine research of pathological processes with exploration of the use of medical care resources, their relative availability in different contexts, and the patient's decision-making processes. In their view, "the patient may be a more relevant primary unit of observation than the disease, the visit, or the admission." Findings from this study examining the relationship between US and UK populations and the experience of illness and different levels of medical treatment suggested that health care delivery and the training of physicians did not bear any logical relationship to the actual experience of illness in a given population. These data suggested that greater attention should be devoted to primary, continuing medical care as opposed to episodes of hospitalization or consultation of specialists. Furthermore, medical education and research should take greater account of the environment of health care and consider more systematically how health care resources should be deployed.
1964–1975	Isle of Wight studies	Extensive longitudinal cohort study over 5 years of intellectual and educational retardation, psychiatric disorder, and physical handicap of the entire population (estimated *N* = 3,500) of children aged 9–11 years. Screening for neuroepileptic disorders among entire population of 5- to 15-year-olds. Survey of 10-year-old children to directly compare to children of the same age range living in an inner borough of London. Additional studies examining the mental health profile of young children age 5–7 years. Innovative research designs that included the following: 1. Multiple-informant data (child, parent, teacher, school records, psychiatric records, and pediatric records).

		2. Two-stage screening strategy. 3. Comprehensive battery of assessments. 4. Identification of psychiatric diagnoses using social impairment as a criterion for severity and symptom pattern as a criterion of type. 5. Longitudinal design to study age of onset, identification of risk factors, and description of course of illness over time. 6. Causal hypotheses of risk factors (e.g., organic brain dysfunction, family discord, reading difficulties). 7. Standardized neurodevelopmental assessments used to relate neurological findings to psychiatric disorders. 8. Examination of differences in participants and nonparticipants.
1966	Avedis Donabedian, "Evaluating the Quality of Medical Care," published in *Milbank Memorial Quarterly*	Proposed conceptual model for the evaluation of quality of care that remains widely used in health services research. Identified three main domains for examining quality: (1) structure, (2) process (technical, interpersonal), and (3) outcomes.
1968–1982	RAND Health Insurance Experiment	The most important health insurance study ever conducted. Addressed two key questions in health care financing: (1) How much more medical care will people use if it is provided free of charge and (2) what are the consequences for their health? Using a large-scale experimental design, different types of health insurance plans were offered to people in five sites across the country. The study examined the relationship between level of insurance coverage and service use rates and health outcomes. As the rate of cost sharing for health care rose, the consumption of health care fell. Of note, cost sharing had particularly adverse effects on the health of vulnerable groups, such as low-income children.
1969	Joint Commission on Mental Health for Children	Raised public awareness of high unmet need for child mental health services and overuse of mental health care delivered in restrictive treatment settings. Recommended establishment of a child advocacy system to coordinate federal, state, and local actions, development of community services focused on prevention and remediation, and delivery of child services in settings resembling normal living conditions. Identified need for research examining the effectiveness of child mental health services.
1974	Large epidemiological study of 2,034 youth age 6–18 years in New York	Included a sample of 1,000 youth in the welfare sector and 1,034 randomly selected youth. Prevalence estimates of psychiatric disorders were higher among children in the welfare sector than in the general population (21.0% vs. 17.5%). Documented high unmet need for services, such that <50% of children with serious impairment were referred for care.
1975	Education for All Handicapped Children Act passed (Public Law 94–142)	Federal law whose purpose is to ensure that all children with disabilities have access to a free appropriate public education that emphasizes special education and related services designed to meet their unique needs; to ensure that the rights of children with disabilities and their parents or guardians are protected; to assist states and localities to provide for the education of all

		children with disabilities; and to assess and ensure the effectiveness of efforts to educate children with disabilities.
1977	President's Commission on Mental Illness and Health	Identified need for studies of the incidence and prevalence of mental disorders in the United States. Recommended an increase in the provision of child mental health services and the capacity to provide a continuum of care to children.
1979	National Institute of Mental Health (NIMH) contracts to develop standardized assessment methods of children and adolescents in general population samples	Stimulated a wave of epidemiological studies examining the reliability and validity of checklists, rating scales, and diagnostic interviews in geographically diverse populations in the 1980–1990s. Promoted the development of assessment tools for use in community-based populations, such as the Child Behavior Checklist, Clinical Global Assessment Scale, Child and Adolescent Psychiatric Assessment, Diagnostic Interview for Children, and Diagnostic Interview Schedule for Children.
1980	Cross-national replication of epidemiological study of 100 3-year-old children	Raised awareness of early onset of mental health problems among preschool-age children in the United States. An estimated 11% of children age 3 years screened positive for a behavior problem.
1980	NIMH Epidemiologic Catchment Area Study	First large-scale, multisite epidemiological study of psychiatric disorders among 20,291 adults in US households and institutions. Stimulated further development of the Diagnostic Interview Schedule and provided prevalence estimates of treated and untreated psychiatric disorders in the community.
1981	Select Panel for the Promotion of Child Health	Acknowledges significant improvement in services to children with disabilities (including serious emotional disturbances) but identifies wide variation in the availability of child-related services. Developed national recommendations to improve the delivery of services to children, including greater access to care, expansion of services to include prevention and early detection and treatment of developmental problems, improved quality of care in residential treatment settings, enhanced community support for child programs, and greater involvement of families in the delivery of mental health services.
1982	Children's Defense Fund report, *Unclaimed Children*	Raised public awareness of high unmet need for child mental health services in the United States. Identified children with severe emotional and behavioral problems as "unclaimed" by the public agencies responsible for serving them.
1984	Child and Adolescent Service System Program (CASSP) established	NIMH-funded program to support states in the development of interagency efforts to improve the system of care for children with mental health problems. Provided technical assistance to community-based programs in the adaptation of systems-of-care values and principles to the delivery of services in children with severe emotional and behavioral problems.
1985	Institute of Medicine	Documented the high societal burden of mental disorders and

	report, *Research on Mental Illness and Addictive Disorders: Progress and Prospects*	substance abuse, progress in the assessment and treatment of mental illness, and need for additional federal funding for research.
1986	Beth A. Stroul and Robert M. Friedman, *A System of Care for Severely Emotionally Disturbed Children and Youth*	Pivotal document from the CASSP Technical Assistance Center, Georgetown University Child Development Center, in Washington, DC, that articulated the core values and guiding principles for the system-of-care philosophy for children.
1986–1992	Medical Outcomes Study	A large, 2-year longitudinal study of variations in practice style and outcomes of care for patients with specific "tracer conditions," including adult major depression, in three US metropolitan areas. Poor functioning among patients with depressive disorder or depressive symptoms was comparable to or worse than that associated with major medical conditions (hypertension, diabetes, advanced coronary heart disease, angina, arthritis, back problems, gastrointestinal disorders). Detection and treatment of depression were significantly lower among depressed patients who visited a medical clinician (45.9% and 51.2%, respectively) compared with those who visited a mental health specialist (78.2% and 86.9%, respectively).
1989	Effectiveness of "typical" psychotherapy in community-based clinics examined	Compared 6-month and 1-year symptom levels among a nine-clinic sample of children completing a course of therapy (*N* = 93) and those who dropped out after intake (*N* = 60). No significant main effects of therapy were found. Raised awareness of the need to reconsider the generalizability of outcomes studies of controlled laboratory interventions when assessing the effectiveness of therapy under usual care conditions.
1989	Agency for Health Care Policy and Research established (later renamed Agency for Healthcare Research and Quality)	The health services research arm of the US Department of Health and Human Services (HHS). Supports research in the following areas: 1. Quality improvement and patient safety. 2. Outcomes and effectiveness of care. 3. Clinical practice and technology assessment. 4. Health care organization and delivery systems. 5. Primary care. 6. Health care costs and sources of payment. Major source of funding and technical assistance for health services research and research training at leading US institutions. A science partner, working with the public and private sectors to build the knowledge base for what works—and does not work—in health and health care and to translate this knowledge into everyday practice and policy making.
1989	System of Care for Severely Emotionally Disturbed Children and Youth	Introduced a philosophy underlying a system of care for children with severe emotional and behavioral problems. Identified core values for system of care for children: Care should be child centered and community based.

		Outlined 10 guiding principles for system of care.
1989–1995	Fort Bragg Demonstration Project	Large-scale effectiveness study of providing a continuum of services to children and their families with four components: 1. Implementation study 2. Quality study 3. Mental health outcome study 4. Cost/use study A longitudinal cohort study comparing outcomes and costs of providing a model continuum of care (Rumbaugh Clinic in Fort Bragg catchment area) vs. traditional mental health services (Fort Campbell and Fort Stewart catchment areas). Compared with traditional mental health services, provision of a continuum of care was related to the following: 1. Improved access to care. 2. Higher adolescent and parent satisfaction with services. 3. Greater costs. 4. Reduced rates of hospitalization or residential treatment. Continuum of care did *not* produce better clinical outcomes than traditional mental health services.
1989	Institute of Medicine report on Research on Children and Adolescents with Mental, Behavioral, and Developmental Disorders	Comprehensive review by national experts of the dimensions, causes and determinants, and interventions for childhood psychiatric disorders, as well as child mental health research infrastructure. Raised public awareness of an estimated 12% of US children having a diagnosable mental illness, advances in the assessment and treatment of childhood disorders, promising research directions, and resource needs for research.
1989	Agency for Health Care Policy and Research created.	Supported by the Omnibus Budget Reconciliation Act of 1989. Mission included "to support research designed to improve the quality, safety, efficiency and effectiveness of health care for all Americans." Activities included large multidisciplinary, multiinstitutional projects that focused on patient results in certain medical conditions, development of practice guidelines, and participating in the development of a health care reform plan.
1990	National Plan for Research on Child and Adolescent Mental Disorders	Comprehensive 5-year plan of how NIMH intended to stimulate new basic and clinical research, promote research training, and provide leadership and coordination to stimulate advocacy and research dissemination in child mental health.
1990	The 1990s declared by the US Congress the "Decade of the Brain"	Provided national public endorsement for federal, state, and community initiatives to support a wide range of mental health research, as well as initiatives to improve the quality of care for the mentally ill.
1990	The National Committee for Quality Assurance is created.	A large, nonprofit organization dedicated to improving health care quality through measurement, transparency and accountability. Products include the Healthcare Effectiveness Data and Information Set (HEDIS), a set of quality measures used to report on quality of care at the health plan level.
1991–1996	Methods for the Epidemiology of Child and Adolescent Mental Disorders	Pilot studies followed by multisite study of 1,285 child–caregiver pairs among four geographic areas using household interviews (Hamden, East Haven, West Haven, Connecticut; DeKalb, Rockdale, Henri Counties, Georgia; Westchester County, New

	(MECA) Study	York; San Juan, Puerto Rico). Stimulated the development of standardized assessment methods of psychiatric diagnosis, impairment, mental health service use, risk factors, and administrative infrastructure for large-scale epidemiological study. Produced prevalence estimates of psychiatric disorders with and without impairment criteria and mental health service use.
1992	Passage of the Comprehensive Community Mental Health Services Program for Children and Adolescents with Severe Emotional Disturbances	Authorized federal funding of more than $100 million/year for implementation of systems of care in 38 different communities. Supported the development of community-based continuum-of-care programs for children, including assessment, case management, outpatient treatment, day treatment, in-home services, respite care, therapeutic foster care, and group homes for children with severe emotional disturbances.
1992	American Academy of Pediatrics, Ad Hoc Task Force on Definition of the Medical Home	The guiding principles for the medical care of infants, children and adolescents should be accessible, continuous, comprehensive, family centered, coordinated, and compassionate. Comprehensive care encompass the following services: 1. Provision of preventive care. 2. Ambulatory and inpatient care for acute illness 24 hours a day, 7 days a week. 3. Provision of care over an extended period of time to enhance continuity. 4. Identification of the need for subspecialty consultation and referral and knowing from whom and where these can be obtained. 5. Interaction with school and community agencies to be certain that special health needs of the individual child are addressed. 6. Maintenance of a central record and data base containing all pertinent medical information about hospitalizations. This record should be accessible, but confidentiality must be assured.
1997–1999	Development of practice parameters by the American Academy of Child and Adolescent Psychiatry	Twenty practice parameters were developed for the assessment and treatment of specific psychiatric disorders, as well as child mental health problems (e.g., suicide, sexual abuse).
1998	National Advisory Mental Health Council's Clinical Treatment and Services Research Workgroup, *Bridging Science and Service*	Work group of researchers, policy makers, and mental health advocates charged by NIMH to advise the council on strategies for increasing the relevance, speeding the development, and facilitating the use of research-based treatment and service interventions for mental illnesses into both routine clinical practice and policies guiding local and national mental health service systems. Developed an action plan to meet the following goals: 1. Increase the usefulness of NIMH research for individuals with mental illnesses, clinicians, purchasers, and policy makers through informed priority setting. 2. Selectively expand the NIMH portfolio in the domains of

		efficacy, effectiveness, practice, and service systems research to foster integration across these fields and to expedite the implementation of research-based practices and policies. 3. Identify research innovations in design, methods, and measurement to facilitate the translation of new information from bench to trial to practice. 4. Strengthen NIMH's leadership and administrative activities to provide the infrastructure to achieve the aforementioned goals stated in a timely manner.
1998	National Institutes of Health Consensus Development Conference on Diagnosis and Treatment of Attention Deficit Hyperactivity Disorder	Review the scientific evidence, public open discussion, and closed-panel deliberations by a 13-member multidisciplinary national expert panel. Findings from this conference support the following: 1. The validity of the diagnosis of attention-deficit/hyperactivity disorder (ADHD). 2. The substantial effect of ADHD on children, their families, and society. 3. Effectiveness of psychosocial and medication treatments. 4. Need for additional research on the long-term effects of stimulant medication treatment. 5. Need to improve early detection, access to care, and quality of evaluation and treatment. 6. Need for further basic science and clinical and intervention research.
1999	White House Conference on Mental Health	First major public introduction to mental illness in the United States and scientific advances in the assessment and treatment of psychiatric disorders. Called for a national anti-stigma campaign for persons with mental illness.
1999	Surgeon General's Call to Action to Prevent Suicide	Developed a national plan to increase awareness and prevent suicide in the United States.
1999	Surgeon General's Report on Mental Health	First Surgeon General's report dedicated to mental health and mental illness. Communicated three main messages: (1) Mental health is fundamental to health; (2) mental disorders are real health conditions; and (3) the efficacy of mental health treatments is well documented, and a range of treatments exists for most mental disorders. Included a chapter on children and mental health.
1999	Multimodal Treatment Study of Children with ADHD (MTA study)	First large-scale, multisite, randomized clinical trial of treatment of a childhood mental disorder. Compared the effectiveness of intensive behavioral treatment, tightly managed medication treatment, combined behavioral and medication treatment, and standard community care for ADHD. A randomly selected sample of 579 children age 7.0–9.9 years recruited from six university-based clinic referral sources, including mental health settings, pediatricians, advertisements, and school notices. Oversampled children from families that are more likely to fully participate in assessment and treatments and less likely to require additional treatments that were incompatible with standardized ADHD treatment protocols.

		Children were randomly assigned to one of four treatment arms. The following were found when using core ADHD symptom reduction as the outcome: 1. Medication management was superior to behavioral treatment and routine community care. 2. Combined treatment did not yield significantly more benefit than medication management alone.
1999	The Agency for Health Care Policy and Research is renamed the Agency for Healthcare Research and Quality	The agency was reauthorized under the Healthcare Research and Quality Act of 1999. Its mission is to produce evidence to make health care safer, higher quality, more accessible, equitable, and affordable. Development of practice guidelines was removed from the new mission and it was made explicit that the agency is not a regulatory body.
1999	National Quality Forum created.	This nonprofit, membership-based organization was created in response to recommendations from the President's Advisory Commission on Consumer Protection and Quality in the Health Care Industry. The main activities are: (1) convene working groups to foster quality improvement in both public and private sectors; (2) endorse consensus standards for performance measurement; (3) ensure that consistent, high-quality performance information is publicly available; and (4) seek real time feedback to ensure measures are meaningful and accurate.
2000	White House Meeting on Child Mental Health	Major public meeting specifically addressing the need to improve the diagnosis and treatment of children with emotional and behavioral disorders.
2000	US Surgeon General's Conference on Children's Mental Health, Developing a National Action Agenda	Developed recommendations for a National Action Agenda on Children's Mental Health based on feedback from a broad cross section of more than 300 child mental health stakeholders
2000	National Institute of Mental Health and the Food and Drug Administration (FDA) Workshop on Psychopharmacology for Young Children, Clinical Needs and Research Opportunities	A nationally sponsored meeting of researchers, practitioners, ethicists, industry staff, and family and patient representatives, whose mission was to examine the current state of knowledge regarding psychopharmacology for young children and discuss a variety of topics relevant to research in this age group, including safety, efficacy, investigational methods, and ethical aspects. The meeting was in response to the increasing use of psychotropic medication among preschool-age children, for which the efficacy and safety of psychotropic medication have not been systematically evaluated. Recommendations included additional research in developmental psychopathology to clarify diagnosis and provide sensitive and specific methods for clinical trials.
2000	National Research Council and Institute of Medicine, *From Neurons to Neighborhoods: The Science of Early Childhood Development*	A 17-member committee of national experts convened to update scientific knowledge about the nature of early child development; disentangle knowledge from erroneous popular beliefs; and discuss the implications of this knowledge base for early childhood policy, practice, professional development, and research. With 11 national recommendations, this monograph advocated for improving the national capacity to meet high unmet need for mental health services among preschool

		children and conducting research examining the effectiveness of early intervention programs for children.
2000	Clinical practice guidelines for ADHD developed by the American Academy of Pediatrics	National recommendations for the evaluation and diagnosis of ADHD, as well as treatment of the school-age child with ADHD in the primary care sector.
2000	Agency for Health Care Policy and Research evidence report, *Treatment of Attention-Deficit/Hyperactivity Disorder*	As part of the Evidence-Based Practice Program, a multidisciplinary research team conducted a systematic review of the scientific evidence for the treatment of ADHD to develop a base from which clinical guidelines, performance measures, and other quality improvement tools could be developed.
2000–2002	Development of quality indicators for childhood psychiatric disorders by American Psychiatric Association Task Force on Quality Indicators for Children	Conceptualized the quality of care for children in five main domains: Prevention, access, quality/process/appropriateness, satisfaction/perceptions of care, and outcomes/effectiveness. Developed multiple recommendations for quality care and corresponding sample indicators.
2001	Surgeon General's Conference on Children's Mental Health, *A National Action Agenda*	Made the following recommendations: 1. Promote public awareness of children's mental health issues and reduce the stigma associated with mental illness. 2. Continue to develop, disseminate, and implement scientifically proven prevention and treatment services in the field of children's mental health. 3. Improve the assessment and recognition of mental health needs in children. 4. Eliminate racial/ethnic and socioeconomic disparities in access to mental health care services. 5. Improve the infrastructure for children's mental health services, including support for scientifically proven interventions across professions. 6. Increase access to and coordination of quality mental health care services. 7. Train front-line providers to recognize and manage mental health issues and educate mental health care providers about scientifically proven prevention and treatment services. 8. Monitor the access to and coordination of quality mental health care services.
2001	National Advisory Mental Health Council's Workgroup on Child and Adolescent Mental Health Intervention Development and Deployment, *Blueprint for Change: Research on Child*	A 21-member work group of national experts that reviewed major research findings on child and adolescent psychiatric disorders over the prior decade and identified three major research priority areas: 1. Basic science and the development of new interventions. 2. Intervention development, moving from efficacy to effectiveness. 3. Intervention deployment, moving from effectiveness to dissemination.

	and Adolescent Mental Health	
2001	Institute of Medicine's Committee on Quality of Health Care in America, *Crossing the Quality Chasm*	Proposed six aims for improving the quality of care for the 21st century: Health care should be the following: 1. Safe: Avoiding injuries to patients from the care that is intended to help them. 2. Effective: Providing services based on scientific knowledge to all who could benefit and refraining from providing service to those not likely to benefit (avoiding underuse and overuse, respectively). 3. Patient-centered: Providing care that is respectful of and responsive to individual patient preferences, needs, and values and ensuring that patient values guide all clinical decisions. 4. Timely: Reducing waits and sometimes harmful delays for both those who receive and those who give care. 5. Efficient: Avoiding waste, including waste of equipment, supplies, ideas, and energy. 6. Equitable: Providing care that does not vary in quality because of personal characteristics such as gender, ethnicity, geographic location, and socioeconomic status.
2002	President's New Freedom Commission on Mental Health	National commission whose mission was to conduct a comprehensive study of the US mental health service delivery system, including both the private and public sector providers and advise the president on methods of improving the system. The main goals were the following: 1. Review the current quality and effectiveness of public and private providers and federal, state, and local government involvement in the delivery of services to individuals with serious mental illnesses and children with serious emotional disturbances and identify unmet needs and barriers to services. 2. Identify innovative mental health treatments, services, and technologies that are demonstratively effective and can be widely replicated in different settings. 3. Formulate policy options that could be implemented by public and private providers and federal, state, and local governments to integrate the use of effective treatments and services, improve coordination among service providers, and improve community integration for adults with serious mental illnesses and children with serious emotional disturbances.
2002	Agency for Healthcare Research and Quality, *Systems to Rate the Strength of Scientific Evidence*	Identified 19 generic systems that fully address key quality domains for a particular type of study and 7 systems that address all three quality domains grading the strength of a body of evidence. These systems may be useful to the development of clinical practice guidelines or other health-related policy advice.
2002	International Consensus Statement on ADHD	A consensus statement developed by a consortium of international scientists that supports the validity of ADHD and its adverse effect on the lives of children and their families using scientific evidence. The statement was developed as a reference on the status of the scientific findings about ADHD to dispel periodic public perception that ADHD is not a real medical condition.
2003	President's New	Recommendations for Transformed Mental Health System:

	Freedom Commission on Mental Health: Transforming Mental Health Care in America	1. Americans understand that mental health is essential to overall health. 2. Mental health care is consumer and family driven. 3. Disparities in mental health services are eliminated. 4. Early mental health screening, assessment, and referral to services are common practice. 5. Excellent mental health care is delivered and research is accelerated. 6. Technology is used to access mental health care and information.
2004	New York/Montreal 2-year study of ADHD treatment with long-term methylphenidate and multimodal psychosocial treatment	Among two clinically based samples of stimulant-responsive children ages 7–10 years who meet diagnostic and impairment criteria for ADHD only (i.e., no comorbidity), combination treatment was not found to be superior over medication treatment alone. Outcomes were symptom reduction, impairment, classroom behavior, academic achievement, and social functioning.
2004	U.S. Food and Drug Administration (FDA) black box warning on pediatric antidepressants	The FDA-directed manufacturers of all antidepressant medication to add a boxed warning that reported (1) antidepressants increase the risk of suicidal thinking and behavior in children and adolescents with major depression and other psychiatric disorders, (2) anyone considering the use of an antidepressant in a child or adolescent for any clinical use must balance the risk of increased suicidality with the clinical need, (3) patients who are started on therapy should be observed closely for clinical worsening, suicidality, or unusual changes in behavior, and (4) disclose whether the particular drug is approved for a pediatric indication(s) and, if so, which one(s).
2005	Caring for California Initiative	First statewide study of the quality of care for children with ADHD, major depression, and conduct disorder in publicly funded outpatient specialty mental health programs.
2006	Institute of Medicine's (IOM) Committee on Quality of Health Care in America, *Improving the Quality of Health Care for Mental and Substance Use Conditions*	Recommended that the prior IOM health care system redesign strategy was applicable to mental and substance use health care but required some adaptation to address greater obstacles to patient-centered care, a weaker quality measurement and improvement infrastructure, more separated care-delivery arrangements, less use of information technology, a more educationally diverse workforce with a greater use of solo practice, and a differently structured marketplace.
2006	National Advisory Mental Health Council's Workgroup on Services and Clinical Epidemiology Research, *The Road Ahead: Research Partnerships to Transform Services*	Six issues driving recommendations shaping the future research agenda to transform mental health services are (1) partnerships in research, (2) quality of care, (3) fairness, (4) recovery, (5) communication, and (6) ongoing evaluation.
2007	Treatment for Adolescents with	Among 327 patients from 13 academic and community sites randomized to combination therapy, fluoxetine therapy, and

	Depression Study (TADS) 36-wk outcomes	cognitive behavior, combined treatment appears to be superior to monotherapy using symptom reduction and overall clinical improvement rating as outcomes.
2007	NIMH MTA study, 3-year follow-up	At 36 months—2 years after treatment protocols (medication only, combined, behavior only, usual community care)—the advantage of medication only or combined treatment was not sustained. Treatment groups did not vary in parent- and teacher-rated ADHD and oppositional defiant disorder symptoms, reading achievement scores, social skills, and functional impairment.
2007	National Stigma Study-Children	First large-scale, nationally representative survey of public knowledge, attitudes, and beliefs on children's mental health reported substantial rates of stigma (35–57%) and negative perceptions of medication treatment (52–85%).
2009	The Children's Health Insurance Program Reauthorization Act	Mandated the identification, refinement and development of child health care measures for voluntary use in Medicaid and Children's Health Insurance Programs. Called for submission of initial core set of 24 quality measures to Department of Health and Human Services by 2010. Funded the 5-year Pediatric Quality Measures Program.
2010	Patient Protection and Affordable Care Act	Landmark legislation for health care reform. Mandated development of a National Quality Strategy and earmarked support for the Patient-Centered Outcomes Research Institute.

In response to increasing adaptation of system of care principles to the delivery of community-based services for children and their families, a large-scale effectiveness study was conducted, namely, the Fort Bragg Demonstration Project. Provision of a continuum of care was found to provide more services and be more costly but did not produce better clinical outcomes. These thought-provoking findings encouraged the field to conceptually expand outcomes for children beyond clinical status (e.g., to system-, community-, family-, and parent-level outcomes) and to integrate the influence of varying service use (e.g., intensity, persistence, type) in the determination of effectiveness.

Table 55.10–2.
Core Values of Children's System of Care and Pediatric Medical Home

Children's System of Care	Pediatric Medical Home
Mental Health Care	Medical Care
Access to a comprehensive array of services	Accessible
Smooth transitions to the adult service system	Continuous
Early identification and intervention	Comprehensive
Full participation of families and surrogate families	Family-centered
Integrated and coordinated care across child-serving agencies	Coordinated
Inclusion of case management	
Individualized services	Compassionate
Least restrictive, most normative environment	
Protection of child rights and effective advocacy efforts	
Equitable and culturally sensitive service delivery	

Scientific advances in the assessment and treatment of ADHD also laid the foundation for conducting the first large-scale, randomized, clinical trial of two treatment modalities. The Multimodal Treatment Study of Children with ADHD, or MTA study, examined the effectiveness of highly standardized psychosocial, medication, and combined treatment protocols for ADHD. Based on the use of reduction of ADHD symptoms as the main outcome at 14 months, medication management was found to be superior to intensive psychosocial treatment and usual community care, and combined psychosocial treatment was found to be of no significantly greater benefit than medication management alone. Findings from the MTA study, however, should not be interpreted as conclusive that psychosocial interventions are inferior to medication treatment. Instead, alternative analyses from this rich data set have illuminated key methodological issues, such as selection of outcome measures, use of composite versus individual outcomes as indicators of effectiveness, and the effect of moderators (e.g., sociodemographic factors, clinical severity, parental education, and income) and mediators (e.g., treatment adherence) in the assessment of an intervention's effectiveness. Nevertheless, treatment effects were found not to be sustained. At 36 months, the treatment groups did not significantly differ on any outcome measure. In addition, based on saliva assays for methylphenidate as an objective indicator of medication adherence, only 53.5 percent of children were consistently adherent to stimulant medication treatment during initial 14-month treatment period. Further, the findings are not generalizable to community-based populations.

In the early 21st century, a report from the Institute of Medicine's (IOM) Committee on Quality of Health Care in America raised national awareness that the "American health care delivery system was in need of fundamental change." The wide difference between the care that should be received and the care that was actually being received was described as the quality chasm. A follow-up report found that the IOM's recommendations to transform the health care system were generally applicable to mental and substance use disorders but also identified distinctive characteristics of health care for mental and substance use conditions. Harold Pincus and colleagues noted that "the [Committee's] fundamental conclusion [is] that coordination and collaboration with the rest of medicine are essential (and vice versa), but it is also critical to ensure access to the depth and expertise provided by psychiatrist and other mental health and substance use specialists."

Within this same time period, national professional organizations developed practice parameters and treatment guidelines that enabled child mental health services researchers to develop quality indicators based on evidence of effectiveness and clinical consensus. Using documented

adherence to quality indicators in the medical record to estimate quality of care, in 1998 to 1999, the Caring for California Initiative (CCI) was the first statewide quality-of-care study for children with common psychiatric disorders in publicly funded outpatient mental health programs. The CCI found that on average less than one half (48.5 percent) of medical records passed all eligibility quality domains at the probable acceptable care level, a rate similar to general health care among US adult and child populations. Medication safety monitoring was particularly weak, such that roughly one fourth (28.5 percent) of the records of children receiving psychotropic medication treatment had documented monitoring of at least one clinically indicated vital sign or laboratory study. National concerns regarding the safety of psychotropic medication were also raised during this time period. In 2004, the U.S. Food and Drug Administration (FDA) issued a black box warning on all antidepressant medication to alert health care providers of an increased risk of suicidality in children and adolescents. Further, high national rates of stigma related to medication treatment raised awareness of the need for further examination of the mechanisms underlying engagement, uptake, and adherence to recommended care for children with psychiatric disorders and their families.

Although improving the quality of child mental health care has been a long-standing national priority, two federal health policies in the early 21st century legislatively mandated the development and use of quality measures for child health and mental health. In 2009, the Children's Health Insurance Program Reauthorization Act (CHIPRA) was signed. This law mandated the identification, refinement, and development of child health care measures for voluntary use in Medicaid and Children's Health Insurance Programs. It called for submission of initial core set of 24 quality measures to Department of Health and Human Services by 2010, and funded a 4-year Pediatric Quality Measures Program (2010 to 2014). Within this program, seven centers of excellence were funded to develop new measures and refine existing ones for "potential core enhancements" as well as 10 demonstration programs to develop, test, and evaluate and/or report on adherence to quality measures.

During the following year, the landmark Patient Protection and Affordable Care Act was signed in 2010. Within this complex legislation, the development of the National Quality Strategy was mandated. This strategy to transform health care had three aims: (1) better care; (2) healthy people and healthy communities; and (3) affordable care. The six priority areas were safety, person or family engaged as partners in care, effective communication and coordination of care, effective prevention and treatment, work with communities to promote wide use of best practices, and make quality of care affordable. This legislation also funded the Patient Centered Outcomes Research Institute (PCORI), to support research that informs better choices among alternative treatment strategies, supports a

patient-centered orientation and directs attention to individual and system differences that may influence strategies and outcomes. Within this funding source, research focusing on child health and mental health is included.

ACCESS TO CARE

Significant gaps continue to exist between clinical need and mental health service use for children with psychiatric disorders in the community. A number of conceptual models were developed to explain differential access to care. Of note, these models attempted to identify factors that can be changed through quality improvement interventions (referred to as *mutable factors*) to improve the likelihood of contact with services among children meriting assessment and treatment. A brief review of historically relevant access models is provided, because their frameworks continue to inform current quality improvement efforts.

Conceptual Models of Access to Care

Donabedian's early model of the medical care process acknowledges the complex interactions between client and provider behaviors, as well as the influence of contextual factors, such as the characteristics of the settings (e.g., formal and informal treatment settings and social, economic, and cultural factors) that take place in the process of seeking and receiving care (Fig. 55.10–1). From the client's perspective, service use and, ultimately, health outcomes are initiated by the recognition of need. This step is followed by the decision to look for care and the processes of seeking care, assuming the sick role, and maintaining and terminating care. On seeking care, provider behaviors also become influential and include diagnosis, therapeutic decision making, and potential collaboration with other providers during these processes.

Subsequent conceptual models further specify factors that are influential to the access to care. Ronald Andersen's Behavioral Model of Health Services Use, for example, proposes that predisposing (e.g., sociodemographic factors such as gender), enabling (e.g., availability of insurance or treatment resources), and need (e.g., illness severity) factors form the basis of the decision-making process. Alternatively, the Health Belief Model suggests that individual psychological attributes, such as attitudes, beliefs, and perceived benefits of treatment, represent the major determinants of seeking care. Other models of access, such as Bernice Pescosolido's Family Network-Based Model of Access to Child Mental Health Services, emphasize the role of social networks in this decision-making process.

Overall, help-seeking pathway models propose a series of links between the initial recognition of a mental health problem and the eventual use of

mental health services, framing these steps within the context of an "illness career" and network experiences thought to influence career progression as well as adherence to professional treatment suggestions. Few studies, however, have implemented study designs complex enough to analyze network influences, temporal sequencing, and combined multisector care patterns for youth. Studies addressing access to care have been most commonly based on the Andersen model, using cross-sectional designs to identify relevant predictors.

FIGURE 55.10–1. Model of the medical care process. The *arrows* represent only a small portion of significant interactions. (Reprinted with permission from Donabedian A. Promoting quality through evaluating the process of patient care. *Med Care*. 1968;7:183.)

Stigma as Barrier to Access

The 1999 Surgeon General's Report on Mental Health identified stigma as an important influence on access and use of mental health services. Youth with mental disorders face significant stigma in its various forms, including public (expressed as prejudice and discrimination), courtesy (stigma suffered by family members or associates of individuals with mental disorders), and self-stigma (stigmatized individual's acceptance of negative views by others). Successful recovery from mental illness requires awareness of stigma and of its potential adverse consequences and effective means to combat it. To examine factors that shape prejudice and discrimination toward children with mental disorders, the recent National Stigma Study-Children used vignettes depicting several stigmatizing scenarios, including ADHD, depression, asthma, or "normal troubles." Results indicate that scenarios of ADHD and depression and those depicting adolescents elicited the highest rejection responses. Respondents who thought a child suffered from a mental illness rather than from asthma or "normal" troubles indicated that they would seek social distance from the affected child, apparently resulting from perceptions that a child with mental illness is dangerous. In a comparison of child and adult depression vignettes, more respondents evaluated childhood depression as serious (83 percent) than adult depression (51 percent) and endorsed treatment of all types, including coerced care, for children with depression. However, high stigma surrounding childhood disorders poses unique access barriers for youth and their families and merits further study to identify ways to combat these harmful perceptions. General societal anti-stigma programs have been developed and implemented, consisting of three paradigms—protest, education, and contact—but insufficient guidance exists for treatment providers on how to combat stigma experienced by individual patients and their families.

QUALITY OF CARE

The Institute of Medicine defined quality as "The degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge." According to Elizabeth McGlynn and colleagues, quality-of-care research is "the conceptualization, measurement, and assessment of the outcomes, process, and structure of both the health delivery system and the context in which it operates." The study of the quality of care thus forges critical feedback loops among those receiving, providing, administering, and planning the delivery of care. For children, most of the early quality-of-care research focuses on descriptive studies of psychotropic medication prescription patterns and the effectiveness of model treatment programs (e.g., continuum care, multisystemic therapy, wraparound services,

therapeutic foster care, and medication treatment algorithms). Findings from these studies have raised questions about the appropriateness and safety of psychotropic medication use among children in the community. They have also underscored the complexities of developing rigorous study methods that can adequately test whether children and families in the community benefit from receiving care that is valued as "good" based on clinical consensus and scientific evidence. Together, these early studies stimulate further research that will ideally link child clinical need with more detailed information about the structure, processes, and outcomes of care over time from child, family, payer, provider, family, and child perspectives.

In response to national recommendations to integrate care, a body of research examining collaborative and integrated care models across primary and specialty mental health care is emerging. With the recommended use of quality measures, new research is examining the feasibility and clinical validity of applying national quality measures to child-level data in large community-based samples is also underway. To introduce this dimension of child mental health services research, a brief review of a well-established conceptual model for evaluating quality of care is provided, followed by summaries of select early quality-of-care research findings and national quality measures as exemplars.

Models of Quality of Care

Components of quality of care are often conceptualized as structure, process, and outcomes, following Donabedian's model of quality of care. Structural factors include system and clinic organizational factors, as well as provider, child, and family characteristics. Examples are health plan benefit structure, care sector, clinic volume, provider caseload, provider training and discipline, and parent education, as well as child insurance coverage, clinical profile, and sociodemographic characteristics. Processes of care are dichotomized into technical and interpersonal aspects of care. A common technical care process is medication treatment, which may, for example, be assessed using quality indicators or criteria pertaining to medication evaluation, use, and monitoring. For children, variables within the domain of interpersonal style may include the assessment of aspects of parent-provider communication and shared decision making. For example, how well a child and/or parent believes his or her concerns are listened to or how much involvement the primary caregiver had in the decision process of making the diagnosis, developing a treatment plan, and participating in the care of his or her child over time. Outcomes may also include child-, parent-, family-, community-, and system-level characteristics. Outcomes for children, parents, and families include symptom reduction, improved functioning, child and parent satisfaction, reduced parent strain, and improved family cohesion. Examples of

community- and system-level outcomes are improved school attendance and reduced costs, respectively. Using this well-established paradigm, most of the early quality-of-care research examines discrete dimensions of quality, such as effectiveness or concordance with a profession's normative standards.

Building on the Donabedian quality of care framework, McGlynn and colleagues proposed an integrative approach for examining quality of care for mental health. As depicted in Figure 55.10–2, the ordering of the components of quality of care are reversed, such that outcomes influence both care processes and structural factors and processes of care directly affect change in structural characteristics. They also suggested that in examining quality of care for mental health problems, an analytical strategy be used that "simultaneously examines the outcomes, the processes associated with producing those outcomes, and the structural context in which the process was delivered." Further, interpretation of findings related to clinical outcomes should be done carefully. Statistical techniques are often applied to adjust for the clinical severity and complexity of a child when examining quality of care. Missing data is also a common problem. For example, clinic follow-up visit rates are often poor, and without follow-up data, it is difficult to determine if the child dropped out of care because no further care is needed or not.

Quality of Care for Child Mental Health

Psychotropic Medication Prescription Trends. National trends in psychotropic medication use, based on secondary databases (i.e., pharmacy claims, encounter data, physician office visits, household surveys), have raised awareness of the need for additional research examining the safety and efficacy of psychopharmacological treatment regimens in larger, community-based child populations, particularly for younger children and those in foster care. Rates of psychotropic medication prescription also may vary by sociodemographic characteristics, psychiatric disorder, insurance status and Medicaid eligibility category. Among a statewide sample, a retrospective analysis of data on mental health and pharmacy services was conducted for 1,491 children age six and younger who were in foster care in 2010 and had at least 365 days in foster care during 2009 to 2011. Approximately 12 percent of children age 6 and younger in foster care for at least 1 year received at least one psychotropic medication over the 3-year study period. With each year of age, the prevalence of ADHD medication and antipsychotic medication and duration increased. In addition, based on data for 2- to 5-year-old children from the 1994 to 2009 National Ambulatory and National Hospital Ambulatory Medical Care Surveys, psychotropic prescription rates were 0.98 percent from 1994 to 1997, 0.83 percent from 1998 to 2001, 1.45 percent from 2002 to 2005, and 1.00 percent from 2006 to 2009. Boys, white children, older children (i.e.,

4 to 5 vs. 2 to 3 year olds), and those lacking private insurance were more likely than children from other groups to receive psychotropic prescriptions. Further, when examining 10-year trends among a statewide sample of children enrolled in Medicaid, the prevalence of antipsychotic use increased from 1.2 percent in 1997 to 3.2 percent in 2006. The increase in odds of antipsychotic use varied by Medicaid eligibility and was greatest for children enrolled in State Children's Health Insurance Program, followed by children in foster care, Temporary Assistance for Needy Families, and Supplemental Security Income. Increases in rates of psychotropic medication were greatest for youths with externalizing behavior disorders and bipolar disorder. The overall proportion youths using antipsychotics between 1997 and 2006 also increased significantly more among African Americans and Hispanics than among whites.

FIGURE 55.10–2. An analytical strategy for research on the quality of mental health services. (Reprinted with permission from McGlynn EA, Norquist GS, Wells KB, Sullivan G, Liberman RP. Quality-of-care research in mental health: responding to the challenge. *Inquiry*. 1988;25:157–170.)

Overall, trends in psychotropic medication use among children should not be interpreted as suggesting inappropriate use of such treatment for children. To begin to address this question, research that examines the

relationship between a child's clinical need for medication treatment and use of appropriate medication treatment over time is warranted. A longitudinal perspective is particularly key for child psychiatric disorders because they are often chronic, and target symptoms and functioning may change with child maturation, contextual changes (e.g., psychosocial stressors), and treatment response.

Gaps between Recommended and Usual Care. Findings from studies examining care processes for child psychiatric disorders suggest that gaps exist between recommended and usual care. Medical record data from a statewide sample of children receiving care for common psychiatric disorders in publicly funded outpatient mental health programs documented that adherence to quality of care indicators for clinical assessment was high (78 to 95 percent) but adherence to quality indicators related to service linkage, parental involvement, use of evidence-based psychosocial treatment, and patient protection were moderate to poor (8.0 to 74.1 percent). Medication safety monitoring was particularly weak, such that roughly one-fourth (28.5 percent) of the records of children receiving psychotropic medication treatment documented the monitoring of at least one clinically indicated vital sign or laboratory study. Using child-level data from multiple data sources, quality of care for ADHD in primary care and specialty mental health clinics in a large managed care Medicaid program was examined using a longitudinal cohort study design. Continuity of care was poor, and in primary care children received on average only one to two follow-up visits a year. In the specialty mental health clinics, less than one-third of children received any stimulant medication, and in both sectors, stimulant medication refill prescription persistence was poor (31 to 49 percent). With few exceptions, ADHD diagnosis, impairment, academic achievement, parent distress, and parent-reported treatment satisfaction, perceived benefit, and improved family functioning did not differ between children who remained in care and those that received no care.

Table 55.10–3.
Operational Definition of ADHD Medication Follow-up Quality Measure Developed by the National Committee on Quality Assurance

Initial Phase: Percentage of children age 6–12 years of age as of the Index Prescription Episode Start Date with ambulatory prescription dispensed for an ADHD medication and who had one follow-up visit with a practitioner with prescribing authority during the 30-day initiation phase.
Continuous and Maintenance Phase: Percentage of children who remained on ADHD medication for at least 210 days and who in addition to the visit in the Initiation Phase, had at least two additional follow-up visits with a practitioner within 270 days (9 months) after the Initiation Phase ended.

National Quality Measures. In response to national recommendations to improve the quality of health care, there has been a proliferation of

quality measures for behavioral health care, mostly dedicated to the care of adults and care in inpatient treatment settings. For children, within the CHIPRA initial core set of 24 quality measures for child health, three were related to mental health care. Between 2009 and 2011, the National Quality Forum reviewed 101 candidate measures reviewed for the Patient Outcomes (Phase III): Child Health and Child Health Measures Projects, and 15 pertained to child mental health care.

Across both initiatives, the well-established quality measure for ADHD medication treatment and follow-up were selected or endorsed. The operational definition of the measure is described in Table 55.10–3. This measure was developed by the National Committee on Quality Assurance (NCQA) and released in 2006. The data source is health plan-level data, but research examining application to real world data is emerging. One recent study found that even within integrated care delivery systems less than one-half of children received ADHD care consistent with NCQA guidelines for initiation and continuation/maintenance of ADHD medications, with higher quality rates for mental health than nonmental health providers. The 2012 NCQA Accreditation report sets the benchmark for the 90th percentile of the national initiation rate at 47 percent for commercial insurers and 51 percent for Medicaid, and of the continuation/maintenance rate at 55 and 63 percent, respectively. This is in notable contrast to benchmarks for asthma care, where the benchmark is set at 96 percent for commercial insurers and 93 percent for Medicaid for appropriate medication use. The study also highlights an important limitation of this widely used quality measure, namely, that of those youth started on ADHD medication, nearly two-thirds were ineligible for quality analyses because they did not receive continuous treatment (210 out of 300 days) required for inclusion in the denominator.

In addition, research to guide further refinement of quality measures and development of new ones is needed. The 2014 National Quality Strategy annual report found however that not all measures are useful, some are redundant, reporting adherence to quality measures can be burdensome, and there were concerns that quality measurement diverted resources away from other quality improvement activities. The development of new child mental health quality measures also poses methodological challenges. The constraints of existing data infrastructure, at the state and provider levels, must be addressed to enhance the capacity to capture data that links measure adherence to improved care and meaningful outcomes.

▲ 55.11 Impact of Terrorism on Children

WANDA P. FREMONT, M.D., AND JAMES S. DEMER, M.D.

Over the last few decades, terrorist attacks, threats, and their aftermath have been increasingly frequent in countries throughout the world. The effects of terrorist activities have a significant clinical impact on children and their families. A growing amount of research documents the effects of this exposure, especially data that help to differentiate reactions to terror from those associated with other types of violence. In addition, the indirect effects of terrorism, including exposure to media and television coverage of violent images, have been noted to be of increasing concern. To develop a proactive and strategic response to these reactions, clinicians, educators, and policy makers must understand the psychological effects of terrorism. Many of the effects of terrorism-induced trauma on children are similar to the effects of other human-caused and natural disasters. Therefore, it is essential for the clinician to have an understanding of children's reactions to trauma. The important contributing influences on children's reactions to trauma include risk and protective factors, developmental factors, neurobiological consequences, and family and community strengths and vulnerabilities. Recently, with the increase in terrorist bombings and access to media coverage worldwide, more studies have examined the unique effects of terrorism-induced trauma on children. This research covers a range of violent acts that are classified as terrorism. These include isolated events in countries not at war (the Oklahoma City bombing and September 11 terrorist attacks) and repeated terrorist attacks in areas of political conflict (terrorist activities in Northern Ireland, state terrorism in Guatemala, the Scud missile attacks during the Persian Gulf War, and bombings and kidnappings in Israel). Earlier studies completed in the 1970s and 1980s were primarily descriptive and anecdotal in nature. More recent studies have been more rigorous and focus on protective and risk

factors that affect children's reactions. They include longitudinal studies that assess the long-term consequences of terrorist activities. Diagnostic implications, clinical interventions, and treatment strategies have developed as a result of the increasing knowledge obtained about the effect of terrorism on children.

DEFINITION OF TERRORISM

The U.S. Defense Department defines terrorism as "the calculated use of violence or threat of violence to inculcate fear: Intended to coerce or to intimidate governments and societies in the pursuit of goals that are generally political, religious, or ideological." The goal of terrorism is not only to cause visible disaster, but also to inflict psychological fear and intimidation at any time—during periods of peace or conflict. Unlike family or community violence or the trauma resulting from war, terrorist activities are not confined to a specific geographical area or time. Terrorist events occur suddenly without any forewarning and frequently result in severe trauma. The threat persists indefinitely. New terrorist threats and actions may exacerbate underlying anxieties. Terrorism capitalizes on media coverage. Powerful visual images create strong emotional responses, including fear, panic, despair, and rage, even in individuals who live far from the traumatic events. The events are given well-recognizable labels (e.g., "the blood bus," "the explosive refrigerator in Israel," "the Chowchilla bus kidnappings," "the Scud missile attacks," "the 9/11 terrorist attacks").

CHILDHOOD REACTIONS TO TERRORISM-INDUCED TRAUMA

Although many of the reactions of children to terrorism-induced trauma are similar to children's reactions to other forms of human-caused violence and natural disasters, terrorism-induced trauma results in unique stressors and reactions in children. The clinician must have a good understanding of the variables that affect children's responses to trauma and the variety of responses that children manifest. It is therefore important to review the literature on childhood reactions to trauma and their clinical manifestations. Children vary in their reactions to traumatic events. Some suffer from anxiety and bad memories that dissipate with time and emotional support. Other children may be more severely traumatized and experience long-term problems that significantly interfere with their functioning. The reader is encouraged to refer to the section in this text on posttraumatic stress disorder in children and adolescents (Section 52.2).

Several factors contribute to a child's differential response to trauma. These include the child's age and level of psychological maturity, the severity and level of exposure to trauma, the duration of exposure to violence, predisposing risk factors, protective factors and resiliency, the influence of parents' responses to disaster, family protective factors, the degree of social and community support (including educational, political,

and religious influences), and the extent and context of displacement and relocation.

Children's emotional reactions may develop immediately after the trauma or may occur later. *Acute stress disorder* (ASD) is the most common psychiatric disorder following a traumatic event. *Posttraumatic stress disorder* (PTSD) is a reaction that may occur after a period of time. Children or adolescents suffering from acute stress disorder or PTSD may re-experience the trauma by having nightmares or recurring flashbacks of the trauma. They may become fearful, distractible, anxious, or depressed. Their play and study may be affected in addition to their pattern of sleep. In young children, repetitive play may occur in which themes or aspects of the trauma are expressed. Their dreams may be frightening but without any recognizable content. Trauma-specific re-enactment may occur. Adolescents and children may feel numb and withdraw from the external world or avoid situations that arouse recollection of the trauma. Symptoms of increased arousal may occur that include hypervigilance, sleep difficulties, irritability, difficulty concentrating, and outbursts of anger.

In addition to acute stress disorder and PTSD, children may develop comorbid disorders, including anxiety disorders (e.g., generalized anxiety disorder, social phobia, specific phobias, panic disorder, agoraphobia, obsessive-compulsive disorder), depression, and substance abuse–related disorders. Children may present with partial or variable symptoms of these disorders.

Children who are indirectly exposed to a traumatic event may also manifest symptoms of anxiety, including trauma-specific fear, fear of being alone, the habit of clinging to others, and event-specific fears.

Children's responses to terrorism-induced trauma include many of the symptoms and reactions to nonterrorist traumatic events. However, terrorism-induced trauma results in unique stressors and reactions in children. Terrorism, by its nature, is likely to cause psychological stress. Because terrorists can strike at any time and at any location, the threat of terrorism is omnipresent and enduring. The unpredictable, indefinite threat of terrorist events, the profound effect on adults and communities, and the effect of extensive terrorist-related media coverage exacerbate underlying anxieties and contribute to a continuous state of stress and anxiety. The resulting anticipatory fear and anxiety may be severe.

RISK AND PROTECTIVE FACTORS FOR CHILDREN EXPOSED TO TERRORISM

Several risk and protective factors influence children's reactions to terrorist events. These include factors relating to the history of the terrorist event and individual, family, and community strengths and vulnerabilities.

History of the Terrorist Event

The level of exposure to terrorist actions, either directly or indirectly, affects a child's response. The degree of exposure to terrorist actions is related to the prevalence of PTSD. The more severe the traumatic event, the greater is the risk of the child developing posttraumatic symptoms. Children who experience loss directly are more symptomatic. Suffering physical injury or witnessing the death or physical injury of others is associated with higher rates of PTSD and comorbid depression and anxiety. The degree of personal loss (i.e., the relationship of the child to the victim) is also correlated with the severity of PTSD symptoms. Knowing an injured or deceased person increases the risk of symptom development. Children who lose a parent manifest the highest rates of PTSD. In addition to the level of trauma, the duration of exposure predicts the risk for development of psychiatric problems in children.

Individual Factors

Individual factors and vulnerabilities that affect a child's differential response to terrorist events are related to developmental factors. These include a child's age and level of psychological maturity. Additional individual factors influencing responses include neurobiological responses, predisposing risk factors, protective factors, and effects of resiliency.

Childhood Development Influences on Terrorism Reactions. How children understand and conceptualize traumatic events resulting from terrorist activities is greatly influenced by their developmental level with respect to cognition, emotional, and social factors.

PRESCHOOL-AGE CHILDREN. Preschool-age children, between the ages 3 and 5 years, express their concerns for safety in terms of separation from parents and other primary caregivers. At this age, they are not able to cognitively understand the finality of death and do not fully understand the actual events that are occurring. Preschoolers rely on cues about danger from caretakers. They are more comforted than older children by reassuring and supportive parental behaviors. They may manifest their anxiety by having difficulties in separating from parents. Regressive behaviors, including thumb sucking, enuresis, and fear of the dark, are not uncommon in young children. In addition, children age 5 years and younger may manifest symptoms of fear, anxiety, sleep problems, and aggressive behaviors.

LATENCY-AGE CHILDREN. Latency-age children, 6 to 11 years, are prone to derive a sense of safety from clear-cut rules. At younger ages, they have difficulty abstracting and thus tend to polarize complex situations into "right" and "wrong" or "good" and "bad." As they mature, they develop an increasing sense of empathy and altruism. Children in this age group recognize the finality of death and are capable of fearing for others.

Latency-age children are extremely influenced by indirect effects of violence and trauma. Their reactions to terrorist events may include depression, PTSD, and anxiety. Symptoms of anxiety include irrational fears, sleep problems, nightmares, somatic complaints (headaches, stomachaches), irritability, angry outbursts, and school avoidance. Signs of depression may include sadness, withdrawal, feelings of hopelessness, and problems with attention. These problems may result in academic difficulties.

ADOLESCENTS. Adolescents, ages 12 to 18 years, are likely to be vulnerable to idealistic notions and an unrealistic sense of immunity to harm and omnipotence. This may influence their judgment regarding the degree of danger in their environment. When exposed to an extreme act of violence, such as a terrorist attack, young adolescents may feel overly responsible for protecting their parents from danger. Adolescent responses to terrorist events are more similar to adult responses. They may exhibit symptoms of acute or posttraumatic stress disorder, including intrusive thoughts, hypervigilance, and emotional numbing. Additional symptoms may include nightmares, sleep disturbances, avoidance, and withdrawal. They are at increased risk to develop depression, substance abuse problems, and peer problems. Shame, humiliation, self-blame, and guilt may result from a sense of powerlessness.

Neurobiological Consequences of Trauma in Children. Research on chronic stress such as child abuse and neglect and acute stress such as disaster, war, or medical trauma supports the hypothesis that trauma produces long-lasting effects on brain functioning. The human brain undergoes significant development during childhood and adolescence. Trauma may have a particularly devastating effect on the developing brain and may cause permanent changes in neurotransmitter systems that are stimulated by stress. Early childhood exposure to traumatic events influences the neurobiological response to stress in the developing brain in such a way that it predisposes affected individuals to mood and anxiety disorders later in life. An important mediator of the stress response is corticotropin-releasing factor (CRF). Charles Nemeroff and colleagues hypothesized that stress causes the hypersecretion of CRF. Dysregulation of the CRF system in the pituitary gland and brain may explain some of the symptomatology of traumatic syndromes, such as an increased startle response, and symptoms of anxiety and mood disorders. More research is needed to understand whether the neurobiological changes are reversible or permanent. An understanding of neurobiological consequences of trauma is important to determine treatment choices.

Predisposing Risk Factors. All children who are exposed to a traumatic

event experience a threatened sense of safety and potential for personal danger. However, children with predisposing risk factors are at greater risk to develop symptoms of anxiety and depression. Risk factors include exposure to past traumatic events during childhood, childhood anxiety, childhood conduct problems and antisocial behaviors, learning disabilities, and a history of psychiatric disorders. Children who have survived the death of a parent or another significant person are more vulnerable to the effects of trauma. In addition, each child reacts differently, depending on temperament and sensitivity and whether he or she tends to internalize or externalize experiences and emotions.

Protective Factors and Resilience. Many children who are exposed to trauma do not develop pervasive chronic posttraumatic symptoms. Factors associated with resilience among children after exposure to traumatic events are related to both psychological and biological characteristics. Resilience is related to the variability in psychological interpretation of physiological arousal. Initial biological responses to a fearful event include an increase in cortisol level in the brain and an increase in heart rate. Recovery from a traumatic event includes the ability to respond to the event in a supportive environment without extreme avoidance and in the absence of persistent physiological arousal. The development of a perpetual state of fear, with both emotional reaction and abnormal physiological response, leads to posttraumatic symptoms. Factors related to resilience include a child's characteristics and resources (persistence, motivation, adaptability, optimism, willingness to approach novel events, self-esteem, intelligence, social skills), developmental stage, family characteristics (support, open communication, consistency), and community support. Understanding risk and protective factors that contribute to a child's response to trauma is important to develop strategic interventions. Early intervention facilitates the process of recovery in vulnerable individuals.

Family Factors and Vulnerabilities

Children's response to trauma and their ability to cope with these disasters are strongly influenced by their parents' response to the violent events. There is a positive correlation between children's and parents' symptomatology. Parental involvement in mediating stress reactions in children exposed to terrorist attacks is a protective factor and helps to reduce a child's vulnerability to the trauma. Parents who underestimate their children's reactions may unintentionally hinder their children's process of mastering the trauma. Terrorist incidents affect adults profoundly. Therefore parents, adult caretakers, and teachers may not be able to provide the support and reassurance needed to help avoid potential long-term emotional harm to their children. Increased levels of distress and less adequate coping skills have been noted in children whose parents

responded to traumatic events with negative emotions. Positive coping responses in children are associated with parents who responded with positive emotional reactions. Family factors that have been shown to increase resiliency and buffer stress responses in children include a stable, secure emotional relationship with at least one parent, a parental model of constructive coping mechanisms, and physical proximity of children to parents.

Community Factors

Children's responses to terrorism are significantly influenced by community members' responses. An increased degree of social support and positive community influences increases resilience. Community educational, political, and religious support fosters moral development in children. The presence of a caring adult who is able to provide emotional support, encourage self-esteem, and promote competence has a moderating influence on acute and long-term mental health outcomes. Community value systems, beliefs, and ideology contribute to resiliency by giving meaning to dangerous events, allowing children to identify with cultural values, and enabling children and adults to function under extreme conditions.

CHILDREN'S RESPONSES TO MEDIA EXPOSURE TO TERRORIST EVENTS

Media coverage of terrorist activities has a significant effect on children's emotional responses. The media plays an important role in providing information to the public, especially during times of disaster. The images portrayed are powerful and intensely emotional. They are frequently repeated over and over again. Terrorist organizations depend on the media dissemination of their activities to increase responses of fear, thus creating an environment of persistent threat. Studies have shown that one-third or more children watch the news. Extensive research has examined the influence of violence and aggression on children and their families. Recently, with the increase in terrorist bombings and access to media throughout the world, more studies have examined the effects of children's reactions to media coverage of terrorism. The results research, covering a range of violent acts, has shown that remote exposure, such as viewing terrorism on television, has a significant clinical effect on children's responses.

Because media exposure is so extensive and the effect on children's reactions is significant, it is important to provide a summary of relevant factors pertaining to children's exposure, interpretation, and constructive and destructive effects of television and the media.

Several studies have examined the extent of children's exposure to the media, which has dramatically increased over the last decades. Forty-one

percent of US households have three or more televisions. Approximately 33 percent of children ages 2 to 7 years and 56 percent of children ages 8 to 16 years have a television in their room. US children ages 2 to 17 years spend an average of 19 hours, 40 minutes per week watching television. During 81 percent of the time that children ages 2 to 7 years watch television they are alone and unsupervised. Day care centers use television during a typical day 70 percent of the time. The average US child spends 900 hours in school and 1,023 hours watching television. In a survey of children and media conducted by Fairbanks and colleagues, 65 percent of children reported watching a television news program, and 44 percent of children read a newspaper. More than 50 percent of the children reported feeling angry, sad, or depressed after watching the news.

Childhood Developmental Influences on Media Responses

Children's understanding and interpretation of television and the media are related to their cognitive and psychological developmental levels. Children are less able than adults to regulate their emotions after watching traumatizing images.

Preschool-Age Children. Preschool-age children are most affected by visual images and emotional sounds. They are more upset by images of dead bodies or bloodied survivors and crying victims or witnesses than falling buildings or announcer commentaries. They are not able to understand the extent of the tragedy. Preschoolers cannot distinguish between live pictures and replays. If events are shown over and over again, they believe that the catastrophe is occurring repeatedly in real life. They are likely to believe that the terrorism is happening at the same time they are watching the coverage, and they believe that it is occurring in close proximity to their home.

Latency-Age Children. Latency-age children (ages 6 to 11 years) have a better understanding of the event but will interpret it concretely. They have difficulty in understanding the effect of the terrorist threats and adult responses to these threats. They are more sensitive to injured children or those whose parents were killed. School-age children are more likely to focus on their safety and their family's safety.

Adolescents. Adolescents are more capable of abstraction than are younger children. They are equally affected by visual images; however, they are also concerned about the effect of threats on the future and community responses. They are able to understand more complex, philosophical, and existential issues such as social justice, politics, and theology. Their personal struggles with identity, meaning, and place in society may be compromised seriously or distorted by the perception of the world and its

human interactions as dangerous, untrustworthy, and immoral. This worldview may have a negative effect on their sense of the future.

Although there has been extensive research about children's exposure to the entertainment media, there is far less scientific research about children's exposure to the news, especially exposure to terrorist media coverage. Media coverage of terrorist events has both positive and negative consequences.

Constructive Effects

Several constructive effects of the media have been emphasized. The media plays a vital role in disseminating information quickly to local, national, and international regions. Media coverage facilitates family and community cohesion. It facilitates the dissemination of educational information, and it can serve as a vehicle for discussion in older children and adolescents. The media, the Internet, and the telephone may serve as an extensive support system. Television stations are able to broadcast advice on how to help children to cope with stress and anxiety related to disastrous events. Data obtained after the September 11, 2001, attacks noted that sustained advertising through multiple media outlets was effective in informing individuals about counseling resources and encouraging them to seek mental health services.

Destructive Effects

The increased incidence of negative effects and stress-related symptoms in children exposed to media coverage of terrorist events has been examined recently in studies of the aftermath of the *Challenger* disaster, the Oklahoma City bombing, the Scud missile attacks and the Gulf War, the World Trade Center attacks, and the conflicts between Palestinians and Israelis. Repeated media exposure is especially detrimental for young children because of their cognitive immaturity. The effect of repeated coverage may promote the trauma and increase the intensity and duration of the effects. The media may also have a negative effect on parents and caregivers, which directly affects the coping abilities of their children. More research is needed to measure the effects of media coverage of terrorist events and to determine whether they have detrimental or positive effects on mental health outcomes.

LITERATURE REVIEW OF TERRORIST EVENTS

Early research on the effects of terrorism indicated that children exposed to violence are greatly affected by the experience. These studies examined children's responses to terrorist activities in Northern Ireland, state terrorism in Guatemala, and terrorist attacks in Israel. Children manifested many psychological symptoms, including anxiety, depression, anger,

feelings of hopelessness with regard to the future, difficulties with trust, anticipatory fears, and an altered sense of security. More recent studies have used statistically valid structured assessments to document children's reactions and symptoms. Research has been conducted in the aftermath of the 1993 World Trade Center bombing, the 1995 bombing in Oklahoma City, the 1991 Gulf War and its effects on Palestinian and Kuwaiti children, Scud missile attacks and terrorist activities in Israel in the last two decades, the 1998 American Embassy bombing in Kenya, and the September 11, 2001, terrorist attacks. These studies emphasized the importance of thorough assessment of children's responses and the influence of the media on children's reactions to a terrorist event. The rates of PTSD in children exposed to terrorist activities range from 28 to 50 percent. Other psychiatric problems have been identified, including anxiety, separation problems, depression, mood changes, sleep difficulties, regressive symptoms, and behavioral problems.

The importance of the influence of risk and protective factors on responses to terrorism has been identified. Research has increasingly focused on factors (personal, family, and community) that contribute to the persistence of psychological problems and factors that foster resilience. The results of these studies have contributed to the design of prevention and intervention strategies to help children and their families to cope and recover from the effects of terrorist attacks.

The 1991 Persian Gulf War and Scud Missile Attacks

Repeated terrorist attacks, including the Iraqi Scud missile attacks and terrorist activities on civilian sites in Israel, occurred during the war in the Persian Gulf in 1991. Further data measuring children's affective reactions and coping skills to terrorist events were gathered during studies conducted by several researchers during and after the attacks. The results of the research supported earlier data that correlated the degree of exposure to trauma to the prevalence of PTSD. Children who directly experienced loss due to terrorist attacks were more likely to develop symptoms of PTSD. The degree of personal loss was also correlated with the number of trauma symptoms. Knowing an injured or deceased person increased the risk of symptom development. The studies in Israel also focused on risk and protective factors and long-term consequences of terrorist activities. Several studies addressed the importance of parental involvement in mediating stress reactions in children. Earlier research identifying the protective effects of family relationships was conducted on Cambodian adolescent refugees who survived 4 years under the Pol Pot regime from 1976 to 1979, during which 1 to 2 million people were exterminated. Adolescents who were able to re-establish contact with a family member had fewer psychiatric symptoms than adolescents who lived alone or in a foster home. The natural families were successful in

maintaining traditional child-rearing practices. Clear adult–child boundaries and high expectations for conformity and responsibility were found in these families. Naomi Bat-Zion and Rachel Levy-Shiff noted that parents' responses were a central mediating factor for Israeli children's reactions to Scud missile attacks. Negative emotional expressions by parents were associated with increased levels of distress in children, whereas positive emotional manifestations were associated with increased coping efforts.

Laor and colleagues studied the long-term consequences on Israeli children of the Scud missile attacks. Children of mothers with poor psychological functioning showed more stress symptomatology in families who were displaced. The association between children's and mother's symptoms was stronger among younger children (ages 3 to 4 years). Unhealthy family interactions—either disengaged or enmeshed styles—exacerbated children's stress. These children manifested more symptoms, and their capacity to recover from the trauma was jeopardized. Conversely, children with adequate family cohesion manifested less stress in reaction to trauma and were better able to recover from the initial effect of the trauma.

Correlation between media exposure of terrorist activities and posttraumatic stress symptoms was verified in several studies. The effect of the media on children living in a war zone was also studied in Palestinian and Kuwaiti children during the Gulf War. Palestinian children who were exposed to traumatic events indirectly by the media had a higher incidence of anticipatory anxiety and cognitive expressions of distress than children who were exposed directly, who in turn manifested more symptoms of PTSD.

1993 World Trade Center Bombing

The first major terrorist attack in the United States occurred on February 26, 1993, when international terrorists bombed the World Trade Center in New York City. Six people were killed, and thousands of persons were trapped inside the building. One study compared the reactions of children who were present in the building at the time of the explosion to a community sample of children who were indirectly exposed (children whose exposure was limited to interpersonal relationships with persons directly affected and media coverage of the event). Children who were directly exposed to the attack were more symptomatic. Children in the comparison group had mild symptoms, which did not interfere significantly with their functioning. A marked discrepancy was noted between the parents' report of PTSD symptoms and fear in their children and the children's direct report of their fears. In a follow-up study 9 months later, parents of both groups noted a decrease in PTSD symptoms and fear in their children. However, the children did not report any significant decrease. The results of this study emphasize the importance of evaluating

children directly in addition to evaluating their parents.

1995 Oklahoma City Bombing

On April 19, 1995, the Alfred P. Murrah Federal Building, a US government office complex in downtown Oklahoma City, Oklahoma, was bombed. Until the September 11, 2001, attacks, it was the deadliest act of terrorism on US soil. A total of 168 people were killed, including 19 children, and more than 800 people were injured. Until then, few studies had examined children's reactions to terrorist events. Several studies were conducted in the aftermath of the attack, most notably those of Betty Pfefferbaum and colleagues. The significance of the effect of media exposure to terrorist attacks was identified in these studies. In one study, preschool-age children who attended day care in a facility near the Federal Building were examined. Although many of these children had minor injuries, none of them died or experienced serious injuries. Parents tended to underestimate symptoms in their children. All children met the exposure criterion for PTSD, although none of their parents reported diagnostic criteria for the disorder. Staff reports of children indicated that they met the exposure and re-experiencing criteria (posttraumatic play, discussion with peers). Only three children met the criteria based on parent report. The importance of direct observation of young children after exposure to trauma is essential for an accurate assessment of their reactions. The results of these studies also supported the literature documenting developmental differences in responses to trauma. Children were more likely to exhibit regressive behaviors and functional problems than the numbing and hyperarousal criteria. None of the preschool children reported symptoms of avoidance, restricted range of affect, or sense of foreshortened future that are typical of older children and adolescents.

Research on the Oklahoma City bombing also addressed the effects of media exposure to terrorist events and of indirect exposure on children's responses. Lenore Terr and colleagues first studied these effects of distant trauma after the Space Shuttle *Challenger* explosion in 1986. She examined the responses of children who had watched the explosion on television rather than directly witnessed the disaster. Terr and her colleagues defined distant trauma as "the reaction (memory, thinking, symptoms) to a disastrous event, observed at the time of the event, but from a remote, and safe distance." Children's responses included symptom patterns similar to PTSD. Children's reactions to distant trauma also included trauma-specific fear, fear of being alone, and clinging behaviors. Children who lived on the East Coast were more symptomatic than children who lived on the West Coast. East Coast children had a significant increase in dreaming, drawing, and behavioral enactment, trauma-specific fears (e.g., death and dying, explosions, fires, airplanes), and clinging behaviors. Children throughout the United States had diminished expectations of the future. Latency-age

children were more affected than adolescents. Most symptoms diminished within 1 year; however, for children with partial PTSD, symptoms (i.e., posttraumatic play for young children and hopeless attitudes about the future for adolescents) often persisted. Terr and colleagues defined a spectrum of trauma-related conditions that resulted from remote exposure to violence, including viewing media coverage of disaster events. Because one of the goals of terrorists is to inflict fear in the broader community, it is important to examine the effects of less direct and distant forms of exposure.

Pfefferbaum and colleagues assessed more than 3,000 middle and high school students 7 weeks after the Oklahoma City bombing. Most of the children heard or felt the blast, more than 40 percent knew someone who was killed or injured, and approximately two-thirds reported extensive television viewing of the bombing. Seven weeks after the event, one-third of the children reported continuing worry about themselves or their families. Female gender, acute reactions of fear and arousal, interpersonal exposure, and bomb-related television viewing were associated with an increase in posttraumatic stress symptomatology. Children who experienced personal losses were at greater risk of watching significantly more terrorist-related television coverage than were children without direct losses. This further exacerbated the traumatic experience. Children who witnessed the bombings on television reported trauma-related stress for more than 2 years. In addition to broadcast media, print media (i.e., newspaper and magazine) exposure was also examined. Print media exposure correlated more strongly with enduring posttraumatic stress than did exposure to broadcast media. Most of the children reported mild posttraumatic stress reactions and minimal effect on functioning. The clinical significance of the results is unclear, and further research is needed to determine whether they are at risk for future stress reactions.

1998 American Embassy Bombing in Nairobi, Kenya

More than 200 individuals were killed and thousands were injured on August 8, 1998, when a terrorist bomb destroyed the American Embassy in Nairobi, Kenya. Pfefferbaum and colleagues extended their studies of children who were indirectly exposed to terrorism, exploring issues that were not examined in the Oklahoma City studies, including exposure to other traumatic events. More than 500 indirectly exposed children in a convenience sample of Nairobi schoolchildren were assessed 8 to 14 months after the embassy bombing. Most of the children in the study lived in a community in which trauma was common and had experienced other crimes of violence and the death, illness, or injury of family or friends. Children who were at greater risk of developing symptoms of posttraumatic stress to the bombing incident had experienced a higher number of previous traumatic events, more severe posttraumatic stress reactions to

past events, and stronger acute reactions. Little or no impairment of children's functioning was noted. Similar to the Oklahoma City school samples, the children in this study experienced little direct exposure to the terrorist actions, and posttraumatic stress reactions and impaired functioning were relatively low. Future studies are needed to explore the significance of risk and protective factors, as well as a more comprehensive set of outcomes, including long-term longitudinal data.

September 11, 2001, Attacks

The deadliest terrorist events were the attacks on September 11, 2001. There were 2,973 fatalities, not including the 19 highjackers—246 on the four airplanes, 2,602 in New York City at the World Trade Center, and 125 at the Pentagon. These events significantly affected US and world history, governmental policies, and the lives of individuals in the United States and other countries. Indeed, "pre-9/11" and "post-9/11" have become commonly used terms worldwide. The terrorist attacks and their aftermath, including repeated media coverage of the events, have had a powerful effect on children and their families.

April 2013 Boston Marathon Bombings

On April 15, 2013 two pressure cooker bombs exploded during the Boston Marathon killing 3 people and injuring an estimated 264 others. A manhunt for the suspects followed. The subsequent investigation determined that the bombings were an act of terrorism. Comer and colleagues studied the psychological impact of exposure to this event on children. He examined the rates of PTSD in children who witnessed the event and the impact of media exposure. Children who witnessed the bombings were six times more likely to develop symptoms of PTSD. Two to six months after the attacks surveys from parents, living within 25 miles of the bombing and manhunt, showed that 11 percent of the parents identified PTSD symptoms in their children. This rate is similar to what was found among 9/11 New York City children 6 months after the attacks. Watching the manhunt on television was even more strongly associated with problems such as conduct issues or anxiety than exposure to the bombings themselves. Most children watched 1.5 hours of coverage on the day of the bombings, with 20% watching greater than 3 hours. About one-third of parents surveyed tried to restrict children's access to the media. Recognizing the potential psychological impact of media exposure on children, researchers advised that, "if there is a child who shouldn't watch an R-rated movie they should not be watching news with the same amount of violence and aggressive behavior."

Children's Reactions. Research on children's reactions to these attacks

corroborates the results of previous research studies. The degree of exposure, proximity to the disaster area, association with parental reactions, experience of distant trauma (including media coverage), and history of preexisting trauma were associated with increased stress symptoms. Children's reactions included symptoms of posttraumatic stress, depression, panic attacks, anxiety, separation anxiety, and agoraphobia. The largest study of children's responses was commissioned by the New York City Board of Education and was supported by the U.S. Department of Education through Project SERV (School Emergency Response to Violence). The study, conducted in collaboration with the New York City Department of Health and Mental Hygiene, surveyed 8,266 randomly selected children in grades four to twelve in the New York City metropolitan area 6 months after the September 11 attacks. Christine Hoven and colleagues surveyed children who attended schools in different areas of proximity to Ground Zero. Those children closest to the World Trade Center were most likely to have seen or heard the planes hitting the towers, seen the flames, been exposed to the dust and smoke, and struggled with fleeing to safety. Children farther away from the towers were more indirectly exposed to the attacks, including interpersonal exposure through direct victimization of a family member or friend or through extensive media exposure.

Seventy percent of all children had either direct or indirect exposure. The incidence of PTSD in this group increased from 2 to 10.5 percent following September 11. Children who lived outside of New York City showed an equal prevalence of symptoms of PTSD and other psychiatric problems (depression, panic attacks, anxiety, conduct problems) as children living within the city. The diagnosis of separation anxiety doubled and that of agoraphobia tripled. Children who were exposed to trauma before the attacks were more likely to experience PTSD and psychiatric problems. More than one half of the total sample of children who exhibited symptoms of PTSD had experienced previous traumatic events. This high frequency of previous trauma exposure emphasizes the need to address and identify prior trauma experiences when conducting needs assessments and intervention strategies following a terrorist event.

Parental stress reactions were also noted to have a significant effect on children's responses. The results of several studies noted a correlation between parents' responses and the frequency and severity of posttraumatic stress symptoms in children. Gerry Fairbrother and colleagues assessed predictors of posttraumatic stress reactions in children using a parent report administered by a New York City telephone survey. Parents reported that almost 20 percent of their children experienced severe or very severe posttraumatic stress reaction, and approximately two-thirds of children had moderate posttraumatic symptoms. Parental reactions were associated with the severity of posttraumatic reactions in

children. Mark Schuster and colleagues surveyed 560 adults throughout the United States 3 to 5 days after September 11 using random-digit dialing. Parents with substantial stress reactions were more likely to report that their children had symptoms. Thirty-five percent of adults surveyed reported that their children had one or more stress symptoms. Forty-seven percent of adults noted that their children were worried about their own safety or that of a loved one. This data continue to support the importance of evaluating parents' reactions to a disaster when assessing children's response and needs for treatment.

Further studies after the September 11 attacks assessed children's psychological and behavioral responses by surveying their parents, either by telephone or web-based interviews and assessments. William Schlenger and colleagues assessed psychological responses 1 to 2 months after the September 11 attacks using a web-based epidemiological survey based on the Posttraumatic Stress Disorder Checklist and the Brief Symptom Inventory. Adult reports indicated that children who were distressed by the events manifested symptoms of sleep disturbances, irritability, and fear in separating from their parents. Another study examined behavioral problems in New York City children by comparing three cross-sectional telephone surveys of adults. Two surveys were conducted after the September 11 attacks. The first survey was conducted 4 and 5 months and the second between 6 and 9 months after the attacks. The results of these surveys were compared to a representative survey conducted before September 11. The results of the study indicated that behavioral problems decreased in the first few months after the attacks but then returned to the predisaster levels after 6 to 9 months. These results support findings in an earlier study of children's behaviors before and after Hurricane Andrew.

Children's Reactions to Media Coverage. The effect of extensive terrorist-related media coverage on children's stress reactions were noted in several different studies after the September 11 attacks. Media coverage was extensive, and repeated coverage of the graphic images of planes striking the World Trade Center caused considerable concern about the added emotional effects of viewing the traumatic events. Results of a national study conducted a few days after September 11 concluded that children ages 5 to 19 years watched 3 hours of television news on the day of the attacks. Only 8 percent of children did not watch any coverage of the event. Parents who reported that their children were upset restricted their children's television viewing. In children whose viewing of television was not restricted, the number of hours of television viewing correlated with the number of stress symptoms. A study commissioned by the New York City Board of Education 6 months after the attacks noted that 62 percent of children spent much of their time and 33 percent of children spent some of their time learning about attacks on television. Approximately 75 percent of

children increased the amount of time they spent reading newspapers and magazines, and more than 30 percent obtained information from the Internet. A total of 10.5 percent (75,000) of students manifested symptoms of PTSD at 6 months after September 11, including children who were not affected directly by the event. Among these children, the prevalence of stress was higher among children who spent more time watching television coverage of the events than children who spent less time. The author noted, however, that these results did not determine a direct causality between television viewing and PTSD rates. Exposure to the images on television may have exacerbated children's stress responses; however, anxious children may have been more likely to seek information from the media than were nondistressed children.

The effects of television viewing of the September 11 attacks also were examined in adults. Specific disaster-related television images were associated with PTSD and depression among persons who were exposed directly to the disaster. The number of hours of television coverage viewed and an index of the content of that coverage were associated with PTSD symptoms.

Studies in several other geographical areas in the United States support the effects of media exposure. The indirect exposure of September 11 via television, the Internet, and printed media was examined in a study of elementary schoolchildren in the southeastern United States by Saylor and colleagues. PTSD symptoms were reported in children who saw reports on the Internet (vs. television and printed material), saw images of death or injury, or feared that a loved one might have died in the attacks. There was no measurable benefit to seeing "positive" or "heroic" images. Older children and boys were noted to have greater media exposure and more trauma-specific PTSD symptoms.

The correlation between television viewing of the September 11 attacks and an increased sense of insecurity and stress symptoms was also demonstrated in a study of elementary school–age children in Washington, DC. A few studies examined reactions of children who lived on the West Coast. One month after the attacks on the World Trade Center, adolescents in California experienced heightened perceptions of vulnerability to death, which extended beyond the terrorist attacks and generalized to unrelated risks. After exposure to the terrorist attacks, even from across the country, adolescents internalized a perception of the world as more risky and dangerous. Children in an ongoing longitudinal study who were assessed after the 9/11 attacks demonstrated posttraumatic stress symptoms and fears at levels comparable to children who directly experienced disasters.

Counseling Interventions. Few studies examined the frequency of counseling interventions following the September 11 terrorist attacks. In a telephone survey 1 to 2 months after the September 11 attacks, more than

100 parents were asked to describe the experiences and reactions of their children, most of whom were in school or day care at the time of the disaster. More than 20 percent of the parents studied reported that they received counseling. Parental posttraumatic stress, male gender, and having more than one sibling living in the household were factors that were correlated with receiving counseling. Two additional phone surveys of 423 and 112 parents, respectively, reported that 10 and 22 percent of symptomatic children received mental health services. These services were more likely to have been accessed by children whose parents reported having current symptoms of PTSD. Gerry Fairbrother noted that only 27 percent of children who had been identified in his first study to have severe or very severe stress reactions received any mental health treatment 4 to 5 months after the September 11 terrorist attacks.

In another survey, military health system beneficiaries in the Washington, DC, area after the September 11 attack on the Pentagon were studied using the Electronic Surveillance System of the Early Notification of Community-Based Epidemics (ESSENCE) database. The number of visits to behavioral health clinics for anxiety disorders and acute stress reactions in children increased after the attack.

Project Liberty. In the aftermath of the September 11 attacks, the largest federal health program in US history, Project Liberty, was created to provide mental health services to approximately 1.5 million people. It was funded through grants totaling $155 million from the Federal Emergency Management Agency (FEMA). The New York State Office of Mental Health (NYSOMH) administered and designed the program and collaborated with almost 200 local agencies to provide service delivery to New York City and ten surrounding New York counties. The overall goal of Project Liberty was to provide free and anonymous community-based disaster services to help individuals to recover from the psychological distress that they experienced as a result of the attacks. Services provided included disaster-related outreach, individual and group counseling, psychoeducation, and referral services for both adults and children. The services were developed based on the assumption that although most persons' distress reactions were disturbing to them, they constituted normal reactions to a traumatic event. Most services were planned to be of short duration, with the expectation that reactions would dissipate over a short period of time. Interventions helped people to identify their trauma responses and understand them as normal reactions to a traumatic event and to reconnect people with their preexisting social supports. Populations identified to need greatest support included victims' families, survivors and their families, displaced individuals, emergency and recovery workers, children, the elderly, persons with limited financial and social support resources, certain cultural and ethnic groups, and persons with a history of psychiatric problems. Project

Liberty provided face-to-face counseling and educational and outreach services to an estimated 1.2 million individuals in the New York City metropolitan area between the time services began a few weeks after September 11 through December 31, 2003, when services were terminated. An important component of Project Liberty was to provide assurance/quality improvement activities to assess the quality of the delivery and effect of services. Data on demographic variables, symptom clusters, variables predictive of further need versus recovery, and long-term outcome were gathered. In addition, data were collected to monitor how well the services provided adhered to treatment manual and guidelines.

As part of the quality assurance program, counselors completed encounter logs that included checklists for reactions to the September 11 attacks. These results were used to help guide program planning and responses to service recipients. Nancy Covell and colleagues collected data on service utilization and reaction patterns among children who received Project Liberty counseling services. Nine percent of Project Liberty community-based service recipients who received counseling between September 2001 and December 2003 were children. Census data for the 15 boroughs and counties serviced by the project indicated that children constituted 25 percent of the population. During a later phase of the project, funded by Project Liberty and organized through the New York City Department of Education, an additional 36,337 children received counseling services between January 2003 and December 2004. With these additional services, approximately 20 percent of Project Liberty's total services for individual (including family) counseling were provided to children. The most commonly reported reactions for children's responses paralleled responses recorded for adults. Reactions included sadness, fear, anxiety, concentration difficulties, anger, irritability, intrusive thoughts and images, and difficulty sleeping. Children's responses differed according to their age. Elementary school–age children were more likely to display signs of withdrawal and isolation, anxiety, and difficulties with concentration and memory. Older children (ages 12 to 17 years) were more likely to exhibit symptoms similar to adults, including avoidance and "numbing" reactions, in addition to substance abuse.

CLINICAL INTERVENTIONS AND TREATMENT

The effectiveness and comparative advantages of specific treatment modalities and interventions for children exposed to terrorism have not been extensively studied. Only recently have researchers developed rigorously designed studies to examine the effectiveness of treatments in children exposed to non–terrorism-induced trauma (e.g., sexual abuse, single-incident traumas, natural disasters, community violence, and war-induced trauma). The results of this research are promising and have significant implications for intervention strategies and treatment of

children exposed to terrorism. These include community, school-based, individual, and family interventions and treatments. Essential components used in all treatment approaches include addressing protective and risk factors. Emphasis is placed on providing assistance to parents and caregivers and including them in treatment. Psychoeducation, cognitive restructuring, exposure, and coping skills management are frequently used treatment strategies. Guidelines and suggestions specifically related to media coverage of terrorist events are also crucial interventions to prevent exacerbation of terrorist-induced trauma. Resources for information on children and terrorism are provided in Table 55.11–1. Guidelines for parents, health care providers, and educators are listed in Table 55.11–2, and guidelines related to media coverage are outlined in Table 55.11–3.

Community-Based Interventions

Based on their research into the effects of the 1995 Oklahoma City bombings, Robin Gurwitch and colleagues identified essential responses to community-wide acts of terrorism that included early community-based intervention; clinical needs assessment to identify children at risk; multimodal, trauma-loss–focused treatment programs; and program evaluation of treatment efficacy. Early community-based interventions focus on safety and protection. Restoration of rest and sleep, emotional support by parents and caregivers in the community, and stress-related symptom reduction are emphasized. Community-wide screening is critical to identifying children at risk. Screening may take place in schools, primary care settings, or neighborhood centers. Although there is no consensus on the most effective method of assessment, numerous structured interviews and self-reports are available. Screening identifies children at risk and children in need of acute, trauma-related service. An essential component of the screening process is distinguishing normal, developmentally appropriate reactions to trauma from abnormal reactions. Screening information may be used to develop specialized treatment programs based on the unique needs of the child, family, or community. Screening results also serve to provide pretreatment data for evaluating outcome studies of treatment effectiveness. Triage and referral, based on knowledge of psychopathology and risk factors, are essential components of intervention. Active involvement of parents, caregivers, health care providers, educators, and community leaders is emphasized.

Community and school interventions, family therapy, adult therapy, and group therapy have been used to treat traumatized children and families, help them with coping skills, and address issues related to trauma and loss, but no systematized studies have shown their effectiveness. Psychoeducational group meetings (i.e., parents or community meetings) reduce symptoms of individual, family, and community fear and arousal levels.

School-Based Interventions

School-based interventions to treat PTSD symptoms have received empirical support in the literature. Annette La Greca and colleagues developed a school-based intervention manual to help children cope after Hurricane Andrew. Their manual has been distributed to schools

internationally and has been used in other disasters, including the Oklahoma City bombing. Robin Gurwitch and Anne Messenbaugh expanded the work of La Greca and colleagues after Hurricane Andrew and the work of Storm and colleagues after the Australian bushfires. They developed a manualized treatment program for use following community traumatic events, including acts of terrorism. The program, Healing After Trauma Skills (HATS), emphasizes the active involvement of parents and caregivers and includes educational materials on basic safety skills and psychological stress responses. It uses treatment exercises to address symptoms and behavioral difficulties associated with trauma and loss. Similar manuals and materials have been developed in the aftermath of the September 11 terrorist attacks. Among the materials that have been widely distributed internationally are *Helping America Cope: A Guide to Help Parents and Children Cope with the September 11th Terrorist Attacks* by La Greca and colleagues, and the American Red Cross publication *Facing Fear: Helping Young People Deal with Terrorism and Tragic Events*. The preliminary results of the interventions and manuals developed to aid children after terrorist attacks are promising. However, outcome data have not been examined, and further research is needed to evaluate their effectiveness.

Table 55.11–2.
Guidelines for Parents, Health Care Providers, and Educators: Terrorism and Trauma

Helping children and adolescents to overcome psychological problems in the aftermath of terrorist events is an important challenge for families and communities. Proactive and preventative methods to help children to cope with loss and anxiety may help to facilitate positive posttraumatic adjustment and allow for healthier outcomes in children's growth and development. Several important general guidelines and suggestions are recommended for parents, health care providers, and educators to help children in the aftermath of terrorist attacks.

Adults should focus on positive ways of understanding and coping with their responses to terrorist events. Since September 11, 2001, many resources have been made available to help parents to cope with the terrorism-related fears and anxieties. The National Mental Health Association, Centers for Disease Control and Prevention, and American Academy of Child and Adolescent Psychiatry are among some of the agencies that have published extensive information.

Any parent who is overwhelmed by the effects of the disaster should seek help from primary care providers, educators, mental health agencies, and clergy. If parents are not able to manage their responses to the trauma, they will not be effective in reassuring their children and helping them to discuss their concerns.

Children cannot be sheltered entirely from knowing about or reacting to the disturbing event. Their fears of not knowing or understanding what has happened may be more disturbing than the truth. It is therefore important for parents to present information to children according to their developmental level. Children should be encouraged to express their concerns, and their feelings should be validated. Listening is more important than talking. All questions should be treated with respect and not ignored or dismissed. Responses should be made with calm reassurance and empathy. If a child's question causes anxiety or discomfort, the adult should not remain silent, because the child might interpret the silence as a sign of danger. It is permissible to tell the child that

the question cannot be answered immediately but will be responded to after the adult has had time to think about it.

Younger children may act out their feelings rather than verbalize them. When possible, children should be encouraged to express their feelings in words. Answers to their questions should be honest and brief. More information than is requested should not be provided.

Older children may be hesitant to talk about their feelings. Discussing terrorist activities with them, without overwhelming them, and encouraging questions or correcting misperceptions are helpful.

Some children's and adolescents' responses may be confusing. Their defenses may be covering up their fears and anxieties. For example, they may make comments such as "We should not be upset, nothing has happened to us." Just as adults should be aware of their own defenses and coping styles, they should be sensitive to children's defenses and ways of coping.

If a child chooses not to talk about the events, the decision should be respected. Children may not be ready to share their experiences immediately; they may wait several days or weeks. Adults should make sure that children know that they are available to listen and discuss their feelings whenever the children need them.

Adults need to reassure children that they are safe and will be protected. Maintaining familiar routines helps children to know what to expect and is comforting to them. Reassuring children that they are loved and that they will be cared for will give them a sense of security. However, they should not be offered false assurance. Children should be taught to manage their fears and anger constructively by showing them how to handle their emotions in healthy ways. They can be made to feel more in control by allowing them to make decisions (meals, what to wear, what movie to see, etc.)

Children may be encouraged to draw pictures or write about their feelings. An important way for children to work through their worries is play. At times, it may be helpful for an adult to redirect the play into caring or helpful themes (such as pretending to make meals for emergency helpers or building hospitals). Focus and attention should be given to those who are helping in the community and nation at that time. Children may feel empowered by participating in events to help those who have suffered. Offering children opportunities to channel their feelings into positive actions allows for healthier outcomes.

Children should be given a reasonable sense of hope for the future. An example may be giving children historical references to how a country overcame previous threats to become a strong nation. Other examples include sharing past problems that children have had with classmates or family members and how they resolved their difficulties, or by giving examples of conflict and resolution within the community.

Children should be educated about racism and stereotyping. They should be told that discrimination and prejudice are unacceptable. Children learn from adults, who must be careful to monitor their own morals and values in front of their children.

Most children will develop healthy coping skills if given the support and reassurance from adults. Some children need more help, especially if they are at greater risk or have experienced the loss of a loved one. Children who may need more intensive help should be referred to a mental health professional. Children's prolonged responses to anxiety and stress may interfere with their ability to function at home, at school, or with peers. The signs of stress may be similar to those seen in adults: Avoidance (refusing to go places that remind them of a traumatic event), emotional numbing (diminished response or lack of feeling), re-experiencing trauma (through nightmares or daytime recollections), and hyperarousal (tendency to be easily startled, sleep disturbances). Children's responses also may differ from those of adults and may include disorganized or agitated behavior rather than fear and helplessness, constant repetitive play of themes of trauma that preoccupy and distract them from their daily activities, and frightening dreams that are not related to terrorist activities. In these cases, children should receive support and help from a mental health professional to prevent these symptoms from continuing to cause problems in the future as children grow.

Individual and Family Interventions

Children and families who manifest significant psychiatric impairment and dysfunction need more intensive health treatment. Cognitive-behavioral therapy (CBT) has been the most rigorously studied treatment for traumatized children. Randomized, controlled studies have shown the effectiveness of CBT in targeting symptoms of PTSD and anxiety in sexually abused children. Additional studies have extended CBT methods to children exposed to other types of trauma. Cognitive restructuring (reprocessing the traumatic event and identifying traumatic triggers), relaxation training, anger management skills, and grief management are important methods of treating PTSD after disasters. However, the effectiveness of CBT for treating children exposed to chronic trauma, comorbid disasters, past history of trauma exposure, and serious family dysfunction has not been studied.

Table 55.11–3.
Guidelines Related to Media Coverage

Because the media plays a major role in informing the public about terrorism and may be a causative agent in symptom formation, it is critical for parents and families to have guidance about the use and misuse of media in traumatic times. Several media-related guidelines have been identified to help prevent traumatizing children specifically from media coverage of terrorist events. Parents, educators, health care providers, politicians, and journalists must increase their awareness about the potentially harmful effects of media exposure on children. Parents should closely monitor disaster-related television viewing by children.

Children's exposure should be limited. Adults would also benefit from limiting their own exposure to reduce their stress reactions so that they and their young children are better able to cope.

Vulnerable persons who have risk factors, such as young children and parents with previous traumatic experiences, should be especially cautious. The use of media should take into consideration a child's developmental level. Young children should not watch adult-oriented shows. Older elementary school–aged children may tolerate being exposed to news "briefs" in which simple concise statements of the facts are made (e.g., reports that occur on major networks between television shows) but may not be ready to watch news shows that spend 30 minutes with interviews, photos, and more detailed discussion of devastation.

Parents and caregivers are advised to watch the coverage with children when they are permitted to watch television. This supervision provides adults with the opportunity to observe children's signs of distress and be available to answer questions and discuss relevant topics.

School staff also must be aware of the importance of monitoring media exposure and should consider policies related to viewing coverage of traumatic events.

Constructive uses of the media should also be taken into consideration. The media may be helpful for parents by providing them access to valuable information to help them when dealing with children in the aftermath of terrorist attacks. Media reports can be used to help reassure children that many adults are working to maintain a safe and protected environment for them Adults may choose to offer taped news reports or specific types of media discussion that will help a child feel secure in the knowledge that adults are taking charge and responding in ways that are protective. Films about resilience, survival, family and community consolidation, and triumph over adversity may play a constructive role by giving children a reasonable sense of hope for the future. Long after an event, children may watch shows with their parents to help them understand terrorism, for example, "Through a Child's Eyes; September 11, 2001," which is an Emmy Award–winning HBO children's special that deals with young school–age children's responses to the September 11 attacks.

Minimal data are available on the effectiveness of pharmacotherapy for treating symptoms of PTSD in children. Sertraline is the only medication that has been approved by the U.S. Food and Drug Administration (FDA) to treat PTSD in children ages 12 to 18 years. Although selective serotonin reuptake inhibitors (SSRIs) have not been approved by the FDA, they have been shown to have therapeutic effects on symptoms of depression in children. Because symptoms of anxiety and depression are common in children following trauma, treatment with SSRIs has been considered a treatment option. However, caution must be used because of concern about the potential increase in suicidal ideation when these medications are used in children. Close monitoring for adverse side effects of suicidal thoughts are necessary when prescribing SSRIs in young patients.

Certain limitations exist when applying trauma-specific interventions to children who have experienced ongoing violence and the continual threat of terrorism. Crisis intervention alone does not prevent the long-lasting effects on children exposed to terrorism. Compounded effects of multiple traumas have not been addressed. The unpredictability of terrorist attacks, the indefinite nature of violent threats, the lack of specific geographical boundaries, and the effects of media coverage result in unique stressors and pose specific challenges for the treatment of terrorism-induced trauma in children.

FAMILY TRAUMATIC GRIEF

Ben was a 7-year-old boy whose maternal uncle, a firefighter, died in the September 11, 2001, World Trade Center attacks. His uncle did not return with his company on that day. Ben was first seen in treatment 1 month after September 11. He was at school when the attacks occurred. His father picked him up. After they returned home, Ben, his parents, and his 5-year-old sister watched the news and the repeated images of the falling towers. Ben knew that his uncle was a firefighter, but he did not know whether he had responded to the attacks. Ben's mother was very distraught as she tried desperately to find out what happened to her brother. Ben's father stayed home from work during the first week after September 11 and assumed most of the household chores and child care, which his mother had been primarily responsible for prior to the attacks. Ben was very worried about his mother. He was aware that the family was concerned about his uncle, and he asked frequent questions about him. His parents had been ambivalent about what to tell their children. Initially, when they did not know for certain whether Ben's uncle had died, they were hesitant to accept the possibility of his death and maintained hope that he was alive. They told their children that they were hopeful that he would be found. Both parents made a conscious effort to make sure that their children were not exposed to television coverage. However, after the children were in bed, they spent several hours watching the news coverage. They talked to their family and friends by phone and tried to protect their children by talking in another room while the children were playing. After Ben's parents were notified of his uncle's death, they struggled with their feelings of shock and grief. They did not tell their children about their uncle's death for several days. By continuing to "not know," Ben's parents may have reacted to their terror and loss by using protective defenses of shock and disbelief. Ben and his sister continued to ask questions: "Was Uncle Gary one of the firefighters who died trying to rescue the people in the tower?" The children's direct questioning challenged the adults' defenses of denial. Ben's mother was irritated by his frequent questions and then felt guilty for being angry with him. Ben in turn became upset, whiny, and oppositional. He also became very clingy and insisted on being with his parents, following them to each room of the house. He did not want to go to the bathroom by himself. At night, Ben would join his parents in their bedroom, which was very uncharacteristic of him.

Ben's parents eventually told their children that their uncle had died. Ben continued to ask questions about his uncle's death. "How did he die? Did he burn to death?" His mother, in a state of traumatic bereavement, did not know how to answer his questions. Ben's father tried to reassure his son that his uncle was now in heaven.

When school resumed the following week, Ben refused to go. He complained of "belly aches" in the morning. When his parents tried to help him to get ready for school and reassure him, he started crying. He refused to get dressed for school and had temper tantrums. Ben's mother took him to school. He went willingly with her, but when it was time for him to leave her and enter the classroom, he started crying and refused to let go of her. She struggled seeing him in so much anguish, and after speaking with the school counselor, decided to take Ben home for the day. The school counselor noted that several of the children had not yet returned to school. Ben had no prior history of school problems and had always enjoyed attending school.

Ben continued to have difficulties separating from his mother and continued to refuse to go to school. He no longer asked questions about his uncle, and his parents avoided talking about him in front of their children. Ben continued to complain of stomachaches. His parents became increasingly concerned and made an appointment for him to see his pediatrician. They noticed that Ben's physical complaints were more frequent on the days he was expected to go to school, but they wanted to make sure that he did not have an underlying medical problem. Ben's pediatrician completed a full medical workup and did not find any underlying organic problems that could be contributing to his complaints of abdominal pain. She reassured Ben's parents that no further medical tests were needed. She explained to them that she believed Ben's current difficulties were related to the recent trauma that the family had experienced and referred them to a child therapist.

The child therapist met with Ben's family initially. Ben's parents focused on their worries about their son. They felt that his problems were related to the recent traumatic events and the death of his uncle. They acknowledged that they felt overwhelmed and were grieving the loss of his uncle. Ben said that he was worried about his parents, especially his mother. "She pretends she is OK, but I don't believe her." The therapist then met with Ben alone. Ben said he was worried about his mother. He was also afraid that another attack would occur. The therapist commented that this was a scary time, and a lot of children were frightened, sad, and mad. Ben was quiet and did not answer. While they were talking, Ben drew a picture of his uncle's fire-truck. The therapist asked Ben about his uncle. He said that he liked to spend time with his uncle who had "awesome baseball cards." Ben and his uncle's family would get together every Sunday. Ben commented that the Sunday before his uncle died, he went to a friend's birthday party while his family visited his uncle's family. He was very sad that his uncle died, but he also felt "bad" that he chose to go to his friend's party instead of spending time with his uncle. The therapist assured Ben that his uncle knew that Ben loved him. She explained to Ben that he did not cause his uncle's death. Ben responded, "I know, but I felt like I jinxed him."

When the therapist met with Ben's parents alone, she asked them how they were coping. Ben's mother noted that in addition to mourning the death of her brother, she was also very frightened that another attack would occur. She had frequent nightmares and was afraid to leave the house. She was afraid for her husband's safety. He worked long hours and commuted to his job in Manhattan by subway. Her main supports were her sister, who lived out of state. She had a few close friends, but their families were also affected by the September 11 attacks, and she did not want to be a burden to them by talking about her fears and loss. Ben's father was also worried about his wife. He noted that he coped with stress "by being a workaholic." Both parents continued to watch the television coverage of the events, usually at night after their children had gone to bed. They stated that they tried to avoid talking about the terrorist attacks in front of their children because they "did not want to upset their children further."

The therapist continued to meet with Ben and his family. Family sessions were held, in addition to individual sessions with Ben and sessions with his parents. Family sessions focused on encouraging the family to communicate more directly with each other and to express their feelings of grief and anxiety. The therapist helped to normalize Ben's parents' reactions by explaining to them that their feelings of fear were normal reactions to an extreme situation. She encouraged them to use their supports, including their friends and family. She helped them to develop coping strategies. Ben's mother had stopped exercising after the attacks, an activity she had previously enjoyed. Ben's father was able to reduce his work hours and spend

more time with his family during the crisis. Both parents were advised to decrease the amount of time they spent watching television. The therapist explained to them how their reactions and defenses affected their children. Ben's parents were given guidance regarding how to talk to their children. They were encouraged to listen to their children, and they were taught how to understand their children's feelings and behaviors. In particular, the therapist helped Ben's parents to understand how his difficulties with separation and school refusal were related to their responses and anxieties, especially his mother's worries. The therapist helped Ben's parents to understand his experience and how he was feeling guilty that he may have caused his uncle's death by not visiting him. The importance of returning to a regular routine and ordinary daily life was emphasized. This included making sure that Ben's parents were consistent in helping him to attend school every day. To facilitate his return to school, the therapist spoke with his school counselor to collaborate on treatment. It was agreed that Ben's mother would drop him off at school and the school counselor would meet him at the school door. Ben would meet with the counselor every day during the first week. He would also be allowed to call his mother during the first week. The therapist and school counselor agreed to collaborate and communicate regularly to make appropriate adjustments to the treatment plan as needed. In addition, once Ben returned to school, he would participate in a peer group that the school counselors had developed to help children with similar experiences and losses.

The therapist also met with Ben individually. She helped to reassure him that the adults in his life, including his parents and teacher, would do their best to make sure that he and the other children were safe. Ben's therapist helped to normalize his feelings, explaining to him that other children also experienced feelings of sadness, anger, fear, and confusion. She facilitated his symbolic expression of his feelings by supporting and joining him in play and in art projects. She listened to him when he expressed his feelings verbally and clarified his feelings by helping him to find words to name his emotions. She avoided probing questions, and followed Ben's lead. Ben's attachment and identification with his uncle was actively facilitated by helping him remember and talk about his uncle.

FUTURE DIRECTIONS

The continuing frequency of terrorist events around the world and their effect on children and families underscore the urgency for an effective public health approach for providing for the needs of children and their families. Mental health organizations and providers must be educated and prepared to help children in the aftermath of terrorist activities. Terrorism is a community mental health issue because terrorism is a form of psychological warfare whose target is to intimidate and cause fear. Several mental health activists have made recommendations to help communities organize and plan appropriate interventions and treatments. Collaboration among community, educational, and mental health care organizations is essential. In addition, collaborative efforts between mental health organizations nationally and internationally have been initiated and continue to grow and develop. In the United States, the mental health approach to disaster has developed over several decades, primarily based on experiences with natural disasters. Following the 1995 Oklahoma City bombings, many modifications to the federal approach were made, including more effective crisis intervention methods and better triage and referral services, to address the unique effects of violent acts of terrorism. The effect of the events of September 11, 2001, further emphasized the difficulties in identifying the extent of services needed, the scope and depth of personnel and funding necessary to provide services, and the anticipated

duration of treatment. The lack of sufficient data and comprehensive information prevented adequate funding by federal mental health agencies to address mental health needs of children and their families. Obtaining money and resources will continue to be a significant challenge. Advocacy for program development and funding to increase community services for children affected by terrorism is needed.

Trained mental health providers who have experience working with children are needed to identify children at risk and provide community-wide services and more intensive treatment interventions. Standards for mental health providers who work with children and families exposed to terrorist events should be established.

The correlation between media exposure of terrorist events and traumatic stress symptoms in children is well documented. Collaboration between community agencies and the media is necessary. Public policy limiting media coverage is a controversial issue but needs to be addressed.

The research on childhood reactions to terrorism-induced trauma highlights the need for a systematic public health approach that provides community-based interventions, screening of children at risk, triage and referral services, community-based trauma and loss programs, and multimodal outcome studies. During the last decade, policy and procedures for the conduct of organized interdisciplinary research have received more attention. These advances resulted in more cooperation between researchers to address the issue of how ethically to obtain research data during times of crisis. Planning to incorporate research infrastructures into disaster preparedness plans is necessary. Further research on terrorism and its unique effects on children and families should be encouraged. More research on the effects of early interventions and treatment is needed to provide for reliable mental health response planning. Further research identifying children who are at risk for developing PTSD and related symptoms will allow for more efficient triage services. Studies on longitudinal effects and the long-term effect on development in children exposed to terrorist violence will provide information useful for initial and later treatment interventions. More reliable and objective measures are needed to quantify parents' reactions and the effects of social supports. Methods for evaluating a child's intrinsic resiliency will help to differentiate coping models learned from parents. Assessment of the capacity of the public health system to respond to terrorist events will help to determine optimal response recommendations for the future. Efforts should be focused on increasing community services for children affected by terrorism and encouraging further research on terrorism and its unique effects on children and families. Responses from mental health providers and organizations, educators, spiritual leaders, and community organizations will be better able to help children to cope and will minimize long-term psychological problems to enhance healthier outcomes and

growth.

▲ 55.12 Impact on Parents of Raising a Child with Psychiatric Illness and/or Developmental Disability

ALICE R. MAO, M.D., DIANE E. TREADWELL-DEERING, M.D., MATTHEW NEIL BRAMS, M.D., AND PIETER JOOST VAN WATTUM, M.D.

INTRODUCTION

The birth of a child is generally anticipated with joy and a myriad of feelings. Parents have conscious and unconscious wishes about the child's appearance, temperament, personality, and other characteristics based on past experiences, hopes, and dreams. Expectations develop about the child's developmental course and future, including education, career, and generational continuity. Parents also have expectations for themselves in their new roles which are shaped by past experiences and other important role models. One of the important tasks of parenthood is the adaptation and modification of these fantasies and hopes to match the reality of the actual child and his or her abilities.

The task of raising a child requires fostering autonomy while providing appropriate limit setting at each developmental stage. The child has an increasing need for separation and individuation as he or she moves into adolescence and then into adulthood, which must be combined with nurturing parental structure and support. Ultimately, the goal is for the child to become an adult who is able to successfully form relationships, support himself or herself, and take on a socioculturally defined mature family and societal role. Unfortunately, if a child is not developing normally or is suffering from a psychiatric disorder that is affecting multiple domains of functioning, his or her ability to achieve these goals is compromised and caregiver burden is increased.

When a child is diagnosed with a psychiatric or a developmental disorder, parents typically undergo a complicated adjustment and grieving process. This may include anger or sadness that their child is not developing normally, coping with the narcissistic injury that the "imperfect" child is a negative reflection of their parental competency. In addition, parents may irrationally blame themselves for causing a disorder to manifest in their child. Disorders with heritable causative factors may lead to parental self-blame and/or blame from nonaffected family members. The contrast between the imagined parenting experience of raising a normally developing child and the reality of caring for a child with a psychiatric and/or developmental disorder may lead to intense disappointment and increased caregiver burden.

This section reviews the effect on parents and caregivers of raising a child with serious psychiatric disorders, specifically bipolar disorder (BPD),

attention-deficit/hyperactivity disorder (ADHD), schizophrenia, and autism/developmental disorders. Unique stressors faced by parents raising children with these disorders compared to normally developing children are summarized. Psychological responses and coping in response to these stressors and research on specific interventions developed to help parents and family members cope effectively are reviewed. Individual psychotherapeutic work with parents of psychiatrically ill children may be enhanced by understanding the life-changing consequences of dealing with a chronic mental illness or developmental disability. Importantly, the parent's ability to implement complex and multimodal treatment interventions for their child is affected by their responses to their situation. Early and effective intervention for parents after their child receives a psychiatric diagnosis may improve the long-term outcome for the child.

IMPACT ON PARENTS OF RAISING A CHILD WITH AN AUTISTIC SPECTRUM DISORDER

Introduction

In the mid-1940s, Leo Kanner and Hans Asperger independently reported on disorders in childhood that were characterized by difficulties in social interaction, presence of repetitive or stereotyped behaviors, and language abnormalities. Initial reports included observations of similarities between parents and their affected children. Asperger suggested possible genetic factors; however, prevailing theories attributed the children's symptoms to their parents' behaviors. Currently, the autistic spectrum disorders (ASDs) are clearly recognized as biologically based neurodevelopmental syndromes.

Unique Stressors

Psychiatrists caring for parents of people with ASDs will be better prepared if they are aware of the myriad of issues that may affect families. This subsection points out the unique stressors associated with raising a child diagnosed with ASD; highlights issues related to the life cycle of the family; summarizes findings from studies of parents' coping with raising a child with ASD; discusses the psychiatric disorders common in these parents—including the "broad autism phenotype" (BAP)—and suggests some approaches to therapeutic work with this population.

The parenting of any child with special needs, especially if accompanied by intellectual disability (ID), is stressful. However, parents of children with ASD cope with unique and more intense sources of stress. These include the uncertainty of diagnosis, the prolonged duration of the diagnostic process, the extreme variability in the child's developmental course, the effect of the child's atypical social communication, the child's typically normal physical appearance, and the burden on parents of

creating and organizing the child's treatment program.

Diagnosis of ASD is often delayed when primary care providers do not screen for or recognize signs of developmental disorders. Referrals to subspecialists may be time consuming and lack definitive results. Siklos and Kerns reported that parents saw an average of 4.5 professionals and waited almost 3 years to obtain a diagnosis. More than 50 percent of parents were dissatisfied with the diagnostic process. Mandell and Palmer found varying ASD prevalence rates when comparing states based on their practicing number of pediatricians and education-related spending. This is further evidence of continued difficulty in obtaining a timely diagnosis and accessing care. Suboptimal disciplining techniques used prior to the correct diagnosis result in caregiver loss of confidence and self-efficacy.

The spectrum of autistic disorders is very broad; therefore, predictions about a specific child's progress are imprecise. Irregular patterns of skill development are common. Developing appropriate expectations for a child and predicting future development is challenging for most clinicians because of wide variations in developmental progression.

Abnormalities in social communication appear to be a particular source of distress for families. Safronoff and Farbotko in 2002, found autistic children's difficulties with verbal and nonverbal communication result in parents feeling unable to meet their child's wants or needs. The inability to understand their child and his or her behavior is significantly more frequently reported by mothers of autistic children than control mothers.

Lack of consistent behavior across time, people, and environment is frustrating and confusing for parents. Children with more obvious impairments, such as those affected with Down syndrome, are excused and tolerated by others, but the typically normal physical appearance of a child with autism leads others to expect appropriate behavior. Fear of their child's unpredictable, disruptive, and unusual behavior, as well as others' responses to it, leads parents to avoid public situations, which in turn leads to restriction of family activities, social isolation, and increased burden in completing everyday household chores, such as grocery shopping.

Typical recommended interventions for children with ASD are obtained from several different systems—public education, ancillary health care therapists, and hospital-based, center-based, and community private practitioners. The family is typically left in charge of coordinating a complicated network of professional providers, who have differing opinions, recommendations, physical locations, and financial/insurance requirements. The lack of curative interventions from traditional care providers, the lack of empirically supported therapies, the nature of ASD symptoms, and the chronicity of these disorders have led to the emergence of unconventional treatments by alternative practitioners with poorly supported claims of cure or rapid improvement. The family is confronted with the challenge of obtaining intensive treatment for their child during a

critical time frame with little professional guidance.

Lifespan Issues

Each developmental stage presents the family with unique and specific issues. Early childhood is characterized by the family's realization of an abnormal developmental trajectory, the diagnostic process, and issues of definitive diagnosis. Parental guilt, mourning the "lost," normally developing child, the responses of extended family members, and the possible additional diagnosis of ID are all issues that color this period. The child's irregular sleep patterns, hyperactive behavior, lack of effective communication, and peculiar eating and elimination habits, as well as safety issues and the lack of ability to obtain appropriate day care or child care, are practical concerns facing most parents. Accepting the diagnosis, finding community services, and planning for the future are tasks for the family. Families report that education about the disorder and information about resources were the most helpful interventions they received. Other useful resources were learning and behavior assistance, speech therapy, and family support.

With a good school program, middle childhood may be a relatively easier life phase. Behavior problems often improve; families have adjusted their expectations of the child and have accepted the delays in development, abnormal social interaction, and communication. Developing an educational program that includes the necessary special education services, offered in the setting that is most successful for the child's learning, is the goal of collaboration with the school system. The focus may be on the development of adaptive behaviors in the areas of self-care, domestic chores, and social behaviors. Parents may grieve anew as they recognize the child's inability to participate in team sports, engage in birthday parties, and other social activities that they see normally developing children doing. Sibling issues, which may occur at any time, are common. The affected child behaves oddly, is not a typical playmate, and requires much of the parents' time and energy. Parents often overestimate siblings' abilities to understand the implications of autism and underestimate siblings' worries.

By adolescence, almost all families report worries about their child's future. Public education services end, and adult services may be uncertain. Aggression, increased sexuality, and increased sense of independence without the skills for self-management are among behavioral concerns. Higher-functioning children may become aware of their differences from peers. Nonaffected siblings may be leaving home, creating a higher burden of care for parents who have relied on their help. The aging of grandparents may also lead to less support and greater family strain.

The most pressing issues for adulthood are appropriate living arrangements and vocational opportunities. The move toward

deinstitutionalization has eliminated the option of residential placement for most families, and many adults with autism continue to live with their families. There are limited opportunities for appropriate social experiences and employment. Young adults with comorbid ID may find services through this diagnosis. Individuals with higher cognitive skills often continue to lack job-related skills and remain un- or underemployed. Seltzer et al. compared children with a developmental disability versus typically developing children and found 57 percent of parents aged 50 or older live with their child with developmental disorder versus 16 percent of normally developed children. Guardianship and long-term estate planning are worrisome issues for parents. The divorce rate has been found to be higher in parents of autistic children when compared with parents raising normally developed children (25 percent vs. 13 percent). Distinct from typically developing children, where the divorce rate is high until approximately age of 8, the likelihood of divorce remains high through early adulthood for parents of children with ASD. The financial strain for therapeutic interventions cannot be overlooked; Lord and Bishop found the economic impact is 3 to 5 million dollars more than for a typical developing child.

Psychological Responses to Raising a Child with an ASD

Stress. Many published studies have documented that parents of children with ASD report more stress than parents of children with other developmental disorders or of typical children. A variety of factors have been found to cause and/or mediate this, the most important of which is gender. The preponderance of studies examining gender differences in parental response soundly endorse the observation that mothers report significantly more stress than fathers in general and within given family units. Explanations for this finding include that mothers shoulder the greater burden of child care, even if they work outside the home; perceived parenting competence contributes more to mothers' self-esteem than to that of fathers; and fathers use more effective coping strategies than mothers.

Most studies support a positive correlation between the amount of stress mothers report and the behavioral problems of the child. These behaviors include oppositionality, noncompliance, aggression, irritability, and unpredictability. None of these are core features of ASD, but they often accompany these disorders. Neither the severity of the ASD per se nor the level of adaptive functioning was found to correlate with reported stress or poor maternal outcome. However, these were not universal findings, and other authors have found that autism severity or the amount of services the child received, which was interpreted as a measure of autism severity, did correlate with levels of maternal stress.

Several studies have aimed at understanding factors other than the

child's autism that affected the well-being of individual family members. Factors such as the partner's depression and anxiety were positive predictors of stress for both mothers and fathers. Attributes of the affected child were predictors for maternal but not paternal stress.

Factors that have been found to decrease stress for parents include positive coping styles, belief in the efficacy of treatment, and social support. Parent education and the acquisition of behavioral management skills have also been found to be beneficial. Greater marital quality is predictive of lower levels of stress.

Coping. Coping is defined as "a process by which individuals respond to threats of stress." These strategies are generally divided into two categories: (1) emotion-focused strategies, which aim to reduce or mask feelings of distress, including engaging in denial, hoping for miracles, having fantasies, using food or drugs, and distancing and avoiding; and (2) problem-focused strategies, which aim to solve or change the problem, including confrontive coping, fighting for what is wanted, expressing anger and other feelings, taking chances, and engaging in positive reappraisal. Several studies have examined the consequences of particular coping styles for parents of ASD children. Emotion-focused styles have been found to correlate with increased depression, isolation, and marital problems. Pottie found that escape, blaming, withdrawal, and helplessness lead to decreased positive mood, whereas problem focused, social support, positive reframing, emotional regulation, and compromise coping resulted in a positive mood. Conversely, problem-focused coping was associated with lower levels of depression. Moreover, coping style more robustly predicted levels of depression than locus of control and social support, although these factors were also contributory.

Research on coping over time suggests that, in general, young adults are more likely to use problem-focused strategies, and middle-aged adults use more emotion-focused methods. Gray found evidence for this in his longitudinal study of coping with children with ASD. Religion and faith became much greater in relative importance as a coping strategy; attachment to the child and greater appreciation for his or her good qualities also emerged as more common strategies. In general, the use of an array of coping strategies is beneficial, although Gray found that parents used fewer strategies over time. Studies show mixed findings regarding increased effectiveness of coping as parents age. Fitzgerald reported that advanced age of affected ASD children was associated with better maternal mental health, implying adaptation on the part of the mothers. However, Smith et al. found high levels of depression in parents of both toddlers and adolescents.

A rare focus on fathers revealed that fathers of children with ASD or Down syndrome reported more use of wish-fulfilling fantasy and

information seeking than control fathers. More effective paternal coping has been hypothesized as the explanation for decreased levels of stress reported by fathers compared to mothers.

Studies show that fathers use avoidance and engagement in outside activities more frequently as coping strategies than mothers.

Tunali and Powers proposed a model of cognitive strategies that would facilitate coping for mothers of children with autism. These strategies included greater emphasis on being a "good mother" rather than on career development; greater frequency of recreation with family members rather than individual recreation; less emphasis on individual leisure; less emphasis on others' opinions of child-rearing practices; greater emphasis on parenting and partner support than on intimacy and shared leisure in marital relationships; and higher tolerance of ambiguity.

Quality of Life. Several authors have used the conceptual framework of "quality of life" (QOL) to understand the impact of rearing a child with an ASD. Defined by the World Health Organization as "individuals' perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns," QOL is a multidimensional concept that includes physical and mental health, relationships, and personal beliefs and values in relationship to the environment. On the World Health Organization Quality of Life-BREF, parents of children with pervasive development disorder (PDD) were compared to parents of children with mental retardation (MR), cerebral palsy (CP), and typical development. Parents of children with PDD showed a significant impairment in QOL as compared to the other groups, whereas few differences were noted between the MR, CP, and typically developing groups. Within the PDD group, mothers had lower QOL than fathers. These differences were posited to be caused by the stress of raising children with severe developmental disorders, the presence of the BAP in the parents or other family members, and parental psychiatric disorders. Analysis of data from the 2003 National Survey of Children's Health (NSCH) revealed significantly poorer QOL in families of children with ASD when compared to families of children with ADHD or typical controls, most notably in the areas of burden of care and isolation. In a population-based study of psychological functioning and coping, mothers of children with ASD rated their overall health as comparable to mothers of nonaffected children, but they reported poorer mental health. In a study of health-related QOL in parents of children with high-functioning autism (HFA) or Asperger syndrome, mothers had lower physical health scores than fathers of affected children and control mothers.

Psychiatric Disorders and the Broad Autism Phenotype

As data were gathered supporting the role of genetics in autism, the idea

gained momentum that the genetic liability for ASD may also be expressed in nonautistic relatives of autistic probands with qualitatively similar but milder behavioral and cognitive features of autism. The concept of BAP is supported by co-twin studies and family studies of siblings and parents. Subsequent work has refined the description of this phenotype, which includes social impairments, communication impairments, and rigidity. Social difficulties include lack of interest in social interaction and lack of close, confiding relationships. In one study, 37 percent of parents of children with ASD reported no friendships, compared with only 4 percent of parents with Down syndrome controls. Communication problems are pragmatic, referring to deficits in the social aspects of language. Clear-cut obsessional and repetitive behaviors occur infrequently; however, rigidity, characterized by resistance to and difficulty in accepting change, is more common. These differences in language, anxiety, rigidity, and communication may cause parents to feel inadequate to help in the behavioral treatment of their children who experience similar impairments. Bolton reported that the BAP was seen in 20 percent of siblings of those with autism versus 3 percent of siblings in the control group. Similar rates for parents have been reported. Bishop et al. reported that 10 of 65 (15.4 percent) of mothers and 17 of 46 (40 percent) of fathers were found to have BAP. Ingersoll et al. (2011) found parental BAP was associated with less social support, increased stress and higher rates of depression. Ingrams et al. found expressing BAP used maladaptive coping strategies.

Studies that focused on the stress of raising a child with autism have found increased rates of several psychiatric disorders in parents of affected children, most robustly major depressive disorder (MDD) and social phobia. Piven and Palmer reported major depression in 33 percent and social phobia in 14.6 percent of proband parents in comparison to 11.7 and 3.3 percent, respectively, in Down syndrome parent controls. Smalley et al. found a lifetime prevalence of major mood disorders in 40.3 percent of parents and 32.4 percent of siblings of children with autism, compared to 19.2 percent of parents with children with tuberous sclerosis or seizures. With regard to major depression, the increased risk does not appear to be due to raising a child with ASD, given that the majority of depressed parents had their first episode prior to the birth of their affected children. Moreover, these psychiatric disorders have not been found to be associated with the presence of BAP. Potential explanatory models for these findings have involved overlap of the risk alleles that are common to both autism and recurrent mood or anxiety disorders or a result of assortative mating of parents with BAP, with spouses with major depression, or social phobia. Other anxiety disorders, mood disorders, and substance use disorders have also been reported to occur more frequently in parents of children with ASD in comparison to control groups of general population parents or

parents of children with other developmental disorders.

Summary

The task of parenting a child with an ASD is a stressful, lifelong process that significantly affects all of those involved. Those caring for such parents need to be aware of the nature and magnitude of this undertaking. Encouragement to become active in the child's therapies, join available support services, and use positive coping strategies is warranted. Monitoring for the development of depression and anxiety disorders and conducting an evaluation for the broader autism phenotype are also indicated. Although specific data are not available for ASD, cultural factors color parents' beliefs about their children's mental health conditions and need to be considered by mental health practitioners who treat the parents.

IMPACT ON PARENTS OF RAISING A CHILD WITH BIPOLAR DISORDER

Introduction

Clinicians and researchers have become increasingly aware of the tremendous burden that is placed on parents and caregivers who are raising a child with BPD. Previous theories implying that the dysfunctional family system is causing the illness in the child, have been replaced by the realization that the child's illness is negatively impacting the family. There is growing evidence to support interventions for family members and caregivers of patients with BPD because decreasing stress may improve long-term outcomes for the family and the child.

Unique Stressors

Research has shown that children, adolescents, and adults who have BPD have severe global impairments in multiple areas of functioning. They are at higher risk for academic failure, poor interpersonal relationships, substance abuse, psychosocial and occupational difficulties, legal problems, suicide attempts, and neuropsychologic deficits. In many cases, the parents of children with BPD may also be struggling with their own mood disorders. The child's unpredictable course may create additional stressors that exacerbate parental illness, leading to impaired parenting. Emotional dysregulation in parent and child may increase conflict and compound family stress. Not only is an episode of illness stressful for each of the family members, but also the fear of relapse is present even when the illness is stabilized.

The diagnosis of pediatric-onset BPD is imprecise. However, there is agreement that the presentation of BPD in children and adolescents differs substantially from the presentation in adults. In contrast to the discrete episodes of manic or depressive symptoms observed in adults, children usually exhibit ultradian cycling, irritability, explosive temper outbursts,

and decreased frequency of interepisode recovery. Due to the unpredictable nature of the illness presentation, accompanying affective instability, and often violent or aggressive behaviors, the caregiver role can be demanding, distressing, and harmful to health and QOL. Frequently, the diagnosis of BPD is delayed because the child's behavior is initially labeled as oppositional or defiant; therefore, appropriate pharmacotherapy and psychotherapy interventions are also delayed.

Lifespan Issues

Parents of children who begin exhibiting symptoms of BPD are generally bewildered by the child's mood swings, disruptive behaviors, and general inability to conform to their same-aged peers. Most often the children appear developmentally normal and have normal intellectual functioning, and so they do not come to the attention of school staff or teachers until they exhibit disruptive behaviors or receive failing grades. Practitioners are often reluctant to diagnose a child with BPD. These children have been described as "diagnostically homeless" because they often exhibit symptoms that can fit the criteria for multiple disorders, such as ADHD, mood disorder not otherwise specified, conduct disorder, and intermittent explosive disorder. When the diagnosis of BPD is finally made, parents have described experiencing an array of emotions ranging from relief to depression.

Adolescents with BPD are even more challenging to parents because their desire for autonomy, coupled with impaired judgment, can lead to harmful consequences. Parents struggle to set limits with adolescents exhibiting promiscuous behavior, dangerous driving habits, substance abuse, and oppositional behaviors. Frequently, the adolescents are not compliant with pharmacotherapy because the medications have side effects such as weight gain or sedation. Some adolescents perceive that the medications alter their personality, making them more subdued and socially inhibited. They frequently take little responsibility for the consequences of their actions and tend to perceive their parents as being overly controlling rather than appropriately protective. Parents struggle with guilt, self-blame, and feelings of helplessness because they can no longer physically restrain the adolescents if they choose to leave the home or refuse to take their medications.

Parents of adults with BPD face the greatest obstacles because they have limited legal recourse to protect or help their children if treatment is refused. Because adults have euthymic episodes with longer periods of interepisode recovery, they may cycle into depression or mania without parents being aware of the polarity switch. Consequently, reinitiating treatment may be delayed. During acute episodes, adults with BPD frequently alienate parents, spouses, or other caregivers with their aggressive, abusive, or impulsive behavior. Parents may be overly taxed by

the responsibility of emotionally and often financially supporting their adult child.

Caregiver Burden

The effects on caregivers of living with an ill relative have been defined as family burden. The burden of caring for a psychiatrically ill family member has been divided into two categories:

1. *Objective burden* is any disruption to family or household life that is verifiable and observable. Examples of objective burden include high rates of separation and divorce in marriages with a psychiatrically ill spouse; restricted social and leisure activities, often related to fears of stigma; and financial difficulties.
2. *Subjective burden* involves the personal feelings of carrying such a burden, such as feeling distressed, unhappy, or upset. The types of subjective burden experienced include guilt if the relative feels responsible for contributing to the illness; rejection toward the patient; anger that the illness has spoilt the relative's life; and grief and a sense of loss contrasting the present with memories of the person before the illness occurred and the diagnosis was made. Subjective burden experienced by relatives has been linked to the development of affective symptoms.

Review of Research on Caregiver Burden for Bipolar Disorder. There are limited data on degree of stress experienced by caregivers of children with pediatric BPD. Some information about the consequences of caring for a family member with BPD can be obtained from studies of caregivers of adult bipolar patients. Factors affecting family burden experienced by caregivers of adult patients with BPD include prolonged illness and high levels of dysfunction among patients, as well as caregiver illness beliefs and coping style.

The Family Experience Study, a longitudinal study of the primary caregivers for patients with BPD, examined the cost and consequence of caring for a relative or friend with BPD. Primary caregivers were evaluated within 1 month after patients entered the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD), using measures of burden, coping, physical health, mental health, resource utilization, and cost. At study conclusion, more than half of the caregivers experienced moderate or high-burden levels, which were related to patient problem behaviors, interference with caregivers' ability to fulfill other role obligations, or disruption of household routine. Caregivers experiencing higher-burden levels reported more physical health problems, depressive symptoms, behavior associated with greater health risk such as smoking and drinking, health service use, and more limited social support than less

burdened caregivers. They also reported having to provide more financial support to their bipolar relative.

Most adult patients with BPD spend more time in periods of remission or with subthreshold symptoms than in an acute episode; however, most studies of caregiver stress are completed when patients are acutely ill, which may overestimate stress. In one study, investigators focused on stress in caregivers of euthymic adult bipolar patients aged 18 to 65, during periods of subthreshold symptomatology. Caregivers showed a moderate level of subjective burden on the Social Behavior Assessment Schedule. The variable most highly related to caregiver distress was found to be the patient's behavior (hyperactivity, irritability, sadness, and withdrawal). Parents were most worried about their children's abilities to perform at work, in school and in social relationships.

Subjective and Objective Burden. Factors that increase caregiver's subjective burden are poorer patient social and occupational functioning, a relapse during the previous 2 years, and history of rapid cycling. Rapid cycling is defined as having four or more episodes of mania or depression per year and is found in a significant fraction of patients with BPD. It has been associated with greater disability and worse prognosis as evidenced by higher use of intensive psychiatric interventions.

Risk factors that have been associated with increased objective burden levels include caregiver responsibility for medication administration, violence from the patient, caregiver social isolation, rejection by the patient during periods of illness, and patient irritability leading to more frequent arguments and conflicts. Some studies have suggested that the effect of clinical variables can be mediated by caregiver coping styles and their level of understanding of the patient's illness and symptoms.

Raising a child with BPD can be complicated if the parent is also suffering from a mood disorder. Research has shown that the offspring of parents with BPD have increased risk for inheriting mood disorders. A meta-analysis of 17 studies of offspring of parents with BPD found that 52 percent of offspring had challenges with the interpersonal, cognitive, and behavioral manifestations of BPD are even less capable of coping with the burden of raising a child with BPD.

Interventions

Family interventions for BPD are generally psychoeducational, with the goals of teaching family members the signs and symptoms of BPD, developing strategies for intervening early with new episodes, and providing consistent medication regimens. The psychoeducational approach recognizes that lack of information about the disorder, compounded by uncertainties about the future, can increase caregivers' stress. Thus, in addition to providing information, clinicians address the

patients' and family members' affective reactions to the illness, its prognosis, and expected treatments and assist them in developing coping strategies relevant to their individual situations.

Although there are some randomized, controlled trials that highlight the positive benefit for the patient of family-focused treatment in addition to pharmacotherapy in BPD, few trials using contemporary methodologies have analyzed the specific effects of caregiver-focused interventions. A randomized, control trial published in 2008, studied the impact that interventions for caregivers had on relapse rates in the euthymic bipolar patients they cared for. Caregivers in the experimental group were provided twelve 90-minute sessions that focused on knowledge of BPD and training in coping skills. The patients did not attend the groups, but were assessed monthly during both the intervention and at the 12-month follow-up. The patients whose caregivers attended the intervention group experienced fewer recurrences than those in the control group. In addition, when type of episode was analyzed separately, significant differences were found in the number of subjects who experienced a hypomanic/manic relapse and the time to such an episode. The differences in depressive and mixed episodes did not reach statistical significance.

Relapse prevention may improve by facilitating early identification of the first signs of an episode, leading to earlier intervention. Additional benefits include dispelling caregivers' misconceptions about the illness and issues such as caregiver criticism or overinvolvement. Some studies have shown that family psychoeducation also increases a mutual understanding with the patient. It also increases positive interactional behaviors and reduced expressed emotion. High expressed emotion with negative affective style and family burden have been related to poor illness outcome.

A 2002 pilot study of manual-driven, multifamily psychoeducation group (MFPG) treatment for families of children with mood disorders represents a rare study focused on pediatric subjects. It addressed two questions: Do families of children with BPD and families of children with MDD or dysthymic disorder (DD) differ at treatment entry, and do they benefit equally from intervention? Conclusions were that BPD families entered treatment with more impaired children and more extensive treatment histories than families of children with MDD or DD; however, all families benefited from intervention. A qualitative analysis revealed that families in the study gained emotional support, improved coping skills, and decision making as it related to their child's illness, shifted their attitudes with regard to the illness, and experienced improved interaction with their affected children. Clinical impressions suggested that interventions combining families of children with BPD and depressive spectrum illnesses were clinically feasible and potentially beneficial. The authors suggested that intervention modalities geared toward families of children with BPD may also include families of children with other mood disorders, given that

both groups may benefit from these types of interventions.

Conclusions

Although most treatment research has focused on pharmacotherapy for pediatric BPDs, a growing literature suggests that psychosocial interventions are also important to provide families with an understanding of symptoms, course, and treatment of BPDs. Interventions to teach youth and parents methods for coping with symptoms (e.g., problem solving, communication, emotion regulation, cognitive-behavioral skills) and prevent relapse have been shown to be helpful to parents. Identifying and addressing stressful aspects of raising an individual afflicted with BPD could reduce the emotional burden and potential negative impact on the caregiver's mental health and QOL. Gaining support from other parents who are raising children with BPD may reduce feelings of guilt, self-blame, and inappropriate feelings of responsibility for their child's condition. Moreover, providing support for the parents may ultimately improve the child's outcome. With support and education, parents are better able to implement multimodal treatment interventions needed to improve adaptive and functional outcomes for their child. In cases of multigenerational BPD, treatment of the parent's mood disorder can also have a positive effect on the child's symptoms, which can bolster parental perceptions of self-competence. In conclusion, psychosocial interventions that involve families, psychoeducation, and skill building may offer added benefit to pharmacotherapy interventions.

IMPACT ON PARENTS OF RAISING A CHILD WITH ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

Introduction

Parenting a child ADHD has challenges similar to those faced by parents of children with other developmental and/or behavioral disorders, including increased parental stress, marital discord, and maternal depression. Advocacy issues and long-term care concerns, although present, are generally less urgent. Nonetheless, rearing children with ADHD involves separate and unique aspects of care that are influenced by both child-derived and parent-derived characteristics. Complicating this scenario is the likely interaction among these characteristics.

Effect of Child Characteristics on Parenting Stress

Several authors report increased parenting stress in mothers with children of ADHD. Child characteristics of ADHD that specifically correlate with parental stress are the severity of ADHD symptoms, aggression, oppositional behavior, and, to a lesser degree, the presence or absence of medical illness in the child. This highlights the effect of comorbid and

associated symptoms on the level of stress within the ADHD family.

Unlike most children with more severe disabilities, children with ADHD, especially of a more moderate level of severity, are expected to master the developmental challenges of typical childhood, adolescence, and adulthood. From kindergarten through middle school, they are expected to relate to peers, join extracurricular peer group activities, participate in sports, and succeed in mainstream education. In adolescence, they drive cars, date, work, and attend school. They are expected to enter early adulthood with the typical goals of learning a trade, going to college, obtaining employment, and establishing long-term relationships and friendships. However, due to the core symptoms of inattention, impulsivity, and/or hyperactivity in these children, these goals are not always readily met. Studies show that children with ADHD, especially those with a hyperactive/impulsive component, are at much higher risk for accidental injuries and trauma, emergency room visits, motor vehicle accidents, grade retention and high school dropout, drug use, unplanned pregnancies, and sexually transmitted diseases. In addition, more than half of these children were fired from one or more jobs by age 21 years. These consequences of ADHD create stress within the family and can lead to a higher incidence of parental divorce or marital discord and child abuse.

Effect of Parent Characteristics on Parenting Stress

Parenting stress is also correlated with specific attributes of the parents who are rearing children with developmental disabilities. For example, maternal depression and the perception of one's share of caretaking burden have been linked to increased stress in parents raising children with autism. Similarly, in Anastopoulos' study of mothers of children with ADHD, parenting stress, as measured by the Parenting Stress Index (PSI), correlated highly with maternal psychopathology (e.g., depression, BPD) and lack of employment outside of the home. Seipp et al. reported that during observed mother–son interactions with boys with ADHD, mothers with greater overt hostility had less positive parenting behavior, which was associated with greater oppositionality in the son. Moreover, mothers with sons with ADHD and comorbid oppositional defiant disorder (ODD) were less responsive to their child's needs and more overreactive than control mothers. This finding may be more directly related to specific maternal or child characteristics or the interplay between the two.

Rearing a child with ADHD is greatly complicated if one or both parents share this diagnosis with their child and struggle with similar cognitive and behavioral manifestations of the illness. It is estimated that 40 to 60 percent of adults with ADHD are rearing an affected child. Because the prevalence of ADHD in adults is estimated at around 4.5 percent, there are millions of parents with ADHD rearing children with ADHD. This situation creates a multitude of additional management issues, increasing the

family's stress level. The parent without ADHD may be unfairly burdened with responsibility for managing the child with ADHD. Parental ADHD, especially if untreated or poorly managed, may contribute to parental neglect, inadequate supervision, inconsistent and inappropriate discipline, and increased parent–child conflict. Furthermore, maternal depression and early maternal negative parenting techniques are predictors of future conduct problems in children with ADHD. Conversely, early positive parenting techniques, including positive feedback, praise, and optimistic affect, are associated with fewer conduct issues.

Mrs. M, a 34-year-old homemaker and mother of two, had been married to a pharmaceutical sales representative for 10 years. Both her 8-year-old son and her husband were diagnosed with ADHD, although only her son was medicated. He continued to have significant impulsive aggression directed toward his younger sibling, serious academic struggles, and poor peer relationships secondary to "immature behavior." Her husband had poor job performance, with deficient organizational skills and failure to attend important meetings due to "forgetfulness." He was reluctant to take medications because of fears of side effects and "drug dependence." Mrs. M's family of high achievers compared her unfavorably to her more accomplished sister and her family. Moreover, her family had a history of depression, and Mrs. M presented with several neurovegetative signs, but worries of stigma interfered with her pursuit of treatment. She and her husband had discussed divorce. She had no sources of emotional support and felt overwhelmed.

Clinical Implications

The assessment of patients who are parents needs to include consideration of the patient's ability to meet the demands of parenthood, especially in the presence of a childhood psychiatric disorder. The consequences of rearing a child with ADHD should not be underestimated, especially given the frequency with which the disorder also affects one of the child's parents. Proper attention to child-based and parent-based characteristics associated with ADHD, as well as to the interplay of these factors, can lead to decreased stress for the parents and improved functioning for the child and for the family as a whole.

IMPACT ON FAMILIES OF RAISING A CHILD DIAGNOSED WITH SCHIZOPHRENIA

Introduction

The National Institute of Mental Health estimated that in 2002, 1.1 percent of the population suffered from schizophrenia. The estimated yearly cost of schizophrenia in the United States was 62.7 billion dollars in 2002. Globally, the cost is estimated to be between 1.5 percent and 3 percent of national healthcare budgets. This subsection discusses the burden borne by parents and siblings of a child with schizophrenia. Whereas the other disorders discussed in this section are usually observed earlier in the child's life, schizophrenia typically develops between the mid-teens to early 30s, with rare cases of earlier onset after a significant period during which the

child appeared to be on track to become a healthy, independent adult.

Early psychodynamic theories of schizophrenia focused on the role of mothers of patients with schizophrenia. They were often called "schizogenic" or "schizophrenogenic," and their lack of maternal warmth was, without any sound scientific evidence, blamed for their child's development of schizophrenia. Only in the mid-1960s was this concept countered, and since then schizophrenia research has been approached from a biopsychosocial perspective based on the notion that expression of the disorder is due to a genetic predisposition combined with exposure to environmental and individual stressors. This puts the role of the parent and family in a different light.

Caregiver Burden

To better assess the issues with which families of schizophrenic patients grapple, Hoenig and Hamilton introduced the concept of "family burden," which was defined earlier in this section. The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study found four factors that caregivers identified as most burdensome in their experience with their ill family member: (1) patient problem behavior, (2) the patient's impairment in activities of daily living, (3) lack of patient helpfulness, and (4) resource demands and disruptions in the caregivers' personal routine. Other factors related to level of burden were social and professional support, age, and education level. Family members who were able to share their experience with others and who received financial support experienced a lower level of burden; younger and less educated caregivers experienced more burden than older and more educated caregivers.

Parents and siblings of patients with schizophrenia often grieve the loss of the child or sibling they knew before the onset of illness. They may also experience feelings of embarrassment and stigma related to their family member's illness, which, in turn, may lead to isolation. Aging parents frequently worry about what will happen to their children when they can no longer care for them. In a study of 157 mothers of children with serious mental illness, only 11 percent reported definite plans for their offspring's future residence; 66 percent had completed financial plans; and 75 percent hoped a family member would assume care, but only 25 percent thought that this would actually occur. Older parents need professional help with planning for the future, in particular estate planning, to enable case management and ongoing services after the parent's death.

Siblings play a unique role in the life of the patient with schizophrenia and may have specific needs. They have additional levels of burden, such as guilt about being healthy, fear of developing schizophrenia, and fear of passing on "bad genes" to their offspring. Several coping mechanisms have been identified in siblings, including normalization, caregiving, and grief. Smith et al. identified several factors that predict whether siblings will be

involved in the future care of the ill sibling. Pull factors, which predict involvement, are early experiences in socialization, strong sibling relationship, and personal caregiver gains, such as developing personal strengths while caring for the sibling. Push factors, which predict disengagement, are geographic distance and a belief that the ill sibling has control of his or her symptoms.

Cultural Aspects of Burden

Across cultures, families of patients with schizophrenia often suffer from stigma that accompanies the diagnosis of a psychotic disorder. Several studies have indicated that black caregivers, on average, experience less distress than Hispanic and white caregivers: a seemingly surprising finding in light of the greater likelihood of additional stressful conditions such as prejudice, discrimination, and lower income that African Americans face. In addition, African American family members tend to be more involved in caregiving activities, which are also associated with higher levels of distress. Potential protective factors, such as religious involvement and social support, do not appear to differ according to race and ethnicity. Studies indicate that QOL for caregivers who live with a chronically ill family member is lower than those living alone or with healthy family members and the financial burden is significant. QOL for siblings is better than for parents and children of schizophrenic patients but, across cultures, women tend to experience more distress than men because they tend to provide more care for ill children or siblings.

Treatment and Family Burden

A multidimensional approach is required to assess and understand the burden experienced by families of schizophrenic patients. The Schizophrenia Patient Outcomes Research Team (PORT) recommended that, in addition to pharmacotherapy, patients with ongoing family contact should be offered family psychosocial intervention lasting at least 9 months, emphasizing education about the illness, family support, crisis intervention, and problem-solving skills training. This may relieve the burden experienced by the family, who in turn is better able to take care of the ill relative. Several support models exist, including single- and multiple-family group models. Although models vary, effective programs share the following characteristics and assumptions:

1. Schizophrenia is an illness.
2. Program leadership is provided by mental health professionals.
3. Participating family members are not seen as patients.
4. Family therapy is not included, to avoid the suggestion that the family is to blame for the relative's illness.
5. The focus remains on patient outcome, including prevention of relapse

and improvement of functioning and well-being of the patient.

Families participating in such programs can reduce relapse rates by up to 50 percent, which is comparable to pharmacotherapeutic effect sizes. However, according to PORT, participation in such programs is limited. Although 75 percent of patients had contact with family members, only 31 percent of families had received information, advice, or treatment. Barriers to access included patient factors (concerns about family burden and confidentiality), family factors (lack of awareness regarding benefits, time constraints, reluctance to become more involved), and provider factors (staff resources, time and training, reimbursement issues, lack of awareness of benefits). Community-based programs, such as the National Alliance for the Mentally Ill (NAMI), Family-to-Family, and Journey of Hope programs, are run by volunteers from patients' families and focus on family needs, advocacy, and system reform. Participation in these programs leads to improved overall well-being for family members, greater facility in navigating the mental health care system, and increased understanding of schizophrenia. Shorter duration and lower costs may make them more accessible to family members.

Conclusions

Schizophrenia is a chronic illness that often causes an enormous burden for the patient's family. However, during the last decade, research has increasingly shown that support for patients and their families through psychoeducation and support programs can have a significant effect on the perceived burden by both families and the patient. It can lead to improved outcome for the patient, with fewer episodes of relapse and better QOL, whereas families are more able to understand the diagnosis and its consequences for their child or sibling and to take on the role of caregiver. In addition, these programs reduce the financial burden of schizophrenia on the health care system. However, many factors hamper implementation of these programs; it is the role of the treatment provider to offer the best possible and evidence-based care to patients and their families.

SUMMARY

This section has described the consequences of having a psychiatrically ill child on his or her parent by considering four diverse disorders that usually first appear in childhood or young adulthood. Although not all inclusive, these disorders were chosen to illustrate themes generally experienced by any family so affected. Common to all of these disorders are the grief and disappointment that parents experience when they realize that their child is not developing typically. Self-blame is frequent, particularly in heritable disorders. Factors that shape parental response include age of onset of the disorder, chronicity of the disorder, the extent to which the disorder affects

acquisition of basic developmental milestones and functioning, the presence of aggression, and the stigma associated with the specific disorder. Presence of the disorder or an associated condition in a parent, as well as in the child, greatly affects the outcome for all members of the family. The lack of appropriate services, especially when the youngster reaches adulthood, is a prevalent dilemma for parents. Psychiatric practitioners need to consider the profound effect that raising a child with a serious psychiatric disorder has on a parent who is their patient.

▲ 55.13 Pediatric Sleep Disorders

JESS P. SHATKIN, M.D., AND ANNA IVANENKO, M.D., PH.D.

INTRODUCTION

Although precise estimates of the frequency of sleep disorders in children and adolescents are somewhat variable among studies, the understanding of the epidemiology of sleep pathology and its relationship to comorbid psychiatric diagnoses has grown substantially in recent years. Research in cognition and brain development over the last 15 years also has significantly advanced the understanding of the genetic and neurobiological bases of sleep disorders in children and adolescents. With an increasing understanding of sleep disorders, treatment interventions have also become more refined and useful.

This section reviews the research and clinical methods used to study sleep, new findings on the neurodevelopmental and cognitive effects of sleep loss and fragmentation, and the clinical description and treatment of sleep disorders in children and adolescents and their interface with psychiatric disorders.

SLEEP EVALUATION METHODS

One of the primary tools for studying sleep is *polysomnography* (PSG), which incorporates a variety of measures of physiological changes experienced during sleep. The American Thoracic Society developed a set of recommendations for the interpretation of pediatric PSG that has become the standard for sleep labs nationally. With the aid of portable technology, PSG is increasingly being performed at home, although the methods and results are not quite as sophisticated as when performed in the lab. While PSG remains the gold standard for sleep studies, other, less complicated and less expensive techniques are available for studying a variety of sleep disorders in children and adolescents.

Actigraphy was developed in the early 1970s and has come into increasing use in both research studies and clinical practice. Actigraphy allows for the study of sleep–wake patterns and circadian rhythms via the assessment of body movements. The device is typically worn on the wrist and can easily be adapted for home use.

A number of survey instruments exist for detecting problematic sleep in children and adolescents, including self-report questionnaires (such as the Sleep Disturbance Scale for Children, the Child Sleep Questionnaire, the Child and Family Sleep History Questionnaire, and the Sleep Disorders

Inventory for Children), sleep diaries, and parent report forms. Sleep logs or diaries provide information on bedtime, sleep latency, wake time, and the number of nocturnal awakenings, in addition to exercise, and the use and timing of caffeine, alcohol, and drug use. Sleep logs are typically completed for a 2-week period by parents and caregivers or adolescents themselves. Although subjective, sleep logs provide a wealth of useful information for treating insomnia and sleep-phase disorders and are available readily in many forms on the Internet. Finally, the Epworth Sleepiness Scale, commonly used with adults as a subjective measure of the propensity to fall asleep in certain situations and to monitor treatment efforts, has recently been modified for use in children and adolescents.

NEUROCOGNITIVE EFFECTS OF SLEEP DISRUPTION

Most of the research examining neurocognitive sequelae of sleep loss and fragmentation in children has focused on the effects of sleep restriction and sleep-disordered breathing on daytime performance in children and adolescents. As little as one night of acute sleep restriction in children can result in significant attention deficit. A study conducted in a sample of 7- and 8-year-old healthy children subjected to 1 hour of sleep restriction for 1 week demonstrated impaired attention and concentration, along with significant reorganization in brain cortical electroencephalographic (EEG) response as measured by multiarray P300 (cognitive) evoked potentials. By contrast, one additional hour of sleep in children aged 8 to 12 years over 1 week resulted in parent and child reports of improved emotional functioning and objective improvements in memory, attention, and math fluency. Similarly, in children 7 to 11 years old, one additional hour in bed, averaging 27 minutes of additional sleep, demonstrated improvements in teachers' blinded ratings of emotional lability and impulsivity.

Obstructive sleep apnea syndrome (OSAS), which is characterized by sleep fragmentation due to multiple arousals and disruption in ventilation following episodes of complete or partial airway obstruction during sleep, has been studied with respect to its effect on neurocognitive functions in children. Numerous studies report academic deficits and learning problems in children with OSAS that appear to be reversible after treatment of the condition. Hyperactive, inattentive, and disruptive behaviors resembling those found in attention-deficit/hyperactivity disorder (ADHD) have been increasingly reported in children with snoring and OSAS. Similar behavioral changes are seen in some children with periodic limb movement disorder (PLMD) and restless legs syndrome (RLS).

In adults, sleep deprivation adversely affects functions mediated by the prefrontal cortex, particularly attention and working memory, upon which most cognition depends. Deduction and critical thinking (logic-based tasks) show little change in accuracy with sleep deprivation, but do reflect cognitive slowing. Divergent skills involved in decision-making, however,

are greatly affected by sleep loss and involve trouble assimilating changing information, updating strategies based upon new information, innovation, risk assessment, maintaining interest, insight, communication, and memory. Unfortunately, a lack of sleep, in addition to increasing levels of responsibility, lead to somewhat of a perfect storm, contributing to the high-risk behavior so commonly observed among adolescents.

A number of studies have indicated reduced intelligence scores among children with sleep-disordered breathing compared to normal controls, including significantly impaired general conceptual ability. Lower academic achievement has also been observed in children with OSAS compared to children without reported histories of sleep-disordered breathing when matched for age, race, gender, socioeconomic status, and school attended.

SLEEP DISORDERS IN CHILDREN

It is estimated that approximately 25 percent of children will suffer from a sleep problem at some point during childhood. The types of problems affecting children vary greatly in their frequency and severity, ranging from the more common bedtime resistance and anxiety to the occasional primary sleep disorders, such as narcolepsy and OSAS. Regardless of the primary complaint, parents frequently report sleep difficulties among their children, and these reports are remarkably consistent with most researchers identifying up to 50 percent of preschool children, roughly 30 percent of school-aged children, and approximately 40 percent of adolescents as having sleep difficulties. Much higher rates of sleep disorders are generally reported among those with neurodevelopmental and psychiatric disorders. Among children with intellectual disability, for example, 30 to 80 percent have sleep problems, while 50 to 90 percent of children with autism spectrum disorders are affected. Despite a high overall prevalence, however, sleep problems are not often discussed during visits with primary care practitioners and are therefore left undiagnosed and untreated.

Classification of Sleep Disorders

The *International Classification of Sleep Disorders*, Third Edition (ICSD-3), and the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5), are the primary classification systems for sleep disorders. While the ICSD-3 and the DSM-5 cover much of the same ground, the ICSD-3 classification is more comprehensive and precise, while the DSM-5 specifies 12 main categories of sleep disorders (see Table 55.13–1).

Sleep-Disordered Breathing

The term *sleep-disordered breathing* (SDB) encapsulates a variety of difficulties, including primary snoring upper airway resistance syndrome

(UARS) and OSAS, and occurs relatively frequently in otherwise healthy children. Although accurate figures are difficult to obtain, it is generally estimated that 2 to 5 percent of all children may be affected by OSAS, and 7 to 12 percent of children may suffer from primary snoring.

Whereas adults with OSAS most often present with *excessive daytime somnolence* (EDS), children rarely exhibit this symptom and instead tend to present with externalizing behaviors, such as hyperactivity, aggression, social withdrawal, and learning difficulties. In one study, fewer than 15 percent of children with OSAS exhibited EDS at all. Diagnosis of OSAS further requires a consistent clinical history and physical examination. To augment these two diagnostic measures and reveal the extent of the effect on sleep, children should also undergo overnight PSG.

Table 55.13–1.
DSM-5 Classification of Sleep Disorders

- Insomnia disorder
  - Hypersomnolence disorder
  - Narcolepsy
  - Breathing-related sleep disorders
    - Obstructive sleep apnea
    - Central sleep apnea
    - Sleep-related hypoventilation
  - Circadian rhythm sleep–wake disorders
    - Delayed sleep-phase type
    - Advanced sleep-phase type
    - Irregular sleep–wake type
    - Non–24-hour sleep–wake type
    - Shift-work type
  - Parasomnias
    - Nonrapid eye movement sleep-arousal disorder
    - Nightmare disorder
    - Rapid eye movement sleep-behavior disorder
    - Restless legs syndrome
- Substance/medication-induced sleep disorder
- Other specified insomnia disorder
- Unspecified insomnia disorder
- Other specified hypersomnolence disorder
- Unspecified hypersomnolence disorder
- Other specified sleep–wake disorder
- Unspecified sleep–wake disorder

Data from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Washington, DC: American Psychiatric Association; 2013.

Children with OSAS present with loud snoring, sweating, agitated sleep, and a variety of related sleep problems (e.g., persistent enuresis, night terrors, somnambulism, bruxism, etc.). EDS, somnambulism, bruxism, and

anxiety are also frequently noted in adolescents with OSAS. Physical examination often demonstrates craniofacial abnormalities and adenotonsillar hypertrophy, and PSG indicates frequent apneas/hypopneas and oxygen desaturations. Outcomes of OSAS can include significant health problems, such as failure to thrive, hypertension, pulmonary hypertension with or without cor pulmonale, and mental health problems.

The most common treatment for pediatric SDB is adenotonsillectomy, which cures the problem in approximately 85 percent of affected children. A continuous positive airway pressure (CPAP) mask is often used for children who fail surgical treatment or for whom surgery is not indicated.

Insomnia

Pediatric insomnia has been much less studied and is more poorly understood than adult insomnia. A number of efforts have been made to define pediatric insomnia, estimate its prevalence among different pediatric populations, and develop clinical guidelines for behavioral and pharmacological treatment.

The prevalence of pediatric insomnia is estimated at about 1 to 6 percent among general pediatric populations, with a much higher prevalence in children with neurodevelopmental and chronic medical and psychiatric conditions. When bedtime resistance and disruptive nighttime awakenings are included, the prevalence of sleep-disrupted behavior approaches 25 to 50 percent in preschool-aged children. Psychiatric symptoms have been reported in almost 50 percent of children with persistent insomnia. It has been proposed that persistent insomnia may also represent an early sign of emotional distress in susceptible children with poorly preserved sleep homeostasis.

The ICSD-3 describes two forms of behavioral insomnia of childhood as unique diagnostic entities to emphasize sleep difficulties that result from inappropriate sleep associations or inadequate parental limit setting. *Limit-setting type* is due to parents having difficulties establishing and enforcing bedtimes, while *sleep-onset association type* is characterized by reliance on maladaptive and inappropriate sleep associations such as rocking, watching television, feeding, and falling asleep in the parents' bed. The child is usually unable to fall asleep in the absence of these conditions at both bedtime and following nocturnal arousals. Behavioral insomnia generally leads to sleep fragmentation and increased nighttime awakenings, insufficient sleep duration, later bedtimes, and daytime sleepiness.

Good sleep hygiene and behavioral interventions, such as extinction or bedtime fading, are the first recommended treatments for pediatric insomnia. Children who do not respond to behavioral interventions may be considered for pharmacological management of their insomnia. There are no U.S. Food and Drug Administration (FDA)–approved medications for

the treatment of insomnia in children. Nonetheless, a large study of over 1,000 child and adolescent psychiatrists found that 96 percent recommended at least one prescription medication and 88 percent advised an over-the-counter medication for sleep in a typical month. Despite the lack of FDA approval, however, limited empirical evidence supports the use of melatonin and clonidine for childhood insomnia. Meanwhile, benzodiazepines, guanfacine, pyrimidine derivatives (e.g., zaleplon and zolpidem), sedating antidepressants (e.g., trazodone and mirtazapine), sedating antipsychotics (e.g., quetiapine), and sedating antihistamines (e.g., diphenhydramine, doxylamine, and hydroxyzine) are often employed to improve symptoms of insomnia in children and adolescents but have virtually no solid evidence to support their use.

Coincident with the increasing use of herbal medications and dietary supplements in the United States, a number of studies have been conducted over the last decade that demonstrate that melatonin is an effective, safe, and well-tolerated agent, especially in cases of sleep-initiation insomnia caused by circadian factors. Several placebo-controlled studies of melatonin in normal, healthy children with idiopathic sleep-initiation insomnia have shown that melatonin administered at bedtime reduces sleep-onset latency time and increases total sleep time.

Little information is available on the use of the non-benzodiazepine hypnotic agents zaleplon and ramelteon, but studies have found both zolpidem and eszopiclone ineffective for ADHD-related insomnia. Additionally, hypnogogic hallucinations and paradoxical agitation have been demonstrated when adult doses of these agents have been prescribed to children and adolescents. At this time there is no evidence supporting the use of these drugs in the treatment of pediatric insomnia.

The most effective treatment for both decreasing sleep latency and improving sleep maintenance in adults is cognitive behavior therapy (CBT). Core components of CBT for insomnia (CBT-I) include sleep education, stimulus control (e.g., removing clocks and cell phones from the bedroom, maintaining a quiet sleep environment, etc.), sleep restriction (e.g., limiting the amount of time in bed until the patient is sleeping 90 percent of the time they are in bed), circadian rhythm maintenance (e.g., going to bed and awakening at the same time each day), sleep hygiene, addressing cognitive distortions (e.g., catastrophizing such as “if I don’t fall asleep soon, I’ll be a complete wreck tomorrow”), and arousal reduction (e.g., relaxation techniques such as belly breathing and biofeedback). Numerous randomized studies of adults demonstrate that CBT-I is even more effective for insomnia than sleep medications. New studies have now demonstrated the benefits of CBT-I for adolescents as well.

Narcolepsy

Major strides in the understanding of the etiology of narcolepsy have been

taken in recent years as remarkable discoveries have identified a new neuropeptide, hypocretin or orexin, which is linked to animal models of narcolepsy. The exact prevalence of childhood narcolepsy is unknown. The youngest patient on record was diagnosed at age 12 months. In retrospective studies, about one-third of adults with narcolepsy indicate onset prior to 15 years of age and roughly 15 percent prior to 10 years of age.

Children with narcolepsy are commonly misdiagnosed with other neurological and/or psychiatric disorders, such as epilepsy, ADHD, mood disorders, and psychotic disorders. Excessive daytime sleepiness is the most common presentation of narcolepsy in school-aged children, although according to some reports 50 to 70 percent of childhood narcolepsy patients present with symptoms of cataplexy. Nighttime sleep is frequently disturbed in patients with narcolepsy, and periodic limb movements during sleep are also common. The diagnosis of narcolepsy requires sleep laboratory assessment, including nocturnal PSG and a multiple sleep latency test.

Effective treatment of narcolepsy in children and adolescents demands establishing a regular sleep schedule, providing extensive education on sleep hygiene, and implementing scheduled daytime naps if possible. Excessive daytime sleepiness in children and adolescents with narcolepsy is commonly treated with psychostimulants such as methylphenidate and dextroamphetamine. Modafinil, a nonstimulant alerting agent, has been successfully prescribed to children and adolescents with narcolepsy in a dose range from 100 to 600 mg/day in divided doses.

Tricyclic antidepressants such as clomipramine, protriptyline, and imipramine have long been known to be effective for symptoms of cataplexy. For the last decade, serotonin-specific reuptake inhibitors and mixed-action antidepressants have also been increasingly prescribed to patients with cataplexy. Sodium oxybate (γ-hydroxybutyrate [GHB]) has been approved by the FDA for the treatment of cataplexy, and there has been at least one report of its use in children with narcolepsy. Due to the complexity of narcolepsy symptoms and their effect on child development, a variety of treatment modalities, including individual and family therapy, school advocacy, and academic interventions, should be used to optimize symptom control.

Parasomnias

Parasomnias are disruptive physical acts that occur during specific sleep stages or during the transition between sleep stages and include non-REM types (somnambulism and sleep terrors), REM sleep behavior disorder, somniloquy, bruxism, nightmares, and RLS. Although the incidence of general psychopathology in children with non-REM sleep parasomnias is quite low, the overall prevalence of having at least one parasomnia by age

13 years has been reported to be as high as 78 percent. The events, although rarely requiring clinical intervention, are often very troubling for parents.

Somnambulism, or sleepwalking, is relatively common in childhood, with annual prevalence rates approaching 17 percent. Although somnambulism rarely results in harm to the subject, it is possible for an episode of somnambulism to become a confusional arousal, in which the likelihood of accidental violence (to oneself or others) is much greater. The prevalence of confusional arousal is less well established, although a 4 percent incidence was noted in a longitudinal study of 212 children of ages 6 to 16 years selected at random in Stockholm.

Sleep terrors are somewhat less common than somnambulism and are difficult to quantify because of the self-report nature of the data and the fact that parents often confuse them with nightmares. Annual incidence rates have been reported as high as 6 percent and prevalence rates as high as 17 percent among children aged 13 years and younger. Most non-REM parasomnias are first noticed by parents of affected children. Although a large percentage of children have at least one incidence of somnambulism, far fewer present with recurrent and disruptive somnambulism. Sleep terrors follow a similar trend, although they are less common than sleepwalking. Numerous studies have demonstrated a connection between anxiety levels and parasomnias in children, showing that increased anxiety correlates with increased prevalence of sleepwalking and sleep terrors.

Although the treatment of non-REM parasomnias has received minimal formal study, there are numerous measures that have been shown to be effective. In addition to safety measures, the use of scheduled awakenings and naps, and in severe cases clonazepam or tricyclic antidepressants, may be effective. In addition, a formal sleep study may be helpful in revealing SDB as a comorbid disorder for which treatment may reduce the apparent severity of the parasomnia.

Sleeptalking, or *somniloquy*, is considered the most common parasomnia, with a reported prevalence of greater than 50 percent in children between the ages of 3 and 13 years. Somniloquy is often comorbid with sleepwalking and sleep terrors, suggesting a common pathophysiology among the three disorders. Nightmares are common among children and adolescents and are only considered abnormal when they are recurrent and cause excessive distress. Although sometimes associated with posttraumatic stress disorder (PTSD), up to 70 percent of children report that the content of their nightmares is influenced by media seen on television or at the movies. Effective treatment for nightmares generally includes CBT and rescripting, but can also include hypnotherapy and medication. REM sleep behavior disorder, in which subjects become aroused during REM sleep and “act out” their dreams due to loss of body paralysis, is not generally observed in children and is more closely associated with brain damage and dementia.

RLS is characterized by an irresistible urge to move the legs commonly associated with discomfort and pain, which is partially relieved by movement. In the adult population, RLS has an estimated prevalence of 10 to 15 percent. PLMD, no longer classified by DSM-5, is characterized by episodic limb movements during sleep, generally involving the leg along with the extension of the ankle and toe.

Only recently has the presence of RLS in children and adolescents been elucidated with studies generally demonstrating a prevalence rate of RLS among the general pediatric population to average around 2 percent. There is considerable interest in the relationship between RLS, PLMD, and ADHD. The prevalence of RLS in patients with ADHD is estimated to be between 10.5 and 44 percent, emphasizing the need to consider both diagnoses and the possible interrelationships between them in children and adolescents.

Prior to the diagnosis of RLS, a child often presents with sleep disturbances and daytime impairments, including extreme fatigue, irritability, and hyperactivity, and the discomfort in the extremities that accompanies the disorder is often confused with growing pains. Other qualitative signs suggestive of RLS include an urge to move the legs with a worsening sensation when sitting or lying down, the alleviation of discomfort through movement, and worsening symptoms in the evening. Several studies have demonstrated an autosomal-dominant inheritance for early-onset RLS. Family history, therefore, is an important indicating factor in diagnosing RLS in children and adolescents.

Most treatments for RLS/PLMD include a pharmacological component, although proper sleep hygiene is also very important. Children and adolescents with RLS/PLMD should reduce caffeine intake, eliminate alcohol and tobacco use, avoid stimulating activities prior to bedtime, and minimize sleep deprivation. Correlation among low ferritin levels, iron deficiency, and RLS symptoms has been identified in both children and adults. Providing ferrous sulfate supplementation for those children who are deficient has been demonstrated significantly to reduce PLMD symptoms. Other medications have also demonstrated efficacy in reducing symptoms. One randomized double-blind, placebo-controlled study of children with RLS aged 7 to 12 years found a combination of carbidopa/L-DOPA to be safe and effective. In adults with RLS, dopaminergic medications, including levodopa, pramipexole, and ropinirole, are most often used. Gabapentin has also been shown to improve RLS symptoms in children. Although these medications are prescribed to children and can be effective in reducing symptoms, none has been approved by the FDA for the treatment of RLS/PLMD in children. As a result, the medications should be administered with great caution and intensive monitoring of potential side effects.

Circadian Rhythm Sleep–Wake Disorders

Circadian rhythm sleep–wake disorders occur due to a misalignment between the internal circadian rhythm and the sleep–wake schedule. Over 10 percent of children are thought to be affected by circadian rhythm sleep problems. Delayed sleep-phase type occurs in as many as 5 to 10 percent of adolescents, while advanced sleep-phase type is more common in the elderly and occasionally in preschool children.

A delay in the normal sleep phase is typical in the peripubertal period, leading to later bedtimes. Extensive homework and extracurricular obligations coupled with early school start times frequently result in excessive daytime sleepiness, academic difficulties, irritability, mood instability, attention and memory impairment, and family conflict. Recognizing the detrimental effects of delayed sleep phase on adolescents, the American Academy of Pediatrics has published a policy statement urging a delay in the school start time so that high school students can achieve adequate sleep.

Treatment of delayed sleep phase typically involves sleep education and hygiene, along with gradual advancement of the sleep phase. Bright light morning therapy (5,000 to 10,000 lux), along with low-dose melatonin (approximately 500 mcg) about 4 to 5 hours before the desired bedtime, have both been found helpful in advancing the sleep phase after several weeks. Chronotherapy, or the gradual delay in bedtime by 3 hours each night until the desired bedtime is achieved, can also be effective, although the schedule is very difficult to maintain.

Nocturnal Enuresis

Although no longer classified by DSM-5 as a sleep–wake disorder, *nocturnal enuresis* is a frequent occurrence, affecting approximately 30 percent of 4 year olds, 10 percent of 6 year olds, 5 percent of 10 year olds, 3 percent of 12 year olds, and 1 percent of individuals aged 15 years or older. *Primary nocturnal enuresis* (never consistently dry at night) is likely to have a multifactorial etiology and may be due to difficulties with bladder musculature stability, central nervous system arousability, pontine reflex function, internal sphincter tone, functional bladder capacity, nocturnal urine production, and a maturational delay in antidiuretic hormone (ADH) secretion. *Secondary nocturnal enuresis* (previously dry for at least 6 months), by contrast, is typically caused by urinary tract infections, diabetes mellitus, and psychological factors.

The first step in treatment is to educate the family and patient regarding proper sleep hygiene. All caffeine and alcohol intake should be discontinued because both decrease ADH secretion, and late-night fluid intake should be strictly limited. On occasion, the introduction of an afternoon nap will be beneficial by virtue of decreasing the quantity of

nighttime deep sleep, thereby making it easier for the patient to awaken to the internal cues of bladder fullness. Finally, parents sometimes find that briefly awakening the child after 2 or 3 hours of sleep and sitting him or her on the toilet will decrease the frequency of enuresis without a significant impairment in sleep efficacy. Should these educational strategies be ineffective, both behavioral and pharmacological treatments exist for nocturnal enuresis.

Behavioral treatment most commonly involves the use of an enuretic alarm, which has the highest cure rate and lowest relapse rate. Other behavioral interventions include bladder training to increase the number of micturitions during the day or to enlarge bladder capacity. The use of reward systems, such as star charts, has also been shown to be useful. Finally, cognitive therapy (e.g., explaining the enuretic process and maintaining a daily diary), motivational therapy, pelvic floor muscle training, and biofeedback also have some reported utility.

The two medications most commonly accepted as appropriate pharmacological treatment for pediatric nocturnal enuresis are desmopressin acetate and imipramine. The use of amitriptyline and anticholinergic agents, such as oxybutynin and tolterodine, however, has also been described.

Sleep Disorders in Children with Psychiatric Disorders

Sleep problems often occur in the context of mental illness, either as primary concerns (e.g., primary insomnia) or secondary concerns (e.g., as a consequence of depression or anxiety). All sleep problems identified early in childhood have been later correlated with anxiety, depression, attentional difficulties, family or parental distress, continued sleep problems, aggression, delinquency, and social problems. Some of the more common psychiatric disorders among children and adolescents and their effect on sleep (and vice versa) will be reviewed here.

Attention-Deficit/Hyperactivity Disorder

Numerous studies based on parent reports have demonstrated the prevalence of sleep disorders among children with ADHD to be higher than that for healthy controls, controls with other psychiatric illness, and healthy sibling controls by up to fivefold. Actigraphy has shown children with ADHD to have greater variation in sleep onset time, wake time, and single-night sleep duration than controls, and in at least one study there were significantly more bedtime struggles and longer total sleep duration in the ADHD group. Although children with ADHD often have difficulty settling down to sleep and may sleep more total hours than controls, restricting the amount of sleep a child receives in an experimental setting can also result in symptoms of ADHD, including inattention, hyperactivity,

impulsivity, and poor cognitive performance.

ADHD is also associated with snoring during sleep. Habitual snoring has been reported to be three times more common in children with ADHD than control children drawn from child psychiatry and pediatric clinics. In addition, children with ADHD have been found to have a greater frequency of PLMD while maintaining normal sleep architecture. Children with ADHD also suffer from SDB at a greater rate than expected. SDB has been associated with poor memory performance on standardized psychometric tests and lower academic achievement in children, whereas in adults, deficits in attention, concentration, memory, and verbal and nonverbal intelligence have been noted.

Children with ADHD may also suffer circadian rhythm abnormalities. Among children with ADHD, there is greater inconsistency or instability in time to sleep onset, wake time, and sleep duration than in controls. Furthermore, a high prevalence of ADHD has been shown among children with chronic sleep-onset insomnia, and sleep-onset insomnia in children with ADHD is associated with later dim-light melatonin release.

Fragmented or disrupted sleep, rather than lessened total sleep time, may be the true culprit behind the daytime behavioral changes and disruptions seen in some children. To that end, recommendations to families with a disruptive or hyperactive child should include an emphasis on basic sleep hygiene. Many children with ADHD take medication regularly, which can further complicate an understanding of their sleep cycle. Much investigation, however, has suggested that children with ADHD still demonstrate more sleep disturbances than controls regardless of medication use, particularly with regard to sleep-onset latency, sleep efficiency, and total sleep time.

Opinions vary greatly on how to manage insomnia due to either ADHD or the stimulant medications that are used to treat it. Typical recommendations include lowering the dose of the stimulant, changing to a shorter-acting preparation, adding a low dose of stimulant (if the insomnia is believed to be secondary to hyperactive “rebound”), or changing to an entirely different stimulant or treatment, such as atomoxetine. If adjunctive pharmacotherapy is used, typical medications include melatonin, clonidine, antihistamines (e.g., diphenhydramine, cyproheptadine), and antidepressants (e.g., trazodone, mirtazapine).

Autism Spectrum Disorders

Children with *autism spectrum disorders* (ASDs) are also susceptible to sleep difficulties, with prevalence estimates ranging as high as 80 percent. Younger children and those with more severe cognitive or intellectual disabilities tend to demonstrate increased sleep problems, which often persist over time. The most frequently reported sleep problems among those with ASD include difficulty falling asleep, restless sleep, frequent

awakenings with difficulty falling back to sleep, early-morning awakenings, irregular sleep–wake patterns, shortened duration of sleep, dyssomnias, and parasomnias.

Numerous hypotheses have been put forth to explain the reported sleep difficulties among children with ASD, including failure to recognize environmental and social cues, poorly developed circadian rhythms secondary to social deficits, altered melatonin production, and abnormalities in the hypothalamic–pituitary–adrenal axis and serotonin systems. Many treatments have been proposed for children with ASD with comorbid sleep difficulties.

Various behavioral treatments have been used with varying success in the ASD population. Most favorably, the use of proper sleep-hygiene techniques, stimulus control, graduated extinction, scheduled awakenings, and daytime nap restriction have all shown utility among children with autism and intellectual disability. Light therapy, in combination with chronotherapy, may also be useful in children with autism who have circadian rhythm abnormalities. Pharmacological treatments also have proven to be useful for many, but not all, children with ASD.

Various prescribed medications have reported utility in the treatment of sleep difficulties in the ASD population, including antihistamines, sedating antidepressants, α-2 agonists, benzodiazepines, and antipsychotics. Melatonin has also demonstrated utility in treating children with neurodevelopmental disabilities and autism.

Mood Disorders

Sleep complaints are among the most prevalent symptoms of major depression in children and perhaps the most prevalent symptom among adolescents. Insomnia has been reported to affect nearly 90 percent of depressed adolescents, whereas *hypersomnia* affects a considerably smaller proportion, perhaps around 25 percent. Some adolescents—around 10 percent—continue to experience insomnia even after remission of depression. The use of actigraphy in diagnosing sleep problems among depressed children and adolescents highlights the compromised sleep quality and abnormal circadian rhythms these individuals experience while depressed. PSG studies in children with depression often demonstrate decreased REM latencies, increased total REM, and increased sleep-onset time.

Many children who are or will be later diagnosed with bipolar disorder present with sleep-related symptoms. When depressed, these children may experience exhaustion, distractibility, irritability, and impulsivity at levels significantly greater than at baseline. In contrast, children experiencing mania may present with unusual amounts of energy and a decreased need for sleep. Such extremes of sleep behavior warrant clinical assessment.

Seasonal affective disorder (SAD) has a reported prevalence of 3 to 4

percent in children and adolescents, for whom more than 20 percent of their parents report that their children are sleepier and generally more tired during winter months. Studies of children with a diagnosis of SAD have found that they did not differ from controls in the level of nocturnal activity but did experience significantly lower diurnal activity levels and had less robust circadian rhythms, with a reduction in amplitude.

There have been a small number of studies examining the effects of pharmacological and behavioral interventions in depressed children and adolescents suffering from sleep problems. A combination of improved sleep hygiene and cognitive behavioral therapy has been shown to be effective in managing the insomnia and awakenings associated with depression. In those cases that require further treatment, the most effective drug therapy appears to be a combination of an antidepressant with the short-term use of a sedative or hypnotic. As noted previously, however, some children and adolescents experience a paradoxical reaction to these medications, which severely limits their utility.

Anxiety Disorders

Although it is difficult to establish causality between early sleep problems and later onset of anxiety and depression, it is clear that anxiety and sleep problems are intimately connected in childhood and that the presence of a sleep problem at age 4 years is significantly correlated with the development of depression and anxiety by age 15 years. Fears at nighttime are common among children, with up to 75 percent of those aged 4 to 12 years reporting such fears, which generally take the form of animals, fictitious characters (e.g., witches, monsters), being kidnapped, or being teased by peers. Although no specific numbers are available, for the majority of children with DSM-5 anxiety disorders, sleep problems typically follow. In addition to the aforementioned concerns, anxiety is also believed to predispose children to parasomnias and nightmares.

The effects of anxiety on sleep are profound, and the clinical presentation depends largely on the specific disorder. Individuals with *generalized anxiety disorder* (GAD) have a wide range of sleep disturbances, which can include insomnia and hypersomnia. These GAD sleep symptoms may be due to central nervous system hypervigilance and hyperarousal such that the individual is unable to relax sufficiently to fall asleep and maintain good sleep quality. Patients with panic disorder tend to present with insomnia, restless and fragmented sleep, and nocturnal panic attacks. These symptoms often result in trouble initiating and maintaining sleep, increased sleep latency, and reduced sleep efficiency.

Children and adolescents with PTSD may experience significant sleep difficulties. Individuals with PTSD often have trouble initiating sleep and experience significant nighttime arousals and disruptive nightmares. Because children with PTSD may have flashbacks to their traumatic

experiences, bedtime can become a stressful time in which they experience increased anxiety and are unable to relax sufficiently for restful sleep. The accompanying nightmares, which are a characteristic symptom of PTSD, and increased limb movements, which are associated with nightmares, lead to disrupted REM sleep.

Cognitive and behavioral techniques, systematic desensitization, and imagery rehearsal therapy have demonstrated efficacy in decreasing nightmares and are integral parts of treating the sleep disturbances accompanying obsessive compulsive disorder (OCD), PTSD, and GAD. Cognitive behavior therapy (CBT), along with systematic desensitization, has been demonstrated to improve the sleep disturbances associated with OCD. In cases that are particularly severe, serotonin-specific reuptake inhibitors such as fluoxetine, sertraline, and paroxetine further aid in the reduction of symptoms. Children and adolescents with PTSD generally have a complex constellation of symptoms, and the primary psychiatric diagnosis must be treated first before the sleep disturbances will resolve. CBT and play or expressive therapies, in which the children process the traumatic events triggering the PTSD, have been shown to be very effective, and antidepressants and anxiolytics may hasten the recovery process in combination with other therapies.

56 Adulthood

CALVIN A. COLARUSSO, M.D.

As science cracks the genetic code and medicine successfully treats and eliminates diseases that in past centuries made survival to middle or old age rarities, the prospect of vast numbers of humans living beyond one hundred years is increasingly becoming a reality. Consequently, the task for future generations of mental health scientists, and authors of this chapter, will be to provide a greater understanding of what are the normal developmental experiences and expectations for those who live to one hundred and beyond.

Anticipating that future and relying on what is currently known about the mental and emotional life of those in "old age," this chapter includes material on healthy development and the rich quality of life and exquisite understanding of the human condition which is increasingly becoming the norm in the decades of the seventies, eighties, and nineties.

MATURITY

Success and happiness in adulthood are made possible by achieving a modicum of maturity—a mental state, not an age. However, the capacity for maturity is a direct outgrowth of the engagement and mastery of the developmental tasks of young and middle adulthood. From a developmental perspective, maturity may be defined as a mental state found in healthy adults that is characterized by a detailed knowledge of the parameters of human existence, a sophisticated level of self-awareness based on an honest appraisal of one's own experience within those basic parameters, and the ability to use this intellectual and emotional knowledge and insight in a caring way in relation to one's self and others.

The achievement of maturity in midlife leads to the emergence of the capacity for wisdom. Those who possess wisdom have learned from the past and are fully engaged in life in the present. Just as important, they anticipate the future and make the necessary decisions to enhance prospects for health and happiness. In other words, a philosophy of life has been developed that includes an understanding and acceptance of the person's place in the order of human existence. That worldview, which varies widely from individual to individual, produces fulfillment when the following aspects of the human condition are accepted and integrated.

The body must be cared for—in health, through regular checkups, exercise, and a proper diet, and in sickness, through prompt treatment and proper care. Caring for the body is not an end in itself, but it is critically important because sentience, the essence of human experience, springs from a healthy brain and body.

Human beings are individuals who are alone with themselves, separated and individuated from all others.

Paradoxically, human beings cannot survive or develop on their own. Helpless at birth and relatively dependent throughout childhood, even the most self-sufficient individuals require the sustaining presence of others. Humans exist in a framework of interdependence, a basic characteristic of all human relationships, be it the parental view of the child as a confirmation of his or her sexuality, the need of the child for the parents' loving care and protection, or the reversal of these roles between child and aging progenitor. The mature adult (unlike the child who takes, uses, controls, and dominates) mutes the grandiose expectations of childhood and propels the self toward interactions characterized by caring and mutuality, thus striking a balance between personal needs and those of others.

Change is a constant in life. A basic aspect of this change is the shifting nature of significant relationships. Adult involvement with loved ones, such as children, parents, colleagues, and friends, is in constant realignment. Healthy marriages deepen in significance, whereas others break up on the shoals of midlife development. Parents die. Children grow, leave, and return with new family members. As opposed to old age and, in some respects, childhood as well, the task for the mature person is to sort out, to categorize, and to set priorities among relationships, while in the process balancing emotional needs and realistic demands and responsibilities. The shifting nature of relationships stimulates the achievement of greater maturity by forcing a constant redefinition of who one is in relationship to others. Mature individuals mourn lost relationships but can remain focused on current and future ones.

All human beings—regardless of wealth, position, power, achievement, appearance, or cultural background—are on the same developmental course. All are born and will die. All have a body with the same functions. All have the same emotional needs for closeness and love and the same vulnerability to loss and deprivation.

Few individuals have an exaggerated importance. The wish for such grandiose prominence is universal, the result of the untempered narcissism of infancy and childhood. In reality, most individuals are important to themselves and a relatively limited number of others who know and love them. The mature individual accepts this fact without despair and uses the knowledge to set realistic goals and priorities that will increase the chances for personal happiness and fulfillment.

Personal time is limited. Everyone will die. Young children do not have the cognitive capacity to understand the notion of personal death. Spurred on by the thrust of physical growth and a seemingly endless future, adolescents and young adults think and act as though they are immortal. The true acceptance of time limitation and personal death occurs in midlife. Then the mature individual, religious or not, stimulated by an awareness of the aging process in the body, the maturation of children, the death of parents and friends, and the arrival of grandchildren, accepts the inevitability of a personal end. As with the realization of the limited importance of each individual, this painful recognition, which precipitates midlife crises in some, stimulates the mature individual to seek fulfillment in each moment, to define what is truly important, and to plan the future to actualize those priorities.

Money and possessions have limited intrinsic value. They are a means to an end, tools for enriching life and improving the human condition of loved ones and the broader community. Ownership of tangible objects is temporary; sooner or later they will be lost, left behind, or given to others.

Work occupies a central position in adult life. Considered a drudgery by some, the wise person recognizes its extraordinary value. In addition to the obvious function of earning a living, work is organizing, an activity that provides purpose and direction, a meaningful way to manage time, and an environment in which to form sustaining relationships. Satisfied midlife workers, at the peak of power and position in the workplace, facilitate the development of the skills and capabilities of younger colleagues while fully realizing that these individuals will, sooner or later, replace them and assume control of the levers of power. Wishes to hold down and to attack younger workers are sublimated into generativity, Erikson's term for enhancing the development of the next generation.

Midlife is the phase of life in which the experience of being human can be realized and enjoyed most fully. Then, the combination of physical health and vigor, power and prestige in the workplace, accumulation of wealth and possessions, and meaningful relationships from within the midst of three or four generations provide the potential for a life overflowing with richness and complexity. The mature life is one in which the triumvirate of human experience—love, work, and play—are successfully balanced to bring true fulfillment.

Unfortunately, the joys of midlife do not last forever. Old age lies ahead. Although the hope and statistical expectation is for many years of mental competence and independence, physical and mental decline, increased dependence, and eventually, death must be anticipated. Late adulthood has its own great pleasure, when there is a focus on continued mental and physical activity, a dominant preoccupation with the present and the future, and involvement with and facilitation of the young. Then, death can be met with feelings of satisfaction and acceptance, the natural end point of

human existence that follows a life lived and well loved.

WISDOM AND FULFILLMENT IN OLD AGE

When individuals have lived into their 70s, 80s and beyond, they have an ability to understand the human condition with a clarity and depth that is reserved for those who are living at the outer limits of the human life span as it exists today. Having experienced many of the joys and tribulations that are an inevitable part of human existence, their wisdom allows them to define the essential components of happiness and fulfillment as they approach the end of life (Fig. 56–1).

Physical and Mental Health

Human happiness and fulfillment are built on a solid foundation of physical and mental health. Physical health increases the ability to function in the world in the relative absence of pain and impairment and most importantly, provides an internal environment in which the brain can function optimally. Human thought and emotion originate in the brain and are totally dependent on brain function for existence. The mind resides within a physical body that profoundly affects mental life and development throughout life as it matures in childhood and ages in adulthood. Thus, caring for the body is absolutely essential to the maintenance and enhancement of sentience, the essence of human existence. Humans live in their bodies. Humans' mental life is totally linked to their physical being, but humans ARE their thoughts and emotions.

FIGURE 56–1. The four essential components of happiness and fulfillment.

Mental health, which may be roughly defined as the absence of significant mental illness—we are all neurotic to one degree or another—allows the individual to experience the inner world as a palace rather than a prison and to experience genuine intimacy in relationships with others. For those who are victims of biologically based mental illnesses, or who suffer from crippling and pleasure-robbing neuroses or worse forms of psychologically determined pathology, the quest for happiness and fulfillment may be difficult or impossible to achieve at any point in life.

Emotional Intimacy

We come into the world alone and leave it alone. But in the decades in between birth and death people live in a state of interdependence with others. When those relationships promote mental and emotional development, the result is emotional intimacy. Because people remain vulnerable to the attitudes and actions of those individuals with whom they are interdependent, these very same relationships can, and do, cause people to experience pain, rejection, and abandonment throughout their lives. There is nothing more exquisitely human than to be both emotionally enriched by those that one love and need, and at the same time continually vulnerable to the pain which their insensitive words and actions, whether intended or not, may cause. Living on this razor edge of pain and pleasure is lifelong and experienced differently as people mature and age. Consider the following:

The rapturous fusion of the infant with a loving mother or the total disintegrating despair caused by maternal rejection or abandonment.

The toddler's elation as experienced within a loving, mother–child, symbiotic dyad, or the terrifying experience of angry voices or physical abandonment during a true temper tantrum.

The empowering grandiosity, when accepted benignly, of the oedipal-age child's challenge and the verbal or physical retaliation of the insecure parent.

The enormously satisfying feeling of acceptance by the latency-age peer group and the cruel rejection of the child who is thought to be different.

The dream-like perfection of the first adolescent infatuation versus the total despair of the inevitable first rejection.

The joy of sharing the miracle of parenthood with a spouse and the crushing pain of losing a child due to illness, divorce, or death.

FIGURE 56–2. Relationships.

The tender intimacy of caring for aging parents and the sadness experienced when they die.

The joyous generativity experienced when giving and relating to younger generations and the jarring pain associated with the realization that all will be lost through death.

In addition to organizing people's lives, relationships that lead to intimacy, stability, and fulfillment occur in varying degrees of intensity. The nature of these relationships may be conceptualized in the form of concentric circles. At the center of the bull's-eye is involvement with spouse and children. In the next concentric ring are relationships with parents and extended family, followed in the third concentric ring by interactions with friends, coworkers, and neighbors. As people get further away from the warmth and sustenance provided by those who love and care about them, they are defined, and to a degree sustained, by the realization that they share all aspects of human experience with members of their particular nation and culture and the seven billion others who currently inhabit this planet (Fig. 56–2).

Work

Meaningful work is presented here as an essential ingredient which is necessary for happiness and fulfillment throughout adulthood and

increasingly in late adulthood. For many adults, including those in their 70s, 80s and beyond, work is a good thing, not something to be minimized or avoided.

The capacity for work begins to develop in the second and third years of life as parents introduce toilet training and other limit-setting experiences. As parents repeatedly say "No!" they frustrate the toddler's wish for total freedom, replace chaos with order, and impose routines and restrictions; they help the child learn to begin to tolerate frustration, delay gratification, and establish the capacity to control mind and body—essential components of a mature capacity to work and of happiness.

As they interact with their child around his or her "jobbies" (stools) and gently insist on adherence to societal demands for bowel and bladder control and cleanliness, parents facilitate the emergence of a core of strength which forms the basis on which the ability to work is built. Character emerges out of toilet training and other limit-setting processes. As Anna Freud described it, "In short, what takes place in this period is the far-reaching modification and transformation of the {personality} which—if kept within normal limits—supply the individual personality with a background of highly desirable, valuable qualities." (1965, p. 77).

During the oedipal years ambition and initiative, then directed primarily toward parental competitors, are integrated into the future worker's armamentarium. To quote Erikson, "while autonomy concentrates on keeping potential rivals out, and therefore, can lead to jealous rage most often directed against encroachments by younger sibling, initiative brings with it anticipatory rivalry with those who have been there first and may, therefore, occupy with their superior equipment, the field toward which one's initiative is directed." (1963, p. 255). Success in the workplace is predicated on the ability to face potential rivals and challenges, to work with and learn from those with "superior equipment," and to direct one's initiative beyond the limits imposed by current-day procedures and knowledge. The child, who successfully traverses the oedipal stage and its developmental tasks, is at the same time internalizing the capacities and characteristics required for success and fulfillment in the workplace.

Latency is the first phase of development in which children in the Western society are expected to work. Their form of work is contained in the "work," in the word homework. In order to be a successful worker-learner, many capabilities must be present to meet the demands of the school-workplace. These capacities also form the nucleus of the skills required by the adult worker, including the ability to comfortably control the body and utilize its potential; to modulate gratification and frustration and remain focused on a task for increasingly long intervals; to possess intellectual skills, and to relate to peers and superiors in a manner which facilitates accomplishment and productivity. All of these characteristics emerge in the elementary school classroom. Erikson recognized the

importance placed on work as a future expectation when he described the developmental dilemma of latency as industry versus inferiority (1963, p. 255).

When the latency-age child succeeds in the classroom, the newly internalized superego becomes "loving and beloved" (Schafer, 1960) in response to work and achievement. Such an individual is self-motivated, focused, and goal oriented, continually responding to a powerful inner compass that directs him or her toward higher levels of achievement. These are the qualities which, 20 years later, produce outstanding academic achievement, new discoveries, the guts to begin a new business, and satisfaction in the workplace.

Adolescence is the first phase of development in which work is performed in actual jobs in the economy for compensation. The desire to partake of the pleasures of adolescent/adult life, necessity, and parental insistence push adolescents into the workforce where, for the most part, they earn money and learn about the demands and expectations connected with work. When necessity requires that adolescents work, they quickly learn about the demands and limitations of employment and are usually forced into low-paying jobs that provide valuable experience but also detract from time which could be more profitably (in every sense of that word) spent on studies, preparing for the future when educational credentials literally translate into dollars, a high standard of living, and meaningful, fulfilling work. Whatever the reason may be that causes adolescents to enter the work force, by midadolescence, or earlier, they have developed the physical, emotional, and cognitive capacities necessary to perform the same work functions as adults.

Work becomes a central, often dominant, activity in young adulthood. When the childhood developmental line leading to adult work is relatively conflict free, there is a relatively smooth transition from high school to on-the-job training or college and beyond. The transition from learning and play to adult work may be gradual or abrupt, but at some point in the late teens or twenties the realization gradually dawns that the pleasure of play and the luxurious life of the student, dripping with freedom and free time, must be subordinated to the temporal and emotional demands of work.

Work becomes a fulfilling activity when the desire to learn and to succeed is driven by healthy curiosity and ambition. Abundant self-esteem is the reward for advancement in the work place and the gradual movement toward self-sufficiency. In addition, friendships are formed with others who are engaged in the same or similar work. Children play together. Young adults work together and in the process become friends.

As they meet, fall in love, and intertwine their lives, young adults begin to work for each other. The gratification derived from work is enormously intensified when children appear. With their presence, mothers and fathers double their efforts to provide a bountiful present and secure future for

their offspring.

While all of this is occurring, slowly but surely, work begins to permeate the deepest recesses of the psyche, becoming an integral part of one's identity, often a source of pleasure, even of security because of the nurturing aspects of its familiar routines. For some lucky ones there are moments, even days, when work becomes a *preferred* activity, replacing play and even relationships as a significant source of pleasure. Love, work, and play—as young adulthood progresses, work becomes elevated to equal status with the other two, completing the triumvirate of activities and relationships which produce lasting adult happiness and fulfillment.

Midlife workers are at the top of the heap. Capable, accomplished, and powerful, they are reaping the rewards of years of effort during which skills were mastered and seniority earned. For these individuals the narcissistic gratifications emanating from work may be considerable. A stable work situation may compensate for the painful realities of life related to aging, parental death, the turmoil surrounding having adolescent and young adult children, and the crush of responsibility related to being in the midst of three or four generations. On occasion, work may become the main source of emotional sustenance and stability, a refuge from doubts, debt, and difficult relationships.

Relationships with younger coworkers stir up considerable ambivalence because of the recognition that educating the next generation is the means of one's replacement. For those with self-confidence and sources of fulfillment outside the workplace, the anger at and envy of promising subordinates is not acted on to any significant degree. Instead, the fantasies and feelings are recognized and processed at a mental level, often sublimated into *generativity,* Erik Erikson's term for caring for the next generation.

Thoughts of retirement are frequently blotted out by those at the peak of their capabilities, but prospects for happiness in later life are greatly enhanced by the ability to take that searing look into the future, to anticipate, to plan. Retirement is clearly not for everyone. For some it does bring true happiness and fulfillment. For others, including many in the mental health field, work remains a sustaining activity well into late adulthood.

Play

Playing peekaboo, hopscotch or football, listening to rock and roll, Sondheim or Sebelius; reading romance novels or watching a Shakespearean play—what do they all have in common? All are expressions of one of the most ubiquitous and intriguing human activities—play. Psychoanalytic theory postulates that play is not a random, carefree action, free from the psychic restraints of more mundane human pursuits. Like all other thought and behavior, it is molded by the forces of the mind and the

environment into nearly endless forms which fascinate people from shortly after birth until the end of life and bring much pleasure, happiness, and relief of tension; thus its inclusion, along with work, as one of the four essentials for happiness and fulfillment.

In a brilliant study of children's play, psychoanalyst, Robert Waelder (1932), determined that children play so incessantly because they have to, not because they want to; because their minds are not fully developed and thus they are not easily able to understand or integrate the multitude of new ideas, situations, and various forms of stimulation which they encounter every day. Thus, children live in a state of "traumatic stimulation." In their play they attempt to master those experiences that are too overwhelming to be integrated in one fell swoop. Two decades later psychoanalyst Lilli Peller (1954) expanded Waelder's ideas, relating the particular forms of children's play to phase-specific developmental challenges. In other words, play will be different at different ages because of gradually increasing levels of mental sophistication and the need to address new challenges that arise as the developmental stages of childhood are traversed.

But what of adults? Better able to meet the challenges of everyday living, they have less need to play but play for the same reasons that children do; namely to deal with the stresses, conflicts, and developmental challenges of adult life. Psychoanalyst Mortimer Ostow (1987) suggested that play provides, not for the unrestrained pursuit of pleasure, but rather for an exposure to realistic or realistic-like challenges, the overcoming of which relaxes tension and replaces it with pleasure. By providing a mechanism for the reduction of stress and the mastery of traumatic experience, play becomes a means of pushing the individual toward new levels of mental and physical competence. Play in adulthood, like that in childhood, consists of both thought and action, and provides both pleasure and fulfillment because it is free of significant negative consequences and can be terminated at will.

In a 1993 paper on the nature of play in adulthood, Colarusso described four levels of play, covering the life cycle from infancy through adulthood. Only levels III and IV are relevant to the consideration of adulthood. Level III play, which could be subtitled *Learning the Games of Your Culture,* occurs for the first time during the latency phase of development (ages 6 to 11 years) because the latency-age child is increasingly capable of a variety of complicated motor skills, has the ability to read and write, has independent peer relationships, and has the capacity to adhere consistently to rules and tolerate frustration. Once the capacity for level III play emerges in latency, it continues to be used throughout life. Although the games of any culture continue to be played throughout life, the underlying developmental themes and conflicts that energize the play change dramatically from developmental phase to developmental phase. When adults around the

world watch football, as billions did during the recent World Cup, they are reacting to a form of play first learned in latency.

But for many adults, particularly older ones, happiness and fulfillment are frequently experienced in level IV play, mental play, the form used continually throughout adult lives to bring the relief of tension, momentary pleasure, and the false illusion that people have control of this life and their place in it.

Watching and Listening: Spectator Play

When Grandpa takes his Grandson to a soccer match they both cheer every goal, both hard at work-resolving developmental conflicts. Through identification with the players on the field, freckle-faced grandson is dealing with latency-age phase-specific issues such as competitiveness and sexual identity. At the same time, 65-year-old Grandpa, also through identification with the players on the field, is mourning for his lost body of youth and coming to terms with success or failure in his chosen fields of endeavor, now that he no longer has the abundant future still available to the younger man playing in the match. Nurtured by their play and each other, when the game is over, the score soon forgotten, both Grandson and Grandpa return to the "real" world.

Listening to music is another extremely common form of play. Highly evocative and capable of stimulating a wide variety of sexual and aggressive fantasies, its ethereal, nontangible nature is consistent with the abstract nature of level IV play. From hard rock to Haydn, the endless variety of musical expression enhances its developmental usefulness to individuals of all ages. Great composers, such as Richard Strauss in his "Four Last Songs," have used music to confront the inevitability of death.

Writing a novel or a play is another form of play that brings great pleasure to both author and reader, as together they create an imaginary world of fantasy. Stimulated by the author's creation, the reader can revel, without fear of discovery or recrimination, in whatever sexual or aggressive fantasies he or she wishes. Unlike the child who is not primarily interested in communication, the author must take into consideration the effect of his or her creation on the audience, filtering fantasies through the organizing and critical influences of the ego and superego. By so doing, the author blends play with work, a blurring of boundaries that occurs frequently in adulthood. On the other hand, the playgoers or readers, who have no responsibility for the creative work, are closer to pure play as they sit in their seats, keep their mental and emotional responses to themselves, and experience a brief respite from the relentless pressures of work and reality.

Thus, it is clear that work and play are essential activities that help grown-ups deal with the huge responsibilities of adulthood and experience pleasure in the process. Work provides the means of caring for one's self and loved ones. Play provides a safety valve from the pressure cooker of

responsibility and furnishes an outlet for the powerful emotions generated therein. In the world of play and make-believe, time stands still, fantasy dominates reality, and the player is in control of life and death, if only for a moment or two.

Wow Moments!

And now to the last component, and certainly the most purely enjoyable one of all the ingredients for happiness and fulfillment, the term Wow Moments! is an attempt to describe in words the feeling of elation that accompanies the awareness, which hopefully occurs many times each day, that life is often truly wonderful, endlessly interesting, and full of beauty. Such moments of elation are obviously highly individual and vary enormously from person to person.

Paradoxically as it may seem, the ability to appreciate how stunningly wonderful life can be is based on the realization that nothing lasts forever, that change is a constant in life, and that the sense of elation experienced during Wow Moments! is transitory, like life itself. Although such moments can occur in childhood as well as adulthood, the awareness of the transient nature of all things, and therefore of Wow Moments! is experienced most fully in middle and late adulthood.

Freud's comments on the subject are particularly relevant to this discussion. In his paper "On Transience" (1916 [1915]) written during the First World War, Freud's attention was drawn to thoughts about loss and impermanence. Speaking about a friend who was a poet, he noted: "The poet admired the beauty of the scene around us but felt no joy in it. He was disturbed by the thought that all this beauty was fated to extinction, that it would vanish when winter came, like all human beauty and all the beauty and splendour that men have created or may create. All that he would otherwise have loved and admired seemed to him to be shorn of its worth by the transience which was its doom." (p. 305).

It is precisely this gradually growing, adult awareness that time is limited and that all things and all beings will eventually be destroyed, or die, that makes Wow Moments! so wonderful, so full of elation—and so transient.

Consider the following examples of Wow Moments!

The sense of exhilaration while taking the first breath of pure air on a sunlit morning beneath a cloudless sky.

The sense of physical, mental, and psychological fusion experienced by an elderly couple who have shared their lives for five or more decades.

The sense of deep satisfaction experienced by a therapist when after several years of therapy, a young adult patient who was terrified of commitment because of a childhood filled with abuse and abandonment was able to overcome his fear of intimacy and ask his girlfriend to marry him.

The feeling of physical intactness and competence experienced by those in their seventies and eighties after a hard workout in the gym or after watching an all too infrequent perfect iron shot land on the middle of the green on the golf course.

The sense of awe created while observing two loving parents care for their young children; the almost palpable experience of watching the next generation being created within the crucible of the nuclear family.

The transcendental joy of listening to the last movement of Mahler's second symphony or Mozart's clarinet concerto or Gershwin's rhapsody in blue.

The thrill of attending a World Cup and sharing the experience with more than a billion other human beings, becoming in that moment a true citizen of the world.

The tingling up and down of one's spine when listening to the Beatles or Soprano, or Marilyn Horne sing Donizetti.

The sense of wonder and connection with past generations and cultures while visiting Machu Picchu, Easter Island, Egypt, or Angkor Wat.

The recognition of individual insignificance when gazing at the heavens on a clear night while realizing at the same time, that in some incomprehensible way, every human being is an integral part of it all.

FUTURE DIRECTIONS

As more and more men and women are living into their 80s, 90s, and even to 100 and beyond, the frontier for the study of adulthood lies in understanding the nature of the developmental processes in late (60 to 80 years) and late late (80 to 100 plus years) adulthood, and the effect of the longer life span on their children and grandchildren. For example, caring for a very elderly parent when the "child" is in his or her 70s or 80s can stretch out the time spent engaging the development task of caring for parents to 30 or 40 years. What effect does that interaction have on the ability to the elderly offspring to focus primarily on their own engagement of the developmental tasks of late adulthood and relationships with his or her spouse, children, and grandchildren?

For example, one patient in her late 60s was struggling to deal with the care of her 103-year-old mother. Although still mentally sharp, if somewhat forgetful, mother had numerous physical problems such as pneumonia and hip surgery after a fall. The husband of the care-taking daughter was becoming deeply resentful of the time, energy, and money that were being expended to care for his mother-in-law. He was not in good health himself and wanted his wife to be more caring and available for him and for them as a couple. In addition, the couple's desire to spend time with their children and grandchildren was compromised. Being caught in the middle of generations (i.e., the "sandwich" generation) for 10 or 20 years, as was the case for most families in the past, has expanded in this family into a

fourth decade.

As the life span lengthens, researchers and clinicians are confronted with new challenges to provide patients and their families with guidelines for this new era in human development.

57 Geriatric Psychiatry

▲ 57.1 Overview

57.1a Introduction to Geriatric Psychiatry

DILIP V. JESTE, M.D.

AGING OF THE POPULATION

The population of the United States is aging rapidly, with both an increased number and increased proportion of older adults. The number of Americans aged 65 and over has increased from 3 million (4 percent of the total population) in 1900 to 43.1 million (13 percent of the population) in 2012. Yet, this historical rise will be dwarfed by that which has started in the year 2011 when the first of the baby boomers (those born between the years 1946 and 1964) reach the age of 65—the traditional definition of "old age." The number of people over 65 will rise to 72 million in 2030 and 84 million (20 percent of the population) by 2050 (Fig. 57.1a–1).

The average life span in the United States has increased from 47 years in 1900 to 79 years today. The more optimistic estimates project an increase in life expectancy at birth from the current figures of 76 years for men and 81 years for women to 86 years for men and 92 years for women by 2050. Men and women who are 65 years old today are expected to live an average of 16 and 19 years, respectively. By 2050, the average life spans at age 65 would have increased to 25 and 30 years, respectively. Thus, reaching age 65 would not indicate imminent death, but rather many more years of life. One of the unwelcome scenarios that could torpedo such an age wave would be a continuation of the current epidemic of obesity in younger and middle-aged individuals, leading to rising incidence of diabetes and other metabolic and vascular diseases that may shorten life spans.

The fastest growing segment of the population in the United States is that of individuals over the age of 85. The 85-and-over age group is expected to increase from about 6 million today to more than 18 million in 2050. Also striking is the growth of the centenarian population. While

there were about 5,000 centenarians in the United States in 1900, today there are around 53,000 people in that age group in the United States, or 1.73 centenarians per 10,000 people in the total population. By 2050, that number will have gone up to about 835,000. A particularly notable fact is that whereas most of the centenarians in the United States today are white, nearly half of those in 2050 will belong to ethnic minority groups.

The aging of the population is not restricted to the United States, but is a global phenomenon. The world is getting older at a pace that has taken demographers by surprise and presented governments with economic and social challenges. Whereas there were about 605 million people over age 60 in the year 2000, that number will reach 2 billion in the year 2050. Two-thirds of all the people in the entire history of the world who have reached the age of 65 are alive today. The number of centenarians in the world will increase from approximately 316,000 at the present time to an incredible 2.2 million by 2050. To put the latter number in perspective, presently the entire population of countries such as Kuwait, Latvia, Macedonia, and the United Arab Emirates is roughly 2 million people each.

The rates of aging of the population vary widely by region. In some developed countries today, the proportion of older persons is close to 20 percent, that is, 1 in 5. During the next several decades, that proportion will reach 1 in 4 and in a few countries as high as 1 in 2 (i.e., 50 percent). More highly developed countries have more stable populations and will experience proportionately less growth of their older populations than developing countries that are undergoing a rapid increase in the number of aged individuals. Figure 57.1a–2 illustrates the changing age structure of the population in more developed versus developing countries from 2005 to 2050.

FIGURE 57.1a–1. Number of Americans 65+ (in millions). (U.S. Census Bureau; 2014.)

FIGURE 57.1a–2. Source: United Nations, Department of Economic and Social Affairs, Population Division.

The definitions of middle age and old age, as well as some of the traditional thinking about chronological aging, may need to be revised. It has been suggested that middle age be defined as age between 51 and 70 years, "young old" between 71 and 90 years, and "exceptionally old" over age 90. With increasing longevity, the timetable for brain aging may have changed as well.

The growth of the older population during the 20th century is attributable to several factors. During the first half of that century, the main factor responsible for the demographic change was a progressive and dramatic decrease in perinatal and infant mortality due to better treatments of infections, improved nutrition, and better prenatal and

postnatal care. In the latter half of the last century, the greater longevity resulted primarily from an increase in average life span, that is, adults lived longer as a result of declines in mortality from pneumonia, heart disease, and other chronic diseases.

Aging is associated with increased heterogeneity. Tables 57.1a–1 to 57.1a–6 show number of people over age 55 in the United States by age and gender, by marital status, by educational attainment, by earnings of full-time workers, by types of household, and by monetary income. The wide range of diversity in socioeconomic status in older adults is remarkable. Factors such as education, marital status, and income have a potential bidirectional relationship with a number of mental illnesses. For example, adults with schizophrenia are likely to have lower levels of education, be unmarried, and have lower income than the general population. These variables could be considered potential risk factors for the illness; it is more likely, however, that these factors are secondary to the development of a serious mental illness. In either case, they are of considerable importance in management of persons with schizophrenia.

WHAT IS NORMAL AGING?

"Normal" aging must be differentiated from disease. Some bodily functions decline with age, but health problems are not inevitable. Most diseases of old age such as heart disease, cancer, and dementia result from pathological processes rather than from normal aging. Disabilities resulting from diseases can usually be treated and sometimes prevented. For example, most hearing problems can be at least partially corrected with hearing aids while the risk of heart disease can be reduced by healthy habits with respect to diet and exercise. The same applies to mental health and many of the mental illnesses in older people.

One point to stress is that aging is associated with more, and not less, diversity. It is a common misconception that older adults look, think, and behave alike. Indeed, there are more differences among older people than among younger adults. Even in the same person, different organs "age" at different rates. It has been suggested that the notion of the chronological age ("how old are you?") should be abandoned, and instead, the stages of aging that a given individual exhibits in different areas of functioning should be considered. Furthermore, just as a child may be at different stages of development mentally and physically, an older adult may have divergent aging of his or her brain, liver, kidneys, and heart. As a matter of fact, not even all the parts of the brain age at the same rate in a person. Thus, an aged person may have relatively intact memory while having deficits in motor function.

It must be recognized that although age cutoffs are needed for defining old age for societal purposes (e.g., qualifying age for starting Medicare or for Social Security), such cutoffs are artificial and arbitrary. No magical

change occurs overnight on the 65th or any other birthday. Also, with increasing longevity, the age cutoffs used currently will need to change.

There is often a tendency to confuse the effects of old age with those of its common, but not inevitable, associations. Thus, medical morbidity increases with aging, but many physical diseases can be managed better, and some (e.g., nutritional deficiencies) can be prevented. The diverse treatment of various physical illnesses by different specialists resulting in polypharmacy has an adverse influence on the treatment of mental disorders in the older adults. Similarly, psychosocial stressors such as financial hardship and lack of appropriate community services impact management of older people with psychiatric symptoms.

Table 57.1a–1.
Population by Age and Gender in the US: 2012 (Numbers in Thousands. Civilian Noninstitutionalized Population[a])

	Both Genders		Male		Female	
Age	**Number**	**Percent**	**Number**	**Percent**	**Number**	**Percent**
All ages	308,827	100.0	151,175	100.0	157,653	100.0
Under 55 years	229,349	74.3	114,685	75.9	114,664	72.7
55–59 years	20,470	6.6	9,879	6.5	10,592	6.7
60–64 years	17,501	5.7	8,278	5.5	9,223	5.8
65–69 years	13,599	4.4	6,461	4.3	7,139	4.5
70–74 years	9,784	3.2	4,519	3.0	5,265	3.3
75–79 years	7,331	2.4	3,122	2.1	4,209	2.7
80–84 years	5,786	1.9	2,421	1.6	3,365	2.1
85 years and over	5,006	1.6	1,809	1.2	3,196	2.0
Under 55 years	229,349	74.3	114,685	75.9	114,664	72.7

DEMOGRAPHICS OF OLDER PEOPLE WITH MENTAL ILLNESSES

Aging and aging-associated disorders (e.g., metabolic and vascular diseases) may influence expression and management of mental illnesses. Yet, psychiatric epidemiological studies have tended to exclude older adults. The common notion that psychiatric disorders are rare among older individuals is just plain wrong. This misconception, prevalent even among nongeriatric mental health experts, is based on studies such as the Epidemiologic Catchment Area (ECA) study conducted by the National Institute of Mental Health in the early 1980s. The ECA study was one of the largest epidemiological investigations of psychiatric disorders using, what was at that time, state-of-the-art methodology including the then-new DSM-III criteria. The ECA study reported that the prevalence of any psychiatric disorder (excluding dementia), either over the previous year or over the entire lifetime of the individuals, was considerably lower among older compared to that in younger adults (Table 57.1a–7). This decrease in the prevalence of mental illness with aging was thought to be due, in part, to higher mortality associated with serious mental illnesses. Yet, an important explanation for this ECA finding could be that psychiatric disorders were underdiagnosed among older adults for a variety of reasons.

[b]Earnings is the sum of wage and salary income and self-employment income.

From U.S. Census Bureau, Current Population Survey. *Annual Social and Economic Supplement.* Washington, DC; 2012. Internet release date: December 2013.

According to the ECA study, 13 percent of people over age 65 would meet the criteria for psychiatric disorders other than dementia. This is, however, likely to be a serious underestimate because of factors such as misattribution of psychiatric symptoms (by patients, caregivers, and raters) to other causes such as cognitive impairment, physical disorders, or "normal aging"; a lack of age-appropriate diagnostic criteria for major psychiatric disorders including substance abuse or dependence; and underreporting of psychological symptoms due to forgetfulness and social stigma. The "real" prevalence of psychiatric disorders other than dementia in older adults is probably at least 25 percent higher, that is, over 16 percent (Jeste et al., 1999). Additionally, over 10 percent of older adults have dementia, usually of the Alzheimer type; neuropsychiatric behavioral disturbances are common in patients with dementia, with at least a third of them (i.e., about 3 percent of the total older adult population) exhibiting psychotic and/or depressive symptoms. Thus, a total of nearly 20 percent of persons over age 65 would have diagnosable psychopathological symptoms.

Furthermore, psychiatric symptoms that do not meet the traditional criteria for psychiatric disorders (that had been developed for use in younger adults) but are nonetheless quite disabling are much more common in the older adults than the ECA study suggests. For example, a diagnosis of major depression requires the presence of at least five symptoms from a list of nine symptoms included in the DSM-5. If a person has four of those symptoms s/he would not meet the criteria for major depression, but may still be quite disabled. Such subsyndromal depression is much more common than major depression in the older adults; yet the patient may not receive the necessary therapeutic attention because the patient was not diagnosed with major depression. Table 57.1a–4 shows the prevalence of mental illnesses among younger (age 30 to 44 years) versus older (>65 years) adults.

From U.S. Census Bureau, Current Population Survey. *Annual Social and Economic Supplement.* Washington, DC; 2012.

Internet release date: December 2013.

There is expected to be a disproportionately greater increase in the number of mentally ill older adults than that of the overall older population. There are several reasons for this demographic change. Excess mortality (from suicide or physical comorbidity) in early life among seriously mentally ill patients such as those with schizophrenia, depression, and substance dependence is likely an important reason for a lower prevalence of nondementia psychiatric disorders in older compared with younger adults. With an improved overall standard of living, better treatment for physical disorders, and more effective treatments for psychiatric illnesses, the high mortality in mentally ill young adults should begin to decrease, resulting in a greater number of those who will reach old age. Also, with the general increase in the number of people older than 65 years, there will be more older adults in the community at risk of developing late-onset psychiatric disorders. Furthermore, aging baby boomers are expected to have a higher risk of depression, anxiety disorders, and substance use disorders than those born before the World War II. For all these reasons, it is estimated that the number of older mentally ill adults in the population will increase by at least 10 percent from 2000 to 2030, that is, it will be about 22 percent. Thus, the number of psychiatrically ill older adults will rise by 275 percent, from 4 million in 1970 to 15 million in 2030, while comparable number for those aged 30 to 44 years will increase by only 67 percent, from over 9 million to 15 million (Fig. 57.1a–3). These estimates are educated crude guesses; nonetheless, they provide some understanding of the magnitude of the challenge facing psychiatry.

Table 57.1a–7.
Prevalence of Psychiatric Disorders among Younger versus Older Adults in the United States

DSM-III-Diagnostic Categoryα	Younger Adults (30–44 Years)—ECAα		Older Adults (ê65 Years)—ECAα		Prevalence of Clinically Significant Symptoms
	1-Year Prevalence	Lifetime Prevalence	1-Year Prevalence	Lifetime Prevalence	
Affective Disorders					
Any	2.7% men	6.6% men	0.6% men	1.6% men	15–25%
Major depression	7.9% women	15.3% women	1.5% women	3.3% women	
Dysthymia	3.9%	7.5%	0.9%	1.4%	
Bipolar I	Not available	3.8%	Not available	1.7%	
Bipolar II	1.2%	1.4%	0.1%	0.1%	
	0.3%	0.6%	0.1%	0.1%	
Anxiety Disorders					
Panic disorder	0.7% men	1.8% men	0.04% men	0.1% men	17–21%
Phobic disorder	1.9% women	3.1% women	0.4% women	0.7% women	
Generalized anxiety disorder	6.1% men	10.5% men	4.9% men	7.8% men	
Obsessive-compulsive disorder	16.1% women	22.6% women	8.8% women	13.7% women	
	3.6%	4.9–6.8%	2.2%	2.6–4.3%	
	2.1%	3.3%	0.9%	1.2%	
Alcohol Abuse/Dependence	14.1% men	27.9% men	3.1% men	13.5% men	7–8% community-dwelling older adults consume 12 to 21 drinks/week; 10–15% of older primary care patients may have alcohol-related problems
	2.1% women	5.5% women	0.5% women	1.5% women	
Drug Abuse/Dependence	Not available	6.7%	Not available	0.1%	
Schizophrenia	1.5%	2.3%	0.2%	0.3%	
Antisocial Personality	1.5%	3.7%	0.0%	0.3%	
Cognitive Impairment					
Severe	0.3% (35–54 years old)	Not available	1.0% (55–74 years old)	Not available	
			5.0% (75 years or	Not available	

			older)	
Mild	3.1% (35–54 years old)	Not available	7.5% (55–74 years) 19.1% (75 years or older)	Not available Not available
Any psychiatric disorder (excluding cognitive impairment)	23%	39%	13%	21%

Note: Although not a psychiatric disorder per se, suicide is generally secondary to a major mental illness such as depression or schizophrenia. Suicide rates increase with advancing age (especially in Caucasian men), and seem to be increasing among more recent cohorts of older persons. Among older patients in primary care, the prevalence of suicidal ideation is 0.7 to 1.2%.

FIGURE 57.1a–3. Estimated number of people with psychiatric disorders in the United States. (From Jeste DV, Alexopoulos GS, Bartels SJ, et al. Consensus statement on the upcoming crisis in geriatric mental health: research agenda for the next two decades. *Arch Gen Psychiatry.* 1999;56:848–853.)

It is also to be noted that not only will the number of older adults with mental illness increase dramatically over the next few decades, but also the types of the patients one will see will change to some extent. For several disorders, there will be higher proportions of patients at the two ends of the severity spectrum. For example, expected advances in the ability to detect Alzheimer disease (AD) in earlier stages and to decrease the rate of decline via use of effective neuroprotective agents may result in greater number of patients who are more mildly affected and who will present different management problems from patients with advanced dementia. Issues regarding employment, financial planning, driving, home care, and day care will become more prominent. At the same time, reduced mortality from severe forms of physical illness (e.g., strokes, heart disease) will lead to increased number of severely demented patients with comorbid medical conditions living longer, raising different clinical, research, and ethical issues.

GERIATRIC PSYCHIATRY AS A SUBSPECIALTY

There are unique diagnostic and therapeutic considerations in the management of older adults with mental illnesses. Just as children are not small adults, the older adults are not merely chronologically more aged people. There are important psycho-bio-social differences that have an impact on the diagnosis, course, and treatment of mental (and physical) illnesses in different age groups. Because of age-related changes in the functioning of liver, kidneys, and brain, older people can only tolerate lower doses of most medications and are at a greater risk of developing a number of side effects. They also have special needs for psychosocial treatments (e.g., they are less likely to be living with their families and more likely to have financial difficulties). Additionally, they tend to have major physical illnesses and disabilities, have visual and hearing impairments, and have even less access to health care than younger adults. As a result, fewer than half of older Americans with mental illness receive the needed mental health services. They face the dual stigma of mental illness and aging. These problems are further compounded by therapeutic pessimism (and even nihilism) fostered by rampant societal as well as professional ageism.

Old-age psychiatry has had a long and distinguished tradition in the United Kingdom and other countries in Europe. In recent years, it has started to come of age in the United States too. Geriatric psychiatry became the second subspecialty of psychiatry (after child psychiatry) recognized by the U.S. Accreditation Council for Graduate Medical Education and by the American Board of Psychiatry and Neurology. There are several geriatric psychiatry organizations such as the American Association for Geriatric Psychiatry, the International Psychogeriatric Association, and the International College of Geriatric Psychoneuropharmacology. There are also several peer-reviewed journals devoted to geriatric psychiatry including the *American Journal of Geriatric Psychiatry*, the *International Psychogeriatrics*, the International Journal of Geriatric Psychiatry, and the *Journal of Geriatric Psychiatry and Neurology*. In basic sciences, there is a growing interest in the molecular biology of aging and neuroplasticity of aging.

Unfortunately, the increasing need for a geriatric mental health workforce is being met with a diminishing availability of experts in the field. There is a severe shortage of workforce trained to provide the necessary mental and physical health care for the growing number of older adults (Table 57.1a–8). Despite an urgent need for a trained workforce with expertise in geriatric mental disorders, the number of American Board-certified geriatric psychiatrists, who have maintained their subspecialty certification, has dropped from over 2,200 a decade ago to fewer than 1,800 today. This number is projected to decrease further to 1,650 by the year 2030, amounting to less than one geriatric psychiatrist for every 6,000 older adults with mental health and substance use disorders. Out of more

than 40,000 psychiatrists in the United States, only about 5,000 list "geriatric or gerontological psychiatry" as one of their three primary areas of interest.

The Institute of Medicine (IOM) has reported that the "tipping point" of an inevitable shortfall in providers has been passed, and it highlights the urgency of expanding and strengthening the geriatric health care workforce. Yet, little is being done to address this challenge. Already geriatric psychiatric services are in high demand and specialists are in short supply. Trainee pool is a critical issue. Currently, there are over 100 geriatric psychiatry fellowship training slots available nationwide, but the number of slots filled has declined from more than 80 percent in 2000 to under 50 percent today. Psychiatry residents, often struggling with large student loans, are drawn away from geriatric psychiatric fellowship, at least partly because of financial concerns. Rates of Medicare reimbursement are decreasing, and the reimbursement system as a whole makes psychiatric care difficult to access for older patients. The dual stigma against aging and mental illness also makes geriatric psychiatry less attractive to many trainees.

COMMON MENTAL ILLNESSES IN OLDER PEOPLE

A brief description of a few of the mental disorders of late life is provided below. A detailed description of each illness, its causes, and treatments is provided in subsequent chapters of the book.

Alzheimer Disease and Other Dementias

AD is the most common form of dementia. It is a progressive brain disorder that results in cognitive deficits such as memory loss, impaired thinking, and abnormal behavior. The number of older persons with AD will increase substantially over the next three decades for several reasons. The prevalence of dementia doubles every 5 years after the age of 60. Thus, 1 percent of the people aged 60 to 64 years are affected; 2 percent of those aged 65 to 69, 4 percent of those between 70 and 74, 8 percent of those 75 to 79 years old, 16 percent of those aged 80 to 84, and 30 to 45 percent of those aged 85 years and older. These figures provide a reasonable guide to the number of patients with AD and other dementias anticipated in over the next three decades. From a different perspective, one of the "hottest" areas of research is developing drugs that delay the progression of brain degeneration in patients with dementia. AD and other dementias are seriously underrecognized at present. In various studies, investigators have found that primary care practitioners recognize only a minority of the AD patients identified by researchers using a structured diagnostic interview. A greater awareness of the need for early detection of AD among professionals as well as among lay public can be expected. Currently, many

researchers are working on developing biological markers to detect early AD. Reliable and valid biological markers will diminish the present dependence on clinical (largely subjective) judgment in diagnosing early AD and enhance the rate of detection of AD even before obvious dementia has set in. Furthermore, as new therapies for the treatment of very early AD (even before dementia is obvious) become available in the coming years, improved recognition of patients before they manifest the disease clinically will increase the number of identified cases in the population.

Interestingly, there are also factors that could serve to reduce the incidence of AD in the future cohorts of the aged individuals. One such factor is education. The prevalence of AD is lower among those with more years of formal education. There will be greater number of older baby boomers with a high school diploma compared to the current cohort of the older adults. Education also has a variety of secondary effects that may reduce the frequency of dementia. For example, head injury has been identified in several studies as a risk factor for AD, and head trauma is less common among those with more education who are more likely to wear safety belts, use protective head gear in contact sports, and avoid driving while intoxicated. Such factors associated with a reduced risk of AD point to the way in which may be able to lower the incidence of AD may be able to be lowered by proactive societal actions.

Neuropsychiatric behavioral disturbances such as agitation, psychosis, and depression are common in patients with AD, and are a frequent cause of institutionalization. About a third of the patients with AD have depressive symptoms, whereas the prevalence of psychosis is about 50 percent. Agitation is even more frequent, especially in later stages. A number of intervention studies of pharmacological as well as psychosocial treatments have been performed for these neuropsychiatric symptoms, with variable results.

Dementias other than AD, such as Lewy body dementia, frontotemporal dementia, and vascular dementia are receiving increasing attention too, mainly in the areas of brain imaging and neuropathology. Again, behavioral disturbances are a common phenomenon in these patients.

Anxiety Disorders

Anxiety disorders are the most common disorders among the older adults with the exception of dementia. There are a number of differences between younger versus older adults in terms of psychopathology of these disorders. For example, older phobic patients tend to have fear of situations or inanimate stimuli, such as heights or lightning, whereas younger individuals are more likely to have a fear of animals. Because of physical and psychosocial changes associated with aging, it might be difficult to distinguish between phobias and nonpathological avoidance behaviors in older patients, such as avoiding leaving home due to arthritis or a fear of

crime. Older adults might be more likely than younger patients to manifest a mixture of anxiety and depression. Such comorbidity could be a result of cooccurrence of two common conditions, or could reflect one being an epiphenomenon or a complication of the other. A syndrome of "mixed anxiety–depressive disorder" might have both heuristic and clinical utility for older patients.

Depression

Numerous studies have shown that depression goes undiagnosed in sizable proportions of older adults. This is due, in part, to frequent denial of depression with its associated social stigma and attributing the symptoms of depression to "normal" aging or to physical illnesses. In the past three decades, some of the SSRIs have become nearly household names, leading to more recognition and acceptance of depression in the public at large. This trend will continue, resulting in reduced social stigma associated with depression. Another important reason for the underdiagnosis of depression in the primary care setting, where most older persons are seen, is the inadequacy of geriatric mental health training at the medical school level. With improvements in medical education, this situation will change in the years to come, resulting in greater detection of depression in the older adults.

Major depression manifests somewhat differently in the older compared to younger adults. Physical symptoms such as change in appetite and body weight, constipation, and sexual dysfunction are more common in the older adults; on the other hand, the physical symptoms in older adults could be a result of an undiagnosed physical illness (e.g., pancreatic cancer). While the point prevalence of subsyndromal depression in the younger adults is comparable to or lower than that of major depression, the prevalence of subsyndromal depression (18 percent) is three times that of major depression (6 percent) in people aged 65 years or older. Thus the predominant form of depression in the older adults appears to be subsyndromal depression. Notably, subsyndromal depression is also associated with significant increases in psychosocial impairment in major domains of everyday functioning.

A number of large epidemiological investigations in several different countries have shown that the risk of depression, as well as depression-related suicides, alcoholism, and substance abuse is significantly higher in the baby boomers than in those born before the World War II. The reasons for this type of "cohort effect" (i.e., different rates of an illness in people from different generations) are not known, but could be related to several different factors: genetic factors such as new mutations among recent generations. A number of environmental factors may also contribute to greater stress and increased risk of depression among the baby boomers; these include changing family structure with nuclear families, higher

divorce rates, changed roles for working women, greater urbanization, and a decrease in "social connectedness" due to geographical mobility and job changes. Finally, depression is known to be much more common among those with physical illnesses than in the physically healthy people. This observation leads to the development of preventive interventions in individuals with physical disorders such as heart disease and cancer.

Schizophrenia and Other Psychotic Disorders

The century-old concept of schizophrenia, based on Kraepelin's definition of dementia praecox, is that this is a disorder with onset in early life, that is, adolescence and early adulthood ("praecox") and progressive deterioration ("dementia"). Yet studies in older patients show that schizophrenia can have onset in middle age (late-onset schizophrenia). Late-onset schizophrenia is more common in women, and is usually of paranoid type. In terms of its course in late life, schizophrenia is typically not associated with a dementing course. Indeed, a small minority of patients with schizophrenia have a sustained remission of their illness in old age.

Psychotic symptoms may manifest for the first time after age 65. This is generally not schizophrenia, but is best labeled very late-onset schizophrenia-like psychosis.

Substance Use Disorders

As better treatments become available for substance use disorders (including alcoholism), the focus in the war on drugs during the coming decades will shift from punishment to treatment. Studies using currently available diagnostic criteria for substance abuse have underestimated the prevalence of drug abuse in the older adults because these criteria were developed and validated only in young and middle-aged samples. For example, DSM-5 criteria for substance use disorders include development of tolerance to the effects of that substance (e.g., a given amount of a stimulant produces less stimulation than it used to), resulting in a need for increased consumption over time. Yet, liver and kidney damage common in old age would produce higher concentrations of that substance in the blood, while age-associated brain changes would serve to enhance the effects of the substance on the brain. Hence, there is likely to be decreased tolerance to that substance in an older individual (i.e., a given amount produces more effect than it used to) leading to a need for decreased consumption. This older person, although still dependent on the substance, may not meet the "official" criteria for diagnosis. One DSM-5 criterion for substance use disorders is a report of being repeatedly unable to carry out major obligations at work, school, or home, such absences or poor work performance, suspensions or expulsions from school, and neglect of children. Such adverse consequences are much less likely to occur in older

adults who often live alone and are unemployed, resulting in underestimation of substance use disorders.

It is generally believed that aging is associated with reductions in and changing patterns of drug use (i.e., reductions in illicit drug use). One theory posits that factors associated with "maturation" associated with aging processes, and increased number of individuals who have been dependent on illicit drugs would become abstinent as they age. This is, however, not entirely supported by empirical data which suggest that there may be increasing number of older addicts and that persons who have been dependent for more than 5 years do not become abstinent as they age. In addition to an increased number of aging "lifelong" drug abusers, a greater number of individuals who, after decades of abstinence, return to drug or alcohol problems are also likely to be seen. Psychosocial stressors including isolation, various types of losses, loneliness, and onset of illness have been related to late-onset drug use.

There is a greater use and acceptance of psychotropic medications among the baby boomers than among those born before the World War II. In contrast to younger substance abusers who most often abuse illicit drugs, substance abuse problems in the older adults may result from misuse or abuse of over-the-counter (OTC) and/or prescription drugs. Older individuals use prescription drugs three times as frequently as the general population, and the use of OTC medications by this group is even more extensive. The estimated expenditure on prescription drugs by the older adults in the United States is $15 billion annually, a fourfold greater per capita expenditure on medications compared to younger individuals. Psychoactive drug use (most often sedative-hypnotic, anti-anxiety, and analgesic) is particularly problematic, including long-acting drugs not recommended for the older adults, and inappropriately high doses of benzodiazepines.

Comorbid physical as well as psychiatric disorders appear to be important predictors of prescription drug use. As greater number of people with chronic physical and psychiatric disorders survive into older age, there will be increased prevalence of substance use disorders in the older population.

The jury is still out whether the legalization of marijuana for medical use or adult recreational use in a growing number of states may negatively affect the health of older adults. Marijuana is the most commonly abused drug in the United States and around the world, but it is likely that with legalizing marijuana, the number of marijuana users would increase.

POSITIVE SIDE OF AGING

Contrary to the concept that aging means progressive and inevitable deterioration of the brain and mind, a number of recent studies across the world shows that psychological well-being and happiness increase with age,

especially after middle age. Some studies have found that subjective feeling of well-being (a sense of contentedness) is high at the beginning of adult life, then declines progressively until it hits the rock bottom in middle age, producing the so-called mid-life crisis, but then starts to rise again. Other investigations report a progressive rise in well-being from age 20 to 80+. Interestingly, the level of happiness in the early 80s is similar to that in the early 20s. The increase in happiness after middle age occurs even as physical, cognitive, and fertility functions decline. This finding has been reported by researchers from several different countries and cultures. Notably, perfect physical health is neither necessary nor sufficient to feel happy as people grow older. Research shows a paradox of aging: physical health and some aspects of cognitive function (for instance, memory for names and faces) decline with age, while happiness, mental health, and management of interpersonal relationships improve.

What are the possible explanations for this counter-intuitive result? Suggested factors include changes in attitude such as greater acceptance of one's physical limitations, contentedness with past accomplishments in life, reduced preoccupation with peer pressure, a more realistic appraisal of one's own strengths and limitations, and increased emotional stability. Intriguingly, a recent study, based on the reports by the individual caretakers of chimpanzees and orangutans in zoos and other protected areas, found an increase in these great apes' well-being after middle age. Thus, better well-being in older age might be rooted, in part, on biological changes in the brain.

Several aspects of aging can be aided significantly by improved health care, greater societal value placed on the older adults, and a more positive conceptualization of old age. Most psychiatrists today would not agree with Freud's assertion in 1924 that near or above the age of 50, the elasticity of mental processes is lacking and, therefore, older individuals are "no longer educable." The so-called problems of aging should become opportunities for a better understanding and improvement of the entire life process.

The aging of the population is generally viewed with concern and alarm about its impact on social security, health care (including Medicare), housing, jobs for younger generations, etc. Yet, this is also a grand opportunity to make positive use of the growing older adults' population so that the new era, dubbed by some as "Silver Tsunami," can be labeled the "Golden Wave." The most important advance in neuroscience in the past two decades has been the demonstration of neuroplasticity of aging—the fact that brain growth and development continue into old age. Furthermore, such a positive outcome is related, not so much to the genes people inherit from their parents, but to their behavior, attitude, and environment. With appropriate physical activities, targeted nutrition, and psychosocial stimulation along with necessary health care and social support, successful aging need not be a dream, but can become a

widespread reality. As the quality of life of older adults improves, they become more productive, contribute more to the rest of the society, and their health care costs go down. The seniors who learn and teach can be wonderful and wise mentors for younger generations. Older citizens can lead efforts at social entrepreneurship in a collaborative manner.

SUCCESSFUL COGNITIVE AND EMOTIONAL AGING

Research on aging has typically focused on disease and disability. However, during the past two decades, this focus has slowly begun to expand to incorporate studies of "successful or healthy aging." Understanding why some people seem to adapt to challenges they encounter in late life when others cannot, would facilitate the development of interventions and policies geared toward older populations. Yet, there are many times as many studies of aging-related disorders as there are on successful aging. One problem in research on successful aging is that it involves multiple components (e.g., physical health, psychological well-being) that extend beyond longevity, and as a result, there are numerous criteria for defining it but no consensus. In 1987, Rowe and Kahn proposed that successful aging involved three components: (1) absence/low probability of disease and disease-related disability, (2) high cognitive and physical functioning, and (3) active engagement with life. According to this model, however, many cognitively intact and socially active older adults would not be categorized as aging successfully because of the presence of chronic physical diseases and disabilities. Also, such criteria fail to take into account the perspectives of older adults themselves about what defines and determines successful aging. Whereas researchers tend to focus on physical health as a critical factor to successful aging, older adults tend to stress the role of psychological factors such as adaptation and acceptance, along with emotional well-being. One focus group study indicated that older adults viewed successful aging as involving a foundation of health and security, along with attitudes and adaptive behaviors that can compensate for difficulties with that foundation, and enable engagement in meaningful activity and stimulation. It is particularly noteworthy that a number of aspects of successful aging identified by older adults in this study (e.g., attitude, health care, financial security) are potentially modifiable.

Successful aging is a complex and multidetermined trait and state, with numerous genes and environmental factors making small contributions to the overall presentation of the phenotype. No single factor is either necessary or sufficient to determine the outcome in a specific individual. Cognitive preservation may, however, be a prerequisite of independent living, positive adaptation, mastery, and growth, all of which seem to be the major determinants of "success."

IMPLICATIONS FOR FUTURE PROGRESS

The impending crisis in geriatric mental health with the projections of dramatic increase in the number of mentally ill older people as the baby boomers reach old age should be a cause of great concern. However, the good news is that there is something that can be done about this issue. First, begin by recognizing the fact that the expected increases in the ranks of older mentally ill adults are not necessarily a bad thing. It is better to diagnose illnesses that are treatable rather than keeping them from being detected in the older adults. Advances in the pharmacological and psychosocial management of psychiatric disorders over the past two decades have already improved the treatment of several serious mental illnesses in older people. Previously unimaginable advances are taking place in the understanding of brain function in normal aging as well as in various neuropsychiatric disorders. New lines of investigation are pointing to possible ways of not just managing but even possibly curing and preventing several diseases for which there was little hope in the past. Brain stem cell implants, gene therapy, and vaccines for AD (despite the initial disappointing results) are among a host of therapies that are moving from the realm of science fiction to reality in a matter of years instead of decades. Early diagnosis of disorders such as depression or AD is important in order to start treatments that will prevent or at least slow their progress. Similarly, it is better that young adults with schizophrenia who currently have a shorter life span than the general population live into old age. Hence, an increase in the number of older adults with mental illnesses will be, in part, a welcome development.

At the same time, some of the increased prevalence of mental illness in older people may be preventable. For example, a proportion of cases of late-onset depression or substance use disorders could be prevented by appropriately treating individuals at high risk of developing these disorders. Thus, support groups for bereaved persons could lower the risk of developing major depression. Similarly, persons with stroke or myocardial infarction are at a high risk of depression, and the incidence of poststroke and postmyocardial infarction depression could be reduced with use of suitable antidepressant treatments and/or psychosocial interventions following strokes or heart attacks. There are new emerging neurobiological data suggesting that physical exercise may be as beneficial for the brain as for the body. Research also needs to be conducted to determine if engaging in specific types of mental activities may lead to delayed onset of dementia.

The less developed regions of the world will undergo proportionately larger demographic shifts in the decades ahead than the more developed ones that have had stable population base for many years. Yet, the less developed nations also have fragile economies and will have limited opportunity to increase health services and treatment for aged individuals. This global situation places a premium on developing diagnostic

technologies and treatments that are sufficiently inexpensive and can be widely applied.

Reducing social stigma associated with aging is as critical as reducing social stigma associated with mental illness. Mental illnesses are brain disorders and as such, should receive the same consideration in terms of insurance coverage.

The age-old stereotype that late life is a gray and dark period of life can be changed to try to make it a "golden" one for senior citizens. There are several aspects of aging that can be aided significantly by improved health care. If the societal value placed on the older population becomes more positive and the scientific openness to conceptualizing old age increases, it will become clear that the so-called problems of aging are actually opportunities for a better understanding and improvement of the whole life process. To quote Alex Comfort, "No pill or regime known, or likely, could transform the latter years of life as fully as could a change in our vision of age and a militancy in attaining that change." The same applies to the attitude toward mental health and mental illness in old age.

57.1b Epidemiology of Psychiatric Disorders

CELIA F. HYBELS, PH.D., AND DAN GERMAN BLAZER, II, M.D., PH.D.

Epidemiology is the basic science of public health. The data provided from epidemiological studies are critical for recognizing the relative burden of varieties of psychiatric disorders. Not only does epidemiology present the situation of psychiatric disorders in the population, it serves as a means for identifying causal factors which can be followed up with clinical and basic science investigations. Data from epidemiological studies are also critical in service planning nationally and at the level of local communities. Perhaps at no time in recent years have epidemiological studies of older adults been of more importance given the increasing numbers of older adults and the frequency of disorders encountered, some of which are apparently increasing in frequency, such as substance use disorders.

Epidemiology as a science is concerned with the patterns of disease in populations. In geriatric psychiatry, this includes identifying the proportion of older adults with a psychiatric disorder (diagnosed using operational criteria such as DSM-5) during a specified time period (*prevalence*) and the frequency of disease occurrence or the proportion of older adults who develop a psychiatric disorder within a specified time period (*incidence*). Incidence and duration of a disorder affect its prevalence. For example, disorders that have a slow progressive course, such as Alzheimer disease, are likely to increase in prevalence if the incidence increases, if survival with the illness increases (duration), and if no treatment is found. But it is the search for determinants of disease patterns (e.g., what characteristics are shared among persons in whom these disorders are most likely to be found and how these identified characteristics affect the course or duration of the disorder) and the identification of risk factors (e.g., which characteristics increase the probability of disease occurrence) that is the goal of most epidemiological research.

Case definition is critical to epidemiology, yet presents special challenges for psychiatric disorders in late life. Not only can these disorders occur for the first time in late life, but their presentation in older adults may also be different from that seen in younger adults. Many older adults may fail to meet specified criteria for psychiatric disorders yet endorse an array of symptoms that are clinically meaningful, suggesting that case definition must include psychiatric symptoms as well as disorders. In addition, through their comorbidity with physical illness and other mental disorders, psychiatric symptoms in older adults present diagnostic, prevention, and treatment challenges to health care professionals. This chapter provides an update to epidemiological data presented in the previous edition of this text while at the same time retaining descriptions and data which remain relevant and have not changed since the previous

edition.

DEMOGRAPHICS OF AGING

The last century has seen a dramatic increase in the number of adults age 65 or older, what some have described as the silver tsunami. In 1900, there were 3.1 million in this age group in the United States, while by the year 2010 the number had increased to 40.3 million. Similarly, those 85 or older, 0.1 million in 1900, numbered 5.5 million in 2010. By the year 2050, the population of persons 65 years of age or older in the United States is expected to be approximately 88.5 million, and those 85 or older are expected to number 19 million. The proportion of adults age 65 years or older is projected to increase from 13.0 percent in 2010 to 20.2 percent in 2050. The proportion age 85 or older is projected to increase from 1.8 percent in 2010 to 4.3 percent in 2050. Similar increases in the proportion of older adults are also expected outside of the United States as better treatments for chronic disease and other physical illness become available.

These projections suggest that even if the proportion of older adults with a current psychiatric disorder remains unchanged the number of older persons with a disorder will increase over the next several decades. In addition, the proportion of younger adults with a psychiatric disorder (excluding the dementias) is much higher than the proportion among older adults, suggesting that as current younger cohorts age the proportion of older adults with a psychiatric disorder may increase as well as the burden due to a higher number of older adults. As better treatments for mental illness are developed, the proportion of adults with a history of mental disorder surviving to old age may increase. Some forecasters have estimated that the number of older adults with a psychiatric disorder in the United States will be 15 million by the year 2030. These numbers emphasize the importance of understanding the epidemiology of psychiatric disorders in older adults.

PREVALENCE OF PSYCHIATRIC DISORDERS IN OLDER ADULTS

From 2001 to 2003, the World Health Organization (WHO) conducted a series of household surveys across 14 countries to estimate the prevalence, severity, and unmet need for treatment of mental disorders, the World Mental Health surveys. In the United States, the survey was called the National Comorbidity Survey Replication (NCS-R), and 9,282 respondents age 18 or older were interviewed. The WHO Composite International Diagnostic Interview (CIDI) was the instrument used to generate fourth revised edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) diagnoses. As shown in Figure 57.1b–1, among adults age 60 or older in the NCS-R, the most prevalent lifetime disorders were major depression (10.6 percent), specific phobia (7.5 percent), social phobia (6.6 percent), and alcohol abuse (6.2 percent). A total of 26.1

percent of the respondents age 60 or older had one or more lifetime psychiatric disorders, 11.6 percent had two or more lifetime disorders, and 5.3 percent had three or more. These lifetime prevalence estimates were lower than those in other age groups. Among those 18 to 29, 30 to 44, and 45 to 59, a total of 22.3, 22.5, and 15.9 percent, respectively, had three or more lifetime disorders.

The Collaborative Psychiatric Epidemiology Surveys (CPES) were sponsored by NIMH to combine three nationally representative surveys: the NCS-R described above, the National Survey of American Life (NSAL) which oversampled adults of African-American and Afro-Caribbean ethnicity, and the National Latino and Asian American Study (NLAAS). By using the same interview structure and the WHO version of the CIDI across the three studies, the CPES allowed for more intensive study of the epidemiology of psychiatric disorders within minority populations. For example, among those age 55 or older in the CPES, non-Hispanic Whites and Latinos consistently had a higher prevalence of psychiatric disorders. African Americans had a lower prevalence of major depression and dysthymia, and Asian Americans were less likely to report any affective disorder. The lifetime prevalence of major depression among adults age 55 or older in the NSAL was 6.7 percent among African Americans and 11.5 percent among Blacks of Caribbean ethnicity, compared to 14.3 percent among Whites. The 12-month prevalence of major depression showed a different pattern: 2.0 percent among African Americans, 4.7 percent among Whites, and 10.7 percent among Caribbean Blacks. Among older Asians in the NLAAS, the 12-month prevalence of major depression was 1.72 percent among those ages 60 or older compared to 1.55 percent among those ages 45 to 59 years, 5.47 percent among those ages 30 to 44 years, and 7.76 percent among those ages 18 to 29 years.

FIGURE 57.1b–1. Lifetime prevalence of selected psychiatric disorders among adults 60 or older in the National Comorbidity Survey Replication (NCS-R).

FIGURE 57.1b–2. Twelve-month prevalence estimates of selected psychiatric disorders in the National Epidemiologic Survey of Alcoholism and Related Conditions (NESARC) by age.

Another large-scale study conducted in the United States from 2001 to 2002 also provided national estimates of DSM-IV-TR disorders. In the National Epidemiologic Survey of Alcoholism and Related Conditions (NESARC), a total of 43,093 persons age 18 or older were interviewed. A structured interview, the Alcohol Use Disorder and Associated Disabilities Interview Schedule-DSM-IV Version (AUDADIS-IV), was used to generate diagnoses. The 12-month prevalence estimates for selected disorders across age groups are shown in Figure 57.1b–2. Among those age 65 or older, the 12-month prevalence of major depression was 2.7 percent, social anxiety disorder was 1.6 percent, generalized anxiety disorder was 1.0 percent, specific phobia was 7.5 percent, panic disorder was 0.8 percent, and alcohol abuse was 1.2 percent. Across all disorders, the prevalence is lowest among older adults in comparison to younger adults. In the NCS-R, the 12-month prevalence of any mood, anxiety, or substance use disorder was 8.5 percent among those age 65 or older compared to 27.6 percent among those ages 18 to 44 years and 22.4 percent among those ages 45 to 64 years.

The estimates from the CPES and the NESARC add to a growing body of literature reporting lifetime, 12-month, and current prevalence estimates across multiple countries. A description of the epidemiology of psychiatric disorders would not be complete without recognizing the contributions of one of the earliest studies of the prevalence of psychiatric disorders, the landmark Epidemiologic Catchment Area (ECA) survey conducted in the

late 1970s and early 1980s in five US communities—New Haven, Connecticut; Baltimore, Maryland; St. Louis, Missouri; Durham, North Carolina; and Los Angeles, California. A total of 18,571 persons participated, including 5,702 persons age 65 or older. Psychiatric disorders were measured using the Diagnostic Interview Schedule (DIS), one of the first structured interviews from which DSM diagnoses could be generated. These structured interviews could be administered by trained lay interviewers, allowing population estimates to be reported.

Across all five ECA sites, the 1-month prevalence of any DIS disorder in adults age 65 or older was 12.3 percent, compared to 16.9 percent in adults 18 to 24 years of age, 17.3 percent in those 25 to 44 years of age, and 13.3 percent in those 45 to 64 years of age. For all disorders, with the exception of substance use, alcohol abuse and dependence, and severe cognitive impairment, the prevalence was higher in older women than that in older men. The prevalences of any DIS disorder within the previous month, excluding the dementias, were 10.5 percent in men 65 years of age or older and 13.6 percent in older women.

Geriatric psychiatrists have suggested that these studies may underestimate the burden of psychiatric illness in older adults and that the frequency of clinically significant psychiatric symptoms in older adults may be much higher. Even so, data from studies conducted in the United States as well as other countries over the last several decades among persons age 60 or older have added much information concerning the prevalence of and risk factors for various psychiatric disorders and their associated subclinical forms in late life. Although they have published varying prevalence estimates of the disorders, these studies have concluded that mental illness in older adults is a significant public health problem.

The reported prevalence and incidence of psychiatric disorders in late life can be influenced by a variety of factors, including case definition, sampling issues, potential bias, and cohort effects.

Case Definition

Research studies generally define cases in one of two ways: (1) persons with psychiatric symptoms and (2) persons who meet criteria for specific psychiatric disorders as defined by the nomenclature. If strict diagnostic criteria are applied, then the prevalence of a psychiatric disorder is generally lower than that if the criteria for a case are more relaxed, such as not reaching the threshold of a DSM diagnosis. For example, the DSM-5 as well as previous editions since 1980 defines cases by the presentation of specific symptoms, often within a specific time period.

There are several instruments that have been used in epidemiological studies to identify persons with specific DSM disorders. Most of these instruments were originally developed for DSM-III through DSM-IV-TR. Large scale epidemiological studies are only beginning to apply DSM-5

criteria. Yet the criteria in DSM-5 have not varied such that the previous estimates are at significant variance from DSM-5 for older adults. The one exception is the addition of the meta-categories of mild (roughly equivalent to mild cognitive impairment [MCI]) (see Alzheimer Disease and Other Dementias) and major neurocognitive disorders (which basically is equivalent to the combination of all dementias). The DIS, previously mentioned, was developed for the ECA program and was based on the nomenclature in place at the time at which the ECA studies were conducted (DSM-III). Other instruments have been developed since that time. The version of the CIDI used in the CPES corresponds to DSM-IV-TR criteria and, like the DIS, can be administered by trained lay interviewers. The AUDADIS-IV used in the NESARC is able to generate DSM-IV diagnoses. The Structured Clinical Interview for DSM-IV-TR (SCID) is another structured instrument to make clinical diagnoses but must be administered by a health professional. It can be expected that modifications to these instruments will be made in order to generate DSM-5 diagnoses. Instruments have also been developed that correspond to the tenth edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) criteria. For example, the Geriatric Mental State Automated Geriatric Examination for Computer-Assisted Taxonomy (GMS-AGECAT) has been used in many studies in Europe to identify clinically significant symptoms of depression, dementia, and other disorders that allow clinicians to identify cases which can be mapped to ICD or DSM criteria.

Other measures used widely in clinical and community epidemiological research identify specific symptoms rather than diagnostic criteria for selected disorders. For example, the Center for Epidemiologic Studies—Depression (CES-D) Scale and the Patient Health Questionnaire (PHQ-9) screen for depressive symptomatology, whereas the Mini-Mental State Examination (MMSE) screens for cognitive impairment. It is important to note that many epidemiological studies of mental illness in older adults include individuals as cases who do not necessarily meet the diagnostic criteria for a particular psychiatric disorder (such as clinically significant depressive symptoms that do not meet criteria for major depression). Prevalence and incidence estimates can vary, therefore, depending on the instrument used to define the cases and whether symptoms or disorders are being reported.

Many older adults have clinically significant symptoms documented by such instruments that, in number or duration, do not meet the DSM-5 or ICD-10 criteria, yet are associated with decreased physical and social functioning and overall quality of life, particularly subsyndromal depression and MCI. As described later in this section, the prevalence of these subclinical forms of the disorders is high and, for some disorders, may be more representative of the disorder in older adults.

Other factors affect case identification. Prevalence estimates may be based on occurrence of symptoms within the past month, 6 months, 1 year, or lifetime. For example, the 1-month prevalence is usually much lower than the lifetime prevalence. Age of onset may affect the lifetime prevalence of a disorder. Older adults may not recall the age at which symptoms were first experienced or even if they have experienced a prior episode. The reported prevalence can be affected if the disorder had to appear before a certain age to satisfy the diagnostic criteria. For example, previous restrictions on the diagnosis of schizophrenia to onset before 45 years of age reduced earlier prevalence estimates of schizophrenia among older adults. Case detection in late life is also complicated by the fact that many psychiatric disorders appear for the first time at a younger age and then reappear in late life. Finally, it is difficult to distinguish psychiatric symptoms in older adults that have a psychogenic origin from those that result from medication use or a physical illness. Older adults may experience symptoms of depression or cognitive impairment that are the result of medication use and may be misclassified as having a psychiatric disorder. Similarly, older adults may experience virtually all of the symptoms of major depression, yet these symptoms may be attributed to a physical illness.

Sampling Issues and Sources of Bias

Estimates of prevalence and incidence are determined by the target population about whom inferences are made. For example, estimates of the prevalence of psychiatric disorders in clinical populations are generally higher than those obtained when the target population is community-dwelling older adults. The prevalence of dementia in older adults is higher in samples from long-term–care facilities in comparison to samples of community-dwelling older adults. Psychiatric disorders for which adults may be less likely to seek treatment may be quite prevalent in community samples yet rarely observed in clinical samples. For example, one of the most surprising findings from the ECA surveys was the high prevalence of phobic disorder in the community population of elders. Because individuals may be unlikely to seek treatment, the population prevalence was not known until a large-scale community sample was undertaken.

Older adults may be more likely than younger adults to experience a physical illness or to be in a long-term–care facility, which can complicate or preclude their participation in a study that uses a representative sample, such as the CPES and the NESARC, resulting in an underestimate of the true prevalence of psychiatric disorders among older adults. Some older adults may not be cognitively able to give consent and to participate in research studies. If individuals with dementia are more likely to have depressive symptoms than those without dementia and demented subjects are excluded, then the prevalence of depressive symptomatology is

underestimated.

Finally, older adults may refuse to consent to participate in research studies, or their family may refuse to allow them to participate. If these persons are more likely to have clinically significant symptoms of mental illness, then differential patterns of nonresponse can result. In particular, studies in which elderly volunteers are recruited may be more likely to enroll healthier subjects than one would get in a random sample.

There are several types of biases that can affect the prevalence of psychiatric disorders in older adults reported from research studies. Misclassification bias is an important issue. Specifically, if the current nomenclature is less applicable to older adults, then elderly adults may be misclassified as not meeting criteria for the disorder. For example, older adults with an array of depressive symptoms but no report of sadness would not meet criteria for DSM-5 major or minor depression. Recall bias is important in studies of older adults who may selectively recall symptom information. Selection bias should also be considered, in that prevalence estimates can be affected by selective survival (i.e., only the healthiest adults survive to old age). As is discussed later in this section, suicide rates are high in late life, which can affect the prevalence of disorders such as major depression.

Cohort Effects

The prevalence of psychiatric disorders can be affected by external circumstances affecting a particular cohort. Specifically, it is important to determine if the observed prevalence of a psychiatric disorder in a particular age group is likely to remain stable over time (i.e., age is a major determinant of the disorder) or whether the prevalence is likely to be associated with a particular cohort. For example, individuals born 80 years ago may carry less burden of psychiatric disorders such as drug or alcohol abuse in comparison to adults born in more recent years. In addition, the oldest-old today may have fewer psychiatric disorders, because they have always been healthier, having survived such occurrences as the Great Depression and World War II. When the prevalence of psychiatric disorders is compared across studies, it is important to note in which time period the particular research was conducted and whether a particular characteristic of a cohort could affect the reported prevalence.

EPIDEMIOLOGY OF SELECTED PSYCHIATRIC DISORDERS IN OLDER ADULTS

Alzheimer Disease and Other Dementias

There have been a number of epidemiological studies conducted to determine the prevalence and incidence of dementia in older persons in community and institutional populations. The focus has shifted from severe cognitive impairment in the ECA to estimates of types of dementia,

such as Alzheimer disease and vascular dementia, to predementia syndromes such as MCI. Studies have also examined subtypes of MCI to identify those that may be more likely to progress to more severe forms of dementia. In DSM-5, a new diagnostic category of mild neurocognitive disorder was created which subsumed MCI. There are not yet studies available to provide the prevalence of this disorder.

The prevalence estimates of cognitive impairment and dementia in persons age 65 or older range from approximately 1 to 20 percent, depending on how cognitive impairment or dementia was defined in the research study as well as the population sampled. In the ECA surveys, the prevalence of severe cognitive impairment in noninstitutionalized adults age 65 or older was 4.9 percent. In the Canadian Study of Health and Aging, a large representative sample of adults age 65 or older residing in the community (N = 9,008) and in institutions (N = 1,255), the prevalence of dementia was estimated to be 8 percent. In the Aging, Demographics, and Memory Study (ADAMS), the prevalence of dementia was 13.9 percent. The prevalence of severe dementia reported from epidemiological studies is somewhat lower than that when mild and severe forms of dementia are combined, and ranges from less than 1 to 7 percent. It is important to note that older adults in the early stages may meet criteria for Alzheimer disease but not meet criteria for severe cognitive impairment or severe dementia.

The prevalence of dementia in institutional samples is generally higher than that reported in community samples. A study in Edmonton, Canada reported that more than two-thirds of the institutional population (69 percent) had mild or severe cognitive impairment, whereas the prevalence of mild impairment in the household sample was 3.3 percent, and severe impairment was not found outside the institutional sample. The prevalence of cognitive impairment among older adults seen in primary care is over 15 percent.

The prevalence of dementia and cognitive impairment is higher in older age groups. In the ECA study, the prevalence of severe cognitive impairment were 2.9 percent in adults 65 to 74 years of age, 6.8 percent in those 75 to 84 years of age, and 15.8 percent in those adults 85 years of age or older. The prevalence of dementia increases with age, with the prevalence estimated to double every 5.1 years in older adults.

Alzheimer disease is the most common type of dementia among older adults and accounts for over 50 percent and perhaps as much as 75 percent of the dementia cases. The prevalence of Alzheimer disease in older adults ranges from 3 to 10 percent and also increases with age. Among those 60 to 65 years of age, the prevalence is less than 1 percent but increases exponentially to be 24 to 33 percent among those 85 or older. Difficulties with sampling prevent investigators from accurately determining if the prevalence of dementia continues to increase or levels off after 90 years of age.

Vascular dementia is found among older adults with cerebrovascular disease. It is not clear whether the cerebrovascular disease is a risk factor for this type of dementia or whether the two disorders share common risk factors. Vascular dementia is also often comorbid with Alzheimer disease. Although less prevalent, other subtypes, including dementia with Lewy bodies, frontotemporal dementia, mixed dementia, Parkinson dementia, and unspecified dementia, have all been noted in community samples of older adults.

In the ECA studies, the prevalence of severe cognitive impairment in those 65 to 74 years of age was higher in men (4.2 percent) than that in women (1.9 percent), but the prevalence was higher in females in the older age groups. Among those age 85 or older in the ECA, the prevalence of severe cognitive impairment was 8.2 percent in men and 19.5 percent in women. Alzheimer disease has been found more often in older women in some studies, yet a true difference in prevalence by gender remains to be determined.

The incidence of dementia and Alzheimer disease also rises exponentially with age at least to as old as 85 or 90 years of age. The estimated incidence of dementia among persons 60 to 69 years of age is 0.7 to 3.5 per 1,000 person-years at risk and then doubles approximately every 5 years of age. It is not clear if the incidence of vascular dementia follows a similar exponential increase with age. Women may have a higher incidence of Alzheimer disease in very old age.

A number of epidemiological studies have focused on syndromes such as MCI and cognitive impairment no dementia (CIND). MCI is generally defined as some evidence of cognitive difficulties on neuropsychological testing or cognitive decline greater than expected for a person's age or education but failing to meet criteria for dementia. These individuals generally fail to meet dementia criteria because the cognitive difficulties do not interfere with daily activities. The prevalence of MCI and CIND ranges from 3 to 39 percent among community-dwelling older adults and 6 to 85 percent in clinical and institutional settings. The incidence of MCI in older adults is 8 to 58 persons per 1,000 per year. MCI is associated with a twofold increase in mortality as well as an increased risk for dementia.

More than half of adults with MCI progress to dementia within 5 years, with the rate of progression being 5 to 35 percent per year. Other studies have shown, however, that a significant proportion of older adults with MCI have normal function 1 year later. Research has focused on identifying subtypes of MCI that may be linked to degenerative, vascular, or psychiatric factors and examining which subtypes are more likely to progress to more severe forms of dementia. For example, some research suggests that older adults with amnestic MCI have a high rate of progression to dementia, particularly Alzheimer disease.

Several risk factors for Alzheimer disease, dementia, and cognitive

decline have been identified. A family history of dementia, Down syndrome, or Parkinson disease is a risk factor for dementia. In one family study, the relative risk of developing Alzheimer disease in those with one first-degree relative with dementia was 2.6 in comparison to those with no relative. The relative risk was 7.5 in those with two or more first-degree relatives with dementia. The relative risk associated with one or more relatives with dementia decreased with increasing age of onset, but even in those with onset after 80 years of age, the familial risk was still significant. Studies have found the epsilon 4 allele of apolipoprotein E (ApoE) on chromosome 19 to be a susceptibility gene for the development of Alzheimer disease. Head trauma such as that experienced by those in military service or involved in professional sports such as football has been suggested as another risk factor for Alzheimer disease or dementia. Other possible risk factors include decreased brain reserves, low education and occupational attainment, and reduced mental and physical activity in late life. The risk of dementia may be higher in older adults who use alcohol. Risk factors for vascular dementia include hypertension, diabetes mellitus, and cardiovascular disease.

Several possible protective factors have been identified. Higher education is associated with a decreased risk of Alzheimer disease, perhaps owing to increased cognitive reserves. Regular exercise or physical activity may decrease the risk of cognitive decline. Taking nonsteroidal anti-inflammatory or cholesterol-lowering (statins) drugs has also been shown to be a protective factor against the onset of Alzheimer disease. Some factors, such as estrogen, have been studied as protective factors for the onset of Alzheimer disease, but results have been inconclusive. There is also some evidence that dietary intake of nutrients such as vitamin B_{12} and folate, antioxidants, omega 3 fatty acids, and unsaturated fatty acids may decrease the risk of Alzheimer disease.

A history of moderate to severe depression has been identified as a risk factor for dementia, but it is difficult to establish causality. Depression may be the result of an awareness of early cognitive decline. Depression and dementia may also share common risk factors. Dementia may also be a risk factor for functional decline. Older adults with dementia are at an increased risk of mortality, and survival may be worse in patients with vascular dementia than in patients with Alzheimer disease. The differential diagnosis between depression and dementia in older adults can be challenging, as patients with depression can experience symptoms of cognitive impairment.

Mood Disorders

Depressive symptoms are common among older adults and are associated with functional impairment and decline, mortality, increased service

utilization, and decreased quality of life. Although the mood disorders are a significant health concern for older adults, the prevalence of DSM-5 major depression is low in comparison to that of younger adults.

The lifetime prevalence of any DSM-IV-TR mood disorder was 11.9 percent in the NCS-R among those ages 60 or older, approximately 50 percent of the lifetime risk among younger adults. The lifetime risk for major depression is higher than that for dysthymia and bipolar disorder. Overall, major depressive disorder carries a lifetime risk of 8.2 to 10.6 percent in older adults. Current prevalence estimates are much lower. In the NESARC, the 12-month prevalence of major depression was 2.69 percent among adults 65 or older, lower than that observed in other age groups (6.39 percent among those ages 18 to 29, 5.52 percent among those 30 to 44, and 5.62 percent among those 45 to 64).

The 1-month prevalence of any mood disorder in community-dwelling adults 65 years of age or older in the ECA surveys was 2.5 percent. The prevalence of major depression was 0.7 percent (0.9 percent in women and 0.4 percent in men). The prevalence of dysthymia was 1.8 percent (2.3 percent in women and 1.0 percent in men). Overall, the prevalence of major depression in community studies of older adults ranges from 0.9 to 9.4 percent depending on the time period assessed.

The prevalence of dysthymia is approximately 2 percent among older adults. Dysthymic disorder was replaced in DSM-5 by the diagnosis "persistent depressive disorder" which also includes chronic depression. Overall, older adults with dysthymia generally report late age of onset, no major depression, and a low family risk of mood disorders. Patients often have experienced stressors such as bereavement. Older age is significantly associated with the prevalence of DSM-5 chronic depressive disorder.

Most elderly adults with depressive symptoms in the community do not meet criteria for major depression or dysthymia. In the Longitudinal Aging Studies Amsterdam (LASA), a longitudinal study of 3,056 community-dwelling older adults 55 to 85 years of age, the prevalence of *minor depression*, defined as positive for depression by the CES-D but not meeting DSM-III-R criteria for major depression, was 12.9 percent. Across various epidemiological studies, the estimated prevalence of minor depression or clinically significant depressive symptomatology among community-dwelling older adults ranges from 1 to 49 percent.

The prevalence of major depression is generally higher in clinical samples than that reported from community samples. The prevalence of major depression in older adults in medical care facilities is approximately 5 to 10 percent. In institutional settings, the prevalence of major depression is estimated in some studies to be more than 42 percent. Older persons with depressive symptoms generally do not seek medical help, so the prevalence of depressive symptoms in primary care may underestimate the true prevalence of clinically significant depressive symptoms not meeting

criteria among older adults.

In the ECA, the incidence of major depression among adults age 65 or older was estimated to be 1.25 per 100 person-years of risk, with a higher incidence among older women (1.48 per 100 person-years) in comparison to men (0.90 per 100 person-years). The incidence of first onset of major depression declines with age, especially for men. In the NESARC, the 3-year incidence of major depression was 3.3 percent among those age 60 or older.

Epidemiological studies have confirmed that, although major depression is less common among older adults than among younger adults, depressive symptoms associated with impairments in functioning may be common in late life and increase with advancing age. This high prevalence of symptoms suggests that the current nomenclature may be less applicable for older adults. Clinically significant depressive symptoms in older adults, although prevalent, also can be serious and chronic. In the LASA study, depressed elderly were followed for 6 years. A total of 32 percent of the sample had a severe, chronic course of depression, whereas 44 percent had an unfavorable but fluctuating course. Those with subthreshold or minor depression had the best outcome, followed by those with major depressive disorder, dysthymia, and, last, double depression, or depression and dysthymia together. Those with subthreshold depression were at a high risk of developing DSM-IV-TR mood disorders.

Major depression and dysthymia as well as depressive symptoms are more common in older women in comparison to men. Racial and ethnic differences in the prevalence of depressive symptoms and major depression have not been consistently observed in older adults residing in the community. Risk factors and correlates of depression in late life include factors such as being widowed or otherwise unmarried, impaired functional status, impaired social support, perceived loneliness, perceived poorer health, and low internal locus of control. Older adults with major depression are more likely to have a family or personal history of major depression. In addition, loss of a partner in the previous year may be associated with risk. Risk factors for depressive symptoms may also include, in addition, fewer years of education, living in an urban area, lower socioeconomic status, having one or more chronic physical illnesses, reporting uncontrolled pain, having MCI, experiencing other recent stressful life events, and personality characteristics, such as neuroticism. In addition to these social and psychological risk factors, depression in late life may be linked to biological risk factors such as underactive serotoninergic neurotransmission and hypersecretion of cortisol.

A “vascular depression” subtype has been observed in older adults. Depressive symptoms in this subtype are associated with white matter hyperintensities in neuroimaging. Vascular depression may have a later age of onset or onset after age 60. Late-onset depression may also be associated

with stressful life events while earlier onset may be associated with a family history of depression.

Bipolar disorder is rare in older adults, with a 12-month prevalence of 0.1 percent and a 1-month prevalence of less than 0.1 percent. The lifetime risk is lower among older adults, 1.0 percent among those age 60 or older in comparison to 3.5 percent among those 45 to 59, 4.5 percent among those 30 to 44, and 5.9 percent among those 18 to 29 years of age. Late-onset bipolar disorder is rare but may be associated with cerebrovascular disease, present with psychotic symptoms, and be less likely to be associated with external stressors.

Major depression and depressive symptomatology are frequently comorbid with anxiety disorders and anxiety symptoms in older adults. Some studies have also found alcohol problems and depression to be frequently comorbid, especially in men. Therefore, major depression and depressive symptoms in late life may be a risk for other psychiatric disorders, or these disorders may place the older adults at a greater risk for depression.

Although disability is a risk factor for late-life depression, depressive symptoms are also a risk factor for functional decline and disability. Depression can also predict cognitive decline. Depression is often present in older patients with neuropsychiatric disorders such as Alzheimer disease or Parkinson disease. Depressive symptoms are associated with an increased risk of mortality in older adults, although this risk is confounded by factors such as physical health and health behaviors, especially alcohol and tobacco use. Finally, major depression is a risk factor for suicide in older adults.

Anxiety Disorders

Epidemiological studies consistently show that anxiety disorders are less prevalent in older adults in comparison to younger adults. Yet, the prevalence of anxiety disorders in this older age group is high when compared to that of other disorders. In the NCS-R, the lifetime prevalence of any DSM-IV-TR anxiety disorder was 15.3 percent among those age 60 or older. Of the disorders assessed, specific phobia (7.5 percent) and social phobia (6.6 percent) had the highest lifetime prevalences. The lifetime prevalence of other disorders in this older age group included generalized anxiety disorder (GAD) (3.6 percent), posttraumatic stress disorder (PTSD) (2.5 percent), panic disorder (2.0 percent), agoraphobia without panic (1.0 percent), and obsessive-compulsive disorder (OCD) (0.7 percent). The lifetime prevalence for each individual anxiety disorder assessed was the lowest in this older age group in comparison to that in other age groups, suggesting that as the number of older adults increases the number with a lifetime prevalence of any anxiety disorder will also increase. Current prevalence estimates are lower than lifetime prevalence estimates. The

current (1-month) prevalence of any DSM-IV-TR anxiety disorder estimated from the Australian National Health and Well-Being Survey was 1.3 percent. In the ECA surveys, anxiety disorders were the most prevalent psychiatric disorders (excluding the dementias) in persons age 65 or older. The 1-month prevalence of any anxiety disorder among noninstitutionalized older adults in the ECA was 5.5 percent, more than two times the prevalence of any mood disorder in this age group. The prevalence was lower in older men (3.6 percent) in comparison to that in older women (6.8 percent). The ECA data did not include estimates of generalized anxiety disorder, which suggests that the overall prevalence may have been underestimated. In addition, the ECA estimated the prevalence of anxiety disorders based on DSM-III criteria, whereas the later studies used DSM-IV-TR criteria. It is important to note that the diagnostic criteria for generalized anxiety disorder changed between DSM-III and DSM-IV-TR, which may account for another difference in estimates across studies. In general, among community studies of older adults, the overall prevalence of any DSM-IV-TR anxiety disorder ranges from 0.7 to 18.6 percent, depending on how *caseness* is defined. Similar to what has been observed in depression, the prevalence of anxiety symptoms in community-dwelling older adults is higher than the prevalence of anxiety disorders and may be as high as 24 percent.

The prevalence of anxiety disorders in institutionalized adults is higher than that observed among community-dwelling elders. In a survey in Edmonton, Canada, the prevalence of any anxiety disorder in older institutionalized women was 7.1 percent, compared to 1.4 percent in women in the community, and the prevalence was 4.1 percent in institutionalized men, compared to 2.7 percent in older men in the community. The prevalence of anxiety symptoms among older adults in clinical samples may exceed 40 percent.

Phobic Disorders

The ECA provided data on the prevalence of any phobic disorder as well as phobic subtypes based on DSM-III criteria. Later work has focused more on the prevalence of specific subtypes of phobia. In the ECA, the 1-month prevalence of any phobic disorder was 4.8 percent. The prevalence was twice as high in older women (6.1 percent) in comparison to that in men (2.9 percent). The 1-year prevalence of any phobic disorder in the ECA was twice as high in older African-American men as that in white and Hispanic men. The prevalence was also higher among African-American women in comparison to that in older white and Hispanic women. In community studies of older adults, the prevalence of any phobic disorder ranges from 0 to 12 percent, with the prevalence consistently higher in women. This wide range is again due primarily to case definition as well as to which phobic subtypes are assessed (usually whether specific phobia is included).

The incidence of any phobic disorder in older adults is estimated to be 4.29 cases per 100 person-years of risk, which is similar to the incidence in younger age groups. In the ECA, incidence was more common in older women (5.52 per 100 person-years) than that in men (2.66 per 100 person-years). Some studies have suggested that, although specific or simple phobia usually has an onset in younger children or adults, agoraphobia can often have its onset in late life. Phobic disorder overall appears to have an earlier age of onset in women. Most cases of phobic disorder among older adults are new cases and are not in individuals with a lifetime diagnosis of phobic disorder. In the NESARC, the 3-year incidence among those ages 60 or older was 1.6 percent for generalized anxiety disorder, 1.4 percent for specific phobia, 0.8 percent for panic disorder and 0.6 percent for social phobia.

Specific Phobia. The most common phobic subtype is specific phobia. In the NESARC, the 12-month prevalence of specific phobia among adults 65 years of age or older was 7.5 percent. Unlike other disorders, this prevalence did not really differ from those among younger adults (8.0 percent among those 18 to 29, 7.6 percent among those 30 to 44, and 7.4 percent among those 45 to 64 years). The lifetime estimates were not significantly higher than the current prevalence estimates. The lifetime estimates of specific phobia range from 6 to 7.5 percent across studies and are lower than that observed in younger age groups. Specific phobia is more common in females than males.

Social Phobia. Older adults also have a decreased lifetime risk of social phobia or social anxiety disorder in comparison to that of younger age groups. In the NESARC, the lifetime prevalence of social anxiety disorder among those 65 years of age or older was 3.0 percent, compared to 5.6 percent among those 45 to 64 years of age. The same pattern was observed in the NCS-R where the lifetime prevalence of social phobia (6.6 percent) was approximately half the risk of that among adults younger than 60. In contrast to specific phobia, current prevalence estimates of social phobia across all age groups are generally lower than lifetime estimates. The 12-month prevalence of social phobia or social anxiety disorder among those 65 years of age or older ranges from 0.2 to 1.6 percent across studies. Whether there are significant differences by sex is not clear.

Panic Disorder and Agoraphobia. Comparisons of prevalence estimates across studies are made somewhat difficult because of the changes in the nomenclature in the way panic disorder and agoraphobia are defined, whether the emphasis is on agoraphobia with and without panic or panic disorder with and without agoraphobia. Overall, however, both panic disorder and agoraphobia are less common in older adults than either

social phobia or specific phobia. Regardless of how these disorders are grouped, the lifetime prevalence of panic disorder and agoraphobia without panic is lower among those age 60 or older compared to that of younger adults. Current estimates of these disorders are also lower than lifetime estimates across all age groups. In the NESARC, the 12-month prevalence of panic disorder among those ages 65 or older was 0.8 percent (0.7 percent for panic disorder without agoraphobia and 0.1 percent for panic with agoraphobia). Regardless of whether studies look at panic and agoraphobia and panic separately or together, the current prevalence of both disorders is less than 1 percent. The prevalence of both agoraphobia and panic disorder is higher in females.

Epidemiological studies of community-dwelling older adults have found that panic disorder is rare, and most of the few cases identified are in older women. The prevalence of panic disorder is slightly higher among those in institutions (1 percent) than that among community-dwelling elders. The 1-year prevalence of panic disorder in the ECA was higher among older white (0.3 percent) and Hispanic (3.4 percent) women than that in African-American women (0 percent). There were no racial or ethnic differences among men. The incidence of panic disorder in older adults has been estimated to be 0.04 percent per 100 person-years at risk, suggesting that the few cases of panic disorder present in late life had an earlier onset.

Generalized Anxiety Disorder

The lifetime prevalence of generalized anxiety disorder among adults age 65 or older is 2.6 to 3.6 percent, half the lifetime risk seen in younger adults. In epidemiological studies of older adults, the 12-month prevalence of generalized anxiety disorder is lower than the lifetime risk and ranges from less than 1 to 2.4 percent. Older females are over twice as likely as older males to meet criteria for generalized anxiety disorder within the past year. In some studies, generalized anxiety disorder accounts for the majority of the cases of anxiety disorder in older adults, whereas, in other studies, specific phobia is much more common. In the Durham, North Carolina, ECA, the 1-year prevalence of generalized anxiety disorder among adults age 65 or older was estimated to be 2.2 percent, with a higher prevalence in women (2.6 percent) in comparison to that in men (1.8 percent). The prevalence was higher in older white men (1.5 percent) than that in African-American men (0.9 percent), whereas there were no racial or ethnic differences for women. In the Durham ECA, approximately 3 percent of those with generalized anxiety disorder had an onset of the disorder at age 65 or older. Later studies have confirmed that generalized anxiety disorder is more than twice as prevalent in older women in comparison to older men.

Obsessive-Compulsive Disorder

The overall estimated lifetime prevalence of obsessive-compulsive disorder from epidemiological studies is estimated to be less than 0.1 to 0.8 percent. The 1-month prevalence of obsessive-compulsive disorder in older adults in the ECA was 0.8 percent, with a prevalence of 0.7 percent in older men in comparison to 0.9 percent in older women. Among institutionalized older adults, the prevalence of obsessive-compulsive disorder is estimated to be as high as 4.7 percent in women and 1.4 percent in men. The annual incidence in those ages 65 or older is less than 1 case per 100 person-years but is estimated to be lower in late life in men than at earlier ages, whereas, in women, the incidence is slightly higher in those age 65 or older.

Posttraumatic Stress Disorder

In the CPES, the lifetime prevalence of PTSD among adults age 55 or older was 3.7 percent. Of those, 1.8 percent had PTSD that persisted into late life. Older adults with persistent or pre-late life PTSD were more likely to have a disability than adults without a history of PTSD.

Risk Factors for Anxiety Disorders

Across all age groups, anxiety disorders are more prevalent in women than men, but these gender differences are less apparent in the older age groups. Risk factors for the onset of anxiety disorders or anxiety symptoms in late life include having another anxiety disorder or other psychiatric disorder, neuroticism, being female, experiencing a traumatic life event, and having an impaired social network. Having any anxiety disorder is also associated with having one or more physical disorders in older adults. In the NCS-R, the presence of a 12-month anxiety disorder among those age 65 or older was associated with female sex, being unmarried, having fewer years of education, and having three or more chronic conditions. Anxiety symptoms, generalized anxiety disorder, and agoraphobia can be associated with decreased quality of life in older adults. Social phobia and specific (simple) phobia in older adults are unlikely to be associated with severe anxiety symptoms, and these phobic subtypes are therefore less likely to lead to decreased functioning.

Data from epidemiological studies suggest, however, that comorbidity between depressive and anxiety disorders is common in late life. Depression has been observed in patients with phobic disorder and generalized anxiety disorder and among residents of long-term–care facilities with anxiety symptoms. Anxiety disorders are also frequent among patients with diagnosed depression and depressive symptoms. Anxiety symptoms are also prevalent in persons with dementia, suggesting that one reason for the decline in prevalence of anxiety disorders with age is the inability of older cognitively impaired subjects to participate in studies. There is less comorbidity of anxiety and medical illness and anxiety

and alcohol abuse in older adults than is seen in those who are younger.

Schizophrenia

Although the prevalence of schizophrenia in older adults is low compared to that of other psychiatric disorders, this small number of adults has complex clinical and service needs. With the number of adults over age 65 projected to increase over the next 50 years, older adults with schizophrenia will increase in number and present particular challenges as they will have spent less time in mental institutions than earlier generations of older adults.

The current prevalence of schizophrenia in community samples in those age 65 or older can range from 0.1 to 0.5 percent. In the ECA surveys, the 1-month prevalence of schizophrenia in noninstitutionalized adults age 65 or older was 0.1 percent, compared to 0.7 percent in those 18 to 24 years of age, 0.9 percent in those 25 to 44 years of age, and 0.4 percent in those 45 to 64 years of age. The prevalence was the same in women and men among older adults. The prevalence was slightly higher in older African Americans (0.3 percent) in comparison to that of whites (0.1 percent). The overall lower prevalence reported by those ages 65 or older may be due in part to fewer persons with the disorder surviving to an older age. Also, the ECA prevalence estimates were based on DSM-III criteria, which specified that the illness had to begin before 45 years of age. In the 1980s, there was evidence that some individuals with schizophrenia become ill in middle age or late life. The DSM-III-R included a separate category for persons who met the symptom criteria but the age of onset was 45 years or later. The DSM-IV-TR and DSM-5 do not differentiate persons by age of onset but note differences among those individuals with a later onset compared to earlier onset.

More recent research has provided updated prevalence estimates. For example, in a study conducted in Finland, the lifetime prevalence of all nonaffective psychotic disorders among those age 65 or older was 2.32 percent (1.71 percent for men and 2.67 percent for women). The lifetime prevalence of schizophrenia in this age group was 0.92 percent (0.78 percent for men and 1.00 percent for women). The 12-month prevalence among mental health patients age 60 or older in an Amsterdam Catchment Area was 0.71 percent, subdivided to 0.55 percent for schizophrenia, 0.10 percent for schizoaffective disorder and 0.03 percent for delusional disorder. In this group, the prevalence was 0.35 percent for early onset, 0.14 percent for late onset, and 0.05 percent for very late onset schizophrenia like psychosis.

As noted for other disorders, the prevalence of symptoms of suspicion or paranoid symptoms in older adults is much higher, between 4 and 10 percent. This prevalence is even higher when older adults in institutions or selected residential settings are included and may be as high as 25 percent.

Incidence rates differ by gender. The incidence is greater in men up to age 39 years and then greater in women over the 50 to 70 years age group. The incidence of late-onset schizophrenia has been estimated at 12.6 per 100,000 persons per year.

Multiple studies have found a later age of onset of schizophrenia among women and an overrepresentation of women in the late-onset group, with an even higher frequency of late-life paranoid symptoms in comparison to men (reflecting the old classification of paraphrenia). In addition, late-onset patients are more likely than early onset patients to have shown good premorbid educational, occupational, and social functioning. Those with a later onset tend to have a greater frequency of paranoid symptoms but fewer negative symptoms, less thought disorder, and better neuropsychological performance in comparison to those with an earlier onset of schizophrenia. Risk factors for late-onset schizophrenia may include psychosocial factors, such as retirement, bereavement, and decline in physical functioning. Relatives of late-onset schizophrenia patients have been reported to have a lower risk of schizophrenia than relatives of patients with an earlier onset of disease, whereas other studies have not found differences in family history between the two groups. Some studies have reported that patients with very late life onset of the disease may have a high prevalence of sensory deficits.

Schizophrenia in late life may be comorbid with other psychiatric illness, such as depression. The prevalence of psychotic symptoms in older patients with depression may be as high as 45 percent. Paranoid symptoms are also not uncommon in persons with dementia. Studies have reported that the prevalence of paranoid symptoms may range from 12 to 19 percent among older adults with dementia in comparison to 1 to 3 percent among those without dementia.

Studies looking at the outcome of schizophrenia in older adults suggest that men may be more severely ill in the first decade of the illness but then improve, whereas women may initially have mild symptoms but become more ill as they age. Older schizophrenia patients experience relatively greater age differences in cognitive functioning than healthier individuals. Older adults with schizophrenia and severe cognitive impairment may have poorer outcomes than those without cognitive problems. Older adults with schizophrenia are also at risk for physical illness. They may underreport symptoms or be less compliant with treatment regimens for the medical illness, and cognitive deficits may affect symptom reporting. The prevalence of successful aging in older adults is significantly lower among adults with schizophrenia compared to healthy older adults, due in part to poorer physical health in the schizophrenia group.

Adverse outcomes of schizophrenia symptoms have been noted. For example, in a longitudinal study of 347 85-year-old community-dwelling Swedish elders, the prevalence of any psychotic symptom was 10 percent,

the prevalence of hallucinations was 7 percent, and the prevalence of delusions was 6 percent. Hallucinations were associated with major depression, disability, and visual deficits. Delusions were associated with disability, and paranoid ideation was associated with visual deficits. Hallucinations, delusions, and paranoid ideation were each associated with incident dementia. In addition, hallucinations and paranoid ideation were associated with increased mortality in older women but not in older men.

Alcohol Use Disorders

In the NESARC, the 12-month prevalence of DSM-IV alcohol abuse among adults age 65 or older was 1.2 percent, whereas the prevalence of alcohol dependence was 0.2 percent. These estimates were lower than those for younger adults. These 12-month estimates are also significantly lower than the lifetime estimates for this older age group—12.7 percent for alcohol abuse and 3.4 percent for alcohol dependence. Both of these lifetime estimates reported from the NESARC are higher than those observed in the NCS-R for adults age 60 or older (6.2 percent for alcohol abuse and 2.2 percent for alcohol dependence). Among adults age 50 or older in the United States, the estimated 12-month prevalence of alcohol abuse and dependence in men was 2.9 percent and 2.1 percent, respectively, in comparison to 0.7 percent for both abuse and dependence in older women. The prevalence of subthreshold alcohol use disorders was higher—8.4 percent in men and 4.4 percent in women. In the NESARC, the 3-year incidence among those age 60 or older was 1.0 percent for alcohol abuse and 0.4 percent for alcohol dependence.

Many persons with a lifetime history of alcohol use and dependence may not survive to an older age. In addition, there may be a cohort effect. That is, social norms have changed over the years. Today's oldest old adults may have consumed less alcohol throughout their lives, whereas the use of alcohol has become more acceptable to those adults growing up in later decades. With the ageing of the population, the number of older adults with alcohol use disorders is expected to increase.

As with some of the other disorders, the diagnostic criteria may be less applicable for older adults, resulting in an underestimate of the burden of alcohol-related problems in this population. For example, middle-aged and older adults show an elevated prevalence of binge drinking that does not meet criteria for an alcohol use disorder. Older adults have an increased sensitivity to the effects of alcohol due to decreases in lean body mass, which results in higher blood alcohol concentration per level of alcohol consumed. Some research has suggested that the recommended limits of alcohol use for older adults should be set lower than those for younger adults. Therefore, the quantity of alcohol reported consumed may not be a good indicator of alcohol problems in late life.

Screening criteria for younger adults may be less relevant to older

adults. For example, those who no longer drive will not be stopped for driving while impaired, those who are retired will not experience work problems, and those who are widowed will not experience marital conflicts related to alcohol. It can be difficult to measure alcohol-related changes in social functioning and social decline in older adults because many older adults have cut back on activities for reasons unrelated to alcohol use. In older adults, therefore, attention must be focused on alcohol-related problems and drinking in excess of standardized limits for older adults. Even changing the case definition is still somewhat problematic for older drinkers, because the diagnosis relies on self-report. Many older adults may not reliably report their use of alcohol. Although the prevalence of alcohol problems in older adults is generally higher in hospital emergency department samples and among hospital admissions, relying on case identification in clinical settings is also problematic. Alcohol problems may be masked by symptoms of physical illness. Physicians are less likely to diagnose alcoholism in an older patient than a younger patient, and even when cases are diagnosed, elderly patients are less likely than younger patients to be referred for treatment. Health care workers may perceive excessive alcohol consumption as understandable given age and circumstances.

Recognizing these limitations, research studies have shown that alcohol consumption decreases with age. However, alcohol use is not uncommon in late life, and over half of older adults report alcohol use within the past year. The prevalence of alcohol problems or excessive consumption is higher than the prevalence of DSM-IV-TR alcohol use disorder and estimated to be between 1 and 20 percent in community samples and 14 and 44 percent in hospital samples. The prevalence of heavy drinking varies according to how stringent the criteria are. When *heavy drinking* is defined as consuming five to seven drinks per week, the prevalence among older adults is 11 to 25 percent, whereas the prevalence is 7 to 8 percent when heavy drinking is defined as 12 to 21 drinks per week. The prevalence in the United States also varies by geographic region, with more heavy drinking in the Northeast than in the South.

Researchers have identified two groups of older adults who drink in excess: An *early-onset* alcoholism, which includes long-term alcoholics who survive into old age, and a *late-onset* alcoholism, which includes those older adults with a recent onset of problem drinking. Those with an early onset are more likely to have a comorbid psychiatric disorder. Those who begin to drink heavily in old age appear to have different social and medical characteristics. Persons with a late onset of alcohol problems may increase their drinking in response to stressful life events, such as retirement and bereavement. Other identified risk factors for late-onset alcoholism include a history of alcohol use, being single, separated, or divorced, more opportunities to drink, loneliness and social isolation, boredom,

psychological problems such as depression or anxiety, lack of social support, and physical illness causing pain or insomnia. Approximately one-third of older individuals with drinking problems had a later onset. The incidence of late-onset problem drinking may be as high as 4 percent in the general population. The prognosis for late-onset problem drinkers, however, is generally more favorable than that for early onset problem drinkers. Over the 1-year follow-up period in the ECA across all age groups, for example, the incidence of alcohol abuse declined with age until 60 years of age and then increased, particularly for men 75 years of age or older.

Alcohol-related problems are more prevalent in older men in comparison to women, as are the quantity and frequency of alcohol use. Racial or ethnic differences in alcohol use are less known, although white older adults may tend to use more alcohol and older African Americans and Hispanics may tend to binge drink more frequently. Older adults with lower income consume less alcohol than those with higher income. Physical health problems are associated with past or current alcohol use in older adults. Psychiatric comorbidity is more likely in persons who consume alcohol than in general populations of older adults. Alcoholism is correlated with anxiety and affective disorders and tobacco or drug dependence, and a history of alcohol use has been associated with cognitive impairment. In the Canadian Study of Health and Aging, the occurrence of all types of dementias, except Alzheimer disease, was higher in those with definite or questionable alcohol abuse.

Other adverse outcomes of alcohol use include increased hospitalization, increased incidence of psychiatric disorders, and increased medical disorders. Alcohol use may interfere with the effectiveness of medications. Overall, the prevalence of physical illness is higher in older alcoholics than that among nondrinking older adults. For example, cirrhosis of the liver is one of the leading causes of death in late life. Although some studies have reported increased mortality due to alcoholism in older adults, it is important to note that there can be a protective effect of moderate alcohol use in late life, resulting in a decreased likelihood of mortality.

Suicide

The last half of the 20th century generally saw a decline in suicide rates among older adults but recent decades have shown an increase. In 1950, the death rate from suicide for persons age 65 or older in the United States was 30.0 per 100,000, while in 2010 the rate was 14.9. In 2010, the death rate for suicide was 17.6 per 100,000 persons for those 85 years of age or older, 15.7 for those 75 to 84 years of age, and 13.7 for those 65 to 74 years of age. For those 25 to 64 years of age, rates of suicide ranged from 15.0 among those 25 to 44 years of age to 18.6 among those 45 to 64 years of age. The rates of suicide in 1950 for adults age 45 or older were higher than

those in more recent years for the corresponding age group. As shown in Figure 57.1b–3, there was a decline in suicides in older adults from 1950 to 1980. The suicide rates were higher in 1980s and then lower in 2000 and 2010. These changes, however, were almost totally explained by declines and increases in suicide deaths by older men. The highest rates of suicide in the United States are observed among older men, particularly white men. In 2010, the suicide rates per 100,000 for white males were 26.3 among those 65 to 74 years of age, 34.9 among those 75 to 84 years of age, and 50.8 among those 85 years of age or older. Because many older adults may commit suicide using less noticeable methods, such as medication overdose or cessation of eating, which can be difficult to detect, especially in older adults who live alone, it is likely that suicide rates in this age group are underestimated.

Older adults tend to give fewer warnings of suicidal intent. The prevalence of suicidal ideation among older adults is lower than that observed among younger adults, but the odds of depression among adults with suicidal thoughts is higher among those in the older age group. Older adults invest more planning and preparing for the suicidal act than younger adults and may also use more violent methods. Attempted suicides are less frequent than in younger age groups, and older adults are more successful in their suicide attempts. Among younger adults, suicide attempts occur 200 times as frequently as completed suicides, whereas, in older adults, one out of every four attempts is successful. Overall, the rates of completed suicide are higher in older adults.

Among older adults, suicide is associated with several psychiatric disorders, particularly major depression, but other disorders such as substance use disorder may be associated with suicide. Studies of risk factors for suicide are difficult to conduct, because the suicide rate, although higher in older adults than that in younger adults, is still low. In an analysis of the multisite Established Populations for Epidemiologic Studies of the Elderly (EPESE) data, there were 12 suicides among the sample of 14,456 adults 65 years of age or older followed for 10 years. Suicide was predicted by depression, perceived heath status, poor sleep quality, and absence of a confidant. Other risk factors identified through research studies include personality traits such as neuroticism and stressful life events such as disruption of social ties. Physical illness and functional decline may be risk factors, but their effect may be mediated by depression. The presence of a firearm is also associated with risk of suicide, even after controlling for psychiatric illness.

USE OF HEALTH SERVICES

Older adults with mental disorders are less likely to receive any treatment and, among adults who receive health care treatment, less likely than younger adults to receive mental health specialty treatment. Being in an

older cohort is associated with failure to make initial contact after first onset and delay in making contact among those who eventually seek treatment. Many older adults with psychiatric disorders or clinically significant symptoms remain untreated. If help from a health professional is sought, then it is generally from the individual's primary care provider. Older adults may be less likely to receive referrals from primary care to mental health specialty care than younger adults. Older adults may not bring problems to the attention of providers, and providers may not recognize the significance of clinical symptoms that do not meet criteria for a psychiatric disorder. Disorders or clinically significant symptoms may be more difficult to recognize in older adults with comorbid physical illness. Additionally, older adults may attribute their symptoms to a physical illness. Reasons for nonuse of mental health services in this age group are many, and can include being in a racial or ethnic minority group, being uncomfortable discussing personal problems, being married or cohabitating, being in a middle versus higher income group, having a mild disorder, and having low versus high perceived cognitive impairment. In the CPES, racial differences in mental health service use were noted. Twenty percent of whites compared to 13 percent of blacks reported use. Differences by region were only significant in the South where whites were twice as likely as blacks to use services. Among adults age 65 or older in the CPES, 6.5 percent received some mental health care in the previous year, although 65.9 percent of those with major depression and 72.5 percent with anxiety did not receive care. Seventeen percent of those with a perceived need for mental health care did not receive it. Older age was positively associated with mental health service satisfaction and perceived amount of benefit.

FIGURE 57.1b–3. Death rates per 100,000 for suicide in the United States from 1950 to 2010.

With the projected increase in the number of adults with a psychiatric disorder in this age group, planning for increased use of health services will be important. Training primary care providers to recognize and treat or refer adults with disorders will be an important part of medical education. The public heath focus should include interventions to treat these symptoms and disorders in older adults to reduce the likelihood of negative outcomes.

FUTURE DIRECTIONS

The future of psychiatric epidemiology for older adults will be shaped by at least three factors. First, work on the DSM-5 has been completed, and this iteration of the nomenclature is more evidence based. Changes have been included in the Neurocognitive Disorders section which now includes Mild Neurocognitive Disorder to be distinguished from Major Neurocognitive Disorder. Therefore, the use of existing epidemiological data for secondary data analysis could provide critical assessment of the criteria for disorders based on the natural clustering of symptoms. Statistical methods such as item response theory could be quite valuable and relatively inexpensive as a means for informing this nomenclature. In addition, existing assessment methods in a number of both cross-sectional and longitudinal data bases provide opportunities for analyses of the usefulness of these criteria both cross-sectional and longitudinal. For example, many surveys of older adults, both community-based and from Alzheimer's Disease Centers, provide a wealth of data on the initial cognitive deficits and progression of the dementias.

Second, psychiatric epidemiology in the future must incorporate biological, especially genetic, markers. For example, though DSM-5 does not include specific use of markers as yet, the widespread and relatively inexpensive approaches to exploring the genome and other markers, such as tau in neurocognitive disorders associated with Alzheimer disease provide the opportunity to obtain extensive individual-specific information about the neuropathology of the disease over time. Yet the complexity of psychiatric disorders almost invariably results from an interaction of the genome and the social environment. This interaction can no better be explored than in clinical and community-based epidemiological studies, often genetic add-on studies to existing epidemiological surveys. This interaction may be especially beneficial, for example, in exploring the frequency, distribution, and complex causes of vascular depression later in life.

Following upon the second factor, psychiatric epidemiologists working with older adults must be better able to define and explore the social

environment of older adults. Recent studies have distinguished individual social risks (such as socioeconomic disadvantage) from community-based factors such as poverty and crime rates as risks for late-life depression. Yet better measures of the individual as well as neighborhoods will advance such studies. For example, many psychiatric disorders are undoubtedly aggravated by the stress experienced by older adults who are isolated in unsafe neighborhoods.

Psychiatric epidemiologists have many opportunities to advance the extensive work reviewed in this section, and such opportunities will be critical given the ageing of society.

▲ 57.2 Assessment

57.2a Psychiatric Assessment of the Older Patient

DAVANGERE P. DEVANAND, M.D., AND GREGORY H. PELTON, M.D.

In the elderly, there is interplay between biological, psychological, and social issues in the presentation of mental illness. Therefore, a thorough evaluation, including assessment of the patient's internal and external environment, is necessary for accurate diagnosis and treatment. In neuropsychiatric disorders, localization of signs and symptoms to specific brain regions should also be attempted to improve understanding of the patient's condition and to facilitate clinical management.

The advent of a variety of brain imaging techniques, genetic testing, and other developments have helped enhance diagnostic assessment, but these approaches are not adequate substitutes for comprehensive history taking and clinical assessment of the older patient. Structured and semistructured interviews and rating scales can be used to supplement the diagnostic interview process.

In elderly patients, the fear of aging and its effects are common. They commonly state that since they are getting old, their symptoms, for

example, depression or cognitive impairment, are normal and are to be expected. In such a patient, it is useful to point out that among people in their own age group, only a small minority has their specific condition and that most people function well.

The evaluation should aim at obtaining a comprehensive assessment of the patient's mental and physical state, and input is often required from the family and significant others. The historical background and values of the elderly patient within a social class and culture influence the perception and presentation of illness and disease.

HISTORY TAKING

The principles in gathering history are similar to those in adults generally: establish rapport, make the patient comfortable, and maintain privacy and confidentiality. Older people have lived a long time, have undergone many stresses, are resilient, and expect to be treated with respect.

The elderly patient expects direct inquiry and examination. Hand contact and reaching out and touching the patient are often useful in establishing rapport. A medical approach is often expected, and respected, by the older patient.

The psychiatrist needs to take an active role and involve the family and significant others whenever feasible. The psychiatrist should explain clearly the nature and purpose of the evaluation, and inquire about the patient's complaints and the patient's and family's goals for the evaluation. The patient's limitations may require modification in the interview technique. In the patient with hearing impairment, the psychiatrist may need to move close to the patient's good ear and speak slowly, loudly, and clearly. Cognitively impaired patients may find it very stressful to perform cognitive tasks in the mental status examination, and may refuse to complete the tests. It is important to explain the nature and purpose of the cognitive tests before administering them, and frequent breaks between tests can help the patient complete the cognitive assessment.

Details about medical illnesses and medications taken are important in elderly patients. Information from other physicians, hospitals, and therapists should be obtained whenever needed to supplement the evaluation. In severely impaired patients, particularly patients with dementia, information from caregivers and professionals involved in social support services is useful. Most elderly patients first see their primary care physician for their psychiatric symptoms, and this is the setting where the majority of them are treated. Therefore, primary care physicians commonly refer their patients to a psychiatrist if diagnosis and management become difficult.

The history should include the following components: identifying data (name, age, sex, education, marital status), chief complaint, history of present illness including onset, duration and symptom course over time,

past psychiatric history, medical history and medications taken, alcohol and substance use history, work history and living situation, and family history of psychiatric, neurological, and other medical disorders.

The initial evaluation session may be long in an older patient, especially if extensive information from collateral sources needs to be obtained. Further, a second visit may be necessary to provide enough time to gather all the additional information from tests and procedures conducted in the interim in order to make an informed diagnosis. In a patient with cognitive decline, laboratory tests to identify potential causes (e.g., syphilis, vitamin B_{12} deficiency, hypothyroidism) of cognitive impairment, and neuropsychological testing and structural/functional brain imaging procedures (CT or MRI, SPECT or PET) may need to be ordered at the first visit. In these cases, the second visit becomes an informing visit at which the patient and family receive the opinion about the diagnosis and likely prognosis. Some diagnostically puzzling cases may need more visits and follow-up to help clarify the patient's condition. In particular, the psychiatrist needs to keep an open mind about the possibility that the initial diagnosis may need to be revised based on the patient's clinical course and response to treatment, for example, change in cognitive status after initiation or withdrawal of medications that have an adverse impact on cognition, for example, benzodiazepines or medications with anticholinergic properties.

HISTORY OF PRESENT ILLNESS

The patient should be encouraged to describe history of the current illness and symptoms and history of the current illness in an open-ended interview, with more structured questions following this initial inquiry. The onset and course of symptoms should be evaluated in relation to other changes including loss of loved ones, relation to daily activities, medication usage, response to treatment if applicable, and intercurrent medical illnesses. Many elderly patients consider insomnia and fatigue to be a normal part of the aging process, and these areas may require explicit inquiry. The time course of development of the present illness is very important in elderly patients. In a patient with cognitive decline, a history of gradual deterioration suggests dementia, episodic cognitive deficits with confusion suggest delirium, focal neurological symptoms or signs suggest cerebrovascular disease, and a short, downhill course may indicate a rapidly progressive dementia like Creutzfeldt–Jakob disease.

Ascertaining age and age at onset of symptoms is critical in the elderly patient. There is considerable evidence that patients with late-onset (onset after 50 to 60 years of age) major depression are less likely to have a positive family history of affective disorder and more likely to have evidence of cerebrovascular disease and cerebral atrophy than elderly patients with early-onset depressive illness. Late-onset schizophrenia

differs in some respects from early-onset schizophrenia, with a greater preponderance of females, paranoid subtype, and some differences in neuropsychological test profiles. Patients with early-onset Alzheimer disease (onset in the 40s or 50s) typically have presenilin I or presenilin II gene mutations, whereas late-onset Alzheimer patients usually do not have these gene mutations though some still have a positive family history of Alzheimer disease.

Based on the clinical presentation, inquiry should focus on pertinent symptoms to make a diagnosis of major depression or psychosis, or anxiety disorder or other axis I or axis II disorder. Potentially serious symptoms that should be reviewed with the patient include depressed mood, suicidal thoughts, lack of interest, agitation/aggression and impulsivity, delusions, and hallucinations.

Insomnia is common in the elderly. During the aging process, there is a small, gradual decline in the number of hours slept per night. Therefore, any significant change in sleep pattern should alert the psychiatrist to the presence of an underlying psychiatric disorder, most commonly a depressive illness. Some patients may downplay insomnia, anorexia, and lack of interest as normal features of the aging process, but this constellation of symptoms should trigger a thorough evaluation for the presence of a depressive disorder. Insomnia, apathy, and anhedonia also occur in early dementia, and the presence of these symptoms should lead to a systematic assessment of cognitive abilities. A gradual decrease in libido and sexual functioning occurs in some older adults, but a rapid deterioration in sexual interest should trigger investigation into the underlying cause. Diabetes, hypertension, and the iatrogenic effects of medication are common causes of sexual dysfunction, but so is depression. Somatization is typical of elderly depressed patients, but there are cultural differences in the degree to which this occurs.

Older adults face a variety of stresses: medical illnesses, physical disability, sensory impairments in vision and hearing, loss of family and friends, loss of social support, changes in relationships with children and significant others, alterations in living situation, and loss of income. One or more of these factors may be related to the onset of the clinical syndrome. The death of a spouse is extremely stressful, as is the death of an adult child. Patients with major depression perceive significantly greater negative emotional impact of the same life events than patients with dysthymic disorder and healthy controls, particularly for interpersonal conflicts.

In the elderly, there is a high rate of delirium after admission to a hospital. This may be related to the lower “cognitive reserve” of older compared to young adults. If there is a suspicion of delirium, potential risk factors should be evaluated, including fever, urinary tract infection, urinary retention, or fecal impaction.

The following symptoms need to be asked of patients with cognitive

decline: difficulties in memory or thinking or concentration, forgetting of recent events, forgetting where things are located, problems in finding the right word to say, getting lost in familiar places, and difficulty in managing finances like balancing the checkbook or paying for items in a store. These symptoms may be the first indicators of dementia. However, the isolated symptom of forgetting names is common during the normal aging process and by itself is not indicative of dementia.

Specific inquiry should also be made about pain, visual and hearing impairment, and possible drug toxicity. For patients in institutional settings, the interpersonal interactions with other residents are important.

PSYCHIATRIC HISTORY

Evaluation of psychiatric history should include the course of illness and types of treatment, that is, psychotherapy, medications, and ECT, and history of response or lack of response to these treatments. Treatments that worked well before in the patient, or worked well in family members, should be given priority.

History of depression, anxiety disorders, and psychosis/schizophrenia, and treatments received in prior and current episodes, should be obtained. Personality disorders are less common in elderly depressed patients compared to young adults with depression. Obsessive-compulsive and avoidant subtypes are more common than borderline, histrionic, narcissistic, and antisocial personality disorders in older adults. Leading questions should be asked about alcohol or substance abuse, history of head trauma, infections like meningitis or encephalitis, stroke, seizure disorder, and other neurological disorders.

FAMILY INTERVIEW AND HISTORY

In the cognitively impaired patient, it is advisable to see the patient alone, then the informant (usually a family member) and/or the patient together with the informant. The informant interview provides an independent assessment of the patient's environment, for example, the cognitively impaired patient may have allowed the home to become disorganized or left the stove on with adverse consequences. In severe dementia, interviewing the informant (or informants) both separately and in a joint interview with the patient is often necessary. In these patients, impairment in memory and other cognitive functions may be so severe that nearly all the history needs to be obtained from the informant. Even at the stage of mild cognitive impairment, the informant's report of the patient's function has been shown to be a much stronger predictor of dementia on follow-up than the patient's self-report of functional ability.

Patients may minimize symptoms in the presence of other people, but may be more revealing about symptoms like depressed mood and suicidal ideation when interviewed alone. Paranoid ideation may not be revealed

when family members are also present in the room. A joint interview with the patient and family (or other informant) may become necessary if there are conflicts about the patient's habits and behavior that need to be resolved, for example, the patient wants to continue driving after developing dementia. However, the family member's report may not always be accurate. For example, in patients with dementia, there is consistent evidence that the informant's report that the patient is depressed often reflects the informant's own depression rather than the patient's mood state.

A genogram is helpful in delineating the familial relationships and the important psychiatric, neurological, and other medical illnesses in different generations. Inquiry should be made about a family history of psychiatric hospitalization, unipolar depression or bipolar disorder, schizophrenia, anxiety disorders, alcohol or substance abuse, suicide, Alzheimer disease, stroke, epilepsy, Creutzfeldt–Jakob, Huntington disease, Parkinson disease, and other neurological disorders. Interviewing more than one family member, and preferably more than one generation, improves accuracy regarding family history.

In elderly patients with functional impairment, family and other caregiver support need to be assessed. The time spent by family members, services provided by family members, perception of family support, and tolerance by family members of changes in behavior are elements that need to be assessed and considered in the development of a treatment plan. Services that may be needed include transportation, nursing services, physical therapy, continuous supervision, homemaker and household services, meal preparation, administrative, legal and protective services, financial assistance, and coordination of delivery of services. These issues may be of greater concern to the patient and family than the clinical symptoms, and usually require coordination with nurses, case managers and social workers in the health support system for the older patient.

The patient and family usually find the transition to assisted living or a nursing home to be very difficult. Guilt, frustration, anger, helplessness, isolation, depression, and demoralization on the part of the caregiver can reduce caregiver effectiveness and impact adversely on the patient. This can lead to an accident like falling and fracturing a hip, inappropriate nursing home placement, or, in some instances, elder abuse. It is important to inquire how the caregiver is coping with the stress of having to take care of the patient, and appropriate referral for the caregiver to seek evaluation and treatment may become necessary.

PERSONAL HISTORY

Details should be obtained about the patient's marital status, living situation, educational background, work history, and the nature of relationships important to the patient. Premorbid personality does carry

into old age, but its impact on illness in the elderly varies considerably. Personality itself may change with aging. This change is believed to be environmentally determined, but it could also be based on changes in neurobiology, for example, catecholaminergic neurons in the locus ceruleus decay markedly with aging and this change may be related to the relatively low rate of late-onset anxiety disorders in the elderly population. Religion is often important to the elderly patient and needs to be included in the history.

The interviewer may be embarrassed to ask about sexual history in the elderly patient, but many older adults do have symptoms of sexual dysfunction and want to talk about it. Inquiry about sexual orientation and sexual dysfunction should cover any history of sexually transmitted diseases, erectile dysfunction (including impotence) in men, and anorgasmia in men and women. Sexual dysfunction can be a side effect of medication, particularly SSRIs and related antidepressants. Diabetes and hypertension are also common culprits.

MEDICAL HISTORY

The elderly patient typically suffers from several medical illnesses and takes a large number of medications. Patients may not keep track of all the medicines they are taking and their list often excludes medications obtained over-the-counter or alternative medications sold in health food stores. Therefore, it is important to inquire about all these categories of medications, and it is a good idea for the psychiatrist to ask the patient to bring all the current medications in a bag. Benzodiazepines, steroids, and anticholinergics can lead to cognitive impairment and even delirium; L-dopa and dopamine agonists prescribed for Parkinson disease can lead to psychosis, and the use of some antihypertensives and steroids have been associated with depression.

Medical history should cover all major illnesses, surgery, hospitalizations, trauma, and treatments. A variety of medical disorders can first present with disturbances in mood, cognition, or psychotic features including infections, electrolyte and metabolic imbalances, and cardiovascular and cerebrovascular disease. Depression can lead to weight loss and malnutrition. Dietary history is important in this regard; the older adult living alone may not obtain adequate nutrition and develop vitamin and other deficiencies.

ALCOHOL AND SUBSTANCE ABUSE

Alcohol abuse is not uncommon in the elderly, and explicit inquiry is usually necessary to elicit this history. Even when alcohol consumption has been constant in amount for many decades, it can lead to cognitive decline in susceptible patients as they grow older because of decreased cognitive reserve due to neuronal loss in the brain. Neuropsychiatric complications

of alcohol abuse and dependence, now subsumed under alcohol use disorder in DSM-5, include varying degrees of amnesia, Korsakoff syndrome, and intention tremor and ataxia (cerebellar damage). Other substance use disorders are less common in elderly patients, but some do use marijuana regularly. Even with the advent of new hypnotics, benzodiazepine use remains fairly widespread. This is of particular concern in the elderly because benzodiazepines can contribute to excessive sedation, unsteady gait and falls, and cognitive deficits. Patients with chronic pain, particularly back pain, may be dependent on narcotics.

MEDICAL EXAMINATION

If a medical examination has not been conducted recently by the patient's primary care physician, the psychiatrist needs to complete this component or arrange to have it done by another physician. The neurological examination is particularly important, and needs to include evaluation of sensorium, cognition, motor strength and function, sensation, reflexes, extrapyramidal signs, vision, and hearing. Neurological deficits, endocrine disorders, cardiovascular disease, occult malignancy, and infections are potential causes of cognitive impairment, agitation, depression, and occasionally psychosis. Urinary tract infection, which can occur without fever, is a common underlying cause of cognitive decline and delirium, particularly in the nursing home.

MENTAL STATUS EXAMINATION

The mental status examination is essential. Serial mental status examinations may be necessary, especially if mental functioning fluctuates over time.

OBSERVATION OF BEHAVIOR

The first part of the mental status examination is general observation of the patient's appearance, personal hygiene, motor activity, any unusual behaviors, speech, attitude toward the examiner, and the presence of hearing and visual aids. Poor hygiene suggests dementia, but conversely the demented patient may look well groomed because of the caregiver's efforts.

In older patients, paranoid delusional thoughts occur not only in schizophrenia and delusional disorder but also in dementia, particularly Alzheimer disease, and during the course of delirium. Apathetic, withdrawn behavior is common in both depression and dementia. Disturbances of motor activity are frequent in elderly patients, and bradykinesia with slow gait is common in the 8th to 10th decade of life. A slow shuffling gait with mask-like facies, resting tremor, and rigidity indicate Parkinson disease or extrapyramidal side effects of antipsychotic medication. Elderly patients

are particularly prone to the neurological side effects of antipsychotics. Lip-smacking and involuntary buccofacial movements suggest tardive dyskinesia in patients with prior antipsychotic exposure, though this has become less common since the advent of second-generation antipsychotics. Impulsive, disinhibited behavior with minimal to mild cognitive impairment may be the first signs of frontotemporal dementia, though increasing apathy is, in fact, more common than disinhibited behavior in frontotemporal dementia.

LANGUAGE AND THOUGHT DISORDER

Speech and language are important to assess in older adults. The quality, quantity, and fluency of speech need to be assessed. Speech can be normally responsive, rapid, pressured, loud or emotional, slow, monotonous, lacking spontaneity, or slurred. Aphasia or slurred speech occurs in stroke and in a variety of neurological disorders. Mutism occurs in late stages of primary progressive aphasia, dementia from a variety of causes, and amyotrophic lateral sclerosis. Repetitive speech with perseveration on the same topic is common in patients with dementia, and tends to be secondary to the loss of recent memory that is a hallmark of the illness.

The patient should be able to understand and answer questions appropriately, and think in abstract terms. Paucity of speech with long latency is characteristic of major depression, particularly the melancholic subtype. Tangentiality and looseness of associations are characteristic of schizophrenia. The patient with Alzheimer disease may display repetition, perseveration, and fragmented ideas. In contrast, patients with subcortical dementias like Huntington or Parkinson disease usually do not show these patterns of thought process.

Thought content abnormalities include preoccupations or obsessions, including preoccupation with health problems in the elderly depressed patient. Delusions can be persecutory, grandiose, somatic, erotic, guilty, or nihilistic. Hypochondriacal delusions are common in delusional depression, for example, bowels are not working or have been destroyed. Delusional depression in the elderly is associated with a high suicide risk. Bizarre, fixed delusions are common in schizophrenia, but they are rare in dementia where transient persecutory ideas are more common. Distinguishing fact from fiction can be difficult in the elderly patient, who may have had personal effects stolen and may not have a persecutory delusion as the evaluation may suggest.

PERCEPTION

Perceptual disorders include hallucinations and illusions. Hallucinations can be simple or complex and organized. Transitory hallucinations can occur in dementia, and in patients with hearing or visual deficits. In these

patients, it is important to distinguish an illusion, that is, perceptual distortion of a real sensory stimulus, from a hallucination that may indicate more severe psychopathology. Memory loss and disorientation help to identify the problem as being related to dementia. A number of other perceptual abnormalities occur in a variety of neurological disorders involving damage to specific brain regions. These syndromes include micropsia, which occurs when objects look smaller than their real size, macropsia, which occurs when objects look larger than their real size, visual agnosia, which is the inability to recognize visible objects, prosopagnosia, which is the inability to recognize familiar faces, astereognosis, which is the inability to recognize objects by touch, and autotopagnosia, which is the inability to recognize parts of one's own body.

MOOD AND AFFECT

Mood is the subjective and affect is the objective emotional state. Many elderly patients describe their mood accurately as depressed or anxious, but some tend to deny and suppress it. For example, an elderly woman who is crying may say that she is not depressed. Somatization is common in older patients, particularly gastrointestinal symptoms like constipation. Some patients are not sure if they are depressed because they have begun to lose interest in activities but do not experience a clear-cut depressed mood. Many of these patients have dysthymia or minor depression. Depression is common in a variety of other neuropsychiatric syndromes, including dementia, stroke, and Parkinson disease. Mania is not common in the elderly, but can occur as a primary late-onset mania or secondary to dementia or stroke, or other neurological insult. Labile affect is believed to be typical of vascular dementia, but it remains unclear if labile affect is more common in vascular compared to other forms of dementia. Pseudobulbar affect is uncontrollable laughing or crying in the absence of the corresponding subjective mood experience, and occurs in neurological disorders like amyotrophic lateral sclerosis and frontotemporal dementia, and less commonly in Alzheimer disease. Medication side effects or toxicity need to be considered as possible etiologies for depression. Of note, late-onset anxiety disorders, including panic disorder, are relatively rare.

SUICIDAL AND HOMICIDAL IDEATION

Inquiry should be made about suicidal and homicidal ideation. Suicidal ideation should be probed by first asking whether the patient thinks that life is not worth living. A positive response should lead to follow-up questions about whether there is a suicide plan or history of a suicide attempt. If this line of inquiry indicates suicidal risk, further questions should focus on whether a gun or other means to commit suicide are easily available, and the appropriate clinical intervention with the patient and family members should then be made. Studies consistently show that

elderly males, particularly white males, are the demographic group with the highest risk of committing suicide, and that they often use guns as the method of suicide. Of note, the majority of patients who commit suicide have visited their primary care physician a few days to weeks before they act.

SLEEP

Approximately half of older adults complain of sleep difficulties. Careful assessment of sleep habits, including factors such as alcohol and caffeine intake that can disrupt sleep, is important. Other factors contributing to sleep impairment include age-related changes in sleep architecture and circadian rhythms, sleep disorders including sleep apnea, dementia, depression, other medical illness, and polypharmacy. The impact of treatment, or withdrawal of treatment, for example, benzodiazepines, needs to be assessed in the context of these factors that can underlie sleep disorders.

SENSORIUM AND COGNITION

Evaluation of sensorium and cognition is critical and essential in elderly patients. Whenever there is suspicion of cognitive impairment by history, it is important to administer a screening test like the Mini Mental State Examination (MMSE) or Montreal Cognitive Assessment (MOCA).

At the start of this portion of the examination, the patient should be told that some of the questions are easy and some a little more difficult, and that people score across a wide range in these tests. This instruction is important because the patient with significant cognitive deficits may not agree to complete the test if they feel that they are taking an examination and that their deficits are being judged critically. Skills that can be tested in this component of the evaluation, and which can be assessed more thoroughly with detailed neuropsychological testing, include attention and concentration, learning, recall, recognition after a delay (memory), comprehension, verbal fluency, repetition, and naming (language), visuospatial abilities, calculation, praxis, and the executive functions of initiation, perseveration, response control, synthesis and integration, and changing mental sets (frontal lobe functions).

A patient needs to be able to focus and be attentive in order to complete the tests. If a patient is distractible and unable to concentrate, the subsequent components of the test may not be valid. Educational achievement and the patient's primary language are important variables to consider in the interpretation of cognitive tests. A patient with low education or a patient for whom English is not the primary language is likely to score poorly on some components of the cognitive assessment, but memory is affected less by these factors. Therefore, a patient with low education who scores 25/30 on the MMSE but recalls 3/3 objects at 5

minutes is less likely to be developing dementia than a patient with a postgraduate degree who scores 28/30 on the MMSE but recalls only 1/3 objects at 5 minutes.

COGNITIVE TESTING

A brief evaluation of cognitive ability can be performed with the MMSE. A score of less than 24 out of 30 is considered indicative of a cognitive deficit. A variety of conditions, including major depression, can be associated with low MMSE scores. In patients with mild cognitive impairment, deficits in recall of three objects after a 5-minute delay, and impairment in the orientation items, suggest an increased likelihood of developing dementia. However, the MMSE by itself is not sufficient to make a diagnosis of dementia. In the early stages of dementia, attention is preserved but short-term memory is impaired. In contrast, attention is impaired in depression but short-term memory is relatively intact, that is, what is registered in the brain is generally retained. Delirium is characterized by disorientation, which occurs only in the mid to late stages of most dementing disorders. If the results of the cognitive screening leave the diagnosis in doubt, which is often the case, referral for detailed neuropsychological testing is usually indicated. Neuropsychological testing is useful in making the diagnosis of dementia in its early stages, but its utility in differentiating subtypes of dementia, for example, Alzheimer versus vascular, or in diagnosing depression in patients with dementia, is not as well established.

INSIGHT

Insight refers to the ability of patients to understand their own symptoms and their potential causes. Insight is impaired in most forms of moderate to severe mental illness, and can disappear in severe dementia. Judgment can be assessed during the course of the interview by inquiring about the patient's opinion and proposed course of action in incidents that they describe in their own history, or in a hypothetical incident. Judgment is compromised in psychotic disorders and dementia.

DAILY FUNCTIONING

Assessment of daily functioning is essential in the evaluation of the older patient, unlike the situation in most young adults. Activities of daily life (ADL) can be classified into basic ADL (e.g., eating, dressing, toileting), instrumental ADL (cooking, shopping, laundry), and more complex social and cognitive functions requiring greater mental effort. Basic and instrumental ADL need to be assessed in the elderly patient. The Pfeffer functional activities scale is widely used in large-scale studies of patients with mild cognitive impairment and Alzheimer disease.

NEUROLOGICAL EVALUATION

Psychiatric, cognitive, and neurological examinations overlap considerably in older adults. While patients with manifest neurological disorders need consultation by a neurologist, the geriatric psychiatrist needs to be able to perform the neurological examination because many patients present with syndromes that overlap between the two specialties. In patients who have cognitive disorders or focal neurological symptoms or signs, a neurological examination is essential. All components of the neurological examination are important, but in the elderly patient presenting to a psychiatrist, the areas of frontal lobe function, basal ganglia function (examination for extrapyramidal signs), motor and sensory function, reflexes, coordination, and evaluation of vision and hearing are essential.

RATING SCALES

Although rating scales are used primarily in research studies, they can serve several possible functions in clinical practice: address specific clinical problems and document change, teach, communicate with colleagues, and strengthen the chart or electronic medical record for medicolegal and insurance purposes. The SCID can be administered to make comprehensive DSM diagnoses, but it requires special training and takes too long to be recommended for routine clinical practice. Some of the widely used scales to assess specific domains of psychopathology and cognitive and daily functioning will be summarized here.

Depression

The Hamilton Rating Scale for Depression (HRSD), Montgomery–Åsberg Depression Rating Scale (MADRS), Geriatric Depression Scale, and Center for Epidemiological Studies-Depression Scale (CES-D) have been used in a variety of research studies. The HRSD and the MADRS are particularly useful in patients with melancholic depression. Another widely used instrument is the Beck Depression Rating Scale, a self-report instrument. Epidemiological studies have typically used the self-report CES-D. The Geriatric Depression Scale, which can be self-rated or observer-rated, is also useful. To assess depression in patients with dementia, the Cornell Scale for Depression in Dementia has been developed.

To assess cognitive impairment, a plethora of rating instruments is available. The most widely used instrument is the MMSE, and the MOCA is comparable in its utility. Education and cultural background can affect performance on these tests, which is one reason why the score obtained should be evaluated in the context of the entire clinical picture.

To assess psychosis, the Brief Psychiatric Rating Scale (BPRS) is commonly used in young adults and can also be used in elderly patients. To address the unique features and methods of assessment of psychosis in dementia, a variety of scales have been developed. These include the

Neuropsychiatric Inventory (NPI), the Columbia University Scale for Psychopathology in Alzheimer's Disease (CUSPAD), CERAD Behavior rating Scale, and the Behavioral Pathology in Alzheimer's Disease (BEHAVE-AD) rating scale. The Cohen-Mansfield agitation inventory is available for use in nursing home patients. Currently, the NPI, which uses a time-efficient, decision-tree approach, is the most widely used scale to evaluate the effects of pharmacological treatment of psychosis and agitation in patients with dementia.

To assess the neurological side effects of antipsychotic medications, the Unified Parkinson's Disease Evaluation Scale and the AIMS scale can be used.

COMPETENCE

The psychiatrist may be asked about the patient's level of competence to give consent for medical treatment, give power of attorney, sign or change a will, or manage personal finances. Competency is a legal term, and the criteria for judging it have never been precisely defined. Competency needs to be judged in a specific framework and context, that is, a patient may be competent to execute one task but not another. There are some specific measures to evaluate financial abilities, but testamentary capacity remains a judgment call. Both cognitive abilities and general functioning need to be evaluated before making this judgment.

SYNDROMES SPECIFIC TO GERIATRIC PATIENTS

There are several syndromes common in geriatric patients who do not fit easily into the current diagnostic nomenclature. These syndromes cut across medical and psychiatric diagnoses, are widely recognized, and need to be incorporated into the evaluation. Apathy is common, and it can be difficult to separate from depression. Frailty is a syndrome that is associated with increased morbidity and mortality, and gait and grip strength are important metrics in the evaluation of frailty. Technology-based assessments that can monitor activity levels and sleep to inform diagnosis are now used mainly in research studies, but over time they are likely to be included in the standard clinical assessment of patients. Similarly, telemedicine can be extended to telepsychogeriatrics, particularly given the aging of the population and the need to provide psychiatric assessment and treatment to the homebound elderly.

SUMMARY

The evaluation concludes with a summary of the key findings and differential diagnoses, which leads to a diagnosis. An etiological formulation using the biopsychosocial model is the next step. Finally, these conclusions are built into the treatment plan and management strategies

for the patient.

57.2b Complementary, Alternative, and Integrative Medicine in Geriatric Psychiatry

HARRIS A. EYRE, M.B.B.S. (HONS.), BERNHARD T. BAUNE, M.D., PH.D., AND HELEN LAVRETSKY, M.D.

INTRODUCTION

Complementary and alternative medicine is "a group of diverse medical and health care systems, practices, and products that are not presently considered part of conventional medicine." Some of these therapies provide promise as novel and effective therapies for treatment and prevention of late-life psychiatric disorders. "Complementary" generally refers to using a nonmainstream approach together with conventional Western medicine. "Alternative" refers to using a nonmainstream approach in place of conventional Western medicine. "Integrative medicine" is another term often used in this CAM field, it aims to combine alternative and complementary medicine with evidence-based Western medicine. From here on, such therapies are referred to as Complementary, Alternative and Integrative Medicine (CAIM). The shift in the societal attitudes to be more inclusive of these practices is reflected in the recent change in the titles of the National Center for Complementary and Alternative Medicine (NCCAM) to the National Center of Complementary and Integrative Health (NCCIH).

CAIM interventions have varying levels of efficacy and evidence, they can include mind–body practices, conventional physical activity, dietary interventions, natural products, as well as body-based practices and other medical system practices. Mind–body practices refer to practices where both physical and mental activity may be combined during training. These can be more exercise-focused (i.e., yoga, tai chi, qigong) or more practice and stress-reduction focused (i.e., mindfulness and relaxation). Physical activity refers to any bodily movement produced by skeletal muscles that requires energy expenditure and may include aerobic, resistance, stretching and toning, or combination activities. Dietary interventions explore the effect of dietary patterns on health and illness and may include Western, traditional, and Mediterranean dietary patterns, as well as caloric restriction, among others. Natural products may include herbs, vitamins, minerals, natural supplements, and probiotics. Body-based practices may include spinal manipulation (e.g., chiropractic, osteopathic medicine), aromatherapy, and massage therapy. Other medical systems include traditional Chinese medicine (including acupuncture), Ayurvedic medicine, or homeopathy. These CAIM interventions are largely based on therapies, which have been utilized in many civilizations and religions for hundreds and thousands of years. It is not since the past 50 to 100 years that empirical science has begun to explore the evidence behind these therapies. For a graphical representation of the CAIM subtypes, refer to Figure 57.2b–1.

There are a number of major reasons why geriatric mental health providers need to recognize the importance of these interventions. (1) *CAIM therapy use is high and rising*. Research suggests 12-month prevalence of any CAIM usage (excluding prayer) in the United States is around 35 to 50 percent; Baby Boomers (adults born from 1946 to 1964) report significantly higher rates of use than the Silent Generation (born from 1925 to 1945) for chronic conditions. (2) *The global population is aging*. The number of older persons (aged ≥60 years) globally is expected to more than double, from 841 million people in 2013 to more than 2 billion in 2050. (3) *CAIM therapies are increasingly cited in clinical guidelines*. It is now commonplace to note the use of therapies like conventional exercise in the management of psychiatric conditions. (4) *CAIM therapies are a source for innovative interventions and have a growing, quality empirical research basis*. Empirical researches into these therapies are exploring their clinical efficacy in trials and the neurobiological mechanism underlying their effects. (5) *CAIM therapies can help to lower utilization of conventional medicines*. CAIM therapies may be used in replacement of conventional medicines for the management of mild illnesses (e.g., relaxation techniques for mild anxiety instead of benzodiazepines which are known to have adverse effects with elderly populations). (6) *CAIM therapies can have significant side effects and CAIM–drug interactions*. With the high use in geriatric populations, this is therefore an important reason why clinicians need to better understand CAIM therapies.

This chapter aims to provide an overview of the importance of understanding CAIM therapies in geriatric psychiatry.

THE EPIDEMIOLOGY OF COMPLEMENTARY AND INTEGRATIVE MEDICINE USE

To appreciate the importance of CAIM therapies in geriatric psychiatry, it is important to explore the epidemiology of, and drivers behind usage. This section will explore these topics in general adult, old age, and psychiatric populations.

CAIM Use in Geriatric Populations

CAIM usage in general adult populations appears to be high, however, there is variability within studies. A recent systematic review of prevalence studies from 1998 onward explored the use of these therapies internationally and included 51 reports from 49 surveys in 15 countries. Estimates of 12-month prevalence of any usage ranged from 9.8 to 76 percent; and from 1.8 to 48.7 percent for visits to health practitioners. Estimates of 12-month prevalence of any usage (excluding prayer) from surveys using consistent measurement methods showed remarkable stability in Australia (49 percent, 52 percent; 1993, 2004) and United

States (36 percent, 38 percent; 2002, 2007). National estimates of CAIM use were highest in East Asian countries such as Japan, South Korea, and Malaysia. Studies consistently show that "average" CAIM users are more likely to be female, better educated, middle-aged, and report poorer health status than nonusers.

Specific data on geriatric populations suggest high use of CAIMs, however, there is variability depending on study populations. A recent study compared CAIM usage between Baby Boomers (adults born from 1946 to 1964; n = 7,734) and the Silent Generation (born from 1925 to 1945; n = 4,682) through analysis of the National Health Interview Survey in the USA. Baby Boomers were more likely to use CAIM within the past year (43.1 percent vs. 35.4 percent) with chronic pain independently associated with greater CAIM use. This data therefore suggest that given Baby Boomers are already using 30 percent more CAIMs than their older counterparts, with the aging Baby Boomer population across the world and associated increases in chronic and painful conditions, CAIM therapies will only continue to increase. By 2030, more than 6 in 10 Baby Boomers will be managing at least 1 chronic disease.

FIGURE 57.2b–1. Types of complementary, alternative, and integrative therapies.

There may be a number of drivers for CAIM use in geriatric populations. The use of CAIMs appears to be influenced by a complex mix of economic and sociocultural factors. First, it appears CAIM use is tied to the movement for self-care. Therefore, CAIM use may provide people with a better sense of control and responsibility over their illness. CAIM therapies such as tai chi and yoga appear to improve patients' quality of life. CAIMs are used in addition to, or in replacement of pre-existing pain medications. CAIM therapies can offer a less harmful management of chronic pain by avoiding unnecessary complexity, polypharmacy, and side effects. In low resource environments where access to biomedical services is poor, there is evidence of a pervasive reliance on traditional healers, even for severe diseases. Delayed medical care—more likely in low resource environments—is associated with CAIM use in the United States. In high resource settings where biomedical services are more readily available, a

significant amount of CAIM therapies are used for health promotion and illness prevention. CAIM therapies are often used as adjuncts to conventional therapies for severe diseases like cancer; and to self-manage chronic health complaints like lower back pain. It appears CAIM usage is driven more so by values and beliefs rather than dissatisfaction with biomedicine. The influence of increasing marketing of CAIM therapies is anecdotal but must be considered.

Persons with Mental Illnesses

Persons with mental illnesses appear to use higher numbers of CAIMs than the general population. In national samples of general adult populations, persons with depression and anxiety symptoms use CAIM therapies more than persons without such disorders. One study indicated that over half of such persons reported CAIM use within the prior year. The presence of psychiatric illness also increases the odds of visiting a CAIM practitioner. Also of significance, the use of CAIM therapies for anxiety and depression was often in conjunction with traditional treatments, raising concerns for how these treatments interact with conventional psychiatric treatments. Relatively less information exists specifically about CAIM use among older adults with mental illnesses. Data from the 2002 National Health Interview Survey indicate that nearly 82 percent of older adults with self-reported depression or anxiety had used CAIM within the prior year (as opposed to 65 percent of older adults without these symptoms). Most of the CAIM use reported by older adults with depression, anxiety, or both was described as being used for nonpsychiatric symptoms. A smaller regional study indicated that older adults in geriatric psychiatry clinics who used CAIM had higher scores for depression, pain, and sleep disturbance, with mind–body practices being particularly associated with depression in older adults.

CAIM MEDICINE IN AGE-RELATED COGNITIVE DECLINE AND DEMENTIA

As of 2013, there were an estimated 44.4 million people worldwide with dementia. This number will increase to an estimated 75.6 million in 2030, and 135.5 million in 2050. Unfortunately for those with Alzheimer disease, pharmacological agents temporarily treat symptoms without having an effect on the underlying pathophysiology of the disease. Conventional treatments for dementia are limited, therefore innovative management strategies are required. There is promising evidence for the use of various CAIM therapies in dementia; alternatively, there is mixed, contradictory, or no evidence for other therapies. This section provides an overview of the salient findings for therapies which show promise for evidence-based use in clinical populations.

Conventional Physical Activity

Conventional physical activity is one of the most promising therapy for the treatment and prevention of age-related cognitive decline and dementia. Importantly, there are a variety of subtypes of physical activity, from aerobic activity, to resistance, to stretching and toning. Currently, the American College of Sports Medicine recommends that exercise programs for older adults include both aerobic and nonaerobic physical activities, such as resistance training, balance training, and stretching, for optimal general health. See Table 57.2b–1 for the latest clinical guidelines on physical activity for older adults.

A recent randomized controlled trial (RCT) examined the efficacy of resistance and aerobic training in the improvement of cognitive functions in subjects with subjective Mild Cognitive Impairment (MCI). MCI—a well-recognized risk factor for dementia—represents a critical window of opportunity for intervening and altering the trajectory of cognitive decline. The study occurred over 6 months and involved 86 community-dwelling women aged 70 to 80 years. Physical activity protocols included twice-weekly resistance training, twice-weekly aerobic training, or twice-weekly balance and toning (BAT) training (i.e., control). Resistance training improved selective attention/conflict resolution and associated memory compared with BAT. In contrast, aerobic physical activity improved general balance and mobility and cardiovascular capacity. The study also found aerobic physical activity improved verbal memory and both resistance and aerobic physical activity improved spatial memory. A recent stringent meta-analysis has examined the efficacy of exercise on cognition in older adults with MCI. MCI was diagnosed on documented criteria or via the Mini-Mental State Exam (MMSE). Fourteen RCTs with 1,695 participants aged 65 to 95 years were utilized. These studies had a duration of 6 to 52 weeks. Overall, 42 percent of effect sizes (ESs) were potentially clinically relevant (ES >0.20) with only 8 percent of cognitive outcomes statistically significant. The meta-analysis revealed negligible but significant effects of exercise on verbal fluency (ES: 0.17 [0.04, 0.30]). No significant benefit was found for additional executive measures, memory, or information processing. The authors critically appraised RCT methods and concluded on a moderate quality with the majority of trial samples being too small for sufficient power. There is clearly some effect for exercise at moderate to high levels of exertion. In addition, nowadays there is an emerging evidence for the effect of low levels of physical activity or “sedentary behaviors” like sitting. Physical inactivity may increase the risk of Alzheimer disease by 82 percent. Approximately 13 percent of Alzheimer disease cases worldwide may be attributable to sedentary behavior. A 25 percent reduction in sedentary behavior could potentially prevent more than 1 million Alzheimer disease cases globally. Sedentary behaviors may contribute to risk of Alzheimer disease and dementia by increased risk of cardiometabolic risk factors—diabetes, hypertension, obesity—diseases

associated with increased risk of dementia.

Table 57.2b–1.
Clinical Suggestions for Geriatric Populations

If 65 years or older, generally fit, and have no limiting health conditions

- ► At least 150 minutes of moderate-intensity aerobic activity (i.e., brisk walking) every week and muscle-strengthening activities on 2 or more days a week that work all major muscle groups (i.e., legs, hips, back, abdomen, chest, shoulders, and arms).

OR

- ► 75 minutes of vigorous-intensity aerobic activity (i.e., jogging or running) every week and muscle-strengthening activities on 2 or more days a week that work all major muscle groups.

OR

- ► An equivalent mix of moderate- and vigorous-intensity aerobic activity and muscle-strengthening activities on 2 or more days a week that work all major muscle groups.

Other comments

- ► If there is a limiting condition, it is recommended the health professional and patient consult a qualified exercise physiologist.
- ► 10 minutes at a time is fine for physical activity.
- ► The following activities count as muscle-strengthening activities: yoga, heavy gardening.

Adapted from the Centers for Disease Control and Prevention Report. Physical activity is essential to healthy aging; 2015.

Recommendations and Summary. Our clinical recommendation is physical activity should be encouraged for all members of society and particularly older adults. More work is required to understand if physical activity recommendations or dementia prevention are the same as generic "healthy aging" recommendations (as in Table 57.2b–1). While shorter-term interventions are useful in the research setting, care must be taken to ensure a sustained engagement in physical activity. Care must also be taken to create an age- and physical-function appropriate prescription given risks of adverse health effects (e.g., falls, cardiovascular events).

Mind–Body Practices

Mind–body practices are varied and can be best divided into exercise and nonexercise type practices. Mind–body physical activity practice includes yoga, tai chi, qigong. Mind–body nonphysical activity practice includes relaxation, mindfulness, meditation, and acceptance therapies. Mind–body physical activity practices are often defined as "physical activity executed with a profound inwardly directed contemplative focus." Mindful physical activity contains the following key elements: (1) a noncompetitive, nonjudgmental meditative component; (2) mental focus on muscular movement and proprioceptive awareness combined with a low to moderate level of muscular activity; (3) centered breathing; (4) a focus on anatomic alignment (i.e. spine, trunk, and pelvis) and proper physical form; and (5)

energy centric awareness of individual flow of intrinsic energy, vital life force, qi, etc. Mind–body nonphysical activity practice doesn't emphasize the physical activity component of the above. There is an emerging body of empirical research exploring the effects of mind–body therapies in geriatric psychiatry disorders.

Mind–Body Physical Exercise. A recent meta-analysis critically evaluated the effects of tai chi on individuals aged 60 and old with and without cognitive impairment. In this study, 20 eligible studies with a total of 2,553 participants were identified that met inclusion criteria for the systematic review; 11 of the 20 eligible studies were RCTs, 1 was a prospective nonrandomized controlled study, 4 were prospective noncontrolled observational studies, and 4 were cross-sectional studies. Overall quality of RCTs was modest, with 3 of 11 trials categorized as high risk of bias. Meta-analyses of outcomes related to executive function in RCTs of cognitively healthy adults indicated a large effect size when tai chi participants were compared with nonintervention controls ($g = 0.90$; $p = 0.04$) and a moderate effect size when compared with exercise controls ($g = 0.51$; $p = 0.003$). Meta-analyses of outcomes related to global cognitive function in RCTs of cognitively impaired adults, ranging from MCI to dementia, showed smaller but statistically significant effects when tai chi was compared with nonintervention controls ($g = 0.35$; $p = 0.004$) and other active interventions ($g = 0.30$; $p = 0.002$).

There is a relative dearth of studies examining yoga and its effects on memory enhancement. One main study of which the authors are aware explores the effects of yoga and exercise in 135 healthy men and women aged 65 to 85 years. In this study subjects were exposed to 6 months of Hatha yoga classes, walking classes or wait-list control; subjects were screened with a variety of mood and cognition tests (e.g., Stroop test). Interestingly, after the intervention there were no effects from either of the active interventions on any of the cognitive and alertness outcome measures. The yoga intervention produced improvements in physical measures (e.g., timed one-legged standing, forward flexibility) as well as a number of quality-of-life measures related to sense of well-being and energy and fatigue compared to controls. This type of study needs to be replicated in populations with MCI to better understand potential effects.

Mind–Body Practices and Stress-Reduction Techniques. Relaxation techniques, such as breathing exercises, guided imagery, and progressive muscle relaxation, are designed to produce the body's natural relaxation response. These relaxation therapies are shown to lower stress levels in elderly subjects, and so are recommended for clinical use.

A recent pilot randomized trial with mindfulness-based stress reduction (MBSR) aimed to test the safety and feasibility of MBSR in older adults

with MCI. The study found adults with MCI can safely participate and adhere to an MBSR program. The qualitative interviews revealed that most enjoyed the program and described improved mindfulness skills, well-being, interpersonal skills, acceptance/awareness of MCI, and decreased stress reactivity. Most data suggest trend toward improvement for measures of cognition and well-being, however, a more formal, large scale RCT is needed.

Recommendations and Summary. Firm clinical recommendations for these activities are not possible given the paucity of sufficient evidence at this stage. However, the authors recommend mind–body therapies as useful stand-alone or adjunctive therapies for the management of mild neuropsychiatric symptoms (e.g., cognitive impairment and psychological distress) and physical health (e.g., balance, strength, coordination). Care must be taken to create an age-, physical- and mental-function appropriate prescription. There recommendations are based from clinical experience, emerging evidence, and the safe nature of these activities.

Natural Products

Natural products may include herbs, minerals, natural supplements, vitamins, and probiotics. A range of these products have been explored with regard to the treatment and prevention of cognitive impairment. There are too many of these products to thoroughly review in this chapter, so only the main products, with a larger body of research and/or epidemiological usage, are reviewed here with further reading recommended.

Omega-3 Polyunsaturated Fatty Acid Supplements. One of the most widely utilized therapies is Ω3 polyunsaturated fatty acids (PUFAs). Over 37 percent of individuals who reported using a nonvitamin, nonmineral natural product in the 2007 NHIS reported using Ω3 PUFAs. Oily fish, such as salmon, mackerel, herring, and sardines are a rich source of Ω3 PUFA which are essential for brain development. It is thought that Ω3 PUFAs may benefit neurodegenerative disorders due to antioxidant and anti-inflammatory effects. Previous research from observational studies has suggested that increased consumption of fish oils rich in Ω3 PUFA may reduce the chance of developing dementia. A recent Cochrane Database systematic review explored the effects of Ω3 PUFAs on the prevention of dementia and cognitive decline in cognitively healthy older people. Information was available from 3 RCTs including 3,536 participants in total. This meta-analysis found no evidence to support a preventative effect following 24 or 40 months of intervention. RCTs suggest that selected patients with an MMSE score >27 were more likely to identify a positive effect of Ω3 PUFA supplementation. It appears that studies of longer

duration are required to further explore this area. The Cochrane review authors' clinical recommendation emphasizes clinician–patient discussions of evidence. Care must be taken with potential side effects of mild nausea, mild increased bleeding, and a fishy aftertaste.

Ginkgo Biloba Supplements . Ginkgo biloba leaf extract is among the most widely sold herbal dietary supplements in the United States. Its purported biological effects include scavenging free radicals, lowering oxidative stress, reducing neural damage, reducing platelet aggregation, and anti-inflammatory, antitumor, and antiaging activities. No standards or guidelines regulate the constituent components of Ginkgo biloba leaf extract, nor are exposure limits imposed. Safety evaluation of Ginkgo biloba leaf extract is being conducted by the U.S. National Toxicology Program. Many RCTs of *Ginkgo biloba* in patients with various types of dementia have yielded contradictory results. Of the studies that revealed cognitive improvement, the effect was minor and did not last more than 6 months. A recent RCT demonstrated the efficacy of once-daily dosed Gingko biloba (240-mg extract EGb 761) in outpatients aged 50 years or older with mild to moderate AD or vascular dementia (VaD) over 24 weeks. Both types of dementia showed improvement in cognition and neuropsychiatric symptoms compared to placebo. However, evidence does not suggest Gingko biloba to prevent dementia. In a trial of AD prevention in older adults, ages 72 to 96 years old, 120 mg of *Gingko biloba* twice a day was not effective in reducing the overall incidence of dementia in the elderly with normal cognition or MCI. Therefore, *Ginkgo biloba* will not prevent the development of AD but may have a minor impact on cognitive decline in those already afflicted with a dementia. However, it should be noted that the data supporting these positive findings come mostly from smaller studies which lack a placebo control group. As with other natural products, Ginkgo biloba comes with risks. It is recommended to use caution when using *Ginkgo biloba* in those who are at increased risk of hemorrhage as it may potentiate bleeding. Nevertheless, a short RCT of males using EGb 761 did not show any effect on coagulation or bleeding time. The short-term use of Ginkgo biloba is acceptable under some conditions, dependent on clinician–patient discussions, with the potential risks being considered.

B-Vitamin Supplements. B-vitamin supplementation is a potential therapy to prevent and treat age-related cognitive decline. It is considered standard procedure to check a vitamin B_{12} level when considering a diagnosis of dementia because it is seen as a reversible cause of cognitive decline. Moreover, a cross-sectional study showed various measures of vitamin B_{12}, including methylmalonate, homocysteine, and cystathionine to be associated with episodic memory deficits, slowed perceptual speed and

decreased total brain volume in a sample of adults aged 65 years and older. Interestingly, data have related elevated homocysteine levels to amyloid and glutamate toxicity and cognitive decline in animal studies. Additionally, vitamin B_3 (niacin) deficiency also referred to as pellagra leads to the classic triad of dementia, dermatitis, and diarrhea. Therefore, it is logical that B vitamin supplementation should benefit cognition. However, the evidence does not support a robust response in cognition with B vitamins. A multicenter RCT of adults over 50 years old with mild to moderate AD and normal vitamin B_{12} and B_9 levels showed no benefit in cognition with supplementation. Another RCT in China failed to show an improvement with supplementation in cognition with older participants, age 60 years or older, with either AD or VaD and normal vitamin levels. However, the evidence appears to be more promising in individuals without cognitive impairment. A recent RCT of older adults, ages 60 to 74 years old, without dementia and normal vitamin B_{12} and B_9 levels showed a benefit in immediate and delayed recall with supplementation. The evidence does not support vitamin B supplementation in treating dementia when levels are normal, however, some data support supplementation improving cognition prior to development of dementia. Additionally, such use of supplemental vitamins may come at a risk, the Iowa Women's Health Study demonstrated an increase in mortality with the use of various dietary supplements including vitamins B_6 and B_9. This study supports the fact that is important for patients and clinicians to acknowledge that being natural is not always safer than "conventional" medicine.

For further details on other utilized CAIM therapies for the treatment and prevention of age-related cognitive decline, refer to Table 57.2b–2.

Potential Side Effects and CAIM–Drug Interactions. As eluded to above, when encountering natural products in a clinical environment, it is important to consider potential side effects and CAIM–drug interactions. Table 57.2b–3 outlines an array of clinical findings and potential pitfalls of natural products. It is important to note that CAIM use may exacerbate polypharmacy in the elderly, which is a risk factor for drug interactions, medication errors, and hospitalization. A survey of 271 British seniors found a mean of 5.91 (range 4 to 7) herbal and nutritional supplements and 2.26 prescription drugs.

Table 57.2b–2.
Other Natural Products and Supplements Suggested for the Treatment of Cognitive Impairment

Herb/Supplement	Suggested Dose	Possible Mechanism of Action	Evidence Base	Side Effects

Bacopa monniera	300 mg/day	An Ayurvedic medicinal plant that acts as a free radical scavenger and in animal models reduces Aβ; may also boost cholinergic function	No convincing evidence: 9 RCTs; 518 subjects in meta-analysis. Limited evidence given poor study design.	GI upset
Curcumin (yellow curry)	2,000–8,000 mg/day	Antioxidant, anti-inflammatory, induces heat shock proteins; antiamyloid effects in animals	Mixed results; no convincing evidence: 2 studies find no effect; 1 study finds beneficial effect.	GI upset
Dehydroepiandro-sterone (DHEA)	100 mg/day	Adrenal steroid that declines with aging, is lower in Alzheimer disease patients, and is neurotrophic in animals	No convincing evidence of benefit. 3 RCTs	Acne, balding, insulin resistance, dyslipidemia, mood changes, hepatic dysfunction, possible effects on hormone-sensitive cancers
Hydergine	3 mg/day	Combination of 4 ergot derivatives with vasodilatory effects and possible effect on mono-amine and cholinergic transmission	2000 Cochrane meta-analysis of 19 trials found some evidence of modest efficacy but many trials conducted before standardized criteria for diagnosing dementia	GI upset, psychosis, flushing, blood pressure changes
Lecithin	3,600 mg/day	An acetylcholine precursor	Review of 11 randomized trials showed no consistent benefit	GI upset, rash, headache, dizziness
Resveratrol	Unknown (phase 1 trials 2,500–5,000 mg/day)	Polyphenol in the skin of red grapes and red wine with antioxidant and antiamyloid properties in animals	Clinical trial linking to increased cerebral blood flow. Needs further study on cognitive effects	Possible estrogen-like effects, as its chemical structure is similar to phytoestrogens
Vitamin E	800–2,000 IU/day	Free radical scavenging	No convincing evidence. Cochrane review—3 studies.	High dose increases all-cause mortality.

GI, gastrointestinal; RCT, randomized controlled trial.

Table 57.2b–3.
Potential CAIM–Drug Interactions between Natural Products and Prescription Medications

Herb/Supplement	Prescription Drug(s)	Possible Interaction
Chamomile	Sedatives (or alcohol)	Oversedation
Garlic extract	Protease inhibitors	Decreased efficacy against HIV
Ginkgo biloba	Anticoagulants	Excessive bleeding
	Omeprazole (CYP2C19 substrates)	Decreased drug levels (2C19 induction)
	Antipsychotic	Priapism
Ginseng	Anticoagulants	Excessive bleeding
	Monoamine Oxidase Inhibitors	Mania, Hypertension, Headache
	Sulfonylureas, Insulin	Hypoglycemia
	Stimulants	Insomnia, Anxiety, Mania
Kava	Sedatives (or alcohol)	Oversedation
	Levodopa	Increased Parkinsonism
Omega-3 fatty acids	Warfarin	Excessive bleeding
St. John wort	Protease inhibitors	Decreased efficacy against HIV
	Cyclosporine	Organ rejection
	Serotonergic antidepressants	Serotonin syndrome
	Oral contraceptives	Ineffective contraception
	Tetracycline	Photosensitivity
Valerian	Sedatives (or alcohol)	Oversedation
	CYP3A4 substrates	Increased drug levels (3A4 inhibition)
Vitamin E	Anticoagulants	Excessive bleeding

Body-Based Practices

Body-based practices may include massage therapy and spinal manipulation. The authors are unaware of any strong evidence supporting these therapies in the prevention and treatment of cognitive disorders, however, they may have merits in stress reduction, pain management, and treatment of anxiety disorders. Massage therapy includes many different techniques in which practitioners manually manipulate the soft tissues of the body. It has found some use in dementia care populations.

Aromatherapy. Aromatherapy, a therapy related to massage, has found some interesting results in small-scale studies. Aromatherapy is the use of essential oils extracted from plants for health purposes. Trials of aromatherapy have at times combined the application of the essential oils with massage while at other times the patients simply inhaled the aromas of the oils. One study reported the combination of aromatherapy (with lavender oil, commonly proposed to have sedating effects) and massage tended to yield less agitation than either condition alone. Another small study in China was positive for simple inhalation of lavender oil versus control oil in reducing agitated behaviors. The most methodologically

sound study of aromatherapy used lemon balm oil (*Melissa officinalis*) in a double-blind, placebo-controlled trial for managing agitation in severe dementia and found significant benefit for aromatherapy. Interestingly, the oil was applied to the skin (though not officially through "massage"), and this plant compound when administered orally. A case example of the potential benefits of CAIM therapies is below.

Mrs. M was an 80-year-old nursing home resident with advanced dementia. She was a "wanderer"; was frequently agitated and rarely verbal. She was a former dancer and responded to music of the 1940s and 1950s by calming down, dancing and singing along. She also responded to aromatherapy and brief massage using oils—especially lavender oil—by calming down and attending more to her grooming. She also liked participating in a group prayer and singing along. A rare smile would fill her face instead of fear, and she looked peaceful for a period of time. Overall, periods of better behavior and quality of life have improved for this patient.

Medical Systems

Chinese or Oriental Traditional Medicine. Acupuncture is a part of Oriental Traditional Medicine (OTM)—it is a technique in which practitioners stimulate specific points on the body—most often by inserting thin needles through the skin. Several reports of positive effects of acupuncture for cognitive and psychiatric symptoms of VaD have emerged from China, but a 2007 Cochrane review found the methodologies of most of these studies to be highly problematic, leaving no convincing evidence of positive benefit.

Ayurvedic Medicine. Ayurveda, which translates as "the science of life" and has been described as "knowledge of how to live," is a complete natural health care system that began in India more than 5,000 years ago and has been used within the context of mental health and aging for memory enhancement and anxiety reduction. Promoting immune system function through anti-inflammatory remedies, Ayurveda is widely used contemporarily in India as a system of primary health care. With the emphasis on developing an individualized regimen for patients that includes dietary, meditation, herbal, and other components, interest in Ayurveda is growing worldwide to treat a number of maladies including depression. Through yoga and/or transcendental meditation techniques, Ayurveda promotes lifestyle change and education about how to release stress and tension. Furthermore, Ayurveda is geared toward treating chronic disorders associated with the aging process, and promising preliminary results related to use of Ayurveda have been found in studies of depression, anxiety, sleep disorders, hypertension, diabetes mellitus, Parkinson disease, and Alzheimer disease. Of concern regarding the quality of certain Ayurvedic products, in 2008, an NCCAM-funded study examined the content of 193 Ayurvedic products purchased over the Internet and

manufactured in either the United States or India. The researchers found that 21 percent of the products contained levels of lead, mercury, and/or arsenic that exceeded the standards for acceptable daily intake.

CAIM MEDICINE IN LATE-LIFE MOOD DISORDERS

Late-life depression is a significant mental illness in older aged populations, with a rising burden expected this century. The most recent global data on late-life depression comes from a contemporary analysis of the World Health Organization's (WHO) Global Burden of Disease Study 2010. This study identified depressive disorders as a leading cause of burden internationally, and suggests major depressive disorder (MDD) was also a contributor of burden allocated to suicide and ischemic heart disease. Depressive disorders were the second leading cause of years lived with disability (YLD) in 2010. The burden of depressive disorders was highest in adults of working age (15 to 64 years) with 60.4 YLDs in 2010, versus adults ≥65 years with 6.1 million YLDs. In addition to the high and rising burden of late-life depression, conventional antidepressant therapies are limited by modest efficacy. In late-life depression, a recent meta-analysis of clinical trials suggests a response rate of 48 percent and a remission rate of 33.7 percent were found, both very similar to response and remission rates found in adult patients. Clearly alternative therapies need to be considered to enhance treatment efficacy.

Conventional Physical Activity

Conventional physical exercise has received considerable attention for its potential role in the treatment of depression, based initially on results of observational studies. A large (N = 6,828) cross-sectional study of men and women aged 20 to 88 years old found that aerobic fitness and physical activity levels as measured by a maximal treadmill test and self-report, respectively, significantly related to degree of depressive symptoms and emotional well-being. Interestingly, these relationships occurred in a graded, dose-dependent fashion, with progressively higher levels of fitness associated with increasingly lower levels of depressive symptoms and higher degrees of self-reported well-being. For physical activity levels, a similar dose–response relationship was observed; however, the greatest benefit was seen at between 11 and 19 miles per week of walking, jogging, or running.

The effects of aerobic exercise in depressed adults age 50 and older was examined and compared to either monotherapy with sertraline as a standard antidepressant or a combination of both approaches. The study found that after 16 weeks, all three groups demonstrated equivalent significant reductions in depressive symptoms as measured by scores on the *Hamilton Depression Scale* and the *Beck Depression Inventory*.

Furthermore, a 10-month follow-up study showed that participants in the exercise group who had improved to the point of remission during the initial study showed lower rates of relapse than those taking antidepressants, and independent continuation of exercising related to a reduced probability of being depressed at the end of the trial. Another study of exercise for older adults found that 10 weeks of weight-bearing exercises classes provided as an adjunctive treatment significantly lessened depressive symptoms in a group of older adults who had not responded to antidepressant therapy alone when compared to a health education course. A systematic review examining the role of physical exercise in the treatment of depression in older adults was conducted in 2009. This study noted 11 RCTs with a total of 641 participants aged >60 years. The study noted short-term (0 to 3 months) positive outcomes were found in nine studies, although there was variation in the type, intensity, and duration of exercise. The efficacy of exercise in the medium- and long-term (3 to 12 months and >12 months, respectively) was less clear. Issues were noted, with only five studies showing appropriate allocation of concealment, five studies showing intention to treat analysis and blinding occurred in seven studies. The effectiveness of a number of lifestyle interventions promoting increases in conventional physical exercise has been recently reviewed. Overall, interventions were relatively successful in initiating increased levels of physical activity in the short run; however, maintenance of these gains were diminished over time, and there was no convincing evidence that behavioral reinforcement strategies were beneficial. Another review of exercise interventions found that while many older adults increase physical activity levels in response to a wide variety of interventions, the amount of increase is seldom enough to convincingly impact health outcomes in a positive manner.

Recommendations and Summary. In summary, preliminary evidence points to exercise as having a significant potential to lessen symptoms in depressed older adults, and furthermore, to prevent relapse of depression and/or development of depressive symptoms in older adults experiencing acute stressors associated with aging. Therefore, the authors recommend physical exercise as a stand-alone therapy in the treatment of mild depression, and an adjunct in moderate depression. Recommendations for engagement are given in Table 57.2b–1.

Mind–Body Practices

Mindful exercise interventions have shown promise in addressing depressive symptoms in older adults. For example, a study of 82 older adult participants with depression randomized to either 16 weeks of qigong practice or newspaper reading groups found that qigong participants showed significantly greater improvements in mood, self-efficacy, and

personal well-being. Practice of yoga typically benefits from instruction by expert instructors and requires the dedication by participants to multiple weekly sessions and continual use for maximal benefit. Prior review of published RCTs of yoga for depression in adults revealed that while all trials found benefit trial methodologies have generally been weak with lack of blinding, short duration of the intervention, variable outcome measures, limited information about subjects, randomization procedures, compliance, and dropout rates. Comparative studies of yoga have likewise been limited, with one trial demonstrating that yoga was as effective as TCAs and another trial showing that yoga may provide benefit as an augmentation strategy for antidepressant treatment. Yoga is commonly used in combination with other treatments for depression, anxiety, and stress-related disorders. Data on use of yoga for anxiety and depression in older adults are more limited; however, 1 significant study of 69 older adults in India did compare the impact of yoga to Ayurveda or a wait-list control condition on sleep and depressive symptoms. Participants in the yoga group practiced physical postures, relaxation techniques, regulated breathing, devotional songs, and attended lectures for more than 7 hours a week during the course of the 6-month trial. Practice of yoga significantly impacted quality of sleep and level of depressive symptoms when compared to the two control conditions, neither of which demonstrated significant effects. In particular, depressive symptoms, as measured by the short form of the *Geriatric Depression Scale*, decreased in the yoga group from a baseline average of 10.6 to 8.1 by 3 months and 6.7 by 6 months. The average time to fall asleep decreased in the yoga group by 10 minutes, while total number of hours slept increased by 60 minutes, and resulted in a greater feeling of being rested after 6 months. A recent study compared the effectiveness of laughter yoga, group exercise therapy, and control in decreasing depression in older adult women (60 to 80 years). In this study, 70 depressed women were chosen if their Geriatric Depression Score was >10. This study went for 10 sessions and found a significant improvement in depression score with both yoga and group exercise therapy as compared with control. While the evidence supporting the use of these therapies in the treatment of late-life mental illnesses is not strong, there are some interesting early results which require further high-quality research.

Recommendation and Summary. We recommend the use of mind–body therapies as a stand-alone or adjunctive antidepressant treatment in the management of geriatric depression, based on individual preference and the severity of depression. Further high-quality data is needed to further inform these recommendations.

Natural Products

Ω3 PUFA Supplementation. Researchers support an antidepressant

effect of Ω3 PUFAs. Low levels of Ω3 PUFAs are seen in individuals suffering from depression as well as in suicidal patients. In general adult populations, a comprehensive review found that actual diagnosis of depression predicted a response to Ω3 PUFA supplementation compared to simply having depressive symptoms, supporting Ω3 PUFA as a beneficial treatment for individuals suffering from a clinical depression as compared to minor depression. Another meta-analysis showed that Ω3 PUFA supplementations with ≥60 percent of EPA were beneficial to depression. Therefore for the general adult population, evidence supports a role for Ω3 PUFA supplementation in treating depression. The data supporting Ω3 PUFA supplementation in the geriatric depression are less extensive. There are no meta-analyses available for the geriatric population, however, some RCTs looking at the antidepressant effect of Ω3 PUFA exist. A small RCT of clinically depressed females, age 66 to 95 years old, who were living in a nursing home that found Ω3 PUFA supplementation improved depression and quality of life. However, another RCT of older adults, age 60 to 80 years old who had recently suffered a myocardial infarction failed to show an antidepressant effect of Ω3 PUFA supplementation. However, when a subsample of individuals from this study who had been diagnosed with clinical depression were evaluated, Ω3 PUFA supplementation did provide an antidepressant effect. These findings are consistent with previous studies in general adult populations in which Ω3 PUFA provide benefit for clinical depression.

St. John Wort. St. John wort (SJW) (Hypericum perforatum) is a wildflower that has been used for medicinal purposes for thousands of years. Various standardized extracts of this natural dietary supplement have been studied. In older adults, the available evidence base for use of SJW as an antidepressant is limited. A small RCT comparing SJW (800 mg extract LoHyp-57) and fluoxetine (20 mg) in moderately depressed older adults (60 to 80 years old) found equivalent efficacy of these agents in reducing depression over 6 weeks. Additionally, a more recent study showed improvement in depressive symptoms with SJW (600 mg extract LI160) in a sample of mixed-aged adults (18 to 70 years) with atypical depression. Therefore, the few studies available which include older adults support the use of SJW for depression. A recent meta-analysis of 23 randomized trials, including outpatients with mild-to-moderate depression found improvement in depressive symptoms compared to placebo. Most studies included in the meta-analysis used dosages of SJW ranging from 300 to 1,000 mg daily. Another meta-analysis showed similar efficacy and better tolerability of SJW when compared to standard antidepressants such as tricyclics and Selective Serotonin Reuptake Inhibitors (SSRIs). Clinical trials have used various divided doses of SJW (600 to 1,800 mg daily), with the most common dose being 300 mg three times daily. Therefore, there is

a strong evidence basis for SJW in treating the general adult population suffering from depression. SJW is relatively well tolerated and safe when used alone, however, when taken in combination with other medications, there can be numerous potentially dangerous drug–drug interactions. SJW acts as a monoamine oxidase inhibitor (MAOI) making its combination with standard antidepressants concerning for precipitating a serotonin syndrome. SJW is also an inducer of cytochrome P-450 3A4 liver enzyme system, which leads to reductions in multiple medications such as warfarin, methadone, alprazolam, clopidogrel, cyclosporine, and verapamil. SJW has also been seen to precipitate a manic episode. For an older adult who would rather not take conventional western medications, SJW can be considered as an alternative natural remedy for mild to moderate depression. However, the ideal patient is free of comorbid medical conditions and all patients using SJW should be informed about potential side effects and drug–drug interactions.

S-Adenosyl-L-Methionine. S-adenosyl-L-methionine (SAMe) is a naturally occurring compound normally synthesized in the body formed from the amino acid L-methionine as part of a multi-step metabolic pathway involving folic acid and vitamin B_{12}. Initial oral formulations of SAMe were relatively unstable, necessitating parenteral administrations. However, the more recent development of stable oral forms of SAMe has allowed for more widespread testing and use of this compound. SAMe is thought to play a role in depression since it is a necessary cofactor for the synthesis of serotonin, norepinephrine, and dopamine. Additionally, cerebrospinal fluid levels of SAMe have been shown to be decreased in depressed patients and levels rise in response to treatment. Clinical studies in the general adult population support an antidepressant effect of SAMe. Meta-analyses found that SAMe is superior to placebo and equivalent to TCAs. This analysis included mostly parenteral formulations and when they were compared to oral formulations, parenteral SAMe showed a slight superiority over oral formulations. Therefore there is strong evidence to support the antidepressant effect of parenteral SAMe in the general adult population for an antidepressant effect. The data supporting oral formulations of SAMe are growing. A more recent open trial looking exclusively at oral SAMe in a mixed age population (18 to 80 years old) supports its clinical benefit as an augmentation strategy in patients showing an incomplete response to conventional antidepressants. Additionally, a small, 6-week open trial of oral SAMe in the general adult population found that response and remission rates were significantly higher than placebo. Among the trials, the oral doses of SAMe ranged from 400 to 1,600 mg/day, with most trials showing benefit with dosing between 800 and 1,600 mg/day. However, dosages up to 3,600 mg/day have been used with success and safety in older populations, supporting higher

dosages may be necessary for clinical benefit. Therefore, there is strong evidence to support the use of SAMe as an antidepressant with parenteral formulation and the support is growing for oral administration. SAMe is generally well tolerated, however, important safety concerns such as increased anxiety, mania, and hypomania have been reported in patients with bipolar disorder. There was one case study of a 61-year-old female suffering from depression, with a family history of bipolar disorder, who took SAMe and attempted suicide by self-burning. Patients with bipolar disorder should not take SAMe without concomitant administration of mood stabilizers coupled with clinical monitoring. Therefore, SAMe can be beneficial for depression, however, the data are lacking for the geriatric population. An ideal candidate for a trial of SAMe could include a mildly symptomatic patient who would not have serious effects if there was a delay in treatment or a person who has failed multiple trials of conventional antidepressants and/or is unable to tolerate side effects.

For other natural products and supplements which may be used for the treatment of late-life depression, see Table 57.2b–4.

Other Therapies

Acupuncture. Prior reviews of RCTs using acupuncture to treat depression have found some evidence for benefit; however, the majority of included studies have been of relatively low quality with placebo acupuncture treatment at times yielding similar results to treatment acupuncture. The Cochrane database review of studies examining acupuncture for depression found insufficient evidence to determine the efficacy of acupuncture compared to standard antidepressants, sham acupuncture, or wait-list controls. Most recently, an RCT comparing electro-acupuncture to control acupuncture in 53 subjects diagnosed with mild to moderate major depression found significant but similar improvements in depressive symptoms for both techniques. For depression in older adults, the literature is limited, with a pilot study of acupuncture for depression in older adults finding positive effects on measures of mood and well-being.

Table 57.2b–4.
Other Natural Products and Supplements Suggested for the Treatment of Late-life Depression

Herb/Supplement	Suggested Dose	Possible Mechanism of Action	Evidence Base	Side Effects
Inositol	6–19 mg/day	Altering serotonin, dopamine, glutamate levels.	Mixed findings: 7 RCTs in depression explored (MDD, PMDD). One positive, some negative.	GI upset

Saffron	30 mg/day	Serotonergic effects, antioxidant, anti-inflammatory, neuroendocrine effects, neuroprotective effects.	5 trials found. Promising findings which need further, high-quality assessment.	Headache, nausea, anxiety, decreased appetite.
Vitamin D	600–300k IU/daily or weekly	Neuroprotection.	Promising findings requiring further research. Meta-analysis of 7 RCTs.	Fatigue, headache.

MDD, major depressive disorder; PMDD, premenstrual depressive disorder; GI, gastrointestinal; RCT, randomized controlled trial.

FUTURE DIRECTIONS

Gaining a better understanding of the clinical effect of CAIMs, as well as their safety is clearly critical for the management of geriatric psychiatry conditions. At present, there is insufficient data on the prevalence, effectiveness, efficacy, safety, and health economic benefits of most CAIM treatments. This means patients, health providers, and other stakeholders are unable to access reliable and rigorous evidence on CAIMs. When considering future directions for this field, it is important to consider the most recent NCCIH strategic plan "Exploring the Science of CAM: Third Plan 2011–2015." This plan has five main objectives which are (1) to advance research on mind and body interventions, practices, and disciplines, (2) advance research on CAIM natural products, (3) increase understanding of real-world patterns and outcomes of CAIM use and its integration into health care and health promotion, (4) to improve the capacity of the field to carry out rigorous research, and (5) to develop and disseminate objective, evidence-based information on CAIM interventions.

Specific to psychiatric clinical practice, the NCCIH authors' have further recommendations for future CAIM trials and clinical utilization. *Researchers must disclose conflicts of interest* matching current trends in pharmaceutical trials. *CAIM trials should aim to replicate the highest trial standards*. This means the adequate blinding, allocation concealment, randomization, complete outcome data presentation, and thorough reporting. *CAIM trials should utilize adequate control groups*. Control groups for holistic treatments should have similar elements to active groups; control groups for biologically based treatments can use placebo. *Randomized clinical trials must include treatment and prevention of all mental disorders in older adults* in order to build a comprehensive evidence for such practices. *Care must be taken to ensure the reliability, safety, and consistency of CAIM supplements*. It is important that doctors and patients are utilizing the same preparations which are free from toxins or other potentially harmful ingredients. *Research must be conducted in other geriatric psychiatry disorders,*for example, anxiety disorders and oncology-related psychological issues. Clinical trial research must occur

more intensively in nutritional psychiatry. For example, Prevención con Dieta Mediterránea (PREDIMED) and the Supporting the Modification of lifestyle In Lowered Emotional States (SMILES) trial.

CONCLUSION

Neuropsychiatric disorders in older adults such as mood, anxiety, sleep, and cognitive disorders are among the most common reasons for older adults to use CAIM therapies. The use of CAIM therapies in geriatric psychiatry is promising with a growing body of empirical research. There is a wide range of research quality within this field, making firm conclusions difficult. Therefore, the authors recommend high-quality research continue into this area to establish efficacy and safety. When promoting safety of various natural products, clinicians can offer important information for those patients who are less comfortable with "conventional" medicine and prefer alternative "natural" therapies, such as advising of drug–CAIM interactions and directing them toward the evidence-based indications. It is clear that CAIM use is significant in older adult populations, will likely increase, so empirical research is essential.

57.2c The Aging Brain

DOUGLAS R. GALASKO, M.D.

INTRODUCTION

Aging is an important factor in health and disease. Over the adult life span,

the body undergoes changes that generally result in loss of functional capacity. These may be driven by fundamental processes that underlie aging, and can be exacerbated by the presence of disease and influenced by lifestyle factors. The brain is not unique in experiencing changes in association with aging that also tend to decrease its capabilities. These changes can be described at different levels, including clinical evaluation, risk and protective factors, biomarkers such as brain imaging, and underlying mechanisms and pathophysiology. Although the current understanding of the mechanisms that underlie brain aging is incomplete, there has been much progress in identifying the contributions of aging and disease processes to changes in cognition, mood, and behavior in the elderly. Many myths about aging have arisen, and old age has often been viewed as a time of physical and mental decline and infirmity. This is challenged by recent research in successful aging—much progress has been made in defining the cognitive strengths and abilities that are preserved in healthy brain aging and in teasing out contributions of diseases to loss of ability. By delineating the clinical features, biomarkers and pathophysiology of conditions that are not part of healthy brain aging and result in impairment of brain function, such as Alzheimer disease (AD) and vascular pathology, specific treatments may be developed to target these age-associated disease processes. Factors that may limit age-related impairment in cognition and other aspects of brain function and result in greater resilience in the face of aging are also receiving attention; these include cognitive stimulation, social and physical activity, and nutrition. This chapter provides an overview of concepts and challenges in studying and measuring brain aging and the effects of aging on brain anatomy. Tools and approaches to measure cognitive aging and neuroimaging studies that have revolutionized how brain aging is studied will be reviewed. The nature and impact of common age-associated brain pathologies and diseases is described. Next, the burgeoning area of identifying factors that may modulate the effects of brain aging and understanding how their effects may be mediated will be reviewed. Finally, approaches that may help to promote healthier brain function during aging are summarized.

CONCEPTS AND CHALLENGES IN STUDYING BRAIN AGING

How are metrics for brain aging defined and established? Some important questions and issues that are critical to this measurement question are listed in Table 57.2c–1. First, is it useful to try to define approximate stages in brain aging based on transitions at specific ages, even though the underlying processes are likely to be continuous and cumulative? Although it is easy to identify age by the passage of time, biological markers of aging processes have not been developed. By default, “milestones” used to define aging are thus measured by chronological age, and may impose artificial divisions and definitions. For example, many aging studies set a cutoff of

65 or older as elderly. Even disease definitions, such as dementia, have considered onset before the age of 65 as presenile and onset after 65 as senile. This arbitrary cutoff at 65 was selected based on an age for retirement benefits that was established in 1889. In developed countries, average life expectancy now exceeds 75, and many people live into their ninth and tenth decades. The number of centenarians in the United States and Europe has steadily increased in the recent past and will continue to do so. So, the concepts of young-old, aged 65 to 75, and oldest-old, aged 85 and older, have arisen. However, there are no agreed-upon measures or markers other than the passage of time that distinguish groups of people in their eighth, ninth, and tenth decades. Studies have not yet shown clearly whether age-associated decline of brain abilities accelerates at particular ages. Indirect support for acceleration comes from epidemiological studies of age-associated syndromes such as dementia, which show an exponential increase in incidence after the age of 65. Therefore, the inadvertent inclusion of some subjects with preclinical dementia influences many studies of "normal aging" with a likely outcome that cognitive decline will appear to accelerate in very old age.

Table 57.2c–1.
Important Questions Regarding Brain Aging

1. Should benchmarks or reference ages be used to calibrate the extent of age-related changes? Are there biomarkers of chronological age?
2. Is brain aging a steadily progressive process or does it accelerate?
3. How can "normal" aging be distinguished from disease-related changes?
4. Are some brain pathological changes inevitable?
5. What factors are associated with more or less severe age-associated brain changes?
6. Are some brain regions more susceptible to age-related changes than others?
7. Do plasticity and cognitive reserve attenuate the loss of function associated with brain aging?

Another question about staging is how to develop benchmarks for "normal" brain structure and performance against which to measure effects related to aging and disease. One approach is to collect normative data for groups of apparently healthy individuals of varying age, that is, to age adjust. This may have clinical utility, for example, to define laboratory test cutoffs or identify suboptimal performance as a likely indicator of disease. Clinical, pathological, and imaging research studies across the life span suggest that the human brain matures, establishes connectivity, and achieves optimal function by the time people reach their mid-to-late 20s. Some decline can be measured beginning as early as the 30s. Should brain structure and performance at age 30 be used as a benchmark to calibrate the magnitude of changes associated with many years of aging? This may be helpful for estimating relative changes in the number of neurons in particular brain regions or changes in connections between neurons, and

may also shed light on how human cognitive performance changes. Many studies have followed people from age 60 or older to derive data on brain structure or performance and compare subjects in later decades to people in their 60s. However, this may underestimate the magnitude of changes across the adult age span. This may particularly affect pathology studies, where studies across the age span have indicated that a disorder such as AD expresses itself clinically only after decades of slowly emerging pathology.

Cross-sectional comparisons across the age span may be inflated by secular changes that may exaggerate differences between younger and older individuals. For example, levels of education, nutritional habits, and the widespread use of medications such as statins and antihypertensives have changed markedly over the past 50 years. These changes may result in differences between cohorts born decades apart, when assessed through cognitive testing during life and even in studies of postmortem brain tissue. Longitudinal data relating measures of clinical performance of the brain to underlying structure are becoming available from imaging studies, but the period covered by serial imaging is usually measured during the framework of a few years rather than decades. Secular changes do not inevitably result in better brain health; inactivity, obesity and increasing rates of type 2 diabetes among adults in Westernized societies may counteract improvements in education and cardiovascular management.

Almost any physiological index shows an increase in its variability in association with aging. This holds true for many aspects of cognitive and motor performance in the elderly. The reasons for increased variability are not well understood, but both genetic and environmental factors may contribute. Identifying factors that contribute to decline in brain performance associated with aging, particularly those that may be modifiable or preventable, may lead to interventions aimed at forestalling or attenuating the degree of age-associated decline that is considered to fall within the spectrum of normal.

Are there boundaries between brain aging and disease? Can disorders like AD be clearly demarcated from normal or optimal brain aging? Aging is associated with an increased prevalence of lesions such as senile plaques (SP) and neurofibrillary tangles, as well as vascular brain changes. Even though the clinical syndrome of progressive dementia associated with AD is different from the lesser degrees of cognitive change associated with aging, the key pathological features of AD are present to some extent in most individuals aged 90 or older. If Alzheimer pathology is an inevitable feature of aging, it is possible that extension of life span will lead to the inevitable development of clinical AD. Even if AD pathology is inextricably linked to the aging process, the pathology builds up slowly, over a decade or longer, and the task of understanding factors that may lead to earlier or later age of onset of clinical dementia and the quest to delay the expression of clinical dementia for as long as possible remains extremely important. Because of

the high frequency of AD lesions in the elderly, it is difficult to carry out studies of brain aging in which the definition of normal requires the exclusion of any degree of AD pathology. It may be possible to dissect the impact of aging from that of AD. In this quest, biomarkers for AD pathology have been used in recent studies to illustrate that there are differences in longitudinal cognitive performance and in magnetic resonance imaging (MRI) indices of brain functional connectivity in people who test positive for amyloid biomarkers compared to those who test negative.

Studying Brain Tissue: Neuroanatomy, Genomics, and Imaging

Neurons vary greatly in structure and connectivity throughout the brain. An important question is whether aging selectively affects certain types of neurons or specific brain regions, or whether changes are relatively uniform and widespread. To provide a systematic answer to this question would require an enormous amount of work obtaining quantitative measures or neuronal numbers and axonal and dendritic structure throughout the brain from a series of tissue samples across a wide age span. Studies of neurons during aging have typically targeted brain regions that whose connections or neurotransmitter circuitry relate to specific brain processes, for example, hippocampal neurons in relation to memory.

An issue that troubled the field for years is the extent of neuron loss with aging. Interest was sparked by an initial series of studies by Harold Brody, supported by other investigators, which suggested that up to 50 percent of neurons were lost between the ages of 18 and 95 in the superior-frontal and superior-temporal cortices and 20 to 30 percent losses occurred in the precentral gyrus and visual cortex. It was later shown that processing of brain tissue caused shrinkage, leading to overestimation of the density of neurons in brains from younger individuals. After appropriate adjustment and when automated counting methods were used, markedly lower estimates of neuron loss were obtained. But the number of neurons is only one of many conceivable measures of neuronal well-being. Recent studies have evaluated the dendritic arbor or synaptic density as indices of neuronal connectivity, and have assessed the strength of neurotransmitter circuits by measuring levels of neurotransmitters or their receptors in the brain. These approaches, assessing structure, connectivity, and biochemistry, provide a more nuanced picture of age-associated changes.

Advances in technology are enabling comprehensive studies of protein and gene expression in discrete brain regions and even in single neurons. To interrogate mechanisms of brain aging, large-scale omic analysis is now feasible. In particular, transcriptional analysis using arrays to measure relative mRNA expression, followed by bioinformatic approaches, allows signaling pathways to be identified and analyzed. For example, the BRAINEAC project (www.braineac.org) analyzed mRNA expression in 10

brain regions, in brains from over 100 people covering the adult age span.

In recent years, neuroimaging studies have brought another dimension to the study of brain aging. It is possible to obtain morphological, functional, and metabolic information about the brain in living people with excellent precision and reliability. The resolution of MRI is sufficient to obtain overall and regional quantitative measures related to the brain. Multimodal brain imaging studies, combining measures of brain structure, connectivity, blood flow, and chemistry in the same individual, are being brought into play to help to understand structure–function relationships.

Thresholds of Pathology, Clinical Disorders, and Cognitive Reserve

To clarify the relationship between the pathology and the clinical expression of brain disorders, many attempts have been made to define thresholds, for example, a burden of pathology or of cell loss that is typically present by the time that a clinical phenotype manifests. For example, studies of postmortem brain tissue of patients with Parkinson disease have suggested that motor symptoms do not appear until 40 percent or more of dopaminergic neurons in the substantia nigra are lost. This exceeds the extent of neuron loss found in this brain region in studies of aging. Impaired reserve and plasticity may play a role in whether age-associated changes in the brain may manifest as disease or not. Subthreshold changes related to aging may increase vulnerability to pathology. For example, an individual with mild Alzheimer pathology may maintain intact cognitive function with aging due to sufficient brain reserve. However, the addition of one or more small strokes may be enough to impair cognition beyond a tipping point, resulting in clinically recognizable dementia. Similarly, age-related decreases in the strength of norepinephrine or dopamine circuits may increase the vulnerability for the development of depression, which may be precipitated by a life event or stressor that would not have done so at a younger age. Finally, brain aging may increase someone's vulnerability to develop adverse cognitive side effects as a result of medications, and also to develop delirium in the setting of systemic illness.

Cognitive reserve may be thought of as resilience that allows performance to be preserved in the face of damage, and it may protect against the onset of a clinical disease phenotype. Two types of reserve have been proposed by Dr. Yaakov Stern: brain reserve refers to differences in brain structure that may result in tolerance of pathology, and cognitive reserve describes differences between individuals in how tasks are performed. Brain reserve may depend on the intrinsic richness of connections between brain structures or possibly on the total number of mature neurons that remain at the end of brain development. Factors such as education, carrying out cognitively demanding activities or physical exercise may assist in the maintenance of these connections during aging.

Neuroplasticity is an important component of reserve. This classically refers to the brain's ability to adapt and strengthen connections or potentially to form new connections between neurons and circuits. Studies of recovery after stroke or ablative brain surgery support this possibility. However, it is generally noted that aging leads to less effective recovery after injury, and the brain is no exception. Neurons have been classically considered to be fully differentiated postmitotic cells, which makes them particularly vulnerable to cumulative damage sustained over the years. Although neurons do not divide, they have the capacity to form new synapses and carry out remodeling. This limited view of the regenerative potential of neurons has changed; exciting research findings over the last two decades have challenged the doctrine that neurons are not actively replaced in mammals. Neural progenitor cells had been identified in birds and rodents and shown to play roles in brain plasticity. A prominent example is neurogenesis that accompanies the acquisition of new songs by birds. In the 1990s, evidence emerged that similar progenitor cells exist in the brain in primates, including humans. In brain regions such as the hippocampus, new neurons can be generated throughout adult life as progenitor cells in the subventricular and granular zones differentiate. Although the roles of these progenitor cells in health and disease are still being defined, their potential to proliferate, differentiate, and migrate expands the repertoire of compensatory changes within the brain. In rodent and primate models, brain injury, for example, due to stroke, leads to the stimulation of neurogenesis. Recent studies have suggested that depression may be associated with deficient neurogenesis.

MECHANISMS IMPLICATED IN BRAIN AGING

The mechanisms and processes that lead to age-related changes throughout the body and ultimately limit life span are not well understood. Aging has been characterized by one of its leading scientists, Dr. Leonard Hayflick, as the effect of an increase in entropy on molecules such as proteins, lipids, and deoxyribonucleic acid (DNA), resulting in the accumulation of structural changes that eventually lead to impaired physiological function at the level of molecules, cells, and ultimately the organism. Many mechanisms may contribute to age-related damage that may impair brain function or reduce brain reserve, as summarized in Table 57.2c–2.

Oxidative stress is particularly relevant to the brain, whose long-lived neurons use oxygen more extensively than any other organ. Although there are many antioxidant defenses and repair mechanisms, over time oxidative damage affects the structure of DNA, ribonucleic acid (RNA), lipid membranes, and proteins. These changes may become irreversible, resulting in impaired function of the affected molecules and of organelles. Mitochondrial damage associated with aging may lead to impairment of energy metabolism; this is well documented for the substantia nigra.

Proteins that undergo oxidative changes such as nitrosylation or carbonylation may be prone to cross-linking and to aggregation. In addition, they impose a load on the degradative machinery of neurons, which may be unable to remove these abnormal proteins effectively or break them down completely. Diabetes, which is increasingly prevalent with aging, may promote oxidative stress through mechanisms such as glycation of proteins and generation of advanced glycation end-products. Caloric restriction has been widely studied in animals as a method that does appear to extend life span, and decreasing oxidative damage and improving insulin signaling are two potential mechanisms that may explain these effects. Whether this is effective for life span extension in humans is unknown, and caloric restriction has not yet been proven to benefit brain health.

Misfolding of proteins, with the adoption of stable insoluble amyloid configurations, is an important theme in many age-associated diseases. For example, aggregates of amyloid-β protein (Aβ) and of the microtubule-associated protein tau form SP and neurofibrillary tangles, the hallmark lesions of AD. In families with early-onset AD, mutations in genes related to Aβ (amyloid protein precursor [APP] and presenilin 1 and 2) are associated with a relative or absolute increase in the production of longer forms of Aβ or produce mutant forms of Aβ that are more prone to aggregate. Evidence to date does not support the overproduction of Aβ in sporadic AD or with aging. It is possible that only a small change in the expression levels of certain proteins is needed to initiate pathology, or aging may predispose to amyloid deposition in the brain through other mechanisms. Impaired degradation or clearance of Aβ is implicated in age-associated plaque formation. Factors that modulate the misfolding, aggregation, and clearance of proteins (proteostasis) during aging continue to receive much research attention.

Table 57.2c–2.
Mechanisms Implicated in Brain Aging

1. Oxidative stress—damage to DNA, proteins, lipids
2. Mitochondrial damage
3. Protein misfolding and aggregation
4. Decreased endocrine support (e.g., estrogen and testosterone)
5. Decreased neurotrophic factor support
6. Impaired axonal transport
7. Impaired neurogenesis

Another age-related factor may be lack of trophic support of certain types of cells or their connections. Estrogen deficiency after menopause or androgen decline with aging may impair the function of neurons that respond to these hormones. Delivery of neurotrophic factors may be

important for synaptic plasticity and for certain populations of neurons. For example, in aged rodents and primates, the administration of nerve growth factor (NGF) to the brain can lead to enhancement of cholinergic neurotransmitter circuits and improvement of performance on cognitive tasks related to memory. Axonal transport is required for neurons to convey proteins and other components needed to maintain the structure and function of their lengthy processes. Impaired axonal transport is one factor that has been implicated in the decrease of growth factors in the aging brain.

Inflammation is a mechanism under exquisite regulatory control throughout the life span. Peripheral inflammation has been invoked as one mechanism related to aging in general. For example, a number of cytokines and inflammatory biomarkers, such as C-reactive protein, are increased in serum with aging, and various types of auto-antibodies can be detected with increasing frequency during aging. In the brain, an increase in microglial activation and in other mechanisms of innate immunity may contribute to damage or to lack of appropriate neuronal or synaptic support.

Although there is no obvious selection or survival advantage for genetic factors that influence brain aging, several genes have been identified that may have an impact on brain aging. As an extreme case, rare genetic causes of premature aging syndromes, such as progeria, result in hallmarks of premature aging, such as cataract development, skin changes, increased risk of cancer, and immune alterations during childhood. However, these syndromes are not clearly associated with accelerated brain aging or decline. There are rare genetic mutations associated with early-onset familial AD, inherited in an autosomal dominant pattern. However, these genes have not been shown to have sequence changes that alter the risk or age at onset of late-life AD. The most common variant associated with the risk of late-onset AD is the gene for apolipoprotein E (APOE), which codes for a lipoprotein involved in cholesterol transport within the brain. There are three APOE alleles, e2, e3, and e4. People who carry one copy of the e4 allele have a two- to threefold increased risk of developing AD, whereas those with two copies have a four- to eightfold increased risk. The e2 allele has a small effect on decreasing the risk of developing AD and has also been shown to be overrepresented in people who live into their 90s or 100s.

The ability to generate new neurons in certain regions of the adult brain has also been shown to decrease with aging in animal studies. Although direct data are lacking from studies of human brain tissue, a decrease in the production of neural progenitor cells may play a role in brain aging. A recent study developed an innovative magnetic resonance spectroscopic index of neural progenitor cells and demonstrated that a specific signal could be detected in cultured cells and in animals. A small group of human volunteers spanning the age range from 20 to 70 showed attenuation of this

signal with age in the hippocampus, an area known to harbor progenitor cells. At present, this represents the best available evidence for age-related decline of neural progenitor cells in humans.

STRUCTURAL CHANGES ASSOCIATED WITH BRAIN AGING

Brain atrophy accompanies aging, but the extent to which this represents loss of neurons is controversial. The belief that thousands of neurons are lost every day derives from studies with methodological flaws. More recent studies indicate that neuronal cell loss is less conspicuous and may be selective for certain brain regions.

Methodological issues are important in brain aging studies. By design, aging studies of human brains are cross-sectional. Secular effects, for example, generational changes in nutrition, general health, and comorbidity can complicate comparisons in brains of individuals in their 30s and 40s with those in their 70s and 80s. Brain weight and size are influenced by height and gender. Counts of neurons should attempt to adjust for these factors. Also, the size of brain regions and the number of neurons vary from person to person, by as much as two- to threefold. To detect significant changes in the face of high variability requires a large number of samples or a large effect size. Ideally, subjects whose brains are used in normal aging studies should have been formally evaluated close to their time of death to establish that they did not suffer from cognitive impairment. As mentioned above, the inclusion of brains with AD pathology is inevitable if an aging study includes individuals in their 80s and 90s. However, staging systems of AD pathology have been developed, allowing people with a substantial lesion burden to be excluded.

Postmortem tissue preparation is highly important—early studies that claimed that extensive neuron loss accompanied aging were flawed because of shrinkage of brain tissue during its preparation. Technical approaches to imaging and counting neurons have improved in recent years, including automated counting of neurons based on profiles, and the availability of cell-specific stains. Stereological approaches to sample neurons in a relatively unbiased manner have become routine. Comparative studies of brain tissue from aging primates and rodents have the advantage of minimizing postmortem changes and optimizing the preparation of brain tissue. These provide valuable data that complement direct studies on human tissue.

Total brain weight reaches a maximum in young adults around the age of 20, followed by a progressive decline thought to begin around the ages of 30 to 40 and reaches its nadir after the age of 85 (Table 57.2c–3). By that age, on average, brain weight has decreased by 11 percent compared to the maximum. Similar findings of an age-associated decline have been found in studies of chimpanzee brains. Neuroimaging studies have provided both cross-sectional and longitudinal data showing that brain volume decreases

with age, accompanied by an increase in the volume of the ventricles. Quantitative MRI studies have shown that brain volume decreases across the adult age span. Some studies have suggested that brain volume loss may accelerate with aging, with about 0.1 to 0.2 percent of brain volume lost per year between the ages of 30 and 50, increasing to about 0.3 to 0.5 percent per year after the age of 70. Preclinical disease related to aging, including vascular changes, amyloid and tau deposition may contribute to this apparent acceleration. Although the whole brain, including gray and white matter, shows loss of volume, regions such as the frontal and parietal cortices and hippocampus are affected to a greater degree than the occipital cortex.

Table 57.2c–3.
Structural Changes Associated with Brain Aging

1. Decline of brain weight
2. Neuron loss
3. Neuronal atrophy
4. Synaptic loss
5. Pruning of dendritic trees
6. Nucleolar atrophy
7. White matter changes
8. Gliosis

What explains the decline in brain weight or volume? Neuron loss, as discussed, has been overestimated in the past. After the introduction of stereological methods (including the dissector and its modification, the optical dissector) by Hege Gundersen and colleagues, studies by Bente Pakkenberg and Gundersen reported less substantial loss of neurons across the adult life span, representing about 9.5 percent. Other studies have questioned whether there was substantial loss of gray matter, attributing age-associated declines to loss of white matter.

Neuron atrophy rather than loss could contribute to the age-related decline in brain weight. For example, a classic study by Dr. Robert Terry and colleagues used a computer-assisted method to estimate neuron numbers and size in the superior-temporal, medial-frontal, and inferior-parietal cortical regions from ages 24 to 100. They found that the number of large neurons decreased in all of these regions, accompanied by a corresponding increase in the number of small neurons. Atrophy of pyramidal cells has been well documented. In particular, pyramidal neurons in the hippocampus and cerebral neocortex show atrophy. This has been associated with shrinkage in the nucleolus or loss of cell body RNA.

Regional and Microstructural Changes

The question of whether certain regions are particularly vulnerable to neuron loss with aging has been revisited. Because of their important roles in memory and learning, the hippocampus and its subregions, such as the entorhinal cortex, CA1, and CA2, have been singled out for study. The use of high-resolution MRI, for example, at 4 or 7 Tesla strength allows regional anatomical information to be acquired in great detail. For example, in a study of healthy individuals spanning the age range from 20 to 85, the CA1 subregion of the hippocampus showed the greatest degree of volume loss with age, whereas the entorhinal cortex, CA2, CA3/4, and dentate gyrus showed much less change. How does this compare with pathology studies? Teresa Gomez-Isla and colleagues applied stereological techniques to the entorhinal cortex and found that there was no appreciable loss of neurons in cognitively healthy individuals in their 70s and 80s; by contrast, there was a substantial degree of neuronal loss in AD, even when clinically very mild. When they similarly studied the superior-temporal cortex, an area representative of the association cortex, once again there was no significant loss of neurons with aging. Stereological studies of the CA1 subfields have been inconsistent. Some investigators have found decreases in neurons in CA1 and the subiculum with age, but others failed to find these effects. Reasons for these discrepancies are unclear. Studies of monkeys, using similar stereological methods, have shown no appreciable loss of neurons with age in the entorhinal cortex, CA1, CA2, or subiculum. However, despite the intact number of neurons, decreases in *N*-methyl D-aspartate (NMDA) receptors were evident in aged monkey brains. This raises the possibility that changes short of neuronal death may occur during aging and may provide a substrate that could explain cognitive decline.

Changes in Synapses and Circuits

Neurons function by exchanging information across circuits and networks. The shape and branching of dendrites varies markedly between different types of neurons and within individual neurons of a particular class. Dendrites have protrusions called spines, which contain excitatory synapses. These vary in density across the length of a dendrite, and increase in number with successive branches of dendrites. Even in the absence of overt neuronal loss, changes in dendritic branches or spines could impair neuronal circuit function. A consistent finding in anatomical studies is age related, prominent in pyramidal neurons, in areas such as the prefrontal, precentral, and superior-temporal cortices. Studies using fluorescent dyes have revealed a marked loss of dendritic spines at all levels of dendrites in aged monkeys. Dendritic changes may be linked to levels of neurotransmitters and strength of certain types of neurochemical circuits. For example, the glutamate R2 and NMDAR1 receptors show decreased

expression in monkeys in association with aging, in areas such as the prefrontal cortex for glutamate R2 and along projections from the superior-temporal cortex for NMDAR1. Detailed studies of postsynaptic non-NMDA glutamate receptors in monkeys have suggested that these remain functionally unchanged in primates in areas such as the prefrontal cortex. However, there appears to be an increase in the level of inhibitory synaptic input to pyramidal cells in this area. This could be attributed to increased release of γ-aminobutyric acid (GABA) from presynaptic neurons. These changes in morphology and biochemistry, in the absence of overt neuron loss, could form a substrate for declining performance on cognitive tasks that assess memory, learning, and cognitive processing speed. Of interest, circuits that are highly vulnerable to undergoing degeneration in AD may also display synaptic changes similar to those described above in association with aging.

Neuroimaging and electrophysiological methods (e.g., EEG and magnetoencephalography [MEG]) have been used to develop functional brain maps, and to identify overall and regional brain connectivity. Functional MRI (fMRI) evaluates cerebral responsiveness to activation in human subjects. This takes advantage of the BOLD signal—a signal related to a decrease in deoxyhemoglobin concentration and an increase in cerebral blood flow that accompany local neuronal activation. Such studies can explore the activation of brain circuitry in response to cognitive tasks. Many fMRI studies have been performed to evaluate neural activation of regions and circuits in the brain in relation to aging. For example, the extent of activation of the hippocampus in response to episodic memory tasks decreases in cognitively intact subjects aged 70 or older compared to younger adults. Resting state fMRI takes advantage of correlated regional blood flow changes at short time scales to investigate and map the degree of large-scale coordination between brain systems. A default network of functionally interacting anterior and posterior brain regions is associated with internally directed mental states and is important in forming a substrate for memory acquisition and planning. Early studies exploring aging, for example, those by Buckner and colleagues, reported a large age-related decrease in functional connectivity between these systems that correlated with worse cognitive performance, particularly prominent after the age of 70. The most likely structural basis for this functional decline was disruption of white matter integrity. The ability to image preclinical amyloid pathology by amyloid PET scanning has led to a reappraisal that connectivity changes in cognitively intact elderly individuals are greater in those with positive amyloid scans than without.

In summary, the level of understanding of structural changes in the brain that accompany aging remains descriptive. It will be a great challenge to define the mechanisms that underlie these changes. Brain imaging provides tools to study effects of risk factors that may explain some of the

variability of brain changes in later life. They also may help to interpret the effects of interventions that may decrease the degree of age-associated decline or enhance the function of brain networks or connectivity, as discussed below.

LESIONS IN THE AGING BRAIN

Various types of pathological markers are visible on microscopic examination of brain tissue from elderly individuals (Table 57.2c–4). Markers such as corpora amylacea, lipofuscin, or neuromelanin, may represent cellular responses to aging that are of uncertain clinical consequence because they do not correlate with clinical disorders or with decline in function. Others such as amyloid deposits and neurofibrillary tangles are markers of AD when they exceed a threshold. In elderly people who lack defined disorders such as dementia, it is likely that the overall burden of these lesions may contribute to cognitive decline attributed to aging. For example, circumscribed distribution of tau aggregates has been recognized as a common part of aging, in the absence of significant amyloid deposits, and the acronym primary age-related tauopathy (PART) was recently proposed. PART may be asymptomatic or associated with mild cognitive changes.

Lipofuscin is the most common age-related marker seen in tissues throughout the body. Postmitotic cells such as neurons accumulate lipofuscin more extensively than mitotic cells. Lipofuscin is particularly evident in neurons in the inferior olive, dorsal root ganglia, anterior horn cells, the dentate nucleus of the cerebellum, and large neurons in the cerebral cortex. Lipofuscin consists of protein and lipid, mostly oxidized and contained within lysosomal membranes. Metals, particularly iron, are also present. Lipofuscin is evident as intracellular autofluorescence or can be seen using lipid stains or via electron microscopy. It is thought that lipofuscin represents the remnants of incomplete mitochondrial breakdown by lysosomes. The accumulation of small amounts of lipofuscin may allow cells to sequester aged mitochondria or cross-linked proteins. When large areas within cells are occupied by lipofuscin, it is less clear that this is adaptive, and it is possible that this could adversely affect cellular processes.

Corpora amylacea are round, cytoplasmic glycoprotein inclusions most commonly seen in astrocytes and are inevitably found in the brain after the age of 40. They may arise due to effects of oxidative stress and iron imbalance within astrocytes. It is uncertain whether they represent a cellular defense that sequesters iron or oxidized components of mitochondria or whether their presence may impair the ability of astrocytes to function optimally. The number of corpora amylacea is increased markedly in the brain in AD.

Neuromelanin may be found within neurons as early as 3 years of age

and increases throughout the life span. It is particularly abundant in the substantia nigra and the locus ceruleus. The function of neuromelanin is not known. It contains melanins, derivatives of dopamine, and lipofuscin. Neuromelanin likely forms after the uptake of extracellular dopamine and its oxidation and may represent a means to sequester potentially damaging dopamine byproducts. Neuromelanin avidly binds iron, which may be protective, but could act as a source of oxidative stress in association with aging.

Table 57.2c–4.
Lesions That Accumulate in the Brain with Age

1. Lipofuscin
2. Corpora amylacea
3. Neuromelanin
4. Amyloid deposits, including senile plaques
5. Vascular amyloid
6. Neurofibrillary tangles and argyrophilic grains
7. Lewy bodies
8. Aggregates of TDP43 and hippocampal sclerosis
9. Vascular (ischemic) lesions

Protein misfolding is a prominent feature in many organs of the body accompanying aging and associated with disease. In the brain, aggregates of Aβ form extracellular SP and also can deposit in the walls of meningeal and intraparenchymal arterioles. Tau forms aggregates with the ultrastructure of paired helical filaments. Tau aggregates may be found in dystrophic neurites, argyrophilic grains, and neurofibrillary tangles. Both plaques and tangles are found in association with aging and in greater abundance in patients with AD. Because there is no unique morphology of plaques or tangles that characterize AD but is absent from cognitively intact elderly individuals, pathological criteria used to diagnose AD are quantitative. The presence of both plaques and tangles is necessary for a diagnosis of AD, and the distribution and burden of tangles has a much stronger correlation with cognitive abilities and the presence of dementia than the presence or severity of amyloid. Several sets of pathological criteria for AD have been developed. These have been updated in the light of increasing knowledge of the anatomical distribution of tau lesions. National Institute on Aging and the Reagan Institute (NIA-Reagan) criteria, combine the presence of abundant neuritic plaques with the anatomical extent of tau pathology (limited to entorhinal cortex, spread to hippocampus, or spread to neocortex) to assign a low, intermediate, or high probability that AD is present. These were recently modified to also score the extent and nature of Aβ pathology as a “phase” of brain amyloidosis.

Studies of individuals with intact cognitive performance close to the time of death have reported an age-associated increase in the number of

plaques and tangles. In fact, about one-third of cognitively normal subjects in their 80s meet NIA-Reagan criteria for intermediate probability of AD. In people without dementia, tangles are usually limited to the hippocampal formation. Spread of these lesions to involve association areas in the temporal neocortex, and more widely, is more clearly linked to the development of clinical evidence of cognitive decline and dementia. In very elderly individuals with AD, there is also a lower tangle burden compared to younger individuals with Alzheimer disease. This suggests that brain reserve is diminished in association with aging, so that only a small increase in tangles is necessary to lead to clinical expression of dementia. The question of whether AD pathology contributes to age-associated changes in general cognitive performance is less clear. Autopsy studies have suggested that amyloid deposition and tangle formation may be found to an extent in the brains of people in their 50s. However, tau pathology does not occur through the brain but instead is usually restricted to hippocampal subregions and the entorhinal cortex, and may represent PART. Age-related declines in cognitive speed and executive function correlate weakly with plaques and tangles.

Two other lesions occur variably in association with brain aging. Hippocampal sclerosis, with loss of neurons in the CA1 and sometimes other hippocampal regions accompanied by gliosis, is not considered part of "normal" aging. It increases in prevalence with age, and can be found in about 15 to 20 percent of brains of people over the age of 90. Hippocampal sclerosis contributes to cognitive loss and dementia when present, and is usually associated with aggregates of a protein called TDP43. Another protein, α-synuclein, forms aggregates within neurons, including structures called Lewy bodies, which are perinuclear intraneuronal inclusions. These are the identifying pathology of Parkinson disease. They occur in subcortical areas such as the locus ceruleus and substantia nigra, and in cortical and limbic regions in small numbers and have been reported in up to 20 percent of elders whose brains were studied at autopsy. Like hippocampal sclerosis, α-synuclein aggregates are more likely to be present in the brains of people with cognitive impairment, and these may be better thought of as markers of preclinical disease processes rather than adaptive changes of brain aging.

Age-associated vascular changes in the brain have received increasing focus. The many faces of vascular pathology include cerebral infarcts, lacunar infarcts, microangiopathy, and amyloid angiopathy. Some of these lesions, in particular infarcts, are not inevitable accompaniments of aging but are related to vascular risk factors such as hypertension and diabetes. Cerebral amyloid angiopathy (CAA), with deposition of Aβ in the walls of leptomeningeal and medium-sized and small arterioles, is present in at least 30 percent of elderly individuals and can occur in the absence of the diagnosis of AD. Vessels laden with amyloid may rupture, resulting in lobar

hemorrhage, which may cause neurological deficits. MRI studies indicate that microhemorrhages, visible on gradient echo MRI sequences, may occur in association with CAA, and if extensive, are associated with impaired cognition. The widespread use of computed tomography (CT) imaging and more recently MRI in studies of aging and cognition has led to an appreciation of white matter changes. On CT, these appear as a periventricular halo of hypodensity. On MRI, they are most clearly seen on T_2-weighted images, where they have various appearances, including periventricular hyperintensity, capping of the ventricular horns, and hyperintense spots of varying size, which may coalesce to form larger cotton–wool-like confluent areas in the fiber tract projections of the centrum semiovale. Initially referred to as leukoaraiosis, these changes were attributed to incomplete ischemias affecting the white matter tracts. Capping of the ventricles is not related to ischemia but to age-related disruption of the ependymal layer, increased accumulation of interstitial fluid, and subependymal gliosis. Neuropathological findings vary, and often include pallor and loss of myelin. Cognitive testing in groups of elderly individuals with white matter changes has revealed decreased performance on timed tests and on tasks dependent on executive function. White matter changes are more extensive on MRI in people with vascular risk factors such as diabetes and hypertension. These vascular factors may worsen the severity of age-dependent changes in the structure of long projecting tracts that extend through the white matter.

Detailed microscopic studies of blood vessel morphology have raised further questions about vascular factors in age-associated cognitive decline. For example, a decrease in the diameter of capillaries in hippocampal subregions, independent of AD-related lesions, raises the possibility that microvascular changes could contribute to neuron loss or damage. It is possible that these changes could alter the available cerebral blood flow to neurons in the hippocampus, resulting in oxidative stress, damage, and eventually death of neurons. Intervention to treat hypertension and diabetes in middle and later life could help to forestall some of the cognitive decline attributed to aging, although clinical trials of antihypertensive treatment have had mixed results on cognitive outcomes to date.

Another vascular measure is cerebral blood flow, which can be measured using positron emission tomography (PET). More recently, the magnetic resonance technique of arterial spin labeling (ASL) has been used to measure cerebral blood flow. This method magnetically tags water protons in the carotid and vertebral arteries at the base of the brain, the major conduits of blood supply to the brain. As these tagged protons enter the brain, they alter the local magnetization state in proportion to blood flow. There have been relatively few large-scale studies of cerebral blood flow with aging. In general, total cerebral blood flow decreases with age, with studies reporting changes of about 0.5 to 0.6 percent/year. Recent

studies that have examined regional cerebral blood flow have identified heterogeneous changes: decreases with age seem to occur mainly in limbic and tertiary association cortices, with little change in regions such as the primary visual cortex. Vascular risk factors may adversely affect global and regional cerebral blood flow.

NEUROCHEMICAL CHANGES IN AGING

Many neurotransmitters and neuropeptides in the brain show age-related alterations. Two of these, dopamine and acetylcholine, will be highlighted because of their importance in cognitive and affective function, and their potential importance in neuropsychiatric disorders. Much of the decline in neurotransmitter concentrations is due to presynaptic changes, often secondary to loss or atrophy of subcortical projecting neurons, for example, the pigmented cells of the locus ceruleus and substantia nigra (which produce norepinephrine and dopamine, respectively) or the nucleus basalis (which produces acetylcholine). Aging may also affect postsynaptic processes that affect transmitter function, including decreased density of postsynaptic receptors and possible decreased efficiency of signal transduction.

Populations of dopaminergic neurons show marked changes during aging. In monkeys, the number of neurons in the substantia nigra that stain positive for tyrosine hydroxylase decreases by as much as 40 to 50 percent. This may be associated with increased α-synuclein content in individual neurons, a potential factor related to decreased strength of dopaminergic transmission in the nigrostriatal system. These changes may account for slowing of movement and possibly, slowing of cognitive processes in association with aging. Recently, detailed anatomical studies in primates have shown that dopamine innervation from the midbrain projects to cover extensive areas throughout the cortex. Two broad groups have been identified, ventral tier neurons that project predominantly to the striatum, and dorsal tier, whose cells express calbindin and project to limbic, cortical, and selected striatal areas. More detailed anatomical studies may be required to evaluate the specific contribution of these different types of cells in relation to aging. A decline in the strength of dopamine transmission in the mesolimbic and mesocortical pathways may contribute to increased vulnerability to disorders such as depression in aging.

PET imaging has been used to obtain quantitative data for indices of dopaminergic neurotransmission during life. Studies have found that there are age-associated declines in levels of the dopamine transporter, dopamine D_2 receptors, $5HT_2$ receptors, and $5HT_{1a}$ receptors. Differential patterns of decline with aging have been reported. For example, dopamine transporters and D_2 receptors show a linear decline with age, but serotonin $5HT_2$ receptors decline rapidly during the fifth decade of life, and then

decline more slowly.

Cholinergic neurons in the nucleus basalis of Meynert and the septal nuclei project widely to the hippocampus and neocortex. They function to activate regions of the brain in relation to sustained attention, long-term potentiation, and memory formation. In animal studies, lesions to cholinergic nuclei result in deficits in memory abilities. Aged rodents, monkeys, and humans show a decrease in the levels of markers of the cholinergic system with age. In AD, there is a more dramatic decrease which parallels the severity of dementia. Although the mechanisms of these age-related declines are unknown, one possible factor is diminished neurotrophic support. Cholinergic neurons respond to NGF, and it is possible that decreased retrograde transport of NGF from targets to the cell body may result in atrophy of the cholinergic cell bodies. Treatment of aged animals, with grafted cells genetically engineered to secrete NGF, resulted in improvement of cognitive test performance and increased levels of cholinergic markers. However, human studies of gene therapy with NGF in AD have been negative.

Table 57.2c–5.
Brain Performance Measures That Worsen with Aging

1. Cognition
   - Mental speed
   - Fluid reasoning
   - Executive function
   - Retrieval
   - Episodic memory
   - Free recall worse than recognition
2. Movement
   - Gait slowing
   - Simple reaction time slowing
   - Upward gaze
   - Balance changes (vestibular, sensory, motor, and brain)

CHANGES IN COGNITIVE AND MOTOR ABILITIES ASSOCIATED WITH AGING

Much research has documented changes in cognitive abilities, in particular memory, accompanying aging (Table 57.2c–5). On tests of episodic memory, both the acquisition of new verbal or visual information and recall after a delay show decline with age. These are evident even when comparing the performance of 40 year olds to that of 20 year olds. On average, subjects at age 80 perform approximately 1.0 to 1.5 standard deviations below the mean for young adults. Whereas performance appears to decrease throughout the adult age span, decline may be a little steeper after the age of 60. Other aspects of cognition, including working memory, perceptual speed, spatial visualization, and inductive reasoning show similar age-related decline. Age-related effects on different types of

cognitive tests are correlated, suggesting that widespread brain changes underlie them. One such factor is cognitive slowing; if time limits are removed from certain types of cognitive tests and the criterion for scoring is accuracy, then elderly individuals show improved performance. Semantic memory and cumulative knowledge, as indexed by measures such as vocabulary, tend to increase with age and remain preserved in old age. However, retrieval of semantic knowledge, including words and names, is impaired in aging, as demonstrated by performance on timed tests.

Many aspects of movement show evidence of slowing with aging. One of the more obvious features is the slowing of gait and tendency to stoop that are so common in the oldest-old. Elderly individuals also show a decline in balance: difficulty being able to stand on one leg or perform a tandem walk usually begins after the age of 70. This is most likely multifactorial, with contributions from declines in nerve and muscle function, changes within the spinal cord, sensory systems (vision and vestibular function), and brain changes involving structures such as the basal ganglia. Simple reaction time and movement time are both slowed with aging, resulting from changes to white matter tracts as well as neuronal networks that initiate and coordinate rapid movements.

AGE-ASSOCIATED BRAIN DISEASES

A number of disorders show a predilection for the aged brain (Table 57.2c–6). Neurodegenerative diseases rank high on the list; among these, AD is the brain disorder most intimately related to aging. Both the incidence and the prevalence of AD show an exponential increase after the age of 60. Parkinson disease has a prevalence of approximately 1 to 2 percent in the general population. The prevalence of Parkinson disease increases with aging and may be as high as 4 to 5 percent in individuals aged 85 or older. However, the frequency of Lewy bodies—the signature pathology of Parkinson disease—in the substantia nigra in series of autopsies from people aged 60 to 90 is higher, typically around 5 to 8 percent. This is consistent with the concept that reserve may protect against the clinical expression of Parkinson disease. Amyotrophic lateral sclerosis (ALS) is much less common than AD or Parkinson disease. Its onset is more common among people aged 60 or older, than at a younger age in the absence of a causative gene mutation.

Table 57.2c–6.
Age-Associated Brain Diseases

1. Alzheimer disease
2. Vascular dementia
3. Normal pressure hydrocephalus
4. Parkinson disease
5. Amyotrophic lateral sclerosis

6. Depression
7. Seizures
8. Sleep disorders
9. Essential tremor

The incidence of stroke increases with age, including both clinically apparent strokes and evidence of stroke on neuroimaging in the absence of a history of stroke (silent infarcts). In population-based studies, silent infarcts are much more common than symptomatic strokes in the elderly, and the overall prevalence of infarcts on MRI may be as high as 20 percent in the elderly. The prevalence of MRI-defined infarcts is associated with aging and with cardiovascular risk factors such as hypertension.

BRAIN AGING IN THE OLDEST-OLD AND IN CENTENARIANS

According to the US 2000 census, there were over 50,000 Americans older than 100 years. Living to 100 or older is a milestone that is especially worthy of celebration if it is accompanied by reasonable physical and cognitive function. A number of studies have tried to determine the prevalence of dementia in centenarians. Difficulty with performing daily activities is common among centenarians, often due to physical impairment or changes in vision and hearing. Because of marked differences in methods of cognitive assessment and incomplete sample ascertainment, estimates vary widely. Longitudinal data such as those that have emerged from the 90+ study of nonagenarians living in Leisure World in Southern California, have identified a marked acceleration in the risk of dementia after the age of 90 with a prevalence of at least 50 percent by age 100.

In the oldest-old, correlations between pathological lesions of AD and cognitive status are weaker than those in younger individuals. For example, the Oregon Brain Aging Study followed people aged 85 or older without cardiovascular or major age-associated diseases. Subjects who died without having shown cognitive decline or dementia had scanty SP or NFT, although there was a correlation between the presence of increasing burden of these lesions and impaired performance on cognitive testing. The Leisure World 90+ study includes cognitive testing, clinical evaluation for the presence or absence of dementia, and a high rate of brain examination at autopsy. Whereas counts of SP weakly distinguished people with dementia from those without, the strongest discriminating features for dementia were reduction of presynaptic biochemical markers, overall tangle burden and the presence of hippocampal sclerosis. Synaptic density may represent a dynamic and adaptive marker that is initially related to the establishment of connectivity during development, remodeled according to use and plasticity, and undermined by age- and disease-related processes.

PROSPECTS FOR HEALTHY BRAIN AGING

In the absence of effective treatment that slows the progression of AD, it is important to consider how to prevent AD and preserve cognitive abilities during aging. Population-based studies of aging and dementia have suggested that there may be modifiable factors associated with the risk of dementia and or age-associated cognitive decline. These include aspects related to lifestyle and diet as well as medical interventions (Table 57.2c–7). These types of interventions are being evaluated in randomized clinical trials beginning in mid or later life. Early results from one of these studies conducted in Finland are encouraging, suggesting that cognitive performance may improve as a result of multicomponent intervention in people who have an unhealthy lifestyle.

Converging evidence suggests that physical activity may modify brain aging. In animal studies, maintained physical activity or exercise is linked to decreased markers of oxidative damage in the brain with aging, increased neurogenesis, increased brain perfusion, and lower expression of amyloid pathology in transgenic mice used as models of plaque deposition and AD. Epidemiological studies have shown that regular physical activity is associated with a decreased risk of developing AD. Vigorous aerobic exercise may not be necessary, as evidence suggests that walking may be associated with risk reduction. Self-reported higher levels of exercise have been associated with better cognitive test scores in elderly individuals. There have been many controlled trials of exercise intervention in elderly subjects; a recent meta-analysis of 18 randomized trials found that aerobic exercise training had beneficial effects for healthy older adults who did not previously exercise regularly. Effects were stronger for tests of executive function and reaction time than for other cognitive processes and were statistically significant only for interventions that used exercise sessions that were at least 30 minutes long. Before making a firm recommendation that exercise will benefit cognitive performance or delay dementia, further research is needed to confirm the findings of intervention studies, establish what types of exercise are beneficial, and determine how long and frequent each exercise session should be. In addition to defining a minimal amount of exercise that may show a positive cognitive effect, studies need to identify exercise regimens that are feasible for most elderly individuals. Along the way, it will be important to clarify how exercise benefits the brain.

Cognitive stimulation, using methods such as environmental enrichment, is associated with reduced deposition of amyloid in transgenic mouse models related to AD. A number of human studies have found that engagement in cognitively demanding pursuits throughout adult life is associated with better cognitive performance and with a decreased risk of incident AD. For example, the Rush Memory and Aging Project enrolled over 1,200 people in Chicago, with an average age of 80, who were

determined to be free of dementia and followed and reevaluated this cohort annually. Subjects were questioned about types of cognitively active pursuits (such as reading books, attending music or plays, playing card games) and their frequencies. Those subjects who had a moderate or high level of cognitive activity had a lower rate of age-associated cognitive decline, which remained significant even after controlling for age, race, education, depressive symptoms, and chronic medical conditions. Further analyses have shown that subjects with higher levels of cognitively demanding pursuits had a 2.6-fold lower risk of developing dementia than subjects with a low level. Other studies have reported similar types of findings, which have given rise to the "use it or lose it" hypothesis. Many factors have been related to higher levels of cognitive activity in later life, including general health, physical function and mobility, and differences in diet and lifestyle, that may be part of a package that contributes to brain function in aging. Many intervention studies have been carried out in this area, and in recent years, these have included computerized training of cognition. The Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE) study was a large-scale intervention that enrolled over 2,800 subjects aged 65 or older. Participants were randomly assigned to receive specific modules of training for memory, reasoning, speed of processing, or no intervention. A subset of subjects received booster training at 11 or 35 months after enrollment. Cognitive training resulted in improvement in the area of cognitive performance that was trained, but did not carry over into other areas. The effect persisted for the 5 years of the study. Reasoning training resulted in slightly less decline on self-reported instrumental activities of daily living; otherwise there was no functional benefit associated with training. This rigorous study highlights a key feature of cognitive intervention, training to task. Computer-assisted training appears to influence the specific area that is trained, and it has been difficult to show broader improvement in other cognitive abilities, or an impact of training on functional abilities. Unless such evidence emerges, there is no clear reason to recommend computer games and interventions to improve brain health and function in aging.

Table 57.2c–7.
Interventions Proposed to Help Maintain Brain Abilities with Aging

1. Control hypertension
2. Treat diabetes and vascular risk factors
3. Regular physical activity
4. Mental activity, e.g., cognitively demanding pastimes
5. Social activity, e.g., friend, family, and community interactions
6. Diet: similar components to a heart-healthy diet, e.g., a diet rich in antioxidants and low in saturated fat, or a Mediterranean-type diet

Nutrition and brain aging is another area of controversy. It is difficult to randomize people to different types of diet for long-term studies, so research efforts in this area have used dietary questionnaires, short-term interventions, and supplements with vitamins or other nutrients. Many components of diet have been linked to cognitive performance with aging. Some examples of factors that may be protective include eating a Mediterranean or heart-healthy diet or consuming foods with a relatively high content of naturally occurring vitamins with antioxidant activities such as vitamin E and vitamin C. Studies of diet need to consider other factors, such as obesity, cardiovascular risk factors, and lifestyle that may also be associated with dietary choices. Intervention studies regarding supplemental antioxidant vitamins, such as vitamin E and vitamin C, have not shown cognitive benefits or reduction of the risk of developing dementia. Homocysteine levels have been associated with the risk of AD and stroke in several studies. In the United States, fortification of grain products with B group vitamins has lowered the population's homocysteine levels. Intervention studies of lowering homocysteine in people with AD had no benefits on cognition. Omega-3 fatty acids are important nutrients for brain function and growth during development. Clinical trials that have used omega-3 supplementation have had no benefits in AD, and have not shown clear effects in altering cognitive decline associated with aging.

Cardiovascular risk factors, in particular hypertension and diabetes, are associated with worse cognitive function with aging. For example, in the ACTIVE study discussed above, participants with hypertension had a faster decline on logical reasoning tasks, and diabetes was associated with faster decline on a test of cognitive processing speed. Population-based studies have found that midlife hypertension is a consistent risk factor for accelerated age-associated cognitive decline, stroke, and incident AD. However, although clinical trials of treatment of hypertension in elderly individuals have shown clear benefits for reducing heart attack and stroke, they have had less consistent benefits on slowing cognitive decline. These studies have been limited by problems such as dropout during long periods of follow-up and the difficulty of maintaining an untreated comparison group. As obesity has increased in adult populations in Western societies, attention has focused on whether metabolic syndrome is associated with cognitive performance in the elderly. Studies have found that components of metabolic syndrome, such as diabetes and abdominal girth, appear to be related to poorer performance on a variety of cognitive measures in cross-sectional studies in the elderly. Much of this risk appears to be due to hyperglycemia, although in some studies biomarkers of inflammation measured in the blood also contribute. Clinical trials are currently in progress to examine whether interventions to maintain stringent control of type 2 diabetes are associated with benefits in cognitive performance.

Even in the absence of evidence from rigorous intervention studies, it

seems reasonable to recommend maintaining physical and cognitive activity, controlling cardiovascular risk factors, and eating a heart-healthy diet to try to preserve general health with aging, with the bonus that there may be positive spin-offs regarding cognitive abilities. These aspects of lifestyle were included in the recommendations of a recent report prepared by the Institute of Medicine. That report also mentioned avoiding delirium and being cautious in use of prescription medications with potential cognitive side effects. It also highlighted the important planning roles that families, communities, and government need to take in developing the environment to support healthy cognitive aging.

Our ability to describe and quantify changes in the brain associated with aging has burgeoned in the past few decades, with parallel advances in studying aging in animal models. Advances in brain imaging continue to have a huge impact on human studies of aging and cognition. Although great progress has been made at a descriptive level, researchers are still handicapped by not understanding which mechanisms are most important in driving the aging process and how they interact to result in biochemical and structural changes in the brain. Because aging is associated with a decline in brain abilities as well as an increased vulnerability to disorders such as dementia and cerebrovascular-associated cognitive impairment, continued research into mechanisms that lead to damage as well as those that support resilience and plasticity within the brain could pay an enormous dividend by improving health and vitality as society continues to benefit from gains in longevity.

57.2d Psychological Changes with Normal Aging

JENNIFER J. DUNKIN, PH.D., AND KIMBERLY ANN CORP, M.S., M.F.T.

INTRODUCTION

Advances in medicine and improvements in living conditions over the past century have resulted in greater and greater number of persons reaching old age. This "graying" of the population is expected to reach its peak over the next 60 years, as the Baby Boom cohort reaches old age. The oldest-old group of elderly individuals—those 85 years of age and older—is expected to grow at the fastest rate. Although on the surface these demographic trends reflect favorably on society's attempts to eradicate disease, reduce infant mortality, and improve standards of living, recent debates have focused on the "hidden costs" of these changes. For example, aging is associated with increased risks of, among other factors, physical illness, personal losses, and cognitive impairment. If these risks translate into significant impairment for the majority of older people, then there will be increased costs to society as greater and greater number of people reach old age.

From both public health and quality-of-life perspectives, it is important to determine how to maximize the health and well-being of the aged population. It is with this in mind that a number of large-scale longitudinal studies have focused on the concept of "successful aging" to determine what characteristics are present in individuals who appear to reach old age with favorable outcomes. The results of such studies have been important in shaping public policy as well as changing societal views on the nature of the aging process itself. For example, although there are clearly unique life challenges that face the elderly, it may be surprising that the majority of research studies suggest that most elderly people report high levels of life satisfaction, cope well with the challenges of late life, and demonstrate considerable resilience in the face of functional and personal losses. Nevertheless, recent studies suggest that even successfully aging individuals are prone to their own negative aging self-stereotypes and that these self-stereotypes cause distress and appear to be related to poorer functional health. Thus, the challenges as a society are to increase the number of elderly persons reaching old age successfully and to decrease negative views of the aging process.

DESIGN AND SAMPLING ISSUES

Design Issues

Most studies in the field of aging are cross-sectional in design, meaning that groups of individuals of different ages are sampled at one point in time. Although meaningful conclusions about differences between age

groups can be drawn from cross-sectional studies, it is inappropriate to draw inferences about change over time from such studies, because individuals are not studied prospectively and there is considerable potential for mistaking cohort differences for longitudinal change. For example, there are vast differences between the average 30-year-old and the average 70-year-old besides age, including average number of years of education, exposure to historical events such as the Great Depression and World War II, and comfort with revealing personal information. Thus, what may resemble change over time may instead be baseline cohort differences. Because of these issues, it is likely that different trajectories of change will be necessary for each individual age cohort. In addition, cross-sectional designs tend to overestimate the relationships between variables that change with time.

Sampling Issues

Until recently, most studies of psychological issues in aging have used predominantly Caucasian, well-educated, healthy, and financially comfortable samples of older adults. Studies have primarily used samples of subjects in the so-called young-old age group (65 to 75 years of age), or, less frequently, the old-old age group (75 to 85 years of age), but rarely the oldest-old group (85 years of age and older). Furthermore, early longitudinal studies of personality development and adjustment used only male samples. The result is that comparatively little is known about minority elderly, elderly women, inner-city and lower-income elderly, and the oldest-old. Similarly, many psychometric and neuropsychological tests that measure cognitive functioning do not have adequate normative data for the oldest age groups. Attrition rates are also important phenomena: Studies rarely compare individuals who drop out of studies with those who remain in the study. This may overestimate the amount of stability and underestimate the amount of decline in psychological functions, as those who decline in functioning tend to have higher attrition rates than those who do not decline. In terms of cognitive aging, studies have varied considerably in terms of whether individuals with medical conditions known to affect brain function were included in the sample. Although such individuals may be “typical” of their age cohort, their inclusion in studies makes it difficult to determine which cognitive changes can be expected as a function of the aging process itself and which changes may be a function of epiphenomena associated with aging, such as medical conditions.

MENTAL HEALTH AND PERSONALITY

Mental Health over the Life Span

With the exception of dementing disorders and delirium, mental disorders are no more common in the elderly as compared to younger age groups.

Epidemiological studies have found that prevalence estimates of common disorders such as major depression, anxiety disorders, substance abuse, and psychotic disorders are generally lower for those over the age of 65 versus younger age cohorts, a finding recently replicated by newly revised prevalence estimates of mental disorders using the NIMH Epidemiological Catchment Area Program data, as well as the National Comorbidity Survey. Furthermore, recent longitudinal studies that have followed individuals for up to 25 years have found no evidence that those rates of emotional distress increase with age.

Age differences in the experience and expression of both positive and negative emotions have also been studied to determine if older adults report more negative emotional experiences than younger adults. In a recent study using a series of large ethnically diverse samples, older adults reported experiencing fewer negative emotions such as sadness, anger, and fear but more positive emotions such as happiness than those in the younger age cohorts. In another study, even among older persons with physical illness, more positive than negative emotions were observed, lending further support to the notion that even advanced age and illness do not necessarily lead to negativity in outlook. In addition, older adults reported a greater sense of emotional control over negative internal emotional states than younger subjects. To explain their data, the authors proposed an *emotional control* model, suggesting that aging is associated with an increased ability to inhibit negative emotional states and maintain positive emotional states.

A recent study found interesting racial differences between elderly blacks and whites on measures of psychological distress. The study included over 1,000 high-functioning older adults between the ages of 70 and 79 and found that blacks were less distressed than whites, particularly at lower educational levels. The finding remained even after controlling for social support, socioeconomic status, and functional status. The authors suggest that elderly blacks may be afforded higher status and stay more engaged within their communities than elderly whites. If so, then the place of older blacks within their communities could serve as a model for other ethnic or racial groups.

Stage Theories of Personality Development

Early personality theorists proposed that development was completed by the end of childhood or adolescence. One of the first developmental theorists to propose that personality continues to develop and grow over the course of the life span was Erik Erikson. Erikson believed that development proceeded through a series of *psychosocial stages*, each with its own conflict that is resolved by the individual with a greater or lesser degree of success. Erikson termed the crisis of the last epoch of life *integrity versus despair* and believed that successful resolution of this

crisis involved a process of life review and achieving a sense of peace and wisdom through coming to terms with how one's life was lived. For example, Erikson proposed that successful resolution of this crisis would be characterized by a sense of having lived one's life well, whereas a less successful resolution would be characterized by feeling that life was too short, that one did not choose wisely, and a sense of bitterness that one will not have another chance to live life over.

Erikson's theory is descriptive and few studies have attempted to empirically validate it. However, a recent longitudinal study of approximately 500 subjects from two age cohorts found not only that the earlier age cohort scored significantly higher on a measure of integrity than the later age cohort but also that scores for both age cohorts on this measure had declined significantly by the final time of testing. These data suggest that the conflict of integrity versus despair may have a more favorable outcome in earlier age cohorts versus later age cohorts, raising the possibility that changing societal values have negatively impacted the struggle for integrity. Although more empirical data are needed, Erikson's theory remains one of the most eloquent descriptions of the potential of late life.

Personality over the Life Span: Stability or Change?

Although Erikson and other stage theorists focused on unique developmental tasks and stages central to each phase of life, other studies have focused on defining core personality traits within the individual and determining their course over the life span. Studies have consistently revealed five basic personality traits: extraversion, neuroticism, agreeableness, openness to experience, and conscientiousness. Further, these personality traits generally remain remarkably stable over the life span. A number of large, well-designed longitudinal studies that have followed individuals over periods ranging from 10 to 50 years have found strong evidence for stability, although with a few notable exceptions. For example, some studies have found that neuroticism decreases as individuals move from young and middle adulthood to old age, after which it remains stable. Other studies have found slight decreases in extraversion as individuals move into the oldest-old age category, possibly linked to deterioration in health and sensory loss, particularly hearing.

Personality factors may even contribute to mortality in old age. For example, recent studies have found that high levels of extraversion and low levels of neuroticism are associated with a reduced risk of mortality in individuals 65 years of age and older. One explanation for this finding may be that personality traits mediate physical, social, and cognitive activity levels that lead to less healthy and supportive lifestyles.

ADJUSTMENT AND COPING IN THE ELDERLY

Individuals can expect to experience periods of change, disruption, and even crisis throughout the life span. There is no doubt that older adults experience significant challenges as they enter and negotiate the last phase of life, including bereavement, loss of socially valued roles such as that of worker, and chronic and accumulating health problems. How age affects the process of managing change and discontinuity has been an important research focus, with some authors proposing that people become less effective as they age, due to depletion in resources, whereas others have hypothesized that people become better at managing stressful life events over time, secondary to a process of learning more effective strategies. These questions have been investigated from a wide range of theoretical perspectives.

Age Differences in Coping Strategies and Coping Effectiveness

"Coping" is a general term that refers to strategies that individuals use to manage stressful life situations that involve perceived or actual threats. It includes strategies designed to reduce emotional distress, such as distraction, passive avoidance, and positive reappraisal, and strategies designed to solve the problem, such as direct action, confrontation, and information-seeking. Cross-sectional studies of age differences in coping strategies have had somewhat mixed results, with some studies finding no differences between age groups in their use of coping strategies, and other studies finding that older adults preferentially use strategies designed to reduce emotional distress, whereas younger adults use more problem-focused coping, although the effect sizes are relatively small. This finding has often led to the conclusion that older adults are more passive in their coping style, yet when the type of stressor is controlled, these differences are often eliminated or reduced. In addition, older adults are often attempting to cope with situations that are less changeable than those faced by younger individuals, and therefore, the use of coping techniques that attempt to reduce emotional distress rather than solve the problem may be a more effective approach. In this vein, a recent study found that older adults who modify their goals and accommodate and adapt to losses and stressors rather attempting to exert control or deny losses have a better outcome.

Coping effectiveness across the life span has been another area of interest for gerontologists. The effectiveness of a coping strategy is defined by its outcome, usually measured by level of distress, depression, or health symptomatology. Clearly, if individuals become less effective at coping with the demands of life as they age, this would have considerable implications for clinical practice and the kinds of interventions that might be used with older adults. However, studies of coping effectiveness have generally not revealed age differences; that is, the old appear to cope as well as the young, and their outcome, in terms of depression and other stress-related

symptomatology, is just as favorable. For example, in a study investigating age differences in coping across a broad range of stressors using a sample of over 2,000 men ranging in age from the late 40s to over 90, there were no significant age differences in the reporting of negative emotional states in response to stressors or perceived efficacy in coping.

Role Transitions

Role transitions play an important part in the aging process, and there is no domain where it is more important to understand issues of coping and adaptation than during transitional phases of life. There are many transitions experienced by the elderly, but older adults are especially likely to experience two major role transitions: Retirement, or the transition from worker to nonworker, and bereavement, or the transition from spouse to widow. These major transitions present the individual with the challenge of having to redefine identity and to create new roles to replace those that have been lost. Indeed, there is evidence that the elderly who are successful in creating new roles for themselves experience a greater sense of well-being than those who are less successful at this process.

Retirement. Retirement is an age-graded event, in that individuals in society are expected to retire at a particular age, regardless of health status or personal preference. It is almost entirely a phenomenon of Western, industrialized, and postindustrialized societies and prior to the late 19th century was largely a personal decision. The transition and adjustment to retirement has been characterized by social gerontologists as a *psychosocial crisis*, and the image of the successful executive deteriorating or dying soon after retirement has been popularized in the press. However, recent studies have suggested that most recent retirees rank retirement quite low in terms of its impact on a list of psychosocial stressors, with 17 percent of men and 11 percent of women reporting dissatisfaction with retirement. Nevertheless, there is some heterogeneity among retirees, and the factors that predict a poor adjustment to retirement include an involuntary or unexpected retirement, low socioeconomic status, health problems, a competitive and highly achievement oriented personality (the so-called Type A behavior pattern), inability to set future goals, and general difficulty adjusting to change. Further, despite early data suggesting that there is an increased risk of death in the first 2 years after retirement, recent studies controlling for health status at retirement have failed to reveal any associations between retirement and mortality. In addition, when preretirement mental and physical health are controlled for, there are no clear associations between retirement and subsequent physical or mental health consequences. Thus, it is important to consider retirement in the context of an individual's life and other changes that they may be experiencing rather than in isolation.

Few studies of retirement have specifically investigated ethnic differences in adjustment. For many ethnic minority groups, retirement represents a significant loss of income, because many are economically disadvantaged and earn lower wages relative to their Caucasian counterparts. Available data suggest that many continue to work past retirement age even in the face of disability and health problems. A recent study suggests that middle-aged African-American males can expect to spend, on average, 2.5 fewer years retired than Caucasian males and therefore can expect to spend more time in the workforce with fewer years of retirement and leisure in their old age.

Spousal Bereavement. Demographic data suggest that 51 percent of women and 14 percent of men over the age of 65 will be widowed at least once. Bereaved spouses consistently rank spousal loss as among the most stressful of all life experiences. Early work on bereavement and the elderly hypothesized that older adults might be less able to cope with the loss of a spouse than younger adults, due to declining physical capabilities and subsequent decrements in the ability to manage stress. Subsequent research has revealed age differences in coping with bereavement but in the opposite direction as predicted: Younger bereaved spouses report greater symptomatology on measures of physical and mental health following bereavement than older spouses. Several factors might account for this difference, including cohort effects, with younger cohorts having a greater comfort level in acknowledging symptoms, or whether the death was expected or unexpected, with unexpected deaths causing greater symptomatology and occurring with greater frequency in younger age groups.

Other recent data are consistent with the idea that, as a group, older adults appear to have a more favorable outcome than expected following the death of a spouse. A recent longitudinal study comparing over 120 older bereaved spouses with age-matched nonbereaved controls found that depressive symptoms peak within the first few months after a death but decline significantly within a year, and after 2 or 3 years of follow-up, although bereaved groups still report significantly higher levels of depressive symptoms than age-matched controls, these differences are very small. Even during the first few months following bereavement, few older adult widows (between 5 and 17 percent) score in the severely depressed range on depression rating scales. Interestingly, although elderly bereaved spouses report that loneliness and performing activities of daily living are factors that complicate adjustment, many older spouses also report positive feelings following a death, such as relief, in contrast to younger samples. There are nevertheless important exceptions; studies suggest that elderly survivors of spouses who committed suicide, who have low social support and who report greater psychopathology at the time of death, are all at a

higher risk of poorer long-term adjustment. In addition, elderly women who are highly dependent on their spouses for assistance appear to be at a higher risk for adverse outcomes and may require more professional intervention.

Recent data reveal an interesting relationship between bereavement and an excess risk of mortality in older adults. Most studies have revealed that actually younger bereaved spouses face a greater risk of mortality than older recent widows. In addition, elderly white widows appear to be at a greater increased risk of mortality than elderly black widows, who may not face an increased risk at all.

Resilience of the Aging Self

The above review of coping and adaptation in aging suggests that older adults appear to cope well with adversities and challenges, despite in many cases the more chronic and accumulating nature of the stressors that they face. The concept of *resilience* has been offered as an explanatory factor for this phenomenon and is defined as the process of both maintaining adaptive behavior and positive emotions when presented with stress as well as recovery from adversity. Resilience may involve a process of *selective optimization*, or an accommodative process of rescaling goals to match one's limitations and the demands of the environment, and investing the fewer resources available in personally salient activities that maintain self-esteem. For example, a recent study found that the psychological impact of physical disability was less for those elders over 80 than that in those younger than 80, suggesting that a process of scaling down expectations with increasing age may occur and may be adaptive.

Maintaining a strong sense of self-worth in the face of accumulating losses may be an important part of resilience in aging. For example, a recent study found that self-esteem actually declined very little over time in a sample of elders with low socioeconomic status and low levels of education, despite experiences of personally meaningful losses. Rather, these older adults appeared to engage in cognitive strategies to protect their sense of self and well-being. In another study, even individuals over the age of 100 who experienced multiple losses in many domains report similar levels of happiness to middle-aged and young-old individuals, and attitudes such as optimism and self-efficacy are more predictive of happiness than objective resources available.

SOCIAL FUNCTIONING IN LATE LIFE

Research over several decades has consistently validated the importance of social support in "buffering" the effects of stress: Given equivalent stressors, those individuals with strong social ties appear to have better outcomes than those who are isolated or perceive that support is

unavailable or unhelpful from those in their network. Yet, the elderly appear to have reduced social networks, the frequency of their social contacts is reduced as compared to those of younger adults, and this may be especially true for the oldest-old, whose social networks have been shown to be one-half the size of those of the young-old. This finding was previously thought to be evidence for the *disengagement* hypothesis of aging, that is, that aging involves a process of withdrawal from society and others and the development of a more inward focus. However, for many older adults, the reduction in social contact is not voluntary and may be more related to disability and reduced mobility than preference. The disengagement hypothesis has been recently reframed as *socioemotional selectivity*, based on the finding that although overall social contacts do decrease in late life, it is only contact with acquaintances and other peripheral individuals that decreases; social contacts with very close friends and family remain stable, and older adults' satisfaction with these close relationships remains high. It may be that as individuals age and resources become fewer, those resources are adaptively invested in maintaining close relationships as opposed to maintaining acquaintanceships. For older adults with a *limited future time perspective* or a greater awareness of mortality, there is even more motivation to maintain emotionally meaningful relationships. However, this phenomenon may be at least partially dependent on the external circumstances of older people's lives. For example, in a recent study of over 500 elderly individuals over the age of 70, the size of social networks and the feelings of connectedness to that social milieu were related to the presence and availability of the nuclear family. Older adults with nuclear family members tended to have social networks that were both larger as well as more emotionally close than older adults without a nuclear family. However, those without a nuclear family reported greater feelings of closeness to friends than those with a nuclear family, suggesting that older adults can adapt to the absence of family by creating satisfying relationships with others.

The social structure of oldest-old has recently been studied, and data suggest that this group may be particularly vulnerable to social isolation due to multiple losses. In a recent study, most individuals over the age of 85 had at least one surviving relative, but approximately one-quarter had little or no contact with that relative. Most social contact was derived from children, and for those individuals without children, social contact and support were not provided from more distant relatives, except within the African-American community, where other relatives and friends were available to provide help and support. For the oldest-old, then, the family, especially adult children, appears to play a crucial role in providing social support.

COGNITIVE AGING

The study of cognition and aging has been an extraordinarily productive area of research over the past several decades. Nevertheless, the existing literature is fraught with difficulties in interpretation, with confusion or disagreement about the inclusion or exclusion of subjects with medical problems and multiple medications and the inadvertent inclusion of subjects with early dementia, which tends to overestimate the effects of age by lowering the overall mean of elderly groups. Furthermore, until magnetic resonance imaging (MRI) scanning was widely used, studies unknowingly included subjects with subcortical ischemic disease, confounding the effects of age with disease. In addition, design issues are important; cross-sectional studies, in which individuals of different age groups are compared at one point in time, almost always show broader and sharper age effects than longitudinal studies due to possible confounding of age effects with cohort effects.

Summary of Age Effects on the Major Cognitive Domains

The broad domain of cognition has been divided into subdomains that include attentional processes, language functions, visuoperceptual abilities, learning and memory, processing speed, and the executive functions.

Attentional Processes. Attentional processes are a complex group of behaviors by which individuals select information for cognitive processing while ignoring competing information, concentrate on information over a sustained period of time, divide attentional focus between two or more aspects of a task at a time, and shift attentional focus from one set of stimuli to another and back again. Basic attention span is the amount of information that can be apprehended at one time and demonstrates little or no relationship to age. Similarly, sustained concentration or vigilance is not affected by the aging process. However, complex attentional tasks such as divided attention that place more demand on cognitive capabilities show significant declines with advancing age.

Language Functions and Verbal Abilities. Language functions remain remarkably stable with age, with few exceptions. Vocabulary and expressive word knowledge may even increase over the life span. Verbal expression and verbal reasoning skills may demonstrate subtle changes with age, as some studies have shown that spontaneous language may become less precise and more repetitious over time, although most of these conclusions were drawn from cross-sectional studies and may be confounded with cohort effects. Finally, the ability to spontaneously retrieve names of objects from the lexicon appears to show reliable but small decreases with age, although these effects are heavily influenced by educational

achievement.

Visuoperceptual and Visuoconstructive Abilities. Visuoperceptual abilities are those functions that involve the recognition and appraisal of nonverbal relationships, specifically those involving shapes, patterns, and objects with spatial relationships to one another. Visuoconstructive abilities are those involving the reproduction of nonverbal material, such as the direct copy of simple and complex designs. Visuoperceptual abilities demonstrate relatively consistent age effects across studies, with older adults generally performing as well as younger adults on tests of simple object and pattern recognition but performing more poorly than younger adults on measures of visual closure and spatial orientation. Similarly, in terms of visuoconstructive functions, older adults perform about as well as younger adults when copying simple two-dimensional designs but more poorly than younger adults when copying three-dimensional complex designs and when planning and strategy are necessary for good performance. It should be noted that age effects are the largest on visuoconstructive tasks that are timed and removing the speed component of the task often considerably reduces but does not remove the age difference.

Learning and Memory. Effects of age on learning and memory are among the most well-documented and well-studied effects in the neuropsychological literature. However, "memory" is an extremely complex set of functions and systems, and the aging process affects some components of memory to a greater degree than others. Sensory memory, or the extremely brief sensory record of a stimulus, primary memory, exemplified by the ability to recall a string of digits long enough to repeat them, and tertiary memory, or memories from childhood, show no significant age effects or mild and subtle effects that can be detected in the laboratory. Research studies have consistently shown that secondary memory, exemplified by the ability to learn information and recall it after a time delay is most the strongly affected by age. Nevertheless, the age-related effects on secondary memory are relatively small: Studies suggest that performance declines at a rate of 10 percent per decade of life beginning in midlife. However, once older adults learn information, it is retained well; studies suggest that older adults retain information at rates only slightly below that of younger adults. In addition, available data suggest that spontaneous recall demonstrates considerably stronger age effects than recognition memory, which is the ability to recognize information that has been previously presented.

Processing Speed. Speed of information processing and pure motor speed demonstrate the most reliable age differences and decrements with

age, whether measured cross-sectionally or longitudinally. Indeed, reduced processing speed in aging may be a crucial component of many age-related effects on cognition, such that in a recent study age effects on a number of neuropsychological tests were considerably diminished after processing speed was partialled out, even on tests where speed of performance was not measured. In addition, recent studies suggest that speed of processing is an important mediator of memory performance, such that some authors have proposed a speed of processing model to account for age-related decrements in memory and other cognitive processes.

Executive Functions. The term "executive functions" refers to superordinate cognitive skills involved in abstract reasoning, problem-solving, planning, response inhibition, the ability to shift cognitive set, and a working memory construct that is defined as the ability to simultaneously hold and process information. Early studies suggested that the executive functions decline with age. However, recent studies that use carefully selected samples and exclude subjects with histories of chronic medical conditions known to affect central nervous system (CNS) functioning or documented evidence of subcortical white or gray matter lesions on MRI scanning reveal very few age differences on executive tasks. Because of the relationship of performance on tests of executive functioning to the presence of medical conditions, especially diseases of the cardiovascular system, these studies suggest that some of these age effects may be preventable.

Models of Cognitive Aging

Taken together, studies suggest that there is a profile of cognitive changes with age that includes significantly reduced information processing speed and pure motor speed and mild decrements in spontaneous recall, executive skills, complex attentional processes, and complex visuoperceptual and visuoconstructive abilities. It should be emphasized that although age-related changes in cognition are statistically significant, most elderly persons still perform within normal limits on cognitive testing. The extent to which these observed changes are related to the process of aging itself, the effects of particular medical conditions on the brain and CNS functioning, and cohort differences in education and experience are not well understood at present, although a recent longitudinal study with a 10-year follow-up interval revealed that significant decline in cognitive functions (excluding psychomotor speed) was apparent only in individuals suffering from poor health. A number of models have been proposed to account for these changes, and these models have included both psychosocial and biological interpretations. First, it is unlikely that all age-related effects on cognition are secondary to cohort differences, because cohort-sequential studies, in which individuals from different age cohorts

are followed prospectively, reveal clear longitudinal decline across age cohorts. Unfortunately, studies specifically addressing this important question are few and have only investigated intellectual abilities and not functions such as memory or other neuropsychological variables. It is likely that cohort effects exert the strongest influence on those abilities most dependent on formal education, but this hypothesis has not been formally tested. It is also unlikely that simple disuse accounts for significant aspects of age-related cognitive decline.

The Cattell–Horn model of intellectual changes over the life span proposes that age affects different cognitive processes differently. The model proposes that general intelligence can be subdivided into *crystallized intelligence*, referring to abilities and information learned through exposure to education and life experience, and *fluid intelligence*, referring to abilities involved in novel problem-solving. The model proposes that crystallized intelligence remains stable or increases over the course of the life span and may even increase into old age, due to continuing exposure to information. In contrast, fluid intelligence, thought to be dependent on the integrity of brain function, was hypothesized to decline with advanced age. Available data have generally supported this model, with studies showing that there is little evidence of decline on measures of such crystallized abilities such as word knowledge or general fund of information, whereas measures of fluid abilities such as novel problem-solving, as discussed above, generally reveal some decline. However, the model, as originally proposed, is limited in that it only discusses changes in intellectual functions, whereas other cognitive functions, such as learning and memory, are not included. Furthermore, the same limitations of studies of executive functions, apply to the fluid intelligence concept.

The processing speed hypothesis hypothesizes that many of the observed age-related changes in cognition are in fact secondary to reductions in speed of processing. The model proposes that the speed at which information can be processed limits both the quantity and the quality of cognitive operations. Slowing affects not only how much information is processed within a given period but may also dilute and weaken the associations between neural networks, leading to more impoverished cognitive processes. The model has received considerable empirical support, with most studies finding that a general speed factor is an important mediator of other cognitive processes, such as memory.

Neuropsychological models of age-related decline have attempted to integrate findings from cognitive testing with findings from brain imaging and neuropathological studies to suggest possible etiologies of cognitive changes. The most promising of these is a model variously termed the frontal deficit hypothesis or the executive function hypothesis, based on the finding that the pattern of cognitive performance in normal aging, although

less pronounced, is similar to that seen in many dementing processes affecting primarily subcortical–frontal circuitry. In addition, neuropathological data suggest that frontal–subcortical structures are the most vulnerable to aging, with many studies revealing that neuronal loss and degeneration of dendritic arborization are most prominent in the frontal cortex and in some subcortical areas. Further, there are definite changes in the vasculature of the brain with age that result in ischemic white and subcortical gray matter disease that predominantly affects cognitive processes mediated by frontal–subcortical circuits. Finally, a recent study found that age-related changes in the dopamine system, particularly declines in D_2 receptor availability in some basal ganglia structures, were related to age-related declines in performance on both motor and executive systems tasks. However, most studies have found that the executive functions appear to decline at the same rate as other cognitive functions and are not among the first age-related cognitive changes to be observed. This casts some doubt on their central role as mediators of age-related cognitive decline.

Finally, some authors have proposed a "common cause" model, suggesting that decrements in sensory functions, including visual and auditory acuity, may explain age-related changes in cognitive processes. As with the processing speed hypothesis, empirical support for this idea is generally strong, with most studies finding that sensory function is an important predictor of age differences in a number of cognitive processes. Nevertheless, it is clear that an as-yet-unnamed variable or group of variables remains unexplained in accounting for variance in cognitive aging, because most studies find that age-related variance remains even after both speed and sensory abilities are partialled out.

It is important to note that the line between a "normal" process of cognitive aging and a pathological process is not well drawn at present. For example, there is considerable disagreement in the field about the inclusion or exclusion of elderly subjects with medical conditions known to affect brain function or individuals with white matter lesions in studies of normal aging and cognition. Because these conditions affect such a high proportion of functional elderly persons, their exclusion may lead to erroneously high estimates of normal expectations of performance and the subsequent classification of many individuals as impaired. In addition, many older individuals without known cerebrovascular risk factors or other medical conditions have periventricular white matter lesions on MRI scanning, confusing further the line between disease processes and normal aging. At present, until this demarcation is better defined, the study of "typical" aging, which attempts to characterize the majority of elderly people, as well as the study of "optimal" aging, which attempts to characterize the ideal outcome of the aging process as well as characterize changes that are a function of aging itself and not epiphenomena of other conditions, are both

important pursuits, as long as the research questions are appropriate to the sample being used.

Finally, it may be that older adults' performance on cognitive testing may be affected by their own ageist stereotypes. A recent study found that when, prior to cognitive testing, older adults were "primed" with positive images of aging, their performance improved on measures of memory, as well as measures of memory self-efficacy, in contrast to older adults who were primed with negative images of aging.

SUCCESSFUL AGING

In recent years, there has been a paradigm shift in gerontology, from a view of aging as inevitable deterioration to one that includes the potential for development and growth. In this section, a number of studies were reviewed that, taken together, support this notion that the process of aging can be managed well by the majority of older adults. In this vein, the construct of *successful aging* was created. In the process, however, there has been considerable debate about how to define successful aging. It has become clear that if one defines successful aging as the absence of deficits in physical, cognitive, and social functioning, then few older adults would be so classified. A recent study examined both objective and subjective indicators of successful aging and found that only 10 percent of their sample could be classified as "successfully aged" based on objective criteria that included quantitative assessments of physical, cognitive, and social functioning and measures of well-being. However, when successful aging was defined as a subjective sense of having adapted well to the demands of life or was self-rated, many more individuals were characterized as having aged successfully. In a recent review of data-based studies, the proportion of successfully aged individuals ranged from 0.4 to 95 percent, thus underscoring this ongoing debate. In general, older adults rate social engagement and positive thinking as more important than physical functioning in their conceptualizations of successful aging. It is likely that any definition should include both objective and subjective definitions of success.

Studies have found that high education, absence of alcohol abuse and cigarette smoking, absence of depression, maintaining appropriate weight, regular exercise, and social support are all significant predictors of successful aging. Social class, however, does not appear to be an important predictor. Intrinsic psychological factors such as resilience, spirituality, and optimism have also been associated with successful aging. As more is learned about successful aging, both in terms of its psychosocial correlates and biological correlates, it may be that this knowledge can be translated into useful interventions that can improve the overall number of elderly reaching old age successfully.

IMPLICATIONS FOR CLINICAL PRACTICE

One of the major points of this section is that, with the exception of cognitive processes, age in and of itself is rarely an important predictor of outcome. Studies of mental health over the life span, coping and adjustment, and personality often fail to reveal any significant age effects, when other factors are controlled. In addition, research has revealed an often surprising degree of resilience in older adults. Therefore, the clinician working with older adults should not expect that age itself is a risk factor for poor outcomes. Unfortunately, this notion has probably been partially responsible for the underidentification of depression in many elderly cohorts; many clinicians used to believe that depression was a "normal" response to the aging process. Clearly, the life themes that older adults struggle with are different from those of younger adults, and the clinician should be prepared to deal with issues of loss, increasing dependency, and the struggle to come to terms with the past. In addition, the concept of resilience may be useful in psychotherapeutic work with older adults; clinicians can encourage patients to selectively invest resources in activities that they find especially gratifying.

The important exception to some of these conclusions may be individuals in the oldest-old category, or those over the age of 85. Research has shown that the oldest-old may be at a higher risk of social isolation than younger age groups, especially those without living children. Clinicians should be alert to the unique life situations faced by individuals in this age group, who may be especially vulnerable not only to isolation but also to increasing frailty and the cumulative deleterious effects of chronic medical conditions. Interventions that both provide social support as well as encourage alternative sources of social support such as senior centers may be especially helpful for individuals in this age group without living family.

In terms of cognitive processes, there are clear decrements in some but not all cognitive processes over the life span. However, with the exception of processing speed, these changes are generally of small magnitude. The result is that the typical changes in cognition should not significantly impact the clinical situation, either the psychotherapeutic encounter or the psychiatric consultation. Some older adults may require more repetition and explanation of material, especially material that is novel and highly abstract, but this can easily be managed with modifications of psychotherapeutic approaches. The pattern of cognitive decline seen in normal aging discussed in this section should alert the clinician to changes that deviate from this pattern that might be cause for concern, especially such things as difficulties with recalling information even after cueing, problems with basic attentional processes, problems with constructing basic two-dimensional designs, or language impairment. At the same time, clinicians need to be alert to the effects of negative age-related stereotypes

and its effects on both performance and self-concept.

Finally, it is worth noting that because research findings are based on the central or average tendencies of groups of individuals, the conclusions drawn often mask underlying heterogeneity. This may be especially true with the elderly, as research has shown that the variability of almost every construct studied, such as personality, cognition, health status, and income, increases over the life span. It is likely that this increased heterogeneity is a complex interactive process of increasingly individualized expressions of genetic predispositions in response to accumulating demands from the environment over the life span. Thus, the clinician working with older adults may have less precise guidelines or standards for normative expectations for elderly patients, because the elderly can present with a much wider range of behavior, personality, and life experience than is found in younger adults.

57.2e Neuropsychological Evaluation

BARTON W. PALMER, PH.D., AND GAURI N. SAVLA, PH.D.

INTRODUCTION

As medical technology advances rapidly, people are living longer, and are active well into "old age," typically considered to be 65 years of age and above. Nevertheless, this particular demographic is also at greatest risk for cognitive deficits related to cerebrovascular, systemic, psychiatric, and neurodegenerative illness. Comprehensive clinical care of older adults, therefore, should almost invariably include some consideration of the presence and influence of neuropsychological deficits. Cognitive decline is a core component of neurodegenerative conditions such as Alzheimer disease, Dementia with Lewy Bodies (DLB), Parkinson disease, as well as cardiovascular conditions such as strokes. Chronic metabolic illnesses (e.g., diabetes) and long-standing autoimmune diseases (e.g., multiple sclerosis) may also be associated with cognitive impairments.

Psychiatric disorders with typically earlier onset that often extend into later life, such as primary psychotic disorders or severe mood disorders, are also often (but not always) associated with mild to moderate deficits in neuropsychological functioning; these deficits tend to remain more or less stable over the course of the illness (i.e., there are rarely sharp declines in later life without the co-occurrence of a new-onset neurodegenerative illness). There is some emerging evidence that cognition in bipolar disorder may continue to deteriorate over time, with repeated affective episodes. This finding, if confirmed, could have particular relevance to older adults with bipolar disorder who have lived with the condition for decades. An important point to consider, however, is that cognitive deficits in

schizophrenia and bipolar disorder have a much stronger predictive relationship to level of adaptive functioning than symptoms of the primary psychopathology.

The bottom line is that an evaluation of neuropsychological functioning can be a critical component of effective diagnosis, and long-term treatment and care planning in geriatric psychiatry settings.

WHAT IS A NEUROPSYCHOLOGIST?

Neuropsychology as a field of scientific inquiry is not a profession or degree unto itself but as a clinical discipline it falls within the broader field of clinical psychology. The term "clinical neuropsychologist" refers to a licensed clinical psychologist, who, in addition to the broader training required for a doctorate and licensure in clinical psychology, has also completed additional training in structural and functional neuroanatomy, neuropathology, and neurobehavioral syndromes. A neuropsychologist, therefore, is an expert in scientifically grounded brain–behavior relationships.

WHAT IS A NEUROPSYCHOLOGICAL EVALUATION?

Standardized neuropsychological tests that measure cognitive abilities and deficits form the core of neuropsychological evaluation. However, neuropsychological evaluation involves much more than administrating and scoring tests. Valid and clinically useful interpretation of test performance requires the neuropsychologist to consider the examinee's performance within the broader context of his or her presenting complaint as well as prior medical history, psychosocial history, and functioning. Thus, in addition to the standardized assessment of neurocognitive abilities, comprehensive clinical neuropsychological evaluations generally include a thorough review of available medical records as well as a clinical interview of the patient and family or other collateral information sources. Personality and emotional functioning are also generally assessed via clinical interview, behavioral observations, clinical rating scales, and/or standardized psychological tests. Neuroimaging is also increasingly used to complement the results of these evaluations.

HISTORICAL DEVELOPMENT

The emergence of neuropsychology as a clinical discipline can be traced back to the early to mid-20th century, particularly the 1930s and 1940s when several pioneers of the field such as Ward Halstead and Arthur Benton began their studies of brain–behavior relationships using psychometric methods. Many of the tests developed or adapted by Halstead (and his battery as subsequently expanded by Ralph Reitan), as well as those by Benton remain core components of contemporary

neuropsychological test batteries. There was also early work on psychometric testing of intelligence and other cognitive functions, as exemplified by the work of Alfred Binet, as well as the Army aptitude testing programs that emerged during World War I. (These are, by necessity of space, only selected examples of a richer and more complex history of psychometric testing.) Another key contributor to the development of clinical neuropsychology was David Wechsler. In 1939, Wechsler published the first version of his Bellevue Intelligence Examination, followed in 1945 by its companion, the Wechsler Memory Scale. Many of the subtests in the Wechsler batteries were adapted from earlier sources. As collective batteries and with appropriate revisions and updates in the ensuing decades, the Wechsler scales have remained among the most widely used measures of cognitive functioning in patients as well as healthy individuals.

The development of modern clinical neuropsychology was fostered by the profound advances in regard to theory and empirical knowledge of brain systems and processes, brain–behavior relationships, and the effects of various neuropathological conditions on everyday functioning. The nature and quality of standardized normative data for valid interpretation of neuropsychological test results have also improved significantly. These advances have occurred in close collaboration with the growth in related fields, such as imaging, behavioral neurology, and cognitive neuroscience as well as in psychometric theory and practice.

COMMON USES OF NEUROPSYCHOLOGICAL EVALUATIONS

Neuropsychological assessment can be invaluable in geriatric mental health care settings; it can aide in the distinction between normal versus pathological cognitive and functional changes, differential diagnosis among neuropsychiatric and neuropathological conditions, and determination of long-term functional needs for treatment and care planning.

Despite the remarkable advances in clinical brain neuroimaging over the past few decades, their clinical relevance (particularly in regard to diagnostic specificity) remains equivocal. For instance, one of the most common concerns with older patients is distinguishing normal age-related changes from early Alzheimer disease or other neurodegenerative conditions. A second frequent presenting concern is determining whether an individual's reports of memory or other cognitive deficits are due to depression or primary neurocognitive dysfunction. With present technology, such distinctions are difficult, if not impossible, to make based on brain imaging results alone but can be readily made by considering the pattern of neuropsychological test performance together with the individual's current and prior medical and psychosocial functioning.

As an example, consider a patient presenting with a report of "poor memory." The term "memory" has a variety of meanings in colloquial use,
