In summary, the molecular structure of PPE-based amphiphilic block copolymers can predict its properties as a drug carrier. By varying the DP of the hydrophilic PEEP residues in triblock copolymers, the CMC can be varied. The ratio of hydrophobic to hydrophilic segments in the copolymer also varies asymptotically to CMC. The rate of drug release from diblock copolymers increases with increasing hydrophilic chain lengths, with at least 20% of drugs released within the first 18 h. There is no apparent impact of structure on drug-loading characteristics for the carriers discussed in this section.

1.123.10. Design of Thermoresponsive PPEs

Thermoresponsive biodegradable materials have attracted great attention because of their unique properties for a variety of biomedical applications. These amphiphilic materials are water soluble, but phase separates when heated above their lower critical solution temperature (LCST). This is attributed to the operation of a two-stage mechanism: a coil-to-globule transition, followed by aggregation of the resultant globules. Support for this proposition has been furnished by light scattering, fluorescence energy transfer, and time-resolved fluorescence anisotropy measurements (TRAMS).[70] There is a general consensus that rapid thermoreversibility of phase separation is effected by the collapse of polymer chains in aqueous solution, but opinions differ as to how to explain this phenomenon. Some favor the idea of a breakdown of polymer–water hydrogen-bonding interactions needed to maintain a coiled polymer conformation, whereas others attribute the polymer chain collapse to changes in the 'hydrophobic effect.' It is likely that both mechanisms occur, but one could dominate the other under varying circumstances. The thermodynamics of hydrophobic hydration on a molecular basis was comprehensively reported for PEO–water system.[71] As the mechanism of thermoresponsiveness in PPEs is likely the latter, we will provide a simplified summary below.

In a soluble (amphiphilic) polymer–water system, the polymer molecules (solute) are 'caged' within a dynamic three-dimensional (3D) network of water (solvent) as water molecules interact with hydrophilic moieties of the polymer, while the hydrophobic moieties of the polymer occupy the interstitial spaces of water network (this dissolution model is also called hydrophobic hydration). As the hydration shell forms around the caged polymer, the water molecules in the vicinity of the polymer chains are more restricted than their counterparts in the bulk region. This enhanced water structure around the polymer is energetically unfavorable ($\Delta S < 0$, hence $-T\Delta S$ is positive). However, the system remains soluble ($\Delta G = \Delta H - T\Delta S$, $\Delta G < 0$) because of a more favorable enthalpy term (ΔH). As temperature reaches the LCST, to continue to maintain a caged structure will require a significant gain of entropy relative to the bulk water molecules (which is now at a higher temperature). Now, the entropy term outweighs enthalpy, causing $\Delta G > 0$, and consequently phase separation ensues. The phase separation behavior is commonly known as the 'salting out' effect and can be metaphorically described as the polymer 'falling out of the cage' when the LCST is exceeded.

1.123.10.1. Molecular Structures of Thermoresponsive PPEs

The molecular structures of thermoresponsive PPEs reported are shown in Table 1(3-1 to 3-6). The thermal responsive behavior of PEEP was first reported by Iwasaki,[72] as shown in Figure 23. $PEEP_{100}$ has a thermal transition (indicated by the presence of an LCST) at 38 °C, indicating that this polymer may be dissolved in water primarily via hydrophobic hydration mechanism described earlier. Thermoresponsiveness is enhanced when a portion of the ethyl side chains is substituted by propyl groups (Figure 23). This enhancement is manifested by a sharper transition. As the proportion of isopropyl ethylene phosphate (IPP) is increased, thermal transition is shifted downward. It was also reported that the hydrodynamic size of $P(I_{24}E_{76})P$ increases from 6 nm at 20 °C to about 6 μm at 50 °C.

A systematic investigation was then conducted on the thermal responsive property of PEEP via PCL–PEEP diblock copolymers.[57] The LCST in the PCL–PEEP diblock copolymer exists if there is a high enough DP of PEEP. The $PCL_{25}PEEP_{42}$ diblock copolymer does not have an LCST. However, as the DP (PEEP) is increased to 103, incomplete transition, measured in terms of the percentage light transmittance, occurs. Full thermal transition is seen at DP (PEEP) 217 and 329. It can also be observed that with a higher DP (PEEP), the cloud point (temperature at which thermal transition occurs) is lower, indicating a downward shift of the LCST. The establishment of LCST in the PCL–PEEP diblock copolymer is attributed to the hydrophobicity of the PEEP side chains. PCL-P(EEP-MEP) is obtained when a portion of ethyl ethylene phosphoester (EEP) residues is replaced with less the hydrophobic methyl ethylene (MEP) residues. As the DP (MEP) increases, transitions are not only incomplete but also shift to higher temperatures until they are totally abolished, indicating abrogation of LCST in a DP (MEP)-dependent manner. On the other hand, the LCST is enhanced in PCL-P(EEP-PEP), where a portion of EEP phosphoester residues is replaced with more hydrophobic isopropyl ethylene residues (PEP) shown in Table 1 (3-4). Compared to the PCL–PEEP diblock copolymer, the LCST of PCL-P(EEP-PEP) is not only shifted lower, but the transition is also sharper. These data demonstrate a well-defined structure–LCST relationship. By tuning the side chains with the right hydrophobicity–hydrophilicity using appropriate proportions of ethyl and propyl groups, PPEs can be designed for a user-defined LCST with the desired sharpness of thermal transition.

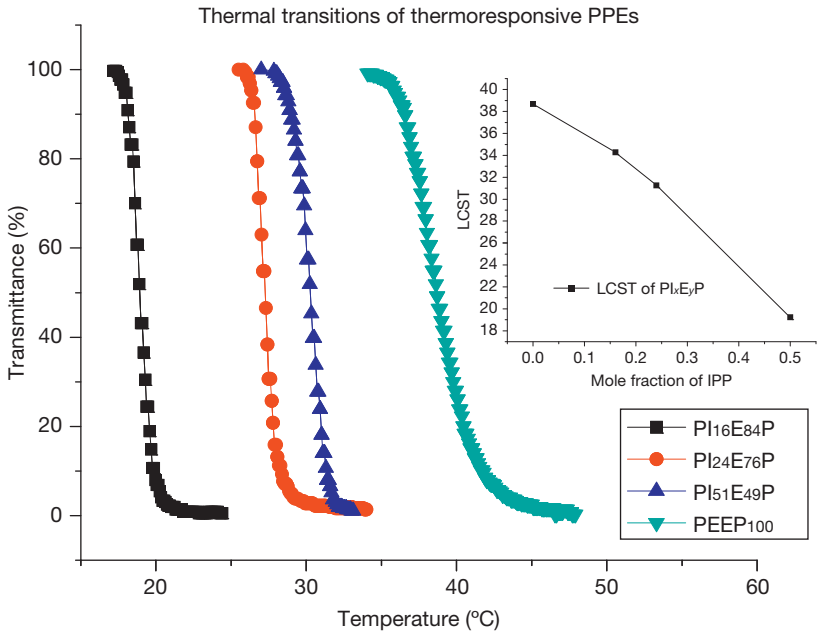

Figure 23 Thermal transitions of thermoresponsive PPEs. Replotted from Wang, Y. C.; Yuan, Y. Y.; Du, J. Z.; Yang, X. Z.; Wang, J. *Macromol. Biosci.* **2009**, *9*, 1154–1164; Wang, Y. C.; Tang, L. Y.; Li, Y.; Wang, J. *Biomacromolecules* **2009**, *10*, 66–73.

1.123.10.2. Effects of Solution Properties on Thermal Transition

For biomedical applications, it is crucial for polymers to retain functionality under physiological conditions. Thermal transitions of thermoresponsive PPEs discussed so far pertained to those dissolved in pure water. As thermoresponsive PPEs have been discovered only very recently, limited data is available on the effects of solution properties on the thermal transition of these PPEs. Such solution properties may include salt concentration, type of salts (mono- or divalent), pH, and the presence of other polyelectrolytes. Nevertheless, the effects of NaCl[57] and PBS[73] have been reported. Wang *et al.* reported that minute amounts of salt cause a downward shift in the LCST and also decrease the sharpness of the thermal transition. Increasing the NaCl concentration from 17 to 154 mM (isotonic saline) shifts the LCST toward lower temperatures but does not further deteriorate the sharpness of transition. As mentioned in an earlier section, phase transition occurs in two consecutive phases: coil-to-globule transition, followed by aggregation of newly formed globules. Iwasaki *et al.* reported that under favorable salt conditions (150 mM NaCl), globules once formed do not further aggregate. But when dissolved in PBS, globules continue to aggregate and eventually precipitate out of the solution. Thus, more work needs to be done to resolve the 'salting out' phenomenon.

1.123.10.3. Thermoresponsive PPEs Conjugated to PEG, Gold Nanoparticles, and Enzyme-Cleavable Side Chains

As mentioned earlier, a prominent advantage of PPEs is structural versatility, which can be translated to functional outcomes. Instead of PCL, PEG is conjugated to thermosensitive P(EEP-PEP) to form PEG-P(EEP-PEP) block copolymers for potential drug delivery applications.[74] The PEG moiety is desirous because of its ability to increase systemic circulation time by avoiding clearance via the reticuloendothelial system. The optimal hydrophobic/hydrophilic ratio needed for thermoresponsiveness can additionally be tuned by varying the segment lengths of P(EEP-PEP) and PEG, respectively. This is an added design flexibility compared to PCL-P(EEP*x*-PEP*y*) and PI*x*E*y*P, where this ratio is tuned by varying only the side chains of the PPE. The critical aggregation temperature (CAT), characterized by a rapid increase in hydrodynamic particle size (above 1 μm), increases with increasing PEG chain length but decreases with increasing PEP segment in the PPE backbone. The CAT is not the LCST, but correlates positively with it.

However, in drug delivery applications, particle size plays a significant role in the effectiveness of the drug delivery system. The CAT is useful as a heat trigger, but it would also be necessary to control the size of the final particle aggregates to achieve drug delivery efficacy. In a further investigation, the desired sizes of the $PEEP_{151}$–PEG_{2000}–$PEEP_{151}$ diacrylate micelle particles are first tuned via temperature and polymer concentration[75] (Figure 24). Diacrylate moieties are then activated to cross-link the core of the swollen particles (at high T) before allowing it to shrink (at lower T). These particles can later be mixed with drug molecules, swollen again at high temperature and cooled rapidly to encapsulate drugs in the interior.

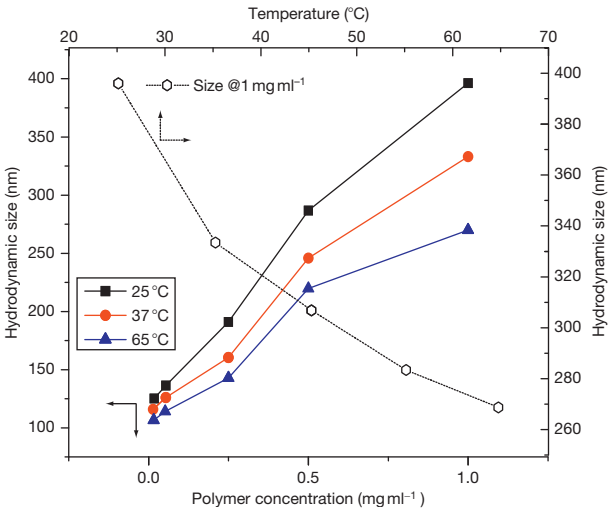

Figure 24 Effects of polymer concentration and temperature on particle sizes of $PEEP_{151}$–PEG_{2k}–$PEEP_{151}$. Replotted from Wu, J.; Liu, X. Q.; Wang, Y. C.; Wang, J. *J. Mater. Chem.* **2009**, *19*, 7856–7863.

Thermoresponsive PPEs modified at both terminal ends have also been reported,[76] as shown in Table 1 (3-6). In this case, one end of P(EEP–PEP) is capped by a PEG segment while the other end is capped by a thioctic acid. The resultant thioctate group can be reduced to release thiol groups, which are known to self-assemble into a monolayer on a gold surface. As a result, the thermoresponsive PPE is conjugated onto surfaces of gold nanoparticles, forming a heat-sensitive corona that extends itself below the LCST and collapses above the LCST. The sharpness of thermal transition of the thermoresponsive PPE–gold nanoparticle is not affected by the presence of gold, but the cloud point is shifted down slightly toward lower temperature, probably due to the thermal conductivity of gold.

A thermoresponsive PPE whose thermal transition can be abrogated by enzymes has also been reported.[73] A very small portion (~6%) of ethyl side chains of PEEP is substituted by acetoxymethyl ester groups, which can be cleaved by esterases. As a result, the thermal responsiveness is muted after 6 h and completely abrogated after 24 h. This is another example of how the chemical versatility of PPE facilitates functionalization and how slight changes to the polymer structure may mediate significant functional consequences.

In summary, thermoresponsive PPEs represent a recent development that should find many interesting biomedical applications. Starting from PEEP, which already has the right ratio of hydrophilic/hydrophobic ratio in its molecular structure for thermoresponsiveness, thermal transitions can be fine-tuned by modifying the main chain (using PEG) or the side chains (isopropyl groups). The polymer can further be modified at the side chains to become enzyme-sensitive or at its ends for conjugation onto gold nanoparticles. These thermoresponsive properties are sensitive to salt concentrations, while the interplay with other desirable PPE properties such as biodegradability and biocompatibility has yet to be investigated. Given these unknowns, more work on thermoresponsive PPEs is expected in the near future.

1.123.11. Design of PPE and PPA Gene Carriers

Polycationic polymers have been increasingly proposed as potential vectors because of their versatility. Rigidity, hydrophobicity/hydrophilicity, charge density, biodegradability, and molecular weight of the polymer chain are all parameters that in principle can be adjusted to achieve an optimal complexation with DNA. As the required characteristics of the DNA nanoparticles, or polyplexes, would differ on the basis of different cells or tissues, or different routes of administration *in vivo*, polymeric carriers with their versatility are well positioned to meet the challenges. Hence, the design of new polymeric gene carriers has been an intensively pursued research area in recent years. Polymers spanning the spectrum of biodegradable, biostable, linear, branched, dendrimeric, and cross-linked have all been investigated. This section concentrates on a series of PPEs and PPAs containing different charge groups in the side chain connected to the backbone through a phosphate (P–O) or a phosphoramide (P–N) bond, respectively. It highlights a systematic design of gene carriers with different strategies for dealing with the barriers of nonviral gene delivery. These PPA- and PPE-based gene carriers have different charge groups, side-chain lengths, and branching structures, but they are structurally related to allow a systematic investigation of the structure–property relationship, including DNA-binding capacity and protection, biodegradability, DNA release kinetics, and transfection efficiency.

1.123.11.1. Molecular Structures of PPE and PPAs Gene Carriers

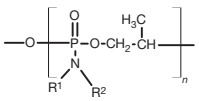
The pentavalency of a phosphorus atom in the backbone of PPEs makes it possible to conjugate functional groups, including charged groups through a phosphate (P–O) or a phosphoramide (P–N) bond as side chains. Starting from the parent polyphosphite, the P–H bonds can be readily converted for conjugation of different chemical structures. Consequently, it is possible to synthesize a series of cationic PPEs and PPAs from the precursor polymer poly(1,2-propylene-*H*-phosphonate) shown in Table 5. This backbone structure is chosen with consideration of biocompatibility. Comprising propylene oxide in the backbone, the potential breakdown products should be relatively innocuous as α-propylene glycol has a favorable safety profile compared to other diols. Conjugation of amino groups to this parent polymer produces water-soluble PPEs or PPAs that can complex efficiently with DNA. In keeping the chemical structure of the backbone and the molecular weight constant, effects of the charge groups on toxicity and transfection efficiency can be systematically studied to establish the structure–transfection efficiency relationship.

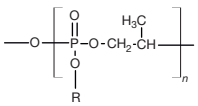
As the gene carrier design is centered on overcoming the various barriers to gene delivery, it would be useful to know these barriers to gene delivery and readers are referred to Mao *et al.*[54] for details. The transfection efficiencies of PPE/DNA complexes vary with a multitude of factors that fall into two categories. The first consists of extrinsic factors such as the nanoparticle composition (e.g., N/P ratio), the ζ potential of the nanoparticles, as well as the cell culture conditions. The second consists of intrinsic factors related to polymer structure, namely, the type of charged groups, length of the spacer, charge density, molecular weight, as well as the backbone structure.

1.123.11.2. Effect of Polymer Backbone on Gene Delivery Applications

For applications that require more stable nanoparticles and/or intracellular delivery, PPA carriers are more suitable than PPEs because the latter degrades at a much faster rate (because of the P–O bond). As such, applications of PPE/DNA particles are limited to local DNA delivery at the sites of injection, acting as a depot to prolong the gene expression in the muscle.[17,61,62,77]

Table 5 Structure of polyphosphoester and polyphosphoramide degradable gene carriers



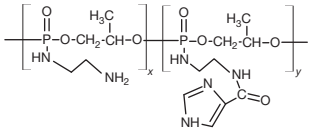


PPA with different types of charged groups	R1	R2
PPA-EA	–H	$-CH_2-CH_2-NH_2$
PPA-MEA	–H	$-CH_2-CH_2-NH-(CH_3)$
PPA-DMA	–H	$-CH_2-CH_2-N-(CH_3)_2$
PPA-TMA	–H	$-CH_2-CH_2-N^+-(CH_3)_3$
PPA with linear side chains		
PPA-EA	–H	$-CH_2-CH_2-NH_2$
PPA-PA	–H	$-CH_2-CH_2-CH_2-NH_2$
PPA-BA	–H	$-CH_2-CH_2-CH_2-CH_2-NH_2$
PPA with branching side chains (different lengths)		
PPA-DEA	$-CH_2-CH_2-NH_2$	$-CH_2-CH_2-NH_2$
PPA-EPA	$-CH_2-CH_2-NH_2$	$-CH_2-CH_2-CH_2-NH_2$
PPA-DPA	$-CH_2-CH_2-CH_2-NH_2$	$-CH_2-CH_2-CH_2-NH_2$
PPA-BPA	$-CH_2-CH_2-CH_2-NH_2$	$-CH_2-CH_2-CH_2-NH_2$

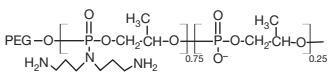
PPE with linear side chains

PPE-EA	$-CH_2-CH_2-NH_2$
PPE-MEA	$-CH_2-CH_2-NH-(CH_3)$
PPE-HA	$-CH_2-CH_2-CH_2-CH_2-CH_2-CH_2-NH_2$
PPE-HE	$-CH_2-CH_2-OH$

PPA with imidazole moiety



PEG-*b*-PPA



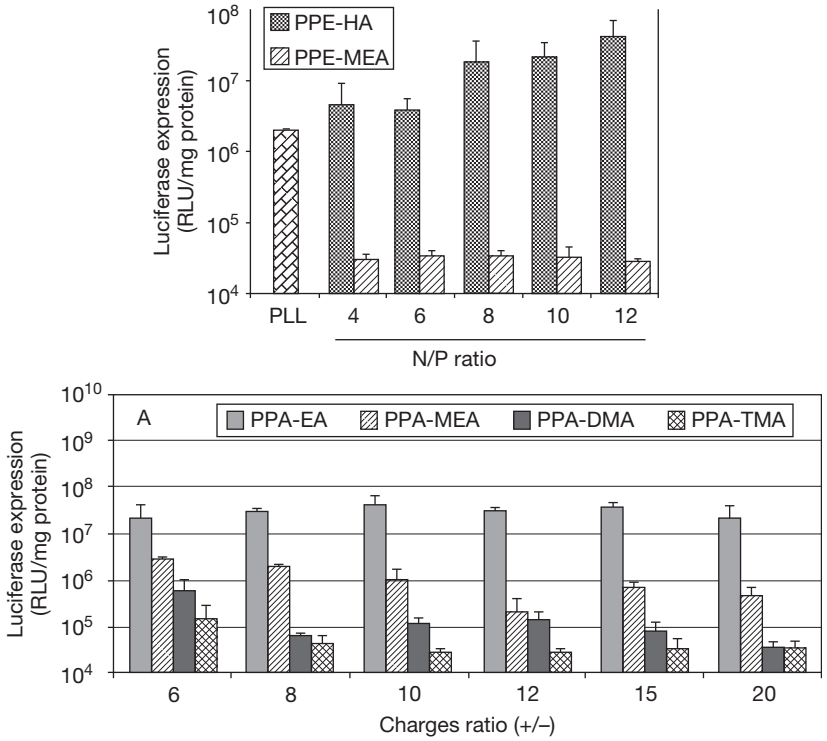


Figure 25 Effects of side chains on the transfection efficiency of PPE and PPA gene carriers. Reproduced from Wang, J.; Huang, S. W.; Zhang, P. C.; Mao, H. Q.; Leong, K. W. *Int. J. Pharm.* **2003**, *265*, 75–84, with permission from Elsevier; Wang, J.; Gao, S. J.; Zhang, P. C.; Wang, S.; Mao, H. Q.; Leong, K. W. *Gene Ther.* **2004**, *11*, 1001–1010.

On the other hand, applications of PPA–DNA particles may be more versatile and can be applied in systemic or oral delivery applications,[78,79] which require the carrier to be stable over longer periods of time. As shown in Figure 25, PPE/DNA particles generally mediate lower transfection efficiencies compared to their PPA–DNA counterparts, resulting in a dearth of information on PPE-based gene delivery system.

1.123.11.3. PPE/DNA Gene Delivery System

Among the three cationic PPEs studied, that is, poly(phosphoester)-ethylamine (PPE-EA), poly(phosphoester)-hexylamine (PPE-HA), and poly(phosphoester)-(methyl)-ehtylamine (PPE-MEA), DNA compaction capacity decreases in the sequence PPE-EA (highest) > PPE-HA > PPE-MEA (lowest).[62,80] PPE-EA, PPE-HA, and PPE-MEA can compact DNA completely at an N/P ratio of 1.0, 1.5, and 4, respectively. Based on gel electrophoresis DNA-retardation assays, the poor DNA compaction of PPE-MEA is due to the rapid degradation of PPE-MEA. GPC analysis further reveals that the side chains of PPE-MEA responsible for compacting DNA are rapidly cleaved during the degradation process. Of the three carriers, PPE-MEA releases DNA too fast to provide a meaningful depot, whereas PPE-HA degrades too slowly. The PPE-EA/DNA particle system is able to release DNA over a few days depending on the formulation, which is subsequently applied as a DNA depot for sustained release in a murine model following intramuscular and intracisternal injections. The success of this strategy is largely dependent upon the N/P ratio. Intramuscular injection of PPE-EA/DNA complexes at N/P ratios of 0.5 and 1 leads to a higher transgene expression than naked DNA injection for both a β-galactosidase expression model (in anterior tibialis muscle) and a systemic delivery model (interferon α2b expression in blood circulation) in Balb/c mice.[77] As the PPE-EA/DNA particles are prepared at higher N/P ratios, the enhancement effect is less pronounced but still higher than that of naked DNA control. However, the enhancement effect decreases (below naked DNA control) when the dosage of PPE/DNA nanoparticles exceeds a threshold value. In a central nervous system (CNS) delivery model,[81] PPE-EA/DNA complexes at an N/P ratio of 2, when injected intracisternally into the mouse cerebrospinal fluid, mediate a persistent level of transgene expression in the brain (mostly in cerebral cortex, basal ganglia, and diencephalons) for at least 4 weeks. At week 4, PPE-EA/DNA complexes maintain a 15-fold higher luciferase expression than naked DNA and about 3-fold higher than PEI/DNA complexes. The difference in optimal N/P ratio observed in these *in vivo* models demonstrates that the optimal carrier–DNA electrostatic interaction is different in different tissues. There can be no one-size-fit-all nanoparticle formulation.

1.123.11.4. PPA–DNA Gene Delivery System: DNA Compaction Capacity of PPAs

All PPAs listed in Table 5 exhibit high DNA compaction capability.[77,79,82] Plasmid DNA in these complexes is partially protected from enzyme degradation, as demonstrated using

DNase I as a model enzyme. The PPAs, except PPA-BA, are able to condense plasmid DNA completely at an N/P ratio of less than or equal to 1, suggesting that these cationic PPA carriers have a high DNA compaction capacity. Among them, PPAs with tertiary amino groups, quaternary amino groups, and those have branching side chains have a slightly higher DNA compaction capacity. At near neutral surface charge (N/P ratio ~1), PPA–DNA nanoparticles tend to aggregate severely in an effort to decrease the surface area to volume ratio. In addition, the average particle size also decreases as the N/P ratio increases because excess positive charges facilitate higher DNA condensation efficiencies. However, particle sizes hit a plateau at an N/P ratio of 8, beyond which excess polymers would not be incorporated into the nanoparticle and remain in the solution as free polymers. All PPA–DNA particles show similar average size ranging from 120 to 140 nm at high N/P ratios (>8). Under these N/P ratios, the surfaces of these particles are positively charged with a ζ potential of about 20–30 mV.

1.123.11.5. Effect of N/P Ratio and Cell Culture Conditions on Transfection Efficiency of PPA–DNA Particles

Similar to those of the other polycationic gene carriers, transfection efficiencies of PPA–DNA complexes are dependent on the charge ratio (N/P) of the carrier to DNA. For example, the transfection efficiency of PPA-BPA/DNA complexes in HEK 293 cells increases with N/P ratio, reaching a maximum at N/P ratios between 15 and 20.[80] In the presence of 100 μM of chloroquine (CQ), the optimal N/P ratios of PPA-BPA/DNA complexes shift to 5–10. Under these conditions, PPA-BPA/DNA nanoparticles transfect cells nearly as efficiently as PEI/DNA and transfast/DNA complexes in HEK 293 cells. As mentioned in an earlier section, PPA forms more stable nanoparticles suitable for delivery over longer durations. One such example is to deliver genes to the CNS through a retrograde transport model. This is a noninvasive approach to deliver genes to the brain by injecting polycation/DNA complexes to the peripheral muscle. Following intramuscular injection of PPA-BPA/DNA nanoparticles (formulated at a sufficient N/P ratio required for particle stability) to the mouse tongue where the hypoglossal motor neurons locate, bcl-2- expression is detected on day 2 in the brain stem of the injected mouse at a level similar to that obtained with PEI/DNA complexes. The nanoparticles are thought to be transported to the neuron body by the motor neuron in the injected muscle via a retrograde transport mechanism.[77]

1.123.11.6. Effect of Charged Groups on Transfection Efficiency of PPA–DNA Particles

PPA-mediated transfection is charge-group dependent, as illustrated in a series of four PPA carriers with an identical backbone, same side-chain spacer, similar molecular weights, but different charge groups containing primary to quaternary amino groups[82] (PPA-EA, PPA-MEA, PPA-DMA, and PPA-TMA, see Table 5). Although the DNA compaction capacities of these PPAs increase in the order PPA-EA (lowest) < PPA-MEA < PPA-DMA < PPA-TMA (highest), their transfection efficiencies decrease in the same order (highest for PPA-EA, lowest for PPA-TMA). PPA-EA/DNA complexes gave the highest transfection efficiency in cell lines at N/P ratios from 6 to 20 (Figure 25). The *in vivo* transfection efficiency of this series of PPA–DNA nanoparticles is evaluated in a rat spinal cord gene expression model following intrathecal injection of PPA–DNA nanoparticles at a charge ratio of 10.[82] Matching the trend of transfection efficiency observed *in vitro*, gene expression level in the spinal cord is dependent upon the type of charge group. At a DNA dose of 4 μg, PPA-EA mediates the highest transgene expression among all four carriers. The luciferase expression activity is comparable to that of PEI, but with lower tissue toxicity. PPA-MEA with secondary amino group side chain follows with a 3.5-fold lower luciferase expression. PPA-DMA and PPA-TMA are not effective in this model, giving only a background level of gene expression. At such, one aspect of structure–transfection relationship can be established. PPA carriers bearing primary amino groups mediate the highest transfection efficiency.

1.123.11.7. Effect of PPA Side-Chain Structure on Transfection Efficiency

The side-chain structure (length and branching of PPA side chains bearing the terminal primary amino groups) is also a factor,[83] as illustrated in a series of seven PPA carriers: PPA-EA, PPA-PA, PPA-BA, PPA-DEA, PPA-EPA, PPA-DPA, and PPA-BPA (Table 5). These gene carriers fall into two groups based on their branching structure of side chains: those with linear side chains and those with branching side chains. Those with branching side chains consequently possess a higher charge density (two positive charges per repeating unit). When PPA–DNA complexes are used to transfect HeLa cells, transfection efficiency correlates strongly with the branching structure of the side chain rather than the length of the side chain. Transgene expression by PPAs with branching side chains generally show about tenfold higher efficiency than those with linear side chains (Figure 26). However, transfection efficiencies are not sensitive to the length of the PPA side chains. The same trend is also observed in transgene expression in primary rat hepatocytes.[79]

1.123.11.8. Combinatorial Approach Nanoparticle Formulated with PPAs Bearing Different Charge Groups

As mentioned in an earlier section, the type of charge group significantly influences the transfection efficiency of the gene carrier. PPAs with primary amino group side chains show high transfection efficiency in culture, whereas PPAs with secondary, tertiary, and quaternary amino groups are significantly less efficient.[82] But it has been speculated that the high transfection efficiency of PEI is a result of the coexistence of primary, secondary, and tertiary amino groups in the PEI structure.[84] Reschel *et al.* also showed that, of all the polymethacrylamide carriers they synthesized, the highest transfection activity was found for a copolymer carrier containing both primary and tertiary amines.[85] Polyamidoamine (PAMAM) dendrimer is a class of polymer that comprises a mixture of primary amino groups (on the surface) and tertiary amino groups (in the interior). Tang *et al.* reported that the fractured dendrimers (by partial hydrolysis to expose the tertiary amino groups) show 50-fold higher transfection efficiency than the

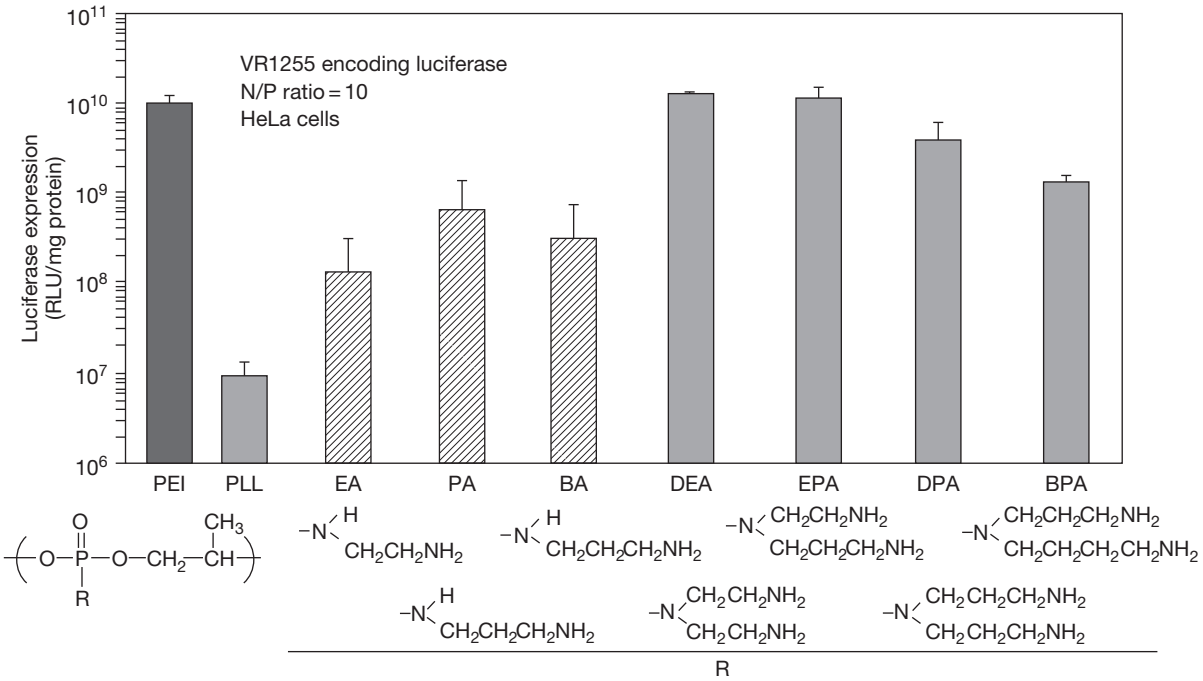

Figure 26 Transfection efficiencies of PPA with different side-chain lengths. Reproduced from Mao, H.; Leong, K. W.; Leaf Huang, M.-C. H.; Ernst, W. *Adv. Genet.* **2005**, *53*, 275–306, with permission from Elsevier.

intact dendrimers.[86] These results suggest that a combination of amino groups, other than primary amines, could enhance the transfection efficiency. However, the mechanism of enhancement is not clear at the current stage. Some groups claim that coexistence of different amine classes in the same polymer molecule enhances transfection efficiencies via proton-sponge effect (PEI) due to favorable apparent pK_a's.[87] However, this buffering effect occurs above physiological pH (8–10) and only a modest buffering effect is observed between pH 4 and 6[88] regardless of the amine class. Despite controversies surrounding the proton-sponge effect, it is certain that coexistence of different amine classes can enhance transfection efficiencies. Our work in PPAs also confirms this observation and will now be discussed.

Synthesizing PPAs with different amino groups in their side chains on the same polymer backbone in a controlled manner is challenging. Instead of synthesizing such a polymer, effects of different amine classes on transfection efficiency can be mimicked by formulating multicomponent complexes (e.g., formulating DNA with a mixture of two types of PPA: one containing 100% primary amino groups and another containing 100% tertiary amino groups). Such a ternary particle system containing DNA and PPAs with primary amino groups (PPA-SP, named as PPA-BPA in **Table 5**) and tertiary amino groups (PPA-DMA) was evaluated.[83] Transfection of COS-7 cells using the ternary complexes (PPA-SP/PPA-DMA/DNA) mediates significantly higher levels of gene expression than PPA-SP or PPA-DMA carrier alone, and the transfection efficiency is dependent on the ratio of the two carriers (**Figure 27**). Under optimal conditions (at a PPA-SP/PPA-DMA molar ratio of 4), the transfection efficiency achieved by the PPA-SP/PPA-DMA mixture is 20 and 160 times higher than PPA-SP and PPA-DMA-mediated transfection, respectively (**Figure 27**). Characterization of the nanoparticles and cellular uptake studies indicate that the enhancement in transfection efficiency by these ternary and quaternary systems appears to be unrelated to their particle size, zeta potential, or DNA uptake. In addition, the titration assay and the transfection experiment using a proton pump inhibitor suggest that the enhancement effect is unlikely due to the slightly improved buffering capacity of the mixture over PPA-BPA. Although the mechanism remains unclear, this study illustrates, from a different approach, that the charge group in the gene carrier, and in a general sense charge group in the nanoparticle formulation, is a crucial parameter determining the transfection efficiency of nanoparticles. This formulation method represents an alternative strategy to modulate the transfection efficiency of DNA nanoparticles.

1.123.11.9. PPA with Imidazole Moiety: Improving Buffering Capacity

All PPA and PPE carriers show a significant enhancement of gene expression in cell culture when chloroquine diphosphate (CQ) is present. This implies that these gene carriers have a low buffering capacity, a property that can facilitate endosomal escape of DNA or complexes into the cytosol. Imidazole moieties possess high buffering capacities. As the side chains of PPAs can be chemically modified, the buffering capacity of PPA carriers can be increased if imidazole groups are conjugated to the side chains of PPAs. As imidazolyl acetic acid is grafted on PPA-EA (two grafting densities were applied: 11 and 43%), the DNA-binding affinity of imPPA-EA (imidazole-modified PPA-EA) decreases as the imidazolyl conjugation degree

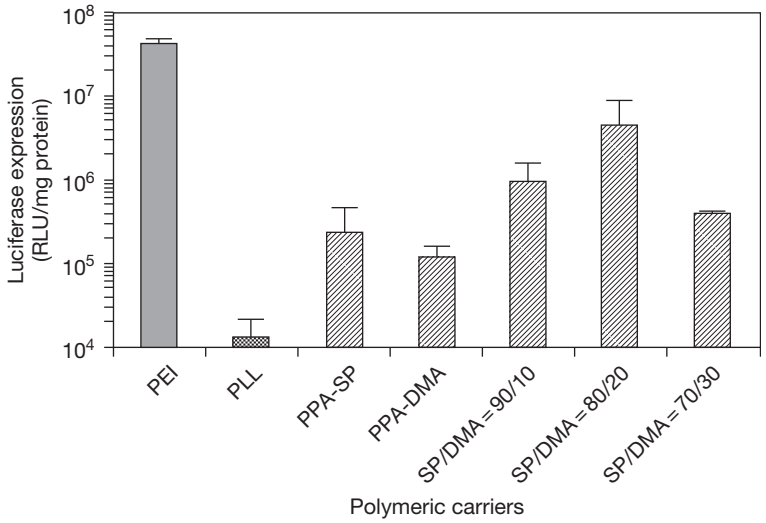

Figure 27 Transfection efficiencies of tenary PPA–DNA particles. Reproduced from Zhang, P.-C.; Wang, J.; *et al*. *Biomacromolecules* **2004**, *6*(1), 54–60, with permission from American Chemical Society.

increases. The minimum N/P ratios to completely complex plasmid DNA for imPPA-EA-11% and imPPA-EA-43% are 1.5 and 6.0, respectively. The ζ-potential of complexes at an N/P ratio of 8 decreases significantly from 34 mV to about 4 mV. Conjugated imidazole groups markedly increase the buffering capacity of imPPA-EA-43% above that of PEI. However, this does not translate into enhancement in gene expression. The transfection efficiency decreases as the imidazole content increases. This is most likely due to the reduced DNA compaction capacity of imPPA-EA, leading to a 'loose' complex. The average diameter of the complexes also increases substantially (from 78 nm for PPA-EA/ DNA to 746 nm for imPPA-EA-43%). These data indicate that DNA compaction capacity is crucial in maintaining the nanoparticle integrity and transfection efficiency.

1.123.11.10. Effect of on Transfection Efficiency by Ligand-Modified and PEG-Modified PPA

Transfection efficiencies may be increased by higher cellular uptake via receptor-mediated endocytosis. One such ligand–receptor pair is galactose and asialoglycoprotein found on hepatocytes. Effect of ligand modification on transfection efficiency is investigated by grafting galactose onto side chains of PPA-DPA with different degrees of ligand conjugation (6.5, 12.5, and 21.8%).[79] Due to multivalency effects, the affinity of Gal-PPA–DNA nanoparticles to galactose-recognizing lectin increases with increasing degree of galactose substitution. However, transfection efficiency for these galactosylated PPAs is decreased in HepG2 cells. This is due to the decreased DNA-binding capacity and decreased particle stability (similar to the observation of reduced transfection efficiency for imPPA-EA carriers discussed earlier). In order to overcome this reduced stability, DNA was precondensed with PPA at a charge ratio of 0.5, yielding nanoparticles with negative surface charge, followed by adding Gal-PPA to the required N/P ratio, resulting in a Gal-PPA–DNA–PPA ternary complex. Such a ternary nanoparticle formulation leads to significant size reduction compared to binary nanoparticles, particularly at low N/P ratios (2–5). In HepG2 cells and primary rat hepatocytes, and at low N/P ratios (2–5), transfection efficiency mediated by ternary nanoparticles prepared with 6.5% Gal-PPA is 6–7200 times higher than that of PPA-DPA/DNA nanoparticles.[79] Such an enhancement effect is not observed in HeLa cells that lack the asialoglycoprotein receptor (ASGPR). The improvement in transgene expression is most prominent at lower N/P ratios. Nevertheless, increasing the galactosylation degree of PPA carrier (higher than 12.5%) significantly reduces the stability of ternary particles, as well as the transfection efficiency. This study demonstrates that ligand conjugation (in this case galactosylation) of PPA carrier significantly affects the physiochemical properties of PPA–DNA nanoparticles as a result of the lowered DNA compaction capacity, reduced stability, and increased particle size. This is so despite the fact that galactosylated nanoparticles can efficiently recognize and bind to galactose-recognizing lectin moieties.

Pegylation is another common strategy in nanomedicine used to increase the transfection efficiency of nanoparticles via avoidance of the reticuloendothelial system and increased colloidal stability. PPA-DPA is pegylated by using PEG as the macroinitiator during the synthesis of PPA-DPA, resulting in the PEG-*b*-PPA copolymer.[78] When compared to PPA-DPA/DNA nanoparticles, PEG-*b*-PPA–DNA nanoparticles are slightly smaller (~100 nm) and possess a lower zeta potential (~+10 mV). Although the *in vitro* transfection efficiency of PEG-*b*-PPA–DNA particles (in primary rat hepatocytes) is lower than its unpegylated counterparts, the *in vivo* efficiency (via intrabilliary infusion of nanoparticles into bile duct, which eventually reaches the liver) is significantly higher. This study demonstrates that PEG is able to increase the transfection efficiency *in vivo* by preventing aggregation of PEG-*b*-PPA–DNA nanoparticles. However, no transfection is detected in lung, kidney, heart, and spleen. Given the fact PEG-*b*-PPA–DNA particles still possess a positive zeta potential, the degree of pegylation might not have been sufficient to avoid clearance by reticuloendothelial system.

In summary, this section highlights a systematic approach to the design of PPE and PPA gene carriers. PPA forms more stable DNA nanoparticles than PPE, leading to higher transfection efficiencies. Effects of charge groups, segment length, side-chain branching, and N/P ratios on the physiochemical properties of PPA–DNA nanoparticles and transfection efficiencies have been investigated. Effort to increase the buffering capacity and cellular uptake of the gene carriers has also been successful by conjugating imidazole moieties and galactose ligand, respectively, but produces overall disappointing results because of the offsetting factors of poorer DNA protection and larger particle size. Combinatorial approach of formulating particles with different classes of amines has proved to be moderately effective in increasing transfection efficiencies. PEG-modified PPA has been effective in reducing incidences of particle aggregation, leading to higher transfection efficiencies *in vivo*. Our investigations hitherto reinforce the notion that an integrative approach addressing all the barriers of the delivery process is crucial to the success of gene carrier development. Along this line, the versatility of the PPE gene carriers offers excellent opportunities for optimization.

1.123.12. Conclusion

In this chapter, we provided an overview of the basics of PLGAs and how they are applied in the context of drug and gene delivery as well as tissue engineering. In particular, different length scales of similar PLGAs differ widely in bulk properties and are consequently applied in different ways. Additionally, we also rigorously reviewed PPEs on how changes in molecular structure not only affect material properties at different length scales but also give rise to novel material properties. We also reviewed that it is possible to tune the material properties of PPE-based biomaterials by changing the molecular compositions of the PPE backbone or the side chains. As medical technologies increasingly demand more complex functions, the call for more sophisticated biodegradable polymers will correspondingly increase. Opportunities abound, for example, to innovate with more sensitive stimulus–responsiveness or shape memory to accentuate the dynamic properties of degradable biomaterials. The best days of biodegradable polymers are still ahead of us.

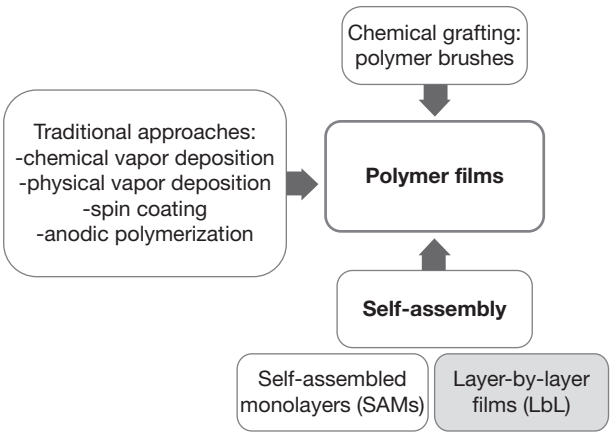
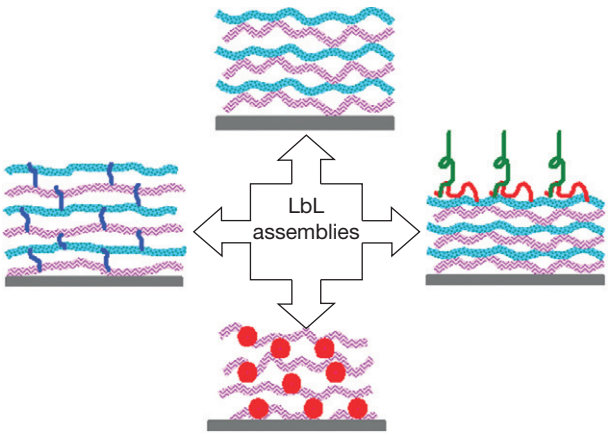
1.124.1. Introduction: Strategies for Surface Modification with Polymers

Along with the bulk properties of biomaterials, the chemistry and structure of biomaterial surfaces are critically important to assure desired biocompatibility, wear resistance, adherence or antifouling properties. Controlled surface modification is therefore the key to developing advanced materials with rationally designed biological responses. Polymer coatings can be deposited at surfaces using traditional techniques established for depositing inorganic materials in semiconductor and microelectronics industries, which include spin-coating, physical and chemical vapor deposition, sputtering, or anodic polymerization[1,2] (Scheme 1). Two other groups of techniques – chemical grafting and molecular self-assembly – include bottom–up approaches with significantly better molecular-level control of surface architectures (Scheme 1). For example, polymer brushes of various chemistry and grafting density can be fabricated at surfaces using a chemical grafting approach which can be subdivided into growing polymer brushes via surface-initiated polymerization or grafting presynthesized polymer chains to surfaces ('grafting from' and 'grafting to' approaches, respectively).[3] Another group of surface modification techniques includes molecular self-assembly which is represented by deposition of self-assembled monolayers (SAMs)[4] and layer-by-layer (LbL) polymer films[5,6] (Scheme 1). In the SAM approach, organic molecules are deposited at the substrate driven by the interaction between the head group of self-assembling molecules and surface-binding sites, while the choice of chemistry of molecular end-group affords great flexibility in decorating substrate surfaces with specific chemical functionalities. A similar advantage of molecular control of surface chemistry is also afforded by the chemical grafting approach. However, while both chemical grafting and SAM approaches are advantageous over more traditional polymer film deposition techniques, they are both significantly limited by the requirement of specific chemistry of the substrate surface. In particular, grafting approaches require decoration of surfaces with specific functional groups or initiators capable of supporting polymerization or grafting chemical reactions. The SAM approach is even more restrictive as it involves formation of covalent Si–O or strong thiol–metal bonds between organic molecules and the surface, and usually can only be applied to a limited number of surfaces, such as silicon, aluminum oxide, or noble metals.

Compared to the above surface-modification techniques, deposition of polymer films at surfaces using LbL self-assembly has emerged as a promising and versatile surface modification technique.[7–12] The LbL procedure is all-aqueous based, and is not restricted by specific chemistry of substrates or depositing polymers. Indeed, conformal LbL films can be produced on substrates of virtually any shape or chemistry. Film growth occurs as polymer molecules sequentially adsorb at a surface driven by a variety of interactions in aqueous environment, for example, through electrostatic interactions, hydrogen bonding, and hydrophobic forces, or even specific 'key-lock' type binding between biological molecules.[8,13] Recently, the versatility of the LbL technique was further extended by the demonstration that LbL films of noninteracting polymers can also be fabricated at surfaces by chemically reacting polymers using 'click chemistry.'[14] Besides earlier reported use of 'as-is' self-assembled multilayers, recent studies showed several promising opportunities in converting self-assembled LbL films into surface-bound functional hydrogels using postdeposition cross-linking followed by release of film components[15] (Scheme 2). Such soft, functional surface coatings have a multilayer-templated, nanoscopic level of control of film thickness, and are attractive for biomedical applications such as soft hydrogel coatings, which can also serve as 'depots' for controlled delivery of bioactive molecules from biomaterial surfaces. In addition, LbL films can also be used as base layers for further decorations of biomaterial surfaces with polymer brushes when one needs to achieve better



Scheme 1 Various techniques for depositing polymer films at surfaces.



Scheme 2 Possible ways of functionalizing surfaces using LbL self-assembly.

lubrication, biocompatibility or antifouling properties of polymer coatings. While the LbL approach has not yet made a strong appearance in everyday applications in practical biomaterials science, we believe that the technique will become a universal tool for engineering multifunctional coatings of next generation biomaterials. Therefore, in this chapter we will discuss fundamentals of depositing macromolecules at surfaces using the LbL technique, internal structure of LbL films, and postassembly modification of polyelectrolyte multilayers (PEMs) into responsive surface hydrogels, all with the central focus on understanding structure–property relationships of such coatings.

1.124.2. Fundamentals of Multilayer Formation: LbL Thin Films

The fundamentals and applications of LbL films as novel types of nanoscopically structured materials are summarized in several recent reviews.[13,16–19] The deposition procedure is temptingly simple and is often viewed as being applicable to virtually any pair of synthetic polyelectrolytes (PEs) or biological macromolecules such as proteins, enzymes, or nucleic acids. Indeed, a variety of interacting macromolecules have been successfully used for multilayer construction. However, here we would like to first focus on the fundamental correlation between the formation of polyelectrolyte complexes (PECs) in solutions and deposition of PEMs at surfaces, and discuss the rarely mentioned cases when such coatings cannot be constructed.

1.124.2.1. Electrostatic Self-Assembly of Polymers from Aqueous Solutions

1.124.2.1.1. Equilibrium and dynamics in PEMs: lessons from PECs

Cohen Stuart and coworkers[20] have clearly emphasized the correlation between the phase behavior of PECs in solution and the deposition of PEMs. Specifically, using a PE pair of poly(dimethylaminoethyl methacrylate) (PAMA) and poly (acrylic acid) (PAA), the authors observed overshoots in the total amount of polymers within a film at the step of the polycation addition. Kovačević *et al.*[21] found that erosion of PAMA/PAA PEMs at ionic strength of 5 mM was explained by the formation of a negatively charged water-soluble PE complex (WPEC) or positively charged WPECs during the deposition of polyanion or polycation, respectively. Because of the interrelationships in behavior of PEMs and PECs, understanding occurrences of PEM erosion is very important as it will eventually provide materials scientists with a 'map' of PEM growth enabling them to rationally avoid unstable regimes during film deposition.[22]

Limitations of the LbL technique were recognized in cases when no interpolyelectrolyte binding occurred, such as for polymers whose charge density is lower than critical.[23,24] Disruption of interpolyelectrolyte binding can also be salt-induced[25] and or pH-induced.[26–28] Other observations, however, were also made of removal of PE chains from the PEM when the substrate is brought in contact with PE solutions. Such chain removal has been reported by several authors[29–31] and is usually related to solubilization of adsorbed chains through formation of WPECs.[32] Competitive removal of PE chains from PEM to WPEC implies that chains remain strongly associated both in the PEM and WPEC, but redistribution of chains occurs, favoring WPECs and resulting in PEM erosion. One then concludes that strong intermolecular association between a pair of PE chains is not the only prerequisite for successful film deposition.

Indeed, when a PEM is brought in contact with a solution of free PE chains (a situation routinely occurring during PEM buildup), erosion of multilayers can occur. Under these conditions, one usually finds a large excess of PE in solution compared to an oppositely charged polymer within the film. For PE systems in which chain exchange occurs at the experimental time scale, such excess of charged chains in solution is most favorable for the formation of WPECs.[33]

Detailed understanding of competition between surface and solution as applied to PEMs requires either selective labeling of polymers and/or the application of techniques which allow chemically specific monitoring of film components, such as *in situ* attenuated total reflection–Fourier transform infrared (ATR-FTIR) spectroscopy. Using this technique, effects of a number of parameters, such as the type of interacting PE chains, the ratio of their lengths, as well as ionic strength and pH of deposition solutions, can be considered to determine the likelihood of multilayer stability or erosion.[22] **Figure 1**, top panel, shows data where 98% quaternized poly-*N*-ethyl-4-vinylpyridinium bromide (QPVP, M_w of 330 K, a polymerization degree DP_{QPVP} of 1600) was assembled with poly (methacrylic acid) (PMAA, M_w of 150 K, DP_{PMAA} of 1700) at pH 8.4, when both components are strongly charged.

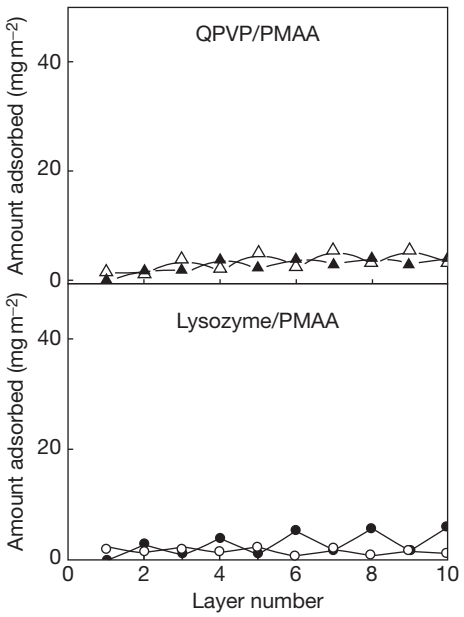


Figure 1 LbL deposition of ten layers in QPVP/PMAA (top panel) and lysozyme/PMAA systems (bottom panel). Assembly of PMAA (open symbols) and QPVP or lysozyme (filled symbols) were performed for 30 min from 0.1 mg ml^{-1} solution in 0.01 M phosphate buffer at pH 8. A similar failure in film deposition occurs when one tries to self-assemble a globular protein, lysozyme (Lys, M_w 14 600, p*I* 11.0), with PMAA at pH 8.4 where PMAA is fully ionized and Lys carries overall positive charge. As shown in Figure 1, bottom panel, Lys is completely removed from the surface to solution at the step of polyacid deposition, and adsorbed polyacid is, in turn, solubilized by Lys. In solution, strong binding between a positively charged protein and charged polycarboxylic acids was found, with formation of WPECs in excess PMAA.[34] Also, solubilization of PE chains by proteins of opposite charge has been observed earlier.[35,36]

In contrast, enhanced deposition of polymer layers, illustrated in Figure 2 (bottom panel), is dictated by the phase diagrams of WPECs (Figure 2, top panel), which shows that formation of water-insoluble complexes is thermodynamically favorable at relatively high salt concentrations. The equilibrated amounts adsorbed depend on phase diagrams for a particular polycation/polyanion pair and may vary greatly between systems. Interestingly, while multilayer formation is prohibited in 0.01 M phosphate buffer solutions, films exhibit significant growth when the concentration of counter ions becomes very low (less than 0.003 M buffer or salt solutions).

The type of PE has been shown to critically affect the binding energy and equilibration time of interacting PEs in solution. In general, polycations with high density of primary amino groups and polyanions with sulfate or sulfonate groups

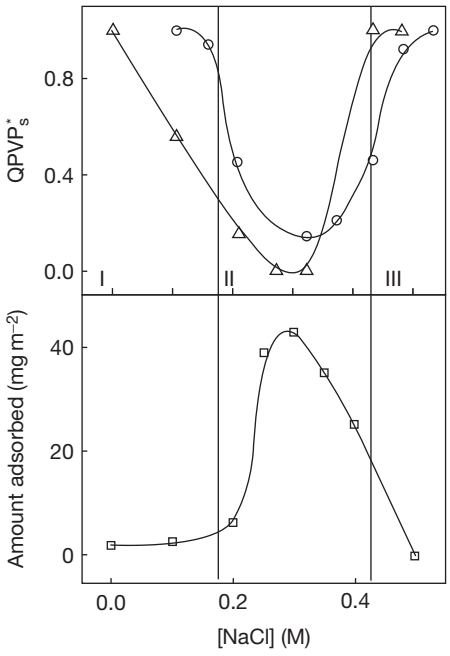

Figure 2 Top panel: Fraction of QPVP remaining in supernatants (QPVP*$_s$) of QPVP/PMAA mixtures for PMAA (M_w 350 K, DP 4000) in excess of PMAA, $f^+ = 0.167$ (circles) and in excess of QPVP (M_w 330 K, DP 1600), $f^+ = 0.833$ (triangles) plotted against concentration of added salt. Bottom panel: Total amount adsorbed of nine-layer QPVP/PMAA films deposited from solution with various salt concentrations. Concentrations of polymers were 0.04 M (in monomer units) in top panel, and 0.1 mg ml^{-1} in bottom panel. In all experiments, 0.01 M phosphate buffer at pH 8.4 was used. show the strongest interpolyelectrolyte binding, resulting in inhibited chain exchange within PECs and/or PEMs. With weakly bound PE pairs – polycations containing quaternary ammonium groups and carboxylate polyanions – WPECs are easily formed, often resulting in erosion of PEMs.

For easily equilibrating PEC systems consisting of polyamines with tertiary or quaternary amino groups and polyacids with carboxylate or phosphate groups, it was shown that WPECs are thermodynamically stable structures, with a measurable chain transfer rate between molecularly dispersed complexes.[37] Here, we consider cases where all participating polymers are highly charged, that is, either the case of strong polyacids and polybases, or weak polyacids/polybases exposed to pH values significantly higher/lower than their pK_a so that macromolecules can be considered strong PEs under these conditions. Binding of two oppositely charged PE chains results in formation of multiple polymer–polymer contacts. The multiplicity of polymer–polymer contacts within polymer complexes has major consequences for PE interactions. Therefore, the observation of chain removal during deposition of strongly charged PEs within PEMs is a common phenomenon when polycations with tertiary or quaternary amino groups and polycarboxylic acid chains are used.

Recently, a quantitative approach to evaluate the binding constants K_1 and K_n, where K_1 is the binding constant of the interacting monomeric units, and K_n is the binding constant between two interacting chains having n polymer–polymer contacts, was proposed based on studies of competitive reactions in three-component PE solutions. Interestingly, for 3,3-ionene/DNA and 3,3-ionene/PAA systems, K_1 values showed only a small difference (1.012 and 1.024 for 3,3-ionene/DNA and 3,3-ionene/PAA, respectively). However, for systems with polystyrene sulfonate (PSS), much larger K_1 values were found. Specifically, for PSS/poly-L-histidine systems K_1 was ~2, that is, twice that of DNA/poly-L-histidine[38] or DNA/3,3-ionene[39] complexes. The large difference reflected irreversible binding of PSS with the polycation in the presence of DNA. This finding is consistent with other reports that in mixtures of polyanions, a polycation preferentially binds with macromolecules with sulfonate and/or sulfate groups such as, poly (vinylsulfonate),[40] PSS,[41–43] or poly(vinylsulfate).[44] The presence of a small number of sulfate or sulfonate groups in the polycarboxylate polymer chains provides strong selective binding with a polycation in polyanion mixtures, even though the mixture contained polycarboxylate polyanions of much higher charge density.[45,46]

Strong binding of sulfate- and sulfonate-based polyanions with polycations also has a profound impact on kinetics of interpolyelectrolyte chain exchange. The first striking observation is a significant acceleration of the substitution reactions, that is, an increase in the transfer rate of polycations from carboxylate to sulfate- and sulfonate-based polyanions. The rate of chain exchange in PECs is enhanced in the presence of low molecular weight electrolytes due to screening and weakening of interpolymer electrostatic interactions.[37] For example, while transfer of QPVP from QPVP/PMAA WPEC to free PMAA chains occurred at a measurable rate in 0.05 M NaCl solution, the competitive displacement of PMAA from WPEC by incoming PSS chains required one order of magnitude lower concentration of salt.[42] Just as PSS is one of the strongest competitors

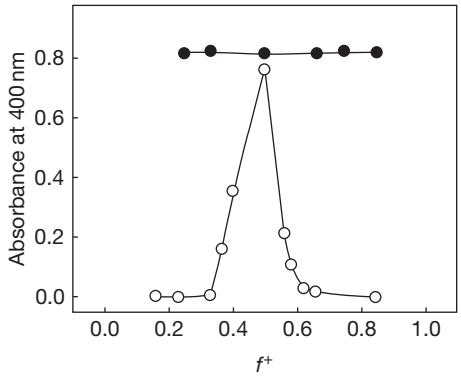

Figure 3 Turbidity of QPVP/PMAA (open circles) and PAH/PMAA (filled circles) mixtures measured as the absorbance of 0.04 M (repeat units) solutions at 400 nm as a function of the mole fraction of positively charged units f^+. The pH of 8.4 was supported by 0.01 M Trizma buffer. PMAA, QPVP and PAH with M_w of 72, 200, and 70 K, respectively, were used for the experiment. Reprinted with permission from Sukhishvili, S. for binding with polycations, polyamines containing primary amino groups are the strongest binders among polycations. When various polyamines were investigated for their binding with DNA, their association strength with DNA increased from quaternary to tertiary-, secondary-, and primary-amine polycations as amino groups became more sterically accessible. In addition, significant contribution of nonelectrostatic dispersive interactions to the binding energy is likely to occur in the case of PSS and/or primary-amine polycations.

Figure 3 contrasts phase behavior of polycation/polyanion mixtures in solution for strongly bound and weakly bound PE pairs. In mixtures of PMAA with the primary-amine polycation, poly(allylamine hydrochloride) (PAH), insoluble complexes are formed in a wide range of polycation-to-polyanion ratios, even when the excess of PMAA or PAH units is large. In contrast, solubility behavior of PMAA mixtures with the quaternized polyamine QPVP is drastically different: precipitation occurs only when f^+ is close to 0.5, that is, close to the equimolar charge ratio. Excess of PMAA or QPVP (at $f^+ < 0.35$ and >0.6, respectively) results in WPECs solubilized by either negative or positive charge in unpaired polymer units.

In contrast to QPVP/PMAA films whose deposition at a surface is greatly inhibited by exchange with solution (see Figure 1, top panel), the irreversible deposition of polymer chains at surfaces occurs under the same conditions for strongly interacting systems such as PAH/PMAA or PAH/PSS. Specifically, formation of very strong and irreversible ionic pairs affords high stability to PAH/PSS films and makes this system a favorite choice for multilayer buildup. Thus, as described above, the trends observed with multilayers directly correlate with properties of PECs in solution.

1.124.2.1.2. Internal structure of electrostatically assembled multilayers

Neutron reflectometry was first utilized to study the internal structure of dip-coated strong PE LbL films containing deuterated PE marker layers.[47–50] In PAH/PSS films, the intensity, width, and wavevector (Q) dependence of the superlattice reflectivity peaks produced by deuterated marker layers provides a wealth of information about the quality of layering within the LbL films. Polymer cationic or anionic components with individual layer thicknesses of several nanometers were partially intermixed, but strong evidence of internal layering was also observed. For example, in PAH/PSS films assembled at high salt concentration (>0.5 M) the interlayer roughness between adjacent PE layers was found to be on the order of 1.2–1.6 nm, comprising ~0.4 d_{bl}, where d_{bl} is the PAH/PSS bilayer thickness, indicating a well-defined layer structure with intermixing between adjacent layers of the same order as the layer thickness.[49,50]

Using neutron reflectometry, well-ordered layered structures were also found in the case of lipid layers[51] or multilayer films made of alternating sheets of rigid cellulose crystals and flexible PAH.[52] Internal layer ordering was shown to be influenced by external parameters such as pH, ionic strength, temperature, and humidity both during deposition and after postassembly treatment.[6,53–56] For example, increasing ionic strength or temperature during deposition resulted in increased interfacial mixing of PAH/PSS films.[57,58] Schlenoff and coworkers demonstrated that postassembly exposure of PEMs to high concentrations of salt (0.8–1.0 M NaCl) induces a significant increase in polymer interlayer mixing.[59]

Neutron reflectometry was also employed to resolve the structure of multilayers composed of weak PEs, which exhibit more diffuse polymer layering as compared to strong PEs.[60] As-assembled films show Bragg peaks characteristic of substrate-mediated layering within the film, as shown in Figure 4(a), with typical 'fussiness' found earlier for different electrostatically self-assembled films.[59,61] Neutron reflectometry applied together with *in situ* ATR–FTIR was used to study postassembly pH treatment of LbL films composed of weak PEs.[60] When a multilayer made of PMAA and a polycation with 20% of charged units (Q20) was deposited at pH 5 and then exposed to pH 7.2, about half the PMAA amount is released, while no mass loss is observed for Q20. The mechanism of response of weak polyelectrolyte multilayers (wPEMs) to pH variation involves pH-induced accumulation of excess charge within wPEMs, when the pH changes are in the region close to the apparent pK_a of a weak PE. *In situ* ATR–FTIR allows quantification of the pH-induced imbalance of negative to positive charges, which correlates with a rapid increase in ionization of self-assembled PMAA upon pH variations. When negative charges accumulate within the film as a result of pH variation, PMAA chains with excess charge are released into solution to bring the film charge ratio back to its original value close to unity.[60]

Importantly, multilayer structure of the weak PE films completely disappeared after pH-induced release of polyacid. The absence of periodic Bragg peaks in the reflectivity profile revealed mixing of the Q20 and PMAA layers, and the reduction of the total polymer layer thickness from 56 to 47 nm implies release of 35–38% of the PMAA originally present in the film (Figure 4(b)). However, after changing the solution pH back to its deposition value (pH 5) in the presence of deuterated PMAA (dPMAA), films recovered 95 ± 5% of their original thickness, implying complete reabsorption of dPMAA (Figure 4(c)). The constant scattering-length-density profile of

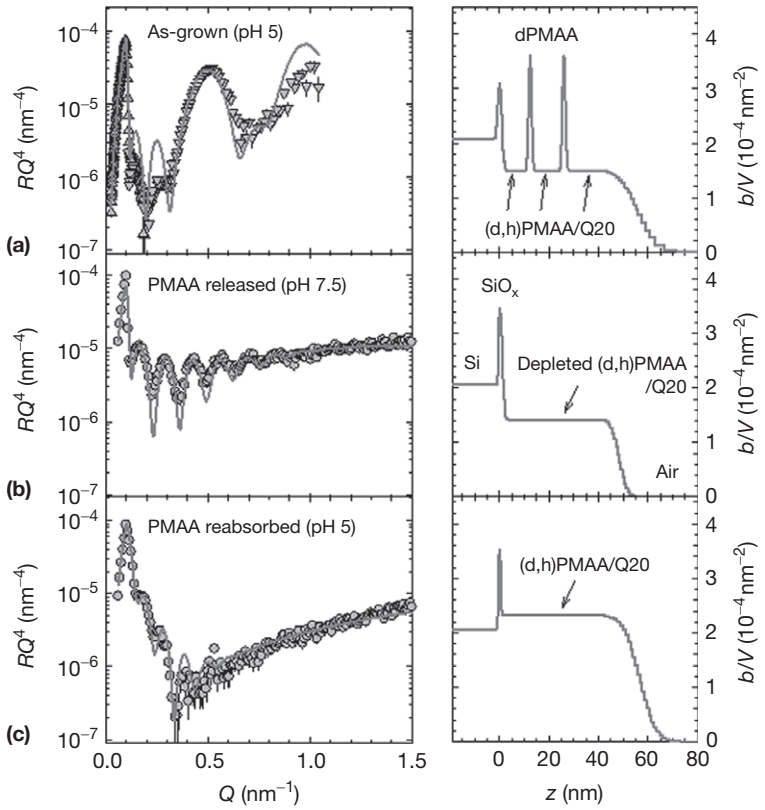

Figure 4 Neutron reflectivity data (left) for air-dried $((PMAA/Q20)_4/(dPMAA/Q20))_4$ films after deposition at pH 5 (a), after exposure to pH 7.5 (b) and after return to pH 5 (c) and fitted scattering-length-density profiles (right) obtained experimentally. Every fifth PMAA ($M_w = 22$ kDa) layer is deuterated to enhance neutron contrast. Reprinted with permission from Kharlampieva, E.; Ankner, J. F.; Rubinstein, M.; Sukhishvili, S. A. *Phys. Rev. Lett.* **2008**, *100*, 128303. Copyright 2008 by the American Physical Society.

the film after reabsorption suggests a uniform distribution of this material throughout the film.

Besides studies of conventional LbL films (obtained by alternating dipping from polymer solutions), neutron reflectometry was also applied to LbL multilayers constructed by spraying.[62,63] It was shown that spraying does not dramatically affect layering quality. However, the sprayed layers were 30% thinner than conventional dipped LbL films obtained under the same conditions.[63]

Neutron reflectometry was also applied to probe the internal structure of spin-assisted layer-by-layer (SA LbL) films composed of electrostatically assembled PEs.[64] SA LbL assembly has been introduced by Char and Wang as a combination of conventional LbL growth with spin coating and was shown to have several advantages over the conventional assembly.[65,66] First, it enables much faster film construction as compared to dipping assembly, and thus is considered to be more 'technologically friendly.' Second, SA LbL films have been found to possess remarkable physical properties, such as high mechanical robustness and strength. Based on this technique, a method to obtain flexible free-standing membranes with thicknesses down to 30 nm and lateral dimensions of several centimeters was developed.[67–69] Finally, SA LbL technique enables deposition of nonpolar hydrophobic moieties not possible using conventional LbL assembly.[70]

Application of neutron reflectometry uncovered distinct layering in SA LbL films when deposited from salt-free solutions and showed that the degree of molecular intermixing of film components could be controlled by varying the type and concentration of salt in the deposition solutions.[64] The addition of 10 mM phosphate buffer induced intermixing. The enhanced layer intermixing was explained as a result of weakening chain-to-chain interactions induced by phosphate buffer caused by an ability of phosphate ions to specifically interact with primary amino groups.[21,71] Indeed, the phosphate–PAH interaction results in partial neutralization of positively charged PAH segments and the formation of a loopy structure upon chain adsorption. However, the presence of 0.1 M NaCl in the phosphate buffer restored layer stratification. In addition, conventional dipped LbL films prepared under identical conditions from buffer solution displayed a more intermixed internal structure as compared to those made by SA LbL assembly.

1.124.2.2. Hydrogen-Bonded Self-Assembly of Polymers from Aqueous Solutions

Apart from LbL assembly of oppositely charged polymers, deposition of polymer films driven by the formation of hydrogen bonds has strongly emerged as a powerful technique. Hydrogen bonding is the key to defining the secondary structure and behavior of many biological molecules, including proteins and poly(nucleic acids). Synthetic chemists mimic approaches existing in nature when producing supramolecular polymeric

structures from short nonpolymeric building blocks.[72,73] In the case of synthetic polymers, multiple hydrogen bonding between polymer components was demonstrated to lead to deposition of LbL films. Since the discovery of such assembly more than a decade ago,[74,75] a great deal of research has been focused on the development of hydrogen-bonded (HB) films as promising surface coatings. This interest stems from the fact that HB LbL materials open new opportunities in LbL films which are harder to achieve with electrostatically assembled components. Specifically, the new attractive features of HB assembly include: (1) the possibility to include polymers which carry no charge; (2) the ease of producing films at mild pH responsive to environmental temperature and/or pH changes; (3) wide possibilities in converting HB films into single- or multiple-component ultrathin hydrogel materials. The above features enable future application of such assemblies as pH- and/or temperature-responsive drug delivery materials or release films compatible with biological tissues, as well as materials with tunable mechanical properties.

In aqueous solutions, the first example of HB assembly involved polyaniline self-assembled with a number of nonionic polymers, such as poly(vinylpyrrolidone) (PVPON), poly(vinyl alchohol) (PVA), poly(acrylamide) (PAAM) and poly(ethylene oxide) (PEO)[74] and a conjugated copolymer of the poly(phenylenevinylene) type containing hydroxyl groups which were capable of hydrogen bonding with amine groups of a co-self-assembled poly(ethyleneimine).[76] The use of aqueous solutions for HB assembly is, however, more attractive[77] as water is a friendly environment for biological and drug delivery applications. HB self-assembly of water-soluble polymers often involves a weak PE, such as a polycarboxylic acid, and a neutral polymer.[78–80] The inclusion of polycarboxylic acids allows for tuning the growth of HB films via variations of film constituents and deposition conditions. Because the HB assembly involves polymers which are electrically neutral, deposition is performed at acidic pH when polyacids are fully protonated.

1.124.2.2.1. Assembly, internal structure, and properties of HB films

As with other materials, HB films exhibit a close correlation between their structure and properties. Although in earlier studies HB multilayers have been assumed to be strongly intermixed,[81] the first direct observation of internal layering within HB LbL was studied using neutron reflectometry.[82] By applying this technique, it was shown that polymer layering deviated significantly from the ideal stratification of polymers within dense polymer layers (**Figure 5(a)**), and the degree of interpenetration of polymer layers, expressed as interlayer roughness, σ, strongly correlates with strength of intermolecular interactions between the adjacent layers. For the dPMAA layer closest to the substrate, the value of σ ranged from 35 to 60 Å for PVPON/PMAA, poly(*N*-vinylcaprolactam) (PVCL)/PMAA, and poly(*N*-isopropylacrylamide) (PNIPAM)/PMAA films. A new and interesting observation was that the polymer layers became more diffuse with increasing distance from the surface and as polymers deposited within the film were found in more random conformations (**Figure 5(b)**). For the PEO/PMAA system, films were completely interdiffused (**Figure 5(c)**), in agreement with weak intermolecular binding and exponential growth of PEO/PMAA films.

The key property of HB multilayers composed of neutral hydrogen-bonding polymers and polycarboxylic acids is that they can be erased by an increase in pH.[80] When carboxylic groups involved in hydrogen bonding become ionized, interpolymer hydrogen bonds are disrupted, eventually causing film dissolution at a critical value of pH (pH_{crit}). Extreme pH variations are not required to erase these films, and film dissolution occurs at slightly acidic or neutral pH values. With weaker hydrogen-bonding systems, films dissolve at a lower pH than that for stronger bound systems. The bilayer thickness of HB films correlates with the number of interpolymer binding points, determined by the intrinsic strength of interpolymer binding. For neutral polymers of comparable length, films

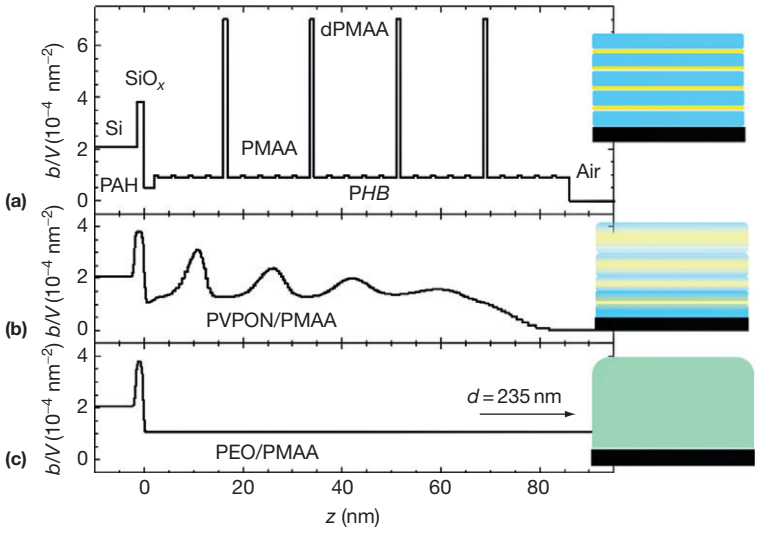

Figure 5 Hydrogen-bonded (HB) layers assuming perfect layering (a) and actual structure of HB LbL PVPON/PMAA (b) and PEO/PMAA (c) films. Scattering density Σ (defined as $\Sigma = b/V$, where b is a scattering length and V is a volume) is plotted against distance from Si template (z). PAH and PHB stands for poly(allylamine hydrochloride) and hydrogen-bonding polymers (PVPON or PEO), respectively. Reprinted with permission from Kharlampieva, E.; Kozlovskaya, V.; Ankner, J. F.; Sukhishvili, S. A. *Langmuir* **2008**, *24*, 11346–11349. Copyright 2008 American Chemical Society.

of PMAA with PEO, poly(vinyl methyl ether) (PVME), PAAM, or poly(2-hydroxyethyl acrylate) (PHEA) show higher bilayer thicknesses than strongly bound systems, such as PMAA assembled with PVPON, PNIPAM or PVCL.[77] Thicker bilayers in the case of PEO/PMAA and PVME/PMAA films are a result of more loopy conformations of self-assembled polymer chains. An analogy can be drawn with electrostatically assembled films where thicker layers are also reported for PEs with lower charge density. The morphology of HB films is also greatly affected by the type of polymer used in self-assembly. Hammond, Char and coworkers included a micelle-forming hydrophobically-modified PEO (HM-PEO) within HM-PEO/PAA HB LbL films and demonstrated that multilayers developed grainy morphologies.[83]

The dependence of bilayer thickness on molecular weight is strikingly different for strongly and weakly bound polymer systems. For example, the weakly bound PEO/PAA system exhibits an approximately sevenfold increase in bilayer thickness when PEO M_w was increased from 1.5 to 20 kDa.[84]

1.124.2.2.1.1. Effect of polymer solution pH

For both weakly bound and strongly bound HB films, bilayer thickness drastically decreased as deposition pH approached pH_{crit}. The effect of the deposition pH is very strong, allowing construction of HB films with bilayer thickness varying from several angstroms to hundreds of nanometers. For example, for PEO/PAA system, film thickness sharply decreased in a range of deposition pH from ~2.8 to 3.5, and films could not be deposited at pH 3.5 or higher. With PEO/PMAA films, this 'modulation window' of film growth inhibition was shifted to slightly higher pH values.[84] For stronger associated PVPON/PAA and PVPON/PMAA polymer pairs, films could not be deposited at a pH higher than 4.0[85] and 4.5, respectively.[77]

The effect of extremely low deposition pH on PVPON/PAA film thickness has also been studied. Films deposited from solution at pH 0.2–1.0 were very rough and unusually thick, with bilayer thickness around 48 nm. These large bilayer thicknesses were explained by the collapse of PAA chains into denser and less soluble globules at the extreme pH values where PAA becomes completely uncharged.[85]

1.124.2.2.1.2. Ionic strength of polymer solutions

There are many effects of salts on the growth of HB films. First, ions screen electrostatic charge within the film and, therefore, increase ionization of weak PEs. Secondly, they may interact with polymers in highly specific ways. Finally, the presence of salts might affect solubility of polymers. All these factors affect the individual layer thicknesses of polymers deposited within HB LbL films. In one example, the addition of monovalent and divalent salts in higher concentrations (higher than 0.5 M) during assembly of PEO/PAA systems resulted in inhibition of film growth[84] probably due to increased ionization of PAA. If both polymers remain uncharged, the effects of moderate concentrations of salts on the growth of HB films include dehydration and ion–dipole interactions and are usually smaller than those in electrostatically assembled systems. For example, in the case of strongly associated PVPON/PMAA films, film thickness increased by only ~10% when self-assembly was performed in 0.5 M NaCl solution.[77] Finally, salt can dramatically decrease the solubility of hydrophobic polymers resulting in thicker layers within the film, as in the case of deposition of a relatively hydrophobic poly(styrene-alt-(maleic acid))[86] within PEO/PSMA films, which gave layers twice as thick in 0.2 M NaCl as compared to those in 0.02 M NaCl solutions.

1.124.2.2.1.3. Temperature of polymer solutions

Caruso and coworkers demonstrated that PNIPAM/PAA films deposited from PNIPAM solutions[86] at 30 °C were of higher thickness and much lower roughness compared to films prepared at 10 or 21 °C.[86] Larger amounts of PNIPAM were deposited within the films when the lower critical solution temperature (LCST) of PNIPAM (32 °C) was approached and PNIPAM became less soluble in water. The behavior of other temperature-responsive polymers, PVME (LCST ~36 °C[87]) and PVCL (LCST ~35 °C),[88] was similar.[77] Bilayer film thickness increased with temperature even for films composed of PEO or PVPON and PAA[77] whose LCST is significantly higher than the temperature of deposition solutions (e.g., LCST of PEO is 100–150 °C depending on molecular weight).[89] Such an increase is due to a positive entropy of binding PEO with polycarboxylic acids,[90] which leads to a stabilization of HB multilayers at high temperatures.

However, if HB films contain a polymer pair with upper critical solution temperature (UCST), thinner layers are deposited within LbL films at higher temperatures.[91] One example is the PAAM/PAA system, for which the UCST of 20–25 °C was reported in the case of PAAM/PAA interpenetrated networks.[92] As temperature is raised above UCST, intermolecular hydrogen bonds between the polyacid and PAAM dissociate, resulting in thinner polymer layers within HB LbL films.

1.124.2.2.1.4. Concentration of polymer solutions

In addition to all the parameters listed above, thickness of HB films is also affected by the concentration of assembly solutions.[93] Similar to electrostatically assembled films, deposition of HB PVPON/PAA films at higher concentrations of assembly solutions resulted in larger amounts of polymer adsorbed at each deposition cycle.[93]

1.124.2.2.2. Temperature-controlled HB release films

Along with pH responsiveness, temperature can be used as an important trigger in manipulating properties of HB films containing temperature-responsive components. Application of HB PNIPAM/PMAA films as temperature-triggered platforms for releasing biological materials from surfaces has been explored.[94] Specifically, cells with attached patches (or 'backpacks') of electrostatically assembled LbL films were harvested from the substrate as a result of lowering the solution temperature to selectively dissolve the PNIPAM/PMAA surface stack and to release cellular backpacks from surfaces. Generality and the mechanism of such temperature-triggered release were studied.[95] Specifically, it was shown that deposition temperature of HB films containing PNIPAM, PVCL, or PVME as a temperature-sensitive neutral component plays a crucial role in pH-triggered dissolution of the films. For example, the critical pH of $(PNIPAM/PMAA)_5$ film disintegration shifted from 5.5 to 5.8 and to 6.1 when films were constructed at 10, 23, and 30 °C, respectively. Such drastic effect of assembly temperature on pH-stability of multilayer HB films of temperature-responsive polymers indicates stronger binding

of PNIPAM segments with PMAA at higher temperatures due to increased hydrophobic interactions.[82] This also correlated with the almost doubled bilayer thickness of PNIPAM/PMAA films deposited at 30 °C compared to that at 10 °C (8.7 nm vs. 4.4 nm, respectively). Importantly, temperature of postassembly solutions also critically affects the pH-stability of HB LbL films. For example, when PNIPAM/PMAA films built at pH 2 and 23 °C were immersed in solutions with increasingly high pH values at 10, 23, and 37 °C, the stability of the films went up from pH 5.2 to 5.8 and to 5.9, respectively. The increased film stability at temperatures close to the LCST is correlated with decreased solubility of PNIPAM and also with the hydrophobic stabilization of hydrogen bonding between PNIPAM and PAA. When poly(carboxylic acid)s were assembled with PAAM, a polymer with a UCST, the opposite effect of temperature on multilayer stability was observed. For example, the value of pH_{crit} decreased when temperature was raised from 10 to 37 °C due to the increased solubility of PAAM at a higher temperature which resulted in weakening intermolecular hydrogen bonds within the film. No such temperature-triggered change in the film pH stability was observed for HB films which did not contain temperature-responsive polymers. Importantly, by selecting different pairs of hydrogen-bonding polymers from a pool of neutral polymers and polycarboxylic acids, the working pH range for such temperature-triggered release films can be controlled and adjusted to neutral and slightly basic pH values. Specifically, the use of poly(ethacrylic acid) (PEAA) instead of PAA or PMAA in film assembly enabled construction of HB LbL films which can be released by applying temperature as a trigger at a near-physiologic pH. This feature makes this approach promising for future biomedical and tissue engineering applications.

1.124.2.3. LbL-Derived Hydrogels

Hydrogel matrix provides an ideal environment for hosting a variety of functional molecules such as drugs or proteins. Unlike macroscopic slab hydrogels, thin hydrogels (<100 nm) enable fast response to external stimuli.[96–98] At the same time, in contrast to polymer brushes,[99–101] SAMs or monolayers of adsorbed polymers, surface hydrogels possess high loading capacity to functional compounds. Such a combination of desirable properties is particularly valuable for applications in biotechnology.

Electrostatic interactions between polymer layers in a multilayer assembly are often used in fabrication of ionic LbL-derived ultrathin hydrogel films and membranes. Although highly swollen hydrogel-like structures can be fabricated using postassembly pH variations of non-cross-linked wPEM,[91] such films often lose their structure and rearrange after long-term exposure to extreme pH environments. HB multilayers, on the other hand, often readily dissolve at neutral and slightly basic pH values. Therefore, cross-linking is usually applied to convert LbL films to surface hydrogels.

The LbL-type surface hydrogels can be fabricated using sequential chemical cross-linking during self-assembly,[102,103] co-self-assembly of linear polymers with microgel particles,[104,105] or postassembly treatment of preconstructed LbL films via thermal-, photo-, or chemical cross-linking.[106,107] Conventionally assembled electrostatic or HB LbL films are converted into ultrathin hydrogels via cross-linking between self-assembled polymer chains of the same type, or between the two different types of polymers. The use of weak PEs for LbL hydrogel fabrication enables the use of pH to control loading and to trigger release of functional molecules from such matrices.

1.124.2.3.1. Hydrogels derived from electrostatically assembled multilayers

Glutaraldehyde (GA) is often used as a cross-linking agent in fabricating LbL-derived ultrathin hydrogels films because of its high solubility in water.[108] Cationic single-component LbL hydrogel films and capsules were initially synthesized by using selective cross-linking of chitosan by GA within chitosan/PAA multilayers.[109] The GA-treated chitosan/PAA films were exposed to carbonate buffer at pH 9 overnight to induce the pH-dependent swelling of the chitosan/PAA membranes as ionization of the polyacid increased. Such a treatment resulted in complete PAA removal from the cross-linked films leaving behind chitosan hydrogel LbL-derived films or hollow capsules. Swelling of the capsules was observed when the pH was changed from the neutral to acidic with a transition at pH ~5.5. By simply changing the cross-linking time, a different degree of cross-linking was achieved. A similar strategy was applied to various multilayer systems of electrostatically interacted weak PEs. For example, GA was also used to selectively cross-link PAH within PAH/PSS capsules via formation of a Schiff base between the aldehyde and the amine groups in PAH.[110] After cross-linking and exposure to pH = 12, the capsules slowly released PSS molecules from the cross-linked networks. After a 2-h cross-linking with GA and partial release of PSS, the permeation coefficient of these films to dextran molecules of M_w ~250 kDa decreased threefold as compared to the initial PAH/PSS capsules, probably due to partial polymerization of GA. In another work, a similar strategy was applied to selectively cross-link branched poly(ethylene imine) (PEI) within PEI/PAA LbL capsule membrane.[93] The resultant cross-linked PEI capsule walls contained physically trapped PAA chains.

Two-component LbL hydrogels can also be fabricated if both film constituents contain reactive functional groups. Carbodiimide chemistry is generally exploited for covalent cross-linking between amine or hydroxyl and carboxylic group-containing moieties of the PE components. For instance, the chemical cross-linking of hyaluronic acid/PAH (HA/PAH) multilayer films and capsules with a mixture of water-soluble carbodiimide, 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC), and *N*-hydroxysulfosuccinimide (NHS) produced biocompatible and noncytotoxic LbL-derived HA–PAH assemblies stable under low and high pH conditions.[111] If non-cross-linked, these HA–PAH assemblies dissolved due to ionization-induced swelling at pH <2 or >7.2. Biocompatible chitosan–alginate LbL capsules assembled from natural polysaccharides on calcium carbonate particles were also chemically stabilized with the GA treatment.[112] Both components, chitosan and alginate, were present in the capsule wall after GA cross-linking as confirmed by the FTIR. Along with the GA cross-linking, carbodiimide chemistry was applied to directly cross-link neighboring layers of chitosan and alginate to increase stability of the films toward

enzymatic erosion and to reduce the release rate of encapsulated indomethacin.[113]

Apart from chemical cross-linking, thermal treatment of electrostatically assembled LbL films and capsules has been applied as a way to stabilize LbL systems against pH-induced dissolution.[114] One example is thermal cross-linking of $CaCO_3$-deposited $(PAH/PAA)_4$ microcapsules at 180 °C for 2 h.[114] The thermal treatment stabilized the polymer network through the formation of PAH–PAA amide linkages. Interestingly, the capsules kept their shape even when severely swollen in highly acidic solutions. Under these low pH conditions, electrostatic pairing between PAH and PAA was disrupted, and the capsule walls were converted to positively charged ultrathin hydrogels capable of binding polyanions, such as PSS.[114]

1.124.2.3.2. Hydrogels derived from HB multilayers

HB LbL assembly of neutral polymers and poly(carboxylic acids) is another route of fabrication for ultrathin hydrogels. HB multilayers are uniquely suited for constructing responsive hydrogel films since polymer–polymer hydrogen bonds can be easily dissociated by exposure to mild values of pH. In contrast, in electrostatically assembled films, dissociation of ionic pairs is more problematic and, if possible, requires exposure to extreme values of solution pH. Therefore, stabilization of HB multilayers through covalent bonds has been recently developing as a novel technique in building ultrathin LbL hydrogel materials with unique properties.[115] The approach extended the use of HB films to neutral and basic range of pH, making such materials promising candidates for biomedical or biosensing applications.

Several cross-linking strategies have been explored to produce stable hydrogels from HB films, including chemical,[116] thermal,[107] or photo-cross-linking.[107] Carbodiimide chemistry has been widely applied to selectively cross-link poly(carboxylic acids) with ethylenediamine (EDA) within polyacid/nonionic polymer HB films or capsules.[117–119] The use of nonfunctionalized PVPON, PVCL, or PEO in the HB LbL assembly resulted in complete release of nonionic polymer from the cross-linked films upon exposure to high pH, yielding single-component polyacid hydrogel films or capsules. Using this route, single-component PAA, PMAA, or PEAA hydrogel membranes were derived from the corresponding HB LbL assemblies. An astounding feature of these membranes is that in a wide range of pH values there is no extensive noncovalent binding between units of poly(carboxylic acid), and that capsule walls, or the surface-attached LbL films exist as highly hydrated (up to 300% swellable at pH 7.5) ultrathin hydrogels.

Also, cross-links were introduced between both components within HB multilayer films and capsules. Rubner and coworkers have reported on PAAM/PAA or PAAM/PMAA hydrogel-like films and capsules fabricated via thermal, photo- or carbodiimide-facilitated formation of amide links between polymer counterparts.[120–122] Hydrogels with strongly enhanced swelling at high pH values were also produced using PVPON- and PVCL-based copolymers. To that end, PVPON- or PVCL-based copolymers with a fraction of units containing amino groups (PVPON-*co*-NH_2 or PVCL-*co*-NH_2, respectively)[123] were assembled with poly(carboxylic acids) through hydrogen bonding. Following exposure to solutions of water-soluble carbodiimide, amide links formed between PVPON-*co*-NH_2 (or PVCL-*co*-NH_2) and polyacid chains, resulting in two-component hydrogel-like films and capsules.[119,123]

Significant differences were found between single- and two-component hydrogel capsules derived from HB assemblies.[119,123] In the case of two-component capsules, when the pH was decreased below the critical value, hydrogen bonds between a neutral counterpart and poly(carboxylic acid) units were reformed. In the case of a single-component hydrogel system, lowering the pH-induced deswelling of such hydrogel capsule walls as a consequence of decreased polyacid ionization. Remarkably, both types of capsules reversibly changed their size in response to variations in pH and/or ionic strength (Figure 6). At the same time, distinct swelling hysteresis occurred in the case of two-component capsules (inset in Figure 6). In particular, larger capsule sizes were detected when the pH was lowered compared to those when the pH was increased. Significantly, at basic pH values, both types of hydrogel capsule walls did not contain HB polymers and were highly swollen.

Recently, hydrogen bonding between PAA and methylcellulose (MC) has also been successfully used as a platform for preparation of thin hydrogel films of 600 nm thickness.[124] Advantageously, these films could be cross-linked by heating at 120 °C for 2–6 h, and swelled at high pH producing freely floating films. HB capsules of hydroxypropylcellulose/PAA (HPC/PAA)[125] dissolved at pH higher than 3.3, and were converted into the pH-stable capsules with hydrogel-like walls through carbodiimide cross-linking between hydroxyl groups of HPC and carboxylic groups in PAA. These two-component LbL-derived hydrogels continuously swelled in the pH range

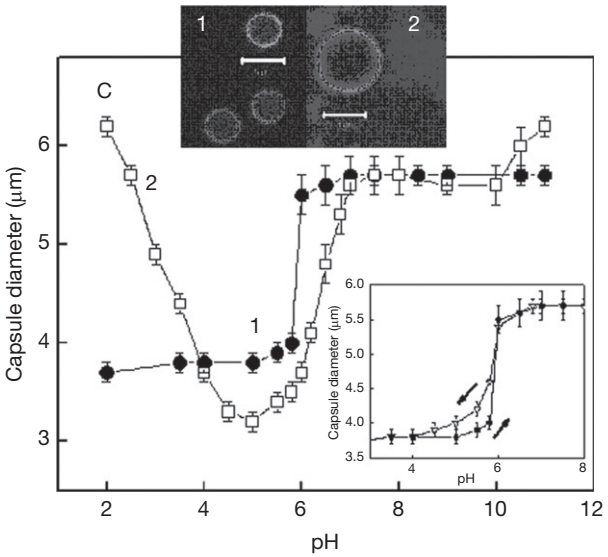

Figure 6 Confocal laser scanning microscopy (CLSM) images of $(PVPON\text{-}co\text{-}NH_2\text{-}20/PMAA)_7$ (1) and $(PMAA)_7$ (2) capsules at pH 2, scale bar is 1 μm; pH dependence of the diameter of $(PVPON\text{-}NH_2\text{-}20/PMAA)_7$ (curve 1, filled circles) and $(PMAA)_7$ capsules (curve 2, open squares) cross-linked for 18 h. The inset shows hysteresis of $(PVPON\text{-}NH_2\text{-}20/PMAA)_7$ capsule size upon increasing (filled circles) and decreasing (open triangles) pH. from 3 to 5 due to deprotonation of the carboxylic groups. The HPC/PAA cross-linked hydrogels required 5–15 days to reach the swelling equilibrium. The prolonged swelling kinetics observed for both lightly and heavily cross-linked HPC/PAA capsules was due to the hydrophobic nature and significant rigidity of the HPC chains.

1.124.2.3.3. LbL-derived hydrogels via click chemistry

An elegant approach to prepare single-component ultrathin LbL films and capsules of PAA via click chemistry was introduced by Caruso and coworkers.[14,126] In click chemistry, covalent reactions with high yields can be performed under mild conditions. Using azide- or alkyne-modified PAA polymers, stepwise growth of LbL films was demonstrated in the presence of copper(I) and sodium ascorbate in aqueous solution.[14] The deposition was promoted by the formation of 1,2,3-triazole cross-links.[126] However, the requirement for the use of copper in the azide–alkyne click chemistry reaction prevents the use of this approach for biological applications. Thiol–ene reaction was also explored for the fabrication of LbL hydrogels.[127] First, thiol-PMAA and ene-PMAA were LbL-assembled with PVPON and the PMAA layers were then cross-linked via thiol–ene reaction initiated by UV-light. The release of PVPON from the film at pH 7 resulted in layered PMAA hydrogel films.

1.124.2.3.4. Mechanical properties of the LbL-derived hydrogel films

Mechanical properties of pH-responsive hydrogel-like capsules were investigated using atomic force microscopy (AFM) single capsule force spectroscopy measurements.[128] The microcapsule stiffness of one- and two-component hydrogel capsules was dramatically pH-dependent. In the case of cross-linked PVPON-*co*-NH_2/PMAA capsules at pH 2, intermolecular hydrogen-bonding interactions of the hydrogel network dominated, and the capsule walls were rigid. Dramatic softening of (PVPON-*co*-NH_2/PMAA)$_7$ capsules occurred in a narrow range of pH between 5.4 and 6, as intermolecular hydrogen bonds dissociated at higher pH values (Figure 7). The corresponding decrease in stiffness of the walls was from 18 ± 9 to 1.4 ± 0.5 mN m^{-1} for pH 5.4 and 6, respectively. A decrease in stiffness from 550 ± 150 to less than 1 mN m^{-1} also occurred for single-component (PMAA)$_{10}$ hydrogel capsules. The large difference between the systems was due to the different capsule wall thickness of 20 and 7 nm for (PMAA)$_{10}$ and (PVPON-*co*-NH_2/PMAA)$_7$, respectively. The important finding was made that mechanical properties of LbL-derived hydrogels can be designed as switchable in response to environmental stimuli, with the switch triggered at mild pH conditions. This possibility of switching mechanical properties holds a significant potential for designing future-generation controlled delivery membranes and containers.

In a different system, a nanoindentation approach employing colloidal probe AFM was used to study the effect of cross-linking on the elastic properties of cross-linked poly(L-lysine)/hyaluronan (PLL/HA) films.[129] Higher concentrations of carbodiimide resulted in a larger number of cross-links within the film and enhanced film stiffness. Similar modulation of stiffness was used to tune cell adhesion properties of cross-linked films of a poly(carboxylic acid) and PAAM.[130] Highly swellable, with a swelling degree of more than 300%, low Young's modulus cross-linked films of PAAM/PAA and PAAM/PMAA were resistant to cell adhesion.

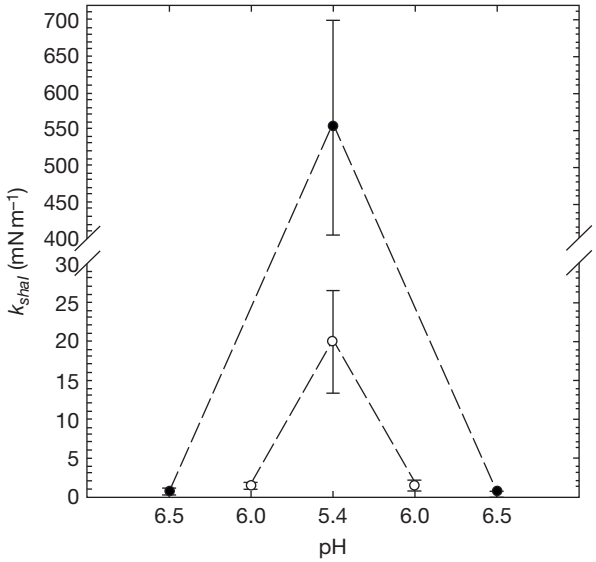

Figure 7 Reversibility of the softening process for cross-linked (PVPON-*co*-NH_2-20/PMAA)$_7$ (open circles) and cross-linked (PMAA)$_{10}$ (filled circles) microcapsules for pH changes from 5.4 to 6 or 6.5, respectively. 1.124.2.3.5. Applications of LbL hydrogels to controlled release of bioactive molecules

Hydrogels derived from HB LbL films are promising materials capable of pH-controlled loading and release of functional compounds. Specifically, loading of proteins and heparin within LbL-derived surface-attached PMAA hydrogels was studied *in situ* using ATR–FTIR and ellipsometry.[15] The loading of Lys, a protein with an isoelectric point of 11.5, within the PMAA hydrogels was fast and saturated after ~15 min when 0.1 mg ml^{-1} protein solutions were used. Almost 98% of Lys loaded at pH 7.5 released when the gel was exposed to pH 4 and carboxylic groups became completely protonated. Excellent correlation of the amount of Lys loaded within the film with the charge density of the PMAA hydrogels points to an essentially electrostatic nature of protein interactions with the hydrogel matrix. A similar trend of reversible binding of positively charged protein within PMAA hydrogels was obtained with another protein, ribonuclease. The hydrogel mesh size was large enough to allow transport of Lys globules through the hydrogel matrix. Negatively charged macromolecules such as heparin could also be included within the amphoteric hydrogels. The amount of heparin loaded at pH 3 was proportional to PMAA hydrogel thickness. Figure 8 contrasts the inclusion of heparin and Lys within surface hydrogels at various pH values. As in the case of Lys, heparin adsorption was irreversible towards dilution with buffer solutions at a constant pH. However, heparin was effectively released from the PMAA hydrogel upon an increase in pH, when the hydrogel carboxylic groups deprotonated and acquired negative charge.

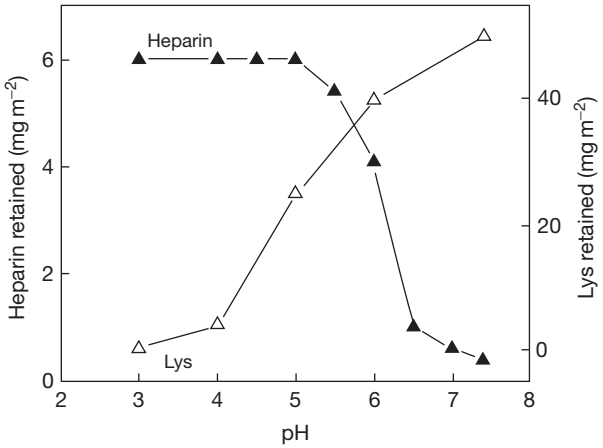

Figure 8 pH dependence of amounts of Lys (open triangles) and heparin (filled triangles) absorbed within $(PMAA)_5$ hydrogel as inferred from *in situ* ATR–FTIR and confirmed with ellipsometry. pH values were supported by 0.01 M phosphate buffer solutions. Reprinted with permission from Kharlampieva, E.; Erel-Unal, I.; Sukhishvili, S. A. *Langmuir* **2007**, *23*, 175–181. Copyright 2007 American Chemical Society.

In a similar way, at physiologic pH values of 7.5, the most abundant plasma protein, albumin, could not be included into the PMAA matrix due to size and charge considerations.

A possibility of constructing functional containers with biodegradable hydrogel walls has also been explored. The walls of such containers consisted of single-component PMAA hydrogel cross-linked via biodegradable disulfide links,[131] produced by treatment of HB multilayers of PVPON and cysteamine-modified PMAA (PMAA-SH) with hydrogen peroxide.[132] The PMAA capsules stabilized with disulfide bonds were able to load proteins, oligonucleotides, or DNA and then to release their cargo under reducing conditions.[133,134] For example, encapsulated fluorescently labeled protein, FITC-transferrin was released after deconstruction of the capsules in the presence of thiol–disulfide exchange reagent – dithiothreitol.

1.124.2.3.6. Nanoparticle-containing layered hydrogel films

The LbL-derived hydrogel matrices in their swollen states possess large number of functional groups able to attract various metal or metal-containing ions. This advantage can be successfully used for the creation of nanoparticle-loaded thin hydrogel coatings by incorporating presynthesized nanoparticles within such hydrogels, or by using the hydrogels as templates for *in situ* synthesis of nanoparticles.

In situ synthesis of nanoparticles has been applied to carbodiimide-cross-linked PAAM/PAA HB precursor matrices to fabricate silver-loaded ultrathin hydrogel films and capsules.[120,121] Metal ions were bound to the carboxylic acid groups when the films were suspended in aqueous solutions of silver acetate and Ag was reduced in the presence of borohydride. Multiple ion loading and reduction cycles were performed to increase nanoparticle size. While the above approach of using carboxylic groups of the hydrogel as binding sites for metal precursor ions is useful for the synthesis of Ag/hydrogel composites, it cannot be used for *in situ* synthesis of gold nanoparticles, as hydrogel

carboxylate groups and $[AuCl_4]^-$ ions are both anionic. The direct synthesis of gold nanoparticles within layered PMAA hydrogel capsules was demonstrated for hydrogels cross-linked with EDA.[135] The $[AuCl_4]^-$ ions were bound with a fraction of amino groups of one-end-tethered EDA cross-linker within the hydrogel. Well-dispersed gold nanoparticles of 10 ± 2 nm were obtained within PMAA hydrogels (Figure 9). Importantly, the pH-responsive properties of the PMAA hydrogel capsules were preserved after the formation of gold nanoparticles. Combining unique properties of metal nanoparticles (localized surface plasmons, thiol-based tethering of biomolecules to nanoparticle surfaces, or antibacterial properties in case of silver nanoparticles, enhancement of mechanical rigidity, biocompatibility and nontoxicity of gold nanoparticles) with responsive behavior of ultrathin LbL-derived hydrogels can result in materials crucially important in biosensing and delivery of functional cargo.

1.124.3. Conclusions

Recent developments in LbL-based surface modifications demonstrate the power of this technique in engineering surface

coatings with controlled thickness, architecture, nanoscopic structure, and mechanical properties. The technique is applicable to the deposition of a broad range of functional polymers at a variety of surfaces including biomaterials, and the deposition procedures for LbL coatings may be varied from sequential dipping to spin-coating[66] or spraying.[136,137] The use of chemical approaches to LbL films, such as postassembly cross-linking, or chemical reactions during polymer assembly, enables fabrication of soft hydrogel surface coatings with controlled thickness and swelling capabilities. Such highly swollen surface coatings are excellent candidates for controlling cellular adhesion and spreading, or endowing surfaces with antifouling properties. Furthermore, LbL hydrogels can be used as versatile matrices for loading and controlled release of bioactive molecules. Versatility of the LbL approach and its value to modification of biomaterial surfaces can be further enhanced by combining the LbL technique with chemical grafting of polymer chains, including polypeptide sequences, to the LbL matrix. Such surface constructs will be capable of dual control of biomaterial interaction with biological tissues by delivering bioactive compounds from the bulk of the film, while additionally controlling cellular adhesion through grafted chemical moieties. These opportunities make LbL films promising candidates for modification of biomaterial surfaces.

Abbreviations

APPJ	Atmospheric pressure plasma jet
DBD	Dielectric barrier discharge
DMAc	Dimethylacetamide
DMBA	Dimethylol butyric acid
DMF	Dimethylformamide
DMPA	Dimethylol propionic acid
DSC	Differential scanning calorimetry
EB	Electron beam (radiation)
EO, EtO	Ethylene oxide
ESC	Environmental stress cracking
ESCR	Environmental stress cracking resistance
HALS	Hindered-light amine stabilizers
HEMA	Hydroxyl-ethyl methacrylate (2-Hydroxyethyl 2-methylprop-2-enoate)
HEPA	High efficiency particulate air (filter)
HMD	Hexamethylene diamine
HMDI	Hexamethylene diisocyanate (1,6-diisocyanatohexane)
IAB	Intraaortic balloon
IARC	International Agency for Research on Cancer
IM	Interfacial modification
IPDI	Isophorone diisocyanate
LDI	L-Lysine methyl ester diisocyanate
LEE	Lysine ethyl ester
LMED	Lysine methyl ester diisocyanate
MDCI	Dicyclohexylmethane 4,4′-diisocyanate
MDI	Methylene diphenyl diisocyanate isomers
MIDE	2,2′-(methylimino)Diethanol (2-[2-hydroxyethyl(methyl)amino]ethanol)
MIO	Metal-oxide-induced oxidation
PAEK	Polyaryletherketone
PBA	Poly(butyleneadipate)
PCL diol	Poly(ε-caprolactone) diol
PDMS	Polydimethylsiloxane (also PSX)
PEEK	Polyether ether ketone
PEU	Poly(ether urethane)
PHB–PHV	Poly(hydroxybutyrate)–poly(hydroxvalerate)
PHMC	Polyhexamethylene carbonate
PHMO	Polyhexamethylene oxide
PIB	Polyisobutylene
PIBd	Polyisobutylene diol
PO	Propylene oxide; epoxypropane
PPG	Polypropylene glycol
PSX	Polydimethylsiloxane (also PDMS)
PTG	The Polymer Technology Group (now DSM Biomedical)
PTMO	Polytetramethyleneoxide (varying molecular weight)
PUs	Polyurethanes
PUT	Putrescine; 1,4-diaminobutane
PUU	Polyurethane urea
RBD	Resistive barrier discharge
RIM	Reactive injection molding
RTV	Room temperature vulcanizing (silicone adhesive)
SAM	Self-assembling monolayer
SAME	Self-assembling monolayer end groups™
SME	Surface-modifying end groups™
SPU	Segmented polyurethane
TAH	Total artificial heart
THF	Tetrahydrofuran
TMP	Trimethoylpropane; 2-(hydroxymethyl)-2-ethylpropane-1,3-diol
TPCU	Thermoplastic polycarbonate-urethane (e.g., Bionate®)
TPU	Thermoplastic polyurethane
TSPU	Thermoplastic segmented polyurethane, also thermoplastic silicone-polyurethane
VAD	Ventricular assist device

1.125.1. Introduction

1.125.1.1. The Polyurethanes and Polyurethane-Ureas

Since the 1960s, polyurethanes (PUs) have been used in the most demanding medical devices and prostheses. As blood- and tissue-contacting components of well-designed chronic implants, they can maintain a function for years while continuously flexing, bearing high loads, or maintaining electrical insulation. With improvements in biostability and the control of bulk and surface properties occurring at a rapid pace, polyurethanes are likely to remain important biomaterials for many years to come.

Macromolecules that contain urethane and/or urea linkages constitute one of the largest classes of industrial polymers – not in volume produced, but in terms of possible structures and compositions. In the 1960s and 1970s, a few members of this

huge family of materials were successfully adopted as biomaterials and continue to be used today. These early polyurethanes with trade names like Lycra®, Adiprene®, Estane®, Pellethane®, and Q-Thane®, were industrial polymers originally developed for a variety of nonmedical applications ranging from shoe soles to textile fibers. Given that they were used with little or no modification, it was serendipitous that they had properties useful to medical device designers. A few false starts in early medical applications did occur, however, when certain compositions now known to degrade in the body were used in chronic implants in which biostable materials were needed. Unfortunately, these exceptions have persisted in the public and scientific consciousness, perpetuating numerous myths and inaccuracies about the suitability of polyurethanes as biomaterials. In addition, the almost limitless variety of polymers commonly referred to as 'urethanes' contribute to the confusion about their suitability as biomaterials. A few commercial suppliers took advantage of this to promote their own polymers in medical applications, adding still more confusion.

The most successful early 'urethane' biomaterials were rubbery polyether-containing elastomers that were found to perform well, particularly when used in contact with blood. One of the most important early uses was as the material of construction of total artificial hearts, ventricular assist devices, intraaortic balloons, and pacemaker leads. The availability of tough, flexible polyurethanes made possible a sea change in the options for treating heart disease. This is especially true in the case of early balloon-, sac-, and diaphragm-type cardiac assist devices, which required thromboresistant materials with outstanding flex life. Certain 'segmented' polyether-urethanes, for example, Biomer™ and BioSpan®, adopted from early DuPont spandex fiber chemistry, provided a unique combination of these two properties that was unavailable in any other elastomer (Figure 1).

Forty years after their initial use in cardiovascular implants, polyurethanes have become important materials in many other biomedical applications, including orthopedic implants, neurostimulation devices, and selectively permeable dense membranes for *in vivo* sensors and drug delivery. This has occurred because new compositions have been developed *specifically* for biomedical use, supported by structure–property relationships elucidated by a number of academic and industrial researchers. The tailoring of physical–mechanical properties is now very straightforward, at least within the narrow group of so-called segmented or block copolymers that have become platform biomaterials. Likewise, the control of permeability is fairly well understood. However, the study of how structure and composition affect biostability has probably had the biggest influence on the growth of polyurethanes as biomaterials. This understanding has supported the continual improvement of the *in vivo* stability of polyurethane biomaterials, driven by the clinical demand for longer service life of prosthetic implants and life-supporting devices.

Among the earliest biomedical polyurethanes was a solvent-cast silicone–urethane 'hybrid' (actually a copolymer-stabilized pseudo-interpenetrating network) known as Avcothane™-51, and later Cardiothane®-51. The suffix '51' was shorthand for the 510th formulation evaluated by its inventor Emory Nyilas, revealing the empirical approach that was used, by necessity, in the late 1960s.[1–3] Until *c.*1975 it was synthesized in fairly crude equipment (Figure 2), until it was scaled up in support of the growing demand for sale of intraaortic balloons, and interest from designers of other blood-contacting devices (Figure 3).

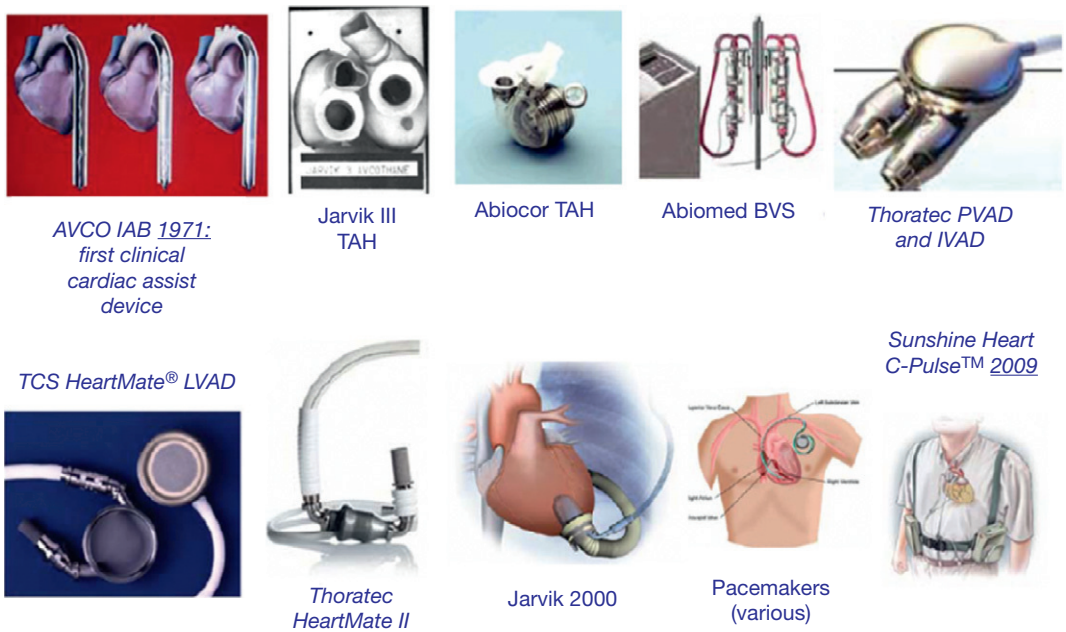

Figure 1 Polyurethanes and silicone–urethanes have been used successfully in clinical cardiac assist devices even before 1971. Balloon-, sac-, and diaphragm-type devices need the flex-life and thromboresistance of polyurethanes and silicone-polyurethanes. A new blood pump (C-Pulse) with no blood-contacting surfaces requires good flex life and abrasion resistance. Even axial flow devices like the HearMate II and Jarvik 2000 use polyurethanes as tough, biostable electrical insulation.

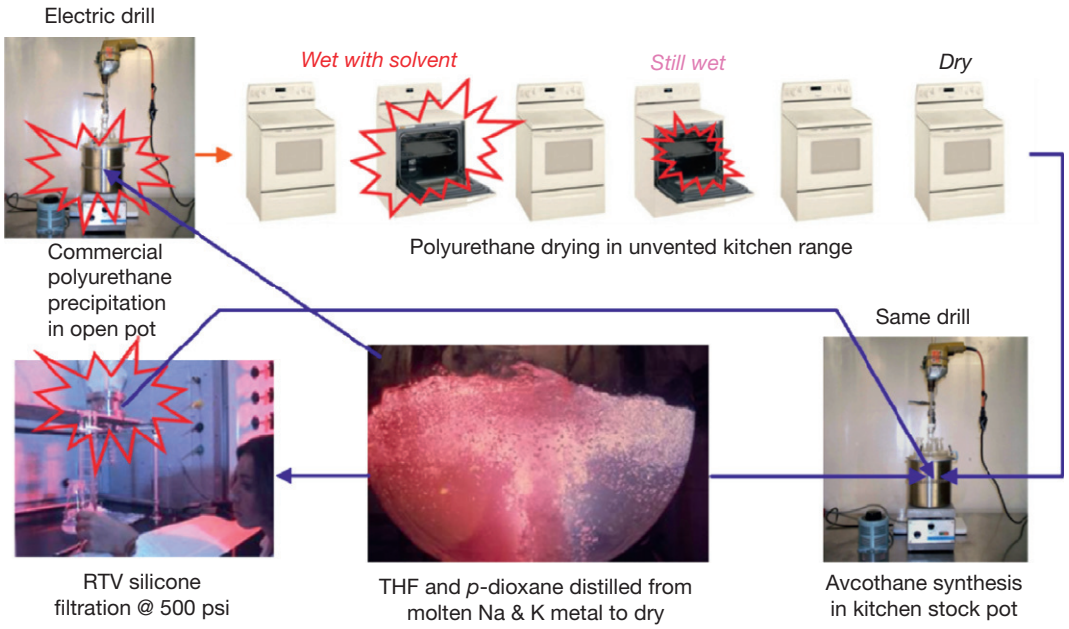

Figure 2 The original manufacturing process for one of the first high-performance biomedical polyurethanes: Avcothane-51 also known as Cardiothane: thermoplastic polyurethane was dissolved in THF and precipitated in methanol. After drying the purified PU was dissolved in anhydrous THF/*p*-dioxane solvent and combined with acetoxy-functional RTV silicone medical adhesive, prefiltered to remove silica filler. The small amount of silicone–urethane copolymer formed by co-condensation of silanol (–Si–OH) and carbinols (–C–OH) apparently stabilized the remaining silicone until device fabrication, drying and cross-linking could occur.

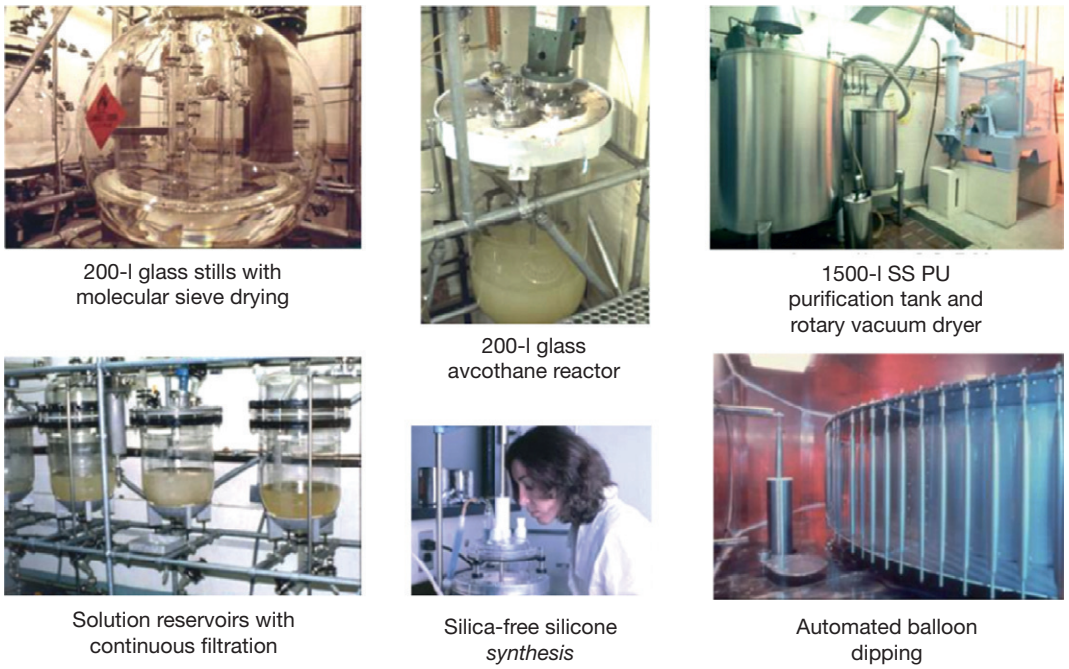

Figure 3 Avcothane/cardiothane production *c*.1976. In addition to improved polymer synthesis, automated balloon dipping within a clean room environment replaced labor-intensive 'candle' dipping techniques used in early IAB manufacturing. Note white color of Avothane solution caused by gross phase separation of the silicone (**Figure 4**) and resulting light scattering.

Although 'Avcothane' was moisture sensitive and difficult to process during device manufacturing, its successful clinical use in intraaortic balloons (IAB) represented an important step forward that demonstrated the benefits of combining polyurethanes with another very useful biomedical polymer: polydimethylsiloxane, also known as silicone (**Figure 4**). By design, the passive *thromboresistance* of Avcothane-51 was excellent relative to peroxide-cured silicone rubber and other

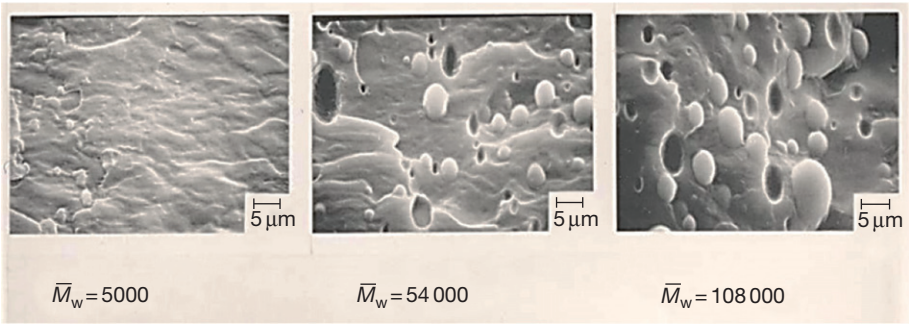

Figure 4 Liquid N_2 fractured Avothane films made with polydimethylsiloxane (PSX) of three different molecular weights: all at 10 wt% silicone. The extremely large silicone domains in the center photo are typical of the standard material. Their size and difference in refractive index from the polyurethane-rich continuous phase cause light scattering and gives this and other admixed silicone–urethane systems their characteristic opacity. Most modern silicone–urethane copolymers are phase mixed, or phase separated on a scale too fine to scatter light, and are, therefore, optically transparent. Covalent bonding within the backbone and much lower silicone molecular weight both contribute to optical clarity.

elastomers available at that time. The *biostability* of Avcothane-51 was also tested with encouraging results, albeit inadvertently, by those occasional IAB patients who could not be weaned from the pump. Based on this anecdotal data, and the known *in vivo* stability of silicones, it was later hypothesized that silicone could enhance the biostability of polyurethanes when copolymerized within the polymer backbone, or used as covalently bonded end groups.[4] This was later confirmed with *in vitro* and *in vivo* experiments that led to new families of highly biostable thermoplastic silicone–urethane *copolymers*, with improved processability. Whereas Avcothane-51 required solvent casting, dipping or spraying within a moisture-controlled (clean-room) environment, the thermoplastic silicone-polyurethanes (TSPUs) can also be injection molded, extruded, and heat sealed.

The development of well-defined silicone–urethane copolymers occurred slowly because the immiscible reactants required modified synthetic procedures. Backward integration to the scale up of stable, high-purity, *difunctional* silicone oligomers (e.g., carbinols) suitable for step growth polymerization was also required. Today, thermoplastic silicone–urethane copolymers belong to a growing class of urethane biomaterials that combine the biostability of silicone with the superior physical properties of segmented urethanes in roughly inverse proportion to their silicone content. They will, therefore, be a major topic within this chapter.

The use of silicone and a second, so-called soft block (e.g., polyalkylene-ether or polyalkylene-carbonate) is a specific example of the use of two or more soft blocks in the same polyurethane. This is an important aspect of a very useful polyurethane structure that serves as a 'biomaterials toolkit' for tailoring bulk and surface properties for specific, and seemingly unrelated, medical devices.

This chapter is based on one author's 40-year experience in the development and application of biomedical polyurethanes. It is intended to be a practical reference for scientists and engineers developing or using polyurethanes in clinical devices and prosthetic implants. Because material performance depends on handling, fabrication, and sterilization, processing methods used in the R&D/manufacturing of medical devices are included. Due to space limitations, only clinically relevant biostable polyurethanes will be covered in detail.

1.125.1.2. World's Largest Class of Polymers

The range of compositions and polymer structures within the class of polymers commonly referred to as polyurethanes is almost unlimited. Even if this long list of materials is abbreviated to include only those polymers synthesized from commercially available reactants, the category is still enormous. By comparison, the list of polyurethane compositions that have been used successfully in prosthetic devices is small. By far the most common polyurethane biomaterials are block or segmented polymers. These are actually *co*polymers containing oligomeric soft blocks and short hard segments along the main polymer chain. Most of the urethane or urea groups are found in the glassy or semicrystalline hard segments, with few, if any, present in the liquid-like soft segment.

Under typical service conditions, the useful properties of these PU and polyurethane-urea (PUU) copolymers are related to the incompatibility of different regions within these composite molecules. At body temperature, soft segments are thermodynamically incompatible with hard segments and have a lower degree of intermolecular attraction. In many linear and branched co-polyurethanes the bonds that hold the hard segments together and provide strength to the polymer are thermolabile, dissociating at melt processing temperatures or in solution to form viscous liquids that can be shaped into device components. Ease of processing requires a degree of phase mixing in the melt or in solution, followed by phase separation, also known as soft-segment/hard-segment 'demixing' after fabrication.[5–7] That is, after cooling from the melt, or evaporation of solvent from a polyurethane solution, the hard segment intermolecular bonds re-form to recreate discrete nanoscale domains. The ability of the hard segments to remain intact under stress, while the attached soft segments deform reversibly gives PU device components their useful properties in the warm, aqueous environment of the body.

Hard segments are literally hard: structural rigidity and isomeric purity increase the efficiency of packing and promote the formation of hydrogen bonds among like segments on adjacent chains. When present at sufficient concentration within the polyurethane backbone, these crystalline or glassy domains retain measurable melting points and/or glass transition temperatures that are well above body temperature.

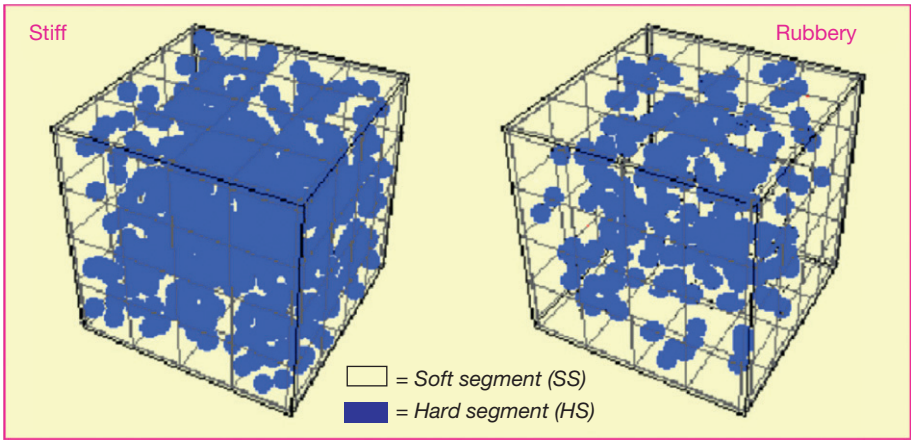

Figure 5 Many useful biomedical polyurethanes are phase separated copolymers at body temperature. Hard segment domains ~100 Å in diameter may be dispersed within a continuous phase of soft segment in elastomeric (rubbery) homologues. If hard segment is increased during synthesis, the hard segment can become the continuous phase in which the soft segments are dispersed. At intermediate compositions both hard and soft segments may form co-continuous phases. Many bulk properties depend on the ratio of soft-to-hard segment in the polymer. In addition to modulus/stiffness, permeability is strongly influenced by the chemistry and concentration of the liquid-like soft segment, as most hard segments are essentially impermeable.

If prepared as high molecular weight homopolymers instead of being used as segments within copolymers, many urethane hard segments would be rigid plastics. In fact, the earliest polyurethane homopolymers made by Otto Bayer in Germany were developed to compete with nylon fibers (Figure 5).

Unlike urethane hard segments, most useful soft segments, for example, dienes, silicones, and aliphatic polyethers and polycarbonates, are viscous liquids at body temperature. Even at high molecular weight, most would be too weak as linear homopolymers to be useful biomaterials. Certain soft segments that are capable of hydrogen bonding with hard segments can produce polyurethanes with improved properties and processability. Polytetramethyleneoxide (PTMO), for example, produces better 'physicals' than silicone (PDMS) or polyisobutylene (PIB), in part because the ether group within the PTMO repeat unit is a hydrogen bond acceptor, absent in both PDMS and PIB: ethers enhance phase mixing in the melt and lower melt viscosities during extrusion and injection molding. Flex life appears to be best in those soft segments that undergo reversible (strain-induced) crystallization during stretching. PTMO is superior in this way to many other soft segments, including other polyethers (e.g., polypropyleneoxide) that do not crystallize when elongated.

Currently, important polyurethanes, polyurethane-ureas and silicone-containing analogues used in medical devices are strong, biostable materials designed (or empirically determined) to be resistant to enzymatic, hydrolytic or oxidative degradation *in vivo*. Early review articles on polyurethane biomaterials are available including those by Lyman *et al.*[8], and the CRC Press, *Polyurethanes in Biomedical Applications* by Lamba *et al.*[9] Later articles on more-recent developments were covered by Zdrahala and Zdrahala.[10] More comprehensive reviews are also available.[11,12] A 2001 review[13] emphasizes specific silicone–polyetherurethane copolymers[14]. It also includes a useful description of the synthesis and processing of biomedical polyurethanes.

A general overview of the chemistry and technology involved in polyurethane synthesis is provided here to orient the reader, but much more detail can be found in the cited references.

1.125.1.2.1. Chemistry and synthetic methods

Although the urethane bond may constitute only a small fraction of the covalent bonds in polyurethane biomaterials, it is an important characteristic of this polymer family. Two main reactions are used to produce the urethane bond: the reaction between bischloroformate and a diamine (releasing hydrogen chloride, Figure 6) or the more commercially useful reaction between a diisocyanate and a diol (Figure 7).

In the presence of hydroxyls or amines in the bulk, or in solution, isocyanates can be very reactive, providing nearly quantitative conversion into urethane or urea groups respectively. Figure 7 illustrates bond formation via the attack of the nucleophilic oxygen of the alcohol on the electrophilic carbon of the isocyanate; this shows a base-catalyzed reaction where the base increases the nucleophilicity of the oxygen through hydrogen-bonding to the adjacent proton.[15] The exact mechanisms are still unclear due to side reactions, the existence of coordination complexes, and the poorly understood role of the optional solvent.

1.125.1.2.2. The urethane and urea bonds

The most important side reactions during urethane synthesis are allophanate formation, which occurs when isocyanate reacts with a preformed urethane group, and biuret formation, in which isocyanate reacts with a urea group. Either side reaction can produce branching or cross-linking, and so must be controlled during synthesis. Polyurethane-ureas are most commonly made by reacting diisocyanates with short-chain diamines instead of diols, together with the hydroxyl-terminated polyols that become the soft segments. The resulting polyurea hard segments are capable of forming twice as many hydrogen bonds as the equivalent urethane hard segment. This structural difference, and the resulting improvement in phase separation, produces polymers with useful properties at much lower

Figure 6 Reaction between bischloroformate and diamine to form a urethane bond.

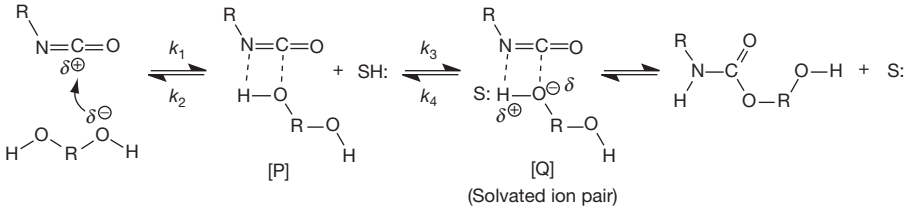

Figure 7 Reaction between isocyanate and diol to form a urethane bond.

hard-segment contents than the corresponding urethanes. Elastomers with excellent flex life and rubber-like elasticity are synthesized in solution using certain diamine chain extenders at only ~15–25 wt% hard segment. An analogous polymer with only urethane groups might require >35% hard segment to achieve comparable strength, but would therefore have a higher modulus and indentation hardness.

Water can also be used as a chain extender yielding only half the urea content of a diamine while evolving CO_2 (Figure 8).

Depending on relative concentration, the reaction of isocyanate groups with water can result in the formation of large amounts of carbon dioxide which can be entrained during the formation of the polymer. The reaction mechanism has been proposed and studied by a number of authors and the kinetics described in detail[16]. With stabilization provided by included surfactants this reaction can produce a foamed product with many industrial and commercial applications.

If thermally stable cross-linking is avoided, water-extended polyurea-urethanes can be melt-processed due to their reduced urea content.[17] However, as TPUs they provide little advantage over diol-extended analogues which are easier to synthesize in bulk. The already enhanced phase separation of polyurea hard segments can be further increased with certain highly incompatible soft segments that do not form hydrogen bonds. Amine-terminated silicone and polyisobutylene oligomers both give processable, albeit relatively weak, thermoplastic polyurea elastomers at hard-segment content as low as 10 wt%.[18–20] In general, however, too high a polyurea content gives polymers that cannot be melt-processed or even dissolved in common organic solvents.

1.125.2. Commercially important PUs and PUUs

Macromolecules containing urea or urethane-rich hard segments covalently bonded to soft segments constitute an important family of industrial polymers. Many contain rigid aromatic or cyclic aliphatic groups in their hard segments, and polyester, polyether, polydiene or aliphatic polycarbonate soft segments. Silicone soft segments are still the exception in commercial urethanes, although relatively large quantities of silicone-ureas are consumed as release coatings for pressure sensitive adhesive and encapsulants for solar cells.[21,22]

An extensive property map can be generated by combining various hard segments, soft segments and chain extenders in different proportions as described in the preceding sections. Polymer hardness ranges from soft sticky gels, to rubber-like elastomers, to flexible 'leathery' polymers, to very rigid homologues that resemble impact-modified plastics. Nonmedical

uses include paints and varnishes, safety glass laminates, skateboard wheels, waterproof moisture-vapor-permeable textile coatings, abrasion-resistant tubing and hose, plasticizer-free cable insulaton, dent-resistant automobile facia, puncture-resistant extruded film, mattress foam, shoe soles and laundry-stable spandex fibers that mimic natural rubber.

Although polyurethanes can be formed from an almost unlimited combination of reactants, in practice, commercial urethanes are only synthesized from raw materials that are readily available at attractive prices. The main synthetic route to commercial thermoplastic PU (TPU) copolymers is step-growth polymerization of a mixture of difunctional reactants including diisocyanates, short-chain diol chain extenders and oligomeric glycols or diamines that comprise the soft segments. Although the range of possible compositions is wide and the synthesis is straightforward, it requires high-purity reactants and precise control of stoichiometry to obtain high molecular weight. Lot-to-lot consistency requires tight controls of these variables, as well as the order of addition, mixing efficiency, reaction time/temperature, pH and the concentration of optional catalyst (e.g., organotin compounds or amines). Another important variable is the concentration of ever-present trace water in the reaction mixture, due to its ability to react with isocyante groups.

The versatility of polyurethanes is due to the many possible combinations of reactants, and their easily varied concentrations and arrangements within the polymer's molecular structure. In the simplest thermoplastic polyurethane, the ratio of the concentration of soft-segment polyol to the diisocyanate-diol reaction product that becomes the hard segments can be used to vary properties significantly. Soft segment molecular weight can also be varied over the range of a few hundred to a few thousand Daltons, to affect changes in rheology and other properties. In addition, intermediate physical properties can be obtained by physically blending members of a single family of polyurethanes that differ in hard segment content. However, even polyurethanes with identical hard segment composition made with different soft segments may be thermodynamically incompatible. This can lead to eventual separation of blends, particularly in solution where stratification may occur on standing.

The manufacture of polyurethanes is a well-developed, commercially mature industry and has been studied and reviewed by a number of authors. There exists a very large body of information on polyurethanes in the patent literature and there are many reviews and journal articles, which provide excellent background and overview.[23] The invention and early developments in the field, including accounts of historical nature, are well described and are referenced widely. The *Polyurethane Handbook*[24] remains a valuable resource that provides an overview of the early literature and a lot of practical information for manufacturers.

In the synthesis of (biostable) biomaterials, the range of raw materials employed is not nearly as large as in the commercial polyurethanes. This is due, in part, to the combination of surface *and* bulk properties required in biomedical applications. It is also due to slow acceptance of completely new compositions by risk-averse device manufacturers who naturally demand extensive testing and documentation before adopting new biomaterials. It is also worth noting that the volume of polyurethanes produced as biomaterials is a tiny fraction of what is sold for nonmedical uses, providing little incentive for manufacturers to create new reactants specifically for high-risk biomedical polymers. Reviews of biomedical polyurethanes by Woods[25] and later by Scycher[26] are noteworthy. Less comprehensive, but equally important, are the review articles by Petrovic and Ferguson[27] and, more recently, Król[28] that provide a detailed review of the catalytic and kinetic processes.

1.125.2.1. Range of Chemical Compositions and Structure Possibilities

Many properties of commonly used biomedical polyurethanes are determined by soft-segment chemistry and concentration. Within the polyurethane backbone, soft segments typically have their dominant thermal transitions below body temperature, making them amorphous liquids at 37 °C. Candidates for the soft segments include polyesters, polylactones, polydienes, polyethers and aliphatic polycarbonates. Currently, polyethers or polycarbonates are used in most biostable polyurethanes (see **Table 1**). Polyesters and polylactones are subject to hydrolytic degradation and are generally unsuitable for biostable compositions. More recently polydimethylsiloxane, also known as silicone, has become an important co-segment for enhancing long-term biostability and/or tailoring permeability. Depending on cost and availability, highly stable polyisobutylene, like silicone, may also become an important soft segment. It is likely to be used in combination with polycarbonate, polyether or other biostable co-soft segments for improved physical–mechanical properties.

Thus, the major polyurethane soft segments that have been used as biomedical polyurethanes are:

1. Polyester (soft segment) containing polyurethanes: although now known to be hydrolytically unstable, they were used in a few early implants. Compositions containing these soft segments are typically made by (co)polymerizing monomeric diols such as ethylene glycol, 1,3-propanediol, and 1,4-butanediol with dicarboxylic acids such as adipic acid, succinic acid, maleic acid, or acid anhydrides. Typical molecular weight range is from 300 to 2000 Da. Polyesterdiols having an even number of carbons in the soft-segment backbone are able to crystallize and phase-separate less than those containing an odd number (e.g., pentane diols vs. hexane diols). Such 'irregular structures' create poor packing of adjacent chains. This discourages hydrogen bonding so intermolecular attractions are weakened and melting points are reduced.[29]

   A number of studies report the effects of synthesis and post processing conditions on mechanical properties of the poly(ester-urethane) polymers, including curing temperatures during and after formation.[30] Poly(ester-urethane)s synthesized from poly(ethylene glycol adipate) (PEG) and 2,4-toluene diisocyanate (TDI) with PEG as soft-segment films and cured above 60 °C possess higher tensile strength and elongation at break, showing that reaction temperature and cure temperature play an important role in structure development, and the resulting mechanical properties, of semicrystalline PU.

Table 1 Commonly used components of biomedical polyurethanes

Reactants/(common name)(a)	*Abb.*	*Structure/IUPAC*	*Comments*
● Methylene diphenyl diisocyanate, ● Methylenebis(phenyl isocyanate), ● 4,4'-Methylenediphenyl diisocyanate	MDI	 1-isocyanato-4-[(4-isocyanatophenyl) methyl] benzene CAS Number: 101-68-8	Pure isomer gives the best physicals and biostability
● 2,4-Tolylene diisocyanate ● 4-Methyl-1,3-phenylene diisocyanate ● 4-Methyl-meta-phenylene diisocyanate	TDI	 2,4-diisocyanato-1-methyl-benzene CAS Number: 584-84-9	Less used in biomaterials; second most produced diisocyanate for PU use
● Methylenedicyclohexyl diisocyanate	HMDI, H12MDI H_{12}MDI	 1-isocyanato-4-[(4-isocyanatocyclohexyl) methyl]cyclohexan CAS Number: 5124-30-1	Mixture of three isomers. Nonyellowing cycloaliphatic structure Biostability and flex life is < with MDI
● Hexamethylene diisocyanate ● 1,6-hexane diisocyanate	HDI	 1,6-diisocyanatohexane CAS Number: 822-06-0	Used in biodegradables to avoid possible toxic degradation products Gives lower strength PUs
Isophorone diisocyanate ● 1-(Isocyanatomethyl)-5-isocyanato-1,3,3-trimethylcyclohexane ● 1,3,3-Trimethyl-1-(isocyanatomethyl)-5-isocyanatocyclohexane ● 1-Isocyanato-3-(isocyanatomethyl)-3,5,5-trimethylcyclohexane	IPDI	 5-isocyanato-1-(isocyanatomethyl)-1,3,3-trimethyl- cyclohexane CAS Number: 4098-71-9	High-strength aliphatic PUs The two isocyanate groups have different reactivities.
Butane diol ● 1,4-Butanediol ● 1,4-Butanediol 1,4-butylene glycol butylene glycol ● 1,4-Butylene glycol	BD	 Butan-1,4-diol CAS Number: 110-63-4	Most commonly used diol in thermoplastics
Ethylene glycol ● 1,2-Dihydroxyethane ● 1,2-Ethanediol ● 1,2-Ethanediol ● 1,2-Ethylene glycol	EG	 Ethane-1,2-diol CAS Number: 107-21-1	
Ethylene diamine ● 1,2-Diaminoethane ● 1,2-Ethanediamine ● 1,2-Ethylenediamine	ED	 1,2-diaminoethane CAS Number: 107-15-3	Main chain extender in polyurethane-urea elastomers, for example, BioSpan® SPU
● 1,3-Cyclohexane diamine	1,3-CHD	 Cyclohexane-1,3-diamine 3385-21-5	Minor chain extender in polyurethane-urea elastomers. Improves fiber spinning from solution
● 1,4-Cyclohexane diamine	1,4-CHD	 Cyclohexane-1,4-diamine CAS Number: 3114-70-3	Has been used in place of 1,3-CHD due to commercial availability

Table 1 (Continued)

Reactants/(common name)(a)	*Abb.*	*Structure/IUPAC*	*Comments*
Polyethyleneglycol ● 1,2-Ethanediol, homopolymer ● Carbowax ● Ethylene glycol polymer ● Macrogol ● Oxirane, homopolymer	PEG, PEO	 poly(oxyethylene) {structure-based}, poly(ethylene oxide) {source-based} CAS Number: 25322-68-3	Oxidatively unstable, hydrophilic soft segment. Increases water permeability and water absorption
Polypropyleneglycol ● 2-Methyloxirane; oxirane	PPO	 2-methyloxirane; oxirane CAS Number: 9003-11-6	Stable against hydrolysis, but does not strain crystallize. Elastomers are inferior to PTMO-containing analogues
Polytetramethylene glycol ● Poly(tetramethylene ether) glycol ● Polytetrahydrofuran ● Terathane ● PolyTHF	PTMO, PTMEG, PolyTHF	 butane-1,4-diol CAS Number: 732189-03-6	Best overall polyether polyol in many *in vivo* applications. Subject to (cobalt-catalyzed) oxidative degradation especially when strained
Polyhexamethylene oxide	PHMO		Oxidatively unstable when strained but has less ether contant than PTMO. H-Bond donor 'compatiblizing' polyol used at low concentration in some silicone–urethanes.
Polyhexamethylene carbonate ● poly(hexamethylene carbonate) diol	PHMC PHMCD		Oxidatively and hydrolytically stable *in vivo* especially when ether free. Gives highest strength TPUs.
Silanol-terminated polydimethylsiloxane ● Dimethyl siloxanes and silicones ● Dimethylpolysiloxane ● Polydimethylsiloxane ● Siloxanes and silicones, dimethyl	PDMS, PSX	 poly(dimethylsiloxane) CAS Number: 63148-62-9	Does not from silicone–urethanes when reacted with diisocyantes. May co-condense with carbinols under certain condtions
Polybutadiene	PBD		Oxidatively and hydrolytically stable *in vivo*. Useful in ultrasonic probes.
Polyisobutylene ● Butyl rubber	PIB		Oxidatively and hydrolytically very stable *in vivo*. Gives low-strength TPUs when used without H-bonding co-blocks.
Octodecanol ● 1-Octadecanol Stearyl alcohol ● 1-Hydroxyoctadecane ● Octadecyl alcohol		 1-Octadecanol CAS Number: 112-92-5	
Carbinol-terminated polydimethylsiloxane ● Dimethyl siloxanes and silicones ● Dimethylpolysiloxane ● Polydimethylsiloxane ● Siloxanes and silicones, dimethyl	PDMS	poly(dimethylsiloxane) CAS Number: 63148-62-9	Silicon-carbon bonds join hydroxy-functional organic group to terminal silicon atoms. Forms silicone–urethanes in reactions with (di)isocanates
Perflourinated octadecanol $C_{18}F_{37}OH$:			Surface-modifying end group self assembles in surface of formed articles US 5929290 Issued Jul 1999
Monofunctional HO-PEO		 R = CH_3, CH_2CH_3, PDMS, etc.,	Surface-modifying end group self assembles in surface of formed articles

(*Continued*)

Table 1 (Continued)

Reactants/(common name)(a)	*Abb.*	*Structure/IUPAC*	*Comments*
Sulphonated alcohol Isethionic acid ● 2-hydroxyethanesulphonic acid ● Ethanolsulfonic acid		 When n = 1: 2-hydroxyethanesulfonic acid CAS Number: 107-36-8	Surface-modifying end group self assembles in surface of formed articles
Ethylene bis-stearamide ● 1,2-Bis(octadecanamido)ethane ● 1,2-Ethylenebis(stearamide)		 *N*-[2-(octadecanoylamino)ethyl] octadecanamide CAS Number: 110-30-5	Leachable, low-molecular weight, waxy processing aid used in many TPUs. Affects surface properties and melt viscosity. Major determinant of surface chemistry when present.
Calcium stearate		 Calcium octadecanoate CAS Number: 1592-23-0	Alternative to ethylenebis(stearamide)
Hindered phenolics, antioxidants Butylated hydroxyanisole ● tert-Butyl-4-hydroxyanisole ● tert-Butyl-4-methoxyphenol	BHA	 2-tert-butyl-4-hydroxyanisole and 3-tert-butyl-4-hydroxyanisole (mixture) 25013-16-5, 8003-24-5, 9009-68-1, 121-00-6, 88-32-4	Stabilizer
Butylated hydroxytoluene ● Butylhydroxytoluene ● 2,6-Di-t-butyl-4-methylphenol	BHT	 2,6-bis(1,1-dimethylethyl)-4-methylphenol CAS Number: 128-37-0	
Free radical traps		 Ascorbic acid  α-tocopoherol

As conventional polyester polyurethanes are subject to hydrolytic degradation they are of little use in long-term implantable devices.[31] A more stable polyester soft segment is polycaprolactone (PCL) diol. Unlike esters prepared from diacids and diols, PCL it is synthesized by ring opening of cyclic caprolactone monomer. Although it is hydrolytically unstable, it degrades slowly *without* releasing autocatalytic acidic byproducts, which are *also* undesirable because they can elicit an inflammatory response in the surrounding tissues. Polycaprolactone is, therefore, a preferred component of *intentionally* biodegradable polymers, although unsuitable for use in implanted biostable polyurethanes, despite its advantages over common polyadipate ester diols.

Compositions containing both polyesters and polyether diols (polycaprolactone as a polyester diol, and polyethyleneoxide (PEO) capped PEO/PO polyether diol containing less than 20% ethylene oxide, EO) with a diisocyanate and butanediol as chain extender, have been described as transparent thermoplastic polyurethanes that have good combinations of clarity, tensile strength, hydrolytic stability and processability compared to TPUs prepared using either polyester or polyether diols alone, or similar combinations with a higher EO polyether diol.[32] In general, however, the use of hydrophilic moieties like PEO together with hydrolytically unstable soft segments like PCL or polyadipate-esters *increases* degradation rate. The *in vivo* water absorption of the bulk polymer is increased by the presence of the hydrophilic PEO, which exposes the hydrolytically unstable segments to a higher average water concentration while increasing the polymer's permeability. This results in faster cleavage of unstable ester bonds.

Recent developments with cross-linked, dual soft-segment poly(ester urethane urea) prepared by extending poly(propylene oxide)-based triisocyanate-terminated prepolymer with a polycaprolactone diol (PCL) have shown promising results in nonhemolytic membrane applications.[33] Such compositions may be suitable in short-term or disposable device applications, but are unlikely to have good long-term biostability for the reasons stated above. In general, polyesters are finding renewed interest in the field of tissue engineering and bioresorbable materials such as stents and sutures (*vida infra*).

2. Polyether (soft segment) containing polyurethanes: generally are much more hydrolytically stable than the polyester-containing polyurethanes, although *oxidative* stability can be lower in softer grades, particularly in the presence of certain metal ions such as cobalt.[34] Examples include PEO (also known as PEG), polypropyleneoxide (PPO) and polytetramethyleneoxide (PTMO). As alkylene chain length within the repeat unit increases the polyethers become more hydrophobic: PEG is water soluble, PTMO is not. Methylene groups adjacent to the ether oxygens are susceptible to oxidation, particularly when the polymer is stretched in use, or compressed, for example, by ligating sutures. In PEO, *all* of the methylenes are adjacent to ether oxygens, making it the least oxidatively stable polyether polyol. Of these three commercially available polyethers polyols, PTMO gives the best balance of physical–mechanical properties and biostability. Unlike PPO, PTMO soft segments undergo reversible strain-induced crystallization, giving elastomers with low tensile hyteresis and good flex life. Attempts to increase the methyelene chain length to six carbons in order to *significantly* enhance biostability were unsuccessful until a high concentration of silicone was included as a co-soft segment at the expense of the PHMO concentration[35,36] (**Figure 9**).

Chang and Wilkes[37] reported the structure property relationship of a variety of hard segments combined with oligomeric PEO, poly(propylene oxide) (PPO), or both PEO and PPO soft segments. They showed copolymers of both PEO and PPO display enhanced domain and anisotropic superstructures and attributed this phenomenon to polymer soft segment incompatibility. The effects on morphology and the effectiveness of different diamines as chain extenders were accounted for by the symmetry, hydrogen bonding and rigidity of the hard segments as well as

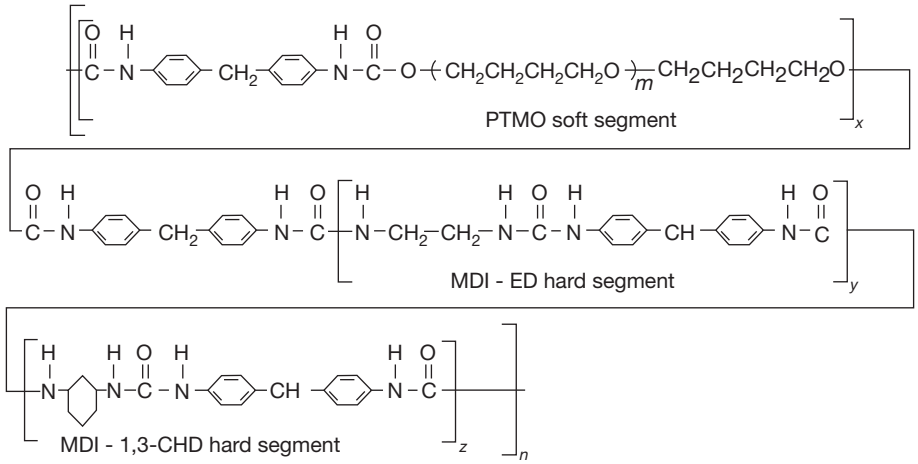

Figure 9 Idealized repeat structure of a so-called segmented polyurethane, for example, BioSpan® and Biomer™ segmented polyurethanes. Prepolymers prepared from polytetramethyleneoxide (PTMO) diols and methylene diisocyanate are chain extended in dimethylacetamide solution with two different diamines:ethylene diamine and 1.3-cyclohexane diamine. They therefore have urea hard segments bonded to the soft segment PTMO chains via urethane groups. At hard segment content of 20–25 wt% these polymers are among the best man-made elastomers ever developed. They were originally developed to replace natural rubber in textile applications and are similar to the structure of commercial Lycra Spandex *c.*1968. In addition to the base polymer the casting solutions contain a complex additive package designed to protect spandex thread *in the laundry cycle*! This composition, which has exceptional flex life, continues to be used in certain sac and diaphragm-type blood pumps primarily for historical/regulatory reasons. Thoralon SPU has similar but not identical structure with a simpler additive package. Thoralon also contains a silicone–polyetherurethane surface modifying additive (SMA) that improves thromboresistance and which may also enhance biostability.

incompatibility with the soft segments. The formation and deformation of superstructures led to a model to account for the formation of the resultant anisotropic structure and mechanical properties.

Materials with equivalent stoichiometries but different hard segment length distributions were prepared by Miller *et al.*[38] in either a one-step polymerization or by the multistep, so-called prepolymer method. Polyurethane block polymers based on poly(tetramethylene oxide) (PTMO), MDI and butanediol (BD) were prepared and evaluated. The single-step polymers were shown to have *fewer* hard segments containing a single MDI unit compared to the corresponding multistep samples. This is counterintuitive as the rationale for the two-step process is often to *discourage* the chain extension/coupling of polyols by maintaining excess diiocyanate during formation of the isocyanate-terminated prepolymer. However, in this study the multistep materials exhibited a *greater* degree of phase mixing, as the very short chain-extending MDI segments were more likely to be dissolved in the soft phase than were the longer hard segments. Another interpretation is that chain extension of soft segment by a single diisocyante introduces hydrogen-bonding urethane groups into the middle of the soft segment, increasing its compatibility with the hard segment, albeit while doubling its molecular weight. The hard phase volume fraction and crystallinity were found to be greater in the single-step materials due to the lower degree of phase mixing in these polymers (and presumably their higher average hard-segment molecular weight).

3. Polyurethanes with polycarbonate soft segments are much more oxidatively stable than polyether-containing polyurethanes, although the inclusion of ether groups into the polycarbonate under certain conditions of polyol synthesis *may* reduce oxidative stability somewhat. It should be noted that the *aliphatic* polyalkylenecarbonate diols used as soft segments in (biomedical) polyurethanes are distinctly different from the rigid *aromatic* bisphenol-A plastic commonly referred to as 'polycarbonate.' Aliphatic polycarbonate polyols contain no bisphenol-A. They can be produced by several methods, most often by ester interchange reaction using an alkane diol and a dialkyl carbonate.[39] An important example includes the tin-catalyzed electrophilic attack of aliphatic hexane diol on the methine carbon of ethylene or propylene carbonate to form polyhexamethylene carbonate diol.[40] Temperature control is essential in the case of ethylene carbonate, because side products resulting in the formation of oxidatively unstable ether linkages in the polymerized polycarbonate diol are possible. Understanding and control of this side reaction has led to the availability of improved ether-free polycarbonate-urethane biomaterials, for example, Bionate® II polycarbonate-urethane. The lack of 'contamination' by hydrogen-bonding ether groups increases toughness but appears to reduce phase mixing in the melt, giving some neat polymers a higher melt viscosity at equivalent molecular weight. This has been overcome with molecular weight control using surface-active, self-assembling octodecyl end groups created from the corresponding alcohol. The resulting C_{18} end groups are surface-active, which improves mold release, and they 'lubricate' the molten chains to improve melt processing. As a monofuntional reactant in the formation of urethane groups, octodecanol conveniently provides molecular weight control by acting as chain stoppers during synthesis.[41–43]

Thermoplastic polyurethane elastomers based on polyhexamethylene carbonate diol and polyhexamethylene–pentamethylene carbonate diol of different molecular weights

and hard segments and consisting of varying ratios of diphenylmethane diisocyanate and 1,4-butanediol have been synthesized in bulk, and the effects on thermal and mechanical properties investigated.[44] As seen in many polyurethanes, increasing soft-segment length, via polyol molecular weight, or increasing the hard-segment content, gives increased microphase separation, more hard-domain order/crystallinity, and higher stiffness. In phase-separated systems better development of the reinforcing hard-domain structure was observed. The 'physical cross-link sites' provided by the hard-segments and the elastic nature of soft segments, make softer homologues elastomeric.

With increasing hard-segment concentration at constant polycarbonate diol molecular weight, properties such as rubbery plateau, modulus, solvent resistance, melting point, hardness, tensile strength and hard-segment run length all 'improve.'[45] Note that in studies of homologous co-polyurethanes with varying block lengths, the soft segment molecular weight actually *determines* hard-segment molecular weight. In a simple linear copolymer of fixed composition, as soft segment molecular weight increases so does the hard-segment molecular weight, because the hard segments are positioned between the soft-segment chains along the linear polymer backbone. In the study by Harris, increasing hard-segment concentration at fixed polycarbonate block length caused an increase in hard-segment molecular weight *and* concentration. It is likely that phase separation increased for both reasons.

In general, the useful properties and processability of PU and PUU block copolymers are related to the relative thermodynamic incompatibility of the different regions within these composite molecules. Depending on molecular weight, soft segments are usually incompatible with hard segments, in part because hard-segment domains have higher cohesive density and the related property of higher solubility parameters. The hydrogen bonds that hold the hard segments together and provide strength to the polyurethane dissociate at melt processing temperatures or in solution in organic solvents. The resulting liquids can be formed into useful device components by a number of different conversion methods. Ease of processing requires a degree of phase mixing in the melt or in solution followed by phase separation, also known as soft-segment/hard-segment demixing after fabrication.[5–7,46] After cooling from the melt or during solvent evaporation, the hard-segment hydrogen bonds reform to recreate separate domains. In use, the ability of certain soft segments to reversibly orient or strain crystallize when stretched, and the ability of hard segments to remain hydrogen-bonded under stress are responsible for many of the desirable properties of polyurethane biomaterials.

1.125.2.2. Lab and Commercial Synthetic Methods

Batch-type laboratory methods for synthesizing polyurethanes generally provide good control of temperature and mixing. However, the control of the stoichiometry necessary in step-growth polymerization can become more precise as reaction scale increases. This consideration and manageable reaction exotherms facilitate scale-up to manufacturing. Synthesis can include bulk, solution, and even emulsion methods (e.g., in water-borne systems using aliphatic diisocyantates).

In bulk and solution synthesis, all the reactants can be combined in a 'single-shot' procedure with intensive mixing, or in the 'prepolymer' or two-step (or even three-step) method mentioned above. The prepolymer technique involves prereacting the soft-segment polyol(s) with excess diisocyanate followed by chain extension with short-chain diols or diamaines. Despite the effect on phase separation mentioned above, it is often more convenient to handle a prepolymer than the more volatile diisocyanate, from which it is made. Less volatile diisocyantes that are solids at room temperature require heated piping and vessels to prevent crystallization. Prepolymers however, are often viscous liquids at or slightly above room temperature and are more easily handled by oven preheating. As already mentioned, mixing intensity, pH, the order and rate of addition, the concentration of optional catalysts, and the concentration of the inevitable traces of water are all determinants of the lot-to-lot consistency of the final polymer.

1.125.2.2.1. Thermoplastic pellets for extrusion and molding

In the batch-type bulk (i.e., solvent-free) synthesis of thermoplastics, the reacting mixture is quickly removed from the reactor prior to solidification, while still exotherming. It is often cast into Teflon-lined pans or polypropylene molds and heated in an oven for several hours to continue the polymerization. During solidification the resulting slab shrinks and can be demolded. Grinding and subsequent melting and pelletization or dicing on a thermoplastic extrusion line is done to complete the reaction and produce pellets for characterization and processing. A major drawback of batch-type bulk synthesis is that the grinding step and added handling may increase particulate contamination in the final polyurethane. Furthermore, little or no feedback of final polymer molecular weight is available to the operator during synthesis (**Figure 10**).

For the manufacturing volumes typical of implantable thermoplastic polyurethanes, an excellent, but capital-intensive method is continuous synthesis on a small twin-screw extruder. In one example, reactants are accurately metered to an injection port on the extruder barrel. The barrel is maintained at melt processing temperatures, usually 190 ± 25 °C, and the screw design and speed of rotation assure good mixing and adequate residence time. Torque, back pressure, and/or electrical current drawn by the constant-speed extruder motor provide continuous feedback dependent on melt viscosity. As melt viscosity increases with chain length, the approximate molecular weight of the product can be predicted and controlled via the stoichiometry determined by individual reactant feed rates. The fully reacted molten polymer may emerge from the extruder through an underwater pelletizer where it forms spherical pellets while cooling. The pellet slurry is dewatered and collected inside a HEPA-filtered enclosure. Later, desiccant hopper driers are used at atmospheric pressure just prior to processing the pellets. Directly after drying, free-flowing pellets are fed to injection molding machines and extruders during the fabrication of device components. 'Pelletized' polymers are also more easily dissolved in solvents for dipping, casting or spraying, or for use as an adhesive in device assembly. This is especially true for recently (re)pelletized polyurethanes, apparently due to the slow reformation of intermolecular allophonate bonds broken in the melt.

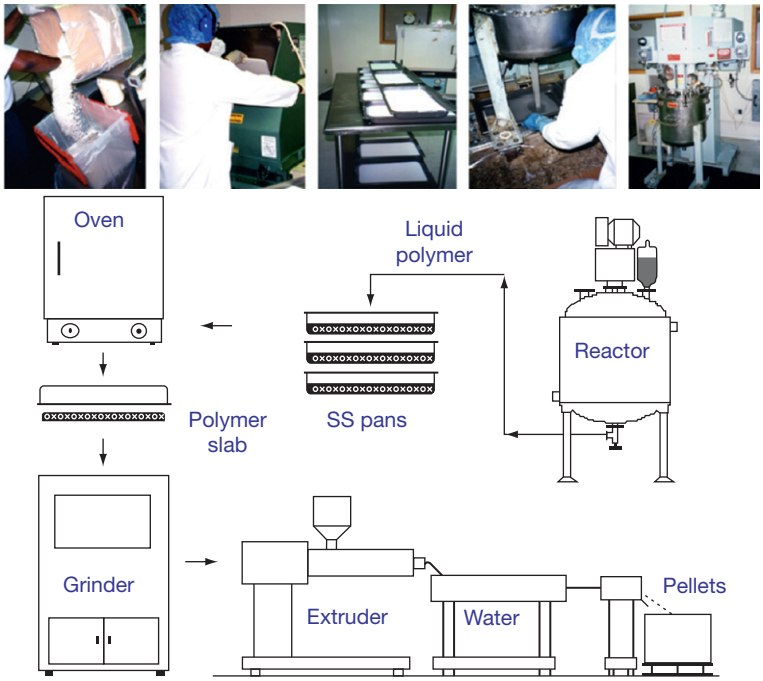

Figure 10 Batch-type synthesis of thermoplastic polyurethanes. From right to left the reaction mixture is chain extended in a batch 'kettle' with intensive mixing. During the resulting exotherm, but before solidification, the reacting mixture is discharged from the reactor into pans for further reaction in an oven. The slabs cure for several hours and shrink enough to allow de-molding and grinding. Roughly shaped ground polymer shown in the photo at extreme left is dried and fed to a thermoplastic extruder to complete the reaction and to form smooth, free-flowing pellets for subsequent processing, for example, molding or extrusion.

Using a 27 mm continuous reactor/twin-screw extruder, an output of 10–40 lbs h^{-1} is achievable and several developmental materials can be produced in a single day. Promising candidates can easily be scaled up by reproducing the reaction conditions used in development runs. These benefits, and the improved cleanliness it provides, make continuous reactive extrusion nearly ideal for manufacturing thermoplastic biomaterials. Scale up is straightforward but expensive, as output and equipment cost increases considerably with the diameter and length of the extruder. The continuous process using an endless belt shown in Figure 11 is capable of producing hundreds of pound per hour of pelletized polyurethane, but it is less versatile during development than the twin-screw reactive extruder.

During melt processing, thermal history and the extent of drying are determinants of polyurethane viscosity and therefore ease of extrusion and molding. As thermal history increases and/or water content is reduced, melt viscosity increases making processing more difficult. For this reason, over-drying must be avoided, and measurement and control of trace water level can greatly facilitate control of extrusion and molding operations.

1.125.2.2.2. Solution synthesis for coating and dipping

A typical two-step solution synthesis begins with the addition of pure diisocyante to the reactor, followed by slow addition of polyol to maintain an excess of diisocyante throughout the reaction. The final *prepolymer* is an isocyanate end-capped oligomer admixed with excess diisocyanate monomer. In addition, a fraction of the polyol may become chain extended, forming dimers or trimers, for example, when one mole of diisocyanate reacts with two moles of polyol, etc. At this stage a dry polar, aprotic organic solvent such as DMF or DMAc is added to the reactor to form a prepolymer solution. The reactive solution is chain extended via addition of a near stoichiometric amount of diamine or diol to form the product polymer solution, at a final concentration of ~5–40 wt%. Concentrated solutions of amine-extended polymers may become very viscous as the reaction proceeds and require dilution before being filtered for use in device fabrication. High-purity, glass-distilled chromatographic-grade solvents are preferred as any nonvolatile solvent impurity will be left behind on the part being dipped, coated, or cast (Figure 12).

Solution synthesis and fabrication is often the only practical method for polymers with aromatic polyurea hard segments which generally cannot be melt-processed. Solution synthesis is used in the preparation of high-flex-life PUU, currently the preferred elastomers for sac- and diaphragm-type cardiac assist devices. However, recovery of neat thermoplastics from a solution synthesis is usually impractical except at laboratory scale. This is due to lower polymer yield per unit of reactor volume, and the need to precipitate in a nonsolvent, rinse, and thoroughly dry the reaction product. This process also requires solvent recovery or licensed waste disposal.

New methods of polyurethane synthesis continue to be developed. Well-defined polyurethane-polydimethylsiloxane particles of tunable diameter in the range of 0.5–20 mμm were synthesized in a 'one-shot' step-growth polymerization using supercritical carbon dioxide as a solvent.[47] This method has the potential to produce very-high-purity polymers as

Figure 11 Top: continuous synthesis of biomedical polyurethanes and silicone polyurethanes with optional Surface Modifying End Groups (SME™) or Self-Assembling Monolayer End Groups (SAME™) is easily accomplished on this reactive extruder with downstream pelletizer and high-efficiency particulate air (HEPA)-filtered collection area. Reactants are metered to a feed port on the extruder barrel (right). The polymer is synthesized within the barrel of the twin-screw extruder/reactor while being mixed and conveyed by the rotating screws. The fully reacted polymer exits through a die into a stream of water where surface tension creates spherical pellets which quickly cool in the flowing water. The slurry is dewatered and pellets are collected in the soft-wall enclosure at the left of the photo. Bottom: an older alternative method of continuous synthesis deposits the molten polymer or reaction mixture on a moving belt. Reaction is completed inside a heated tunnel that is temperature controlled and HEPA filtered. A solid ribbon of polymer emerges from the tunnel and passes through a dicer to produce, hexagonal pellets.

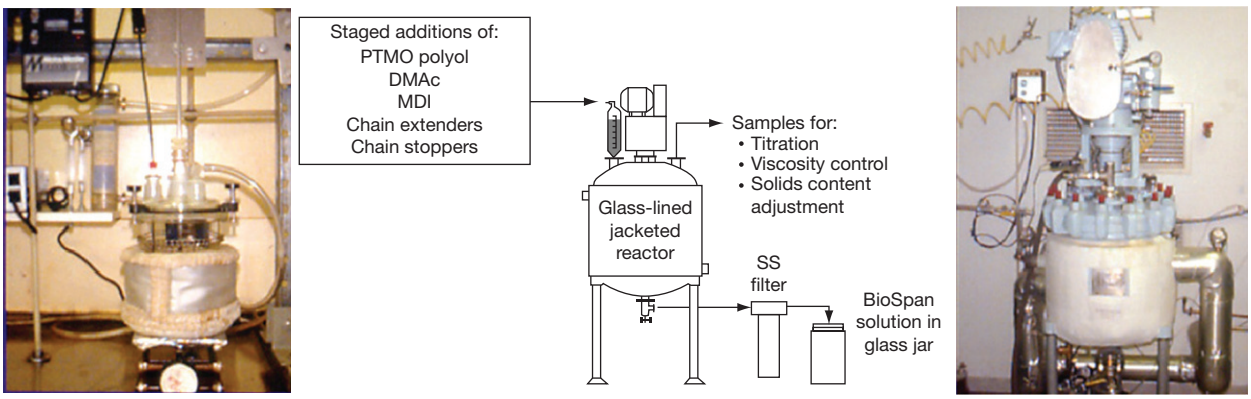

Figure 12 Batch-type solution synthesis of polyurethane-urea of the structure shown in **Figure 9**. A 2-l lab-scale reactor is shown on the left. The 10 gallon glass-lined Pfaudler-type reactor on the right is used in manufacturing the relatively small volumes needed for implantable applications.

product recovery involves simply reducing the pressure of the reaction mixture to allow polymer precipitation and recovery of carbon dioxide gas. Of course, solubility in super critical CO_2 is required, so the method may not work for all (e.g., silicone-free) polyurethanes.

1.125.2.2.3. 100% solids curable prepolymer systems for potting and encapsulation

Two-component polyurethane liquid systems capable of rapid curing are often referred to as potting compounds.[48] Bulk-synthesized reactive liquid prepolymers can be stored in dry containers at reduced pH to extend shelf life. When mixed with a chain extending diol or triol, or analogous amines, polymerization takes place. The pot life is also controlled via pH and catalyst concentration, to allow time to for mixing, degassing and transfer of the reacting mixture into molds. In this way potting resembles batch-type bulk synthesis of thermoplastics, without the grinding and pelletizing steps. This technique can be used to encapsulate electrical coils and circuits, and to make cast parts. If mixing and mold filling are done on a specially designed injection molding machine, it is called reactive injection molding (RIM) and is capable of making large complex parts. However, the advantages of slow-speed *hand* casting are low equipment cost and the ability to encapsulate delicate parts due to the low viscosity and flow rate of the reacting mixture. The use of polyfunctional reactants to make cross-linked parts with improved thermal and chemical resistance is also possible. The amount of unreacted diisocyanate present in the prepolymer determines the amount of chain extender/cross-linker required and therefore the resulting hardness of the polymer. By varying soft-segment composition and concentration, a wide range of physical properties can be obtained. In this way, electrical properties including dielectric strength, arc/trac resistance and dissipation factor, along with properties such as coefficient of thermal expansion, elasticity and speed of sound can be optimized. Biomedical applications include insulation (for electrical circuits and transcutaneous power transmission coils), ultrasonic probes and vascular access ports. Due to the absence of a melt-processing step following chain extension, mechanical properties of un-cross-linked cast parts may be inferior to thermoplastics of identical composition.

As mentioned in Section 1.125.1.2.2 neat prepolymers can be chain extended with water and the CO_2 generated can foam the reaction mixture. In the presence of an optional foam-stabilizing surfactant (e.g., a silicone–polyether copolymer) a porous construct will result. Open-cell or 'reticulated' versions have application as tissue engineering scaffolds, wound dressings, and sponges. Closed-cell foams can be used in sewing cuffs and vascular grafts with tailored compliance that minimize bleeding when stuck with a needle. A more controlled approach in device fabrication is to include a pore former like sodium chloride, sugar, or soluble polymer particles in the urethane, which is leached out after device fabrication to produce pores (Figure 13).

1.125.2.2.4. Water-borne dispersions for coatings

The manufacture of polyurethane dispersions generally involves synthesis of polyurethanes having carboxylic acid or nonionic hydrophiles like PEG incorporated into, or pendant from, the polymer backbone. Carboxylic acids are usually neutralized with a tertiary amine, which creates an ionic center enabling the pre-polymer to be dispersed in water as emulsions.[49] The much faster amine–isocyanate reaction relative to the water–isocyanate reaction is used to convert the prepolymer emulsion to a fully reacted polyurethane emulsion or dispersion upon the addition of amine.

Recently, aqueous polyurethane dispersions derived from various polycarbonate-diols, di(4-isocyanatocyclohexyl) methane (HMDI) and various carboxylic diols, including dimethylol propionic acid (DMPA), dimethylol butyric acid (DMBA) and a carboxylic polycaprolactone-diol have been prepared and shown to exhibit higher temperature resistance when compared with those derived from isophorone diisocyanate (IPDI).[50] Biodegradable and biocompatible poly(ester-urethane)s have been synthesized by *in situ* homogeneous solution polymerization of poly(ε-caprolactone) diol, dimethylolpropionic acid (DMPA) and methylene diphenyl diisocyanate in acetone followed by solvent exchange with water.[51]

Certain water-borne polyurethanes are useful as coatings over a variety of substrates including preformed polyurethanes, particularly when a solvent-based coating would damage thin underlying layers, for example, in sensors. However, some water-borne polyurethanes do require 'coalescing solvents' to facilitate fusion of polymer micelles into a dense film during drying. Biostable water-borne polyurethane coatings may be candidates for use in subchronic implantable devices, for

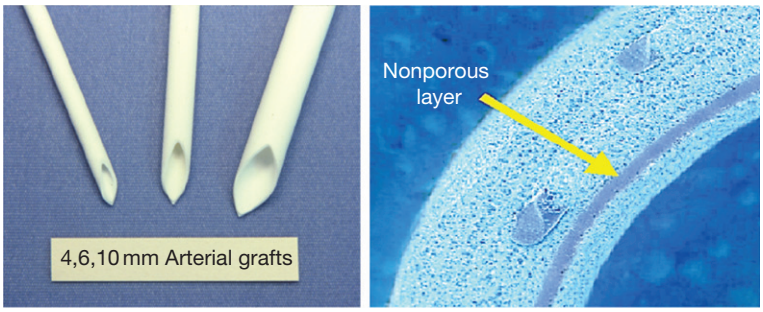

Figure 13 Prototypes of the Thoratec Vectra vascular graft fabricated from segmented polyurethane. The cross section shown at right reveals alternating layers of porous and nonporous polymer, and a fiber reinforcement that prevents kinking. Varying the pore size and void volume allow tailoring the radial compliance in an attempt to match natural arteries. The dense layer close to the luminal surface prevents seromas and helps seal after needle sticks when the graft is used for blood access (in dialysis).

example, as antimicrobial or lubricious coatings. However, the wet strength and biostability of the final coating may be lowered by residual hydrophilic moities.

1.125.3. Utility of PUs and PUUs as Biomaterials

The selection of a biomaterial for a critical device invariably requires specifying both bulk and surface property requirements. Bulk properties include hardness, modulus, tensile and compressive properties, flex life, permeability, water absorption, dielectric strength, optical clarity, density, leachable fraction and biostability. Surface properties include thromboresistance, wettability, (non)specific protein adsorption, abrasion resistance, coefficient of friction and cell and protein interactions. The wide range of reactants available for use in polyurethane synthesis provides the raw materials for tailoring *bulk* properties, and many useful structure-versus-bulk property relationships are reported in the literature. Even when limiting the choice of reactants to those already known to be safe and biostable, the material scientist has a lot to work with. On the other hand, less is known about the relationship between the bulk composition and structure and their effect on the chemistry and nanostructure of the surface region that comprises the biological interface. This complicates the understanding of how the polyurethane surface affects biological interactions, and favors the use of research techniques such as self-assembling monomers adsorbed on gold, in place of actual biomaterials. New methods have been developed that promise similar control of the surface region of actual polyurethane biomaterials (see Section 1.125.6.1.3).

1.125.3.1. Biostable PUs and PUUs

The long-term stability of segmented/block polyurethanes in the body depends on a number of factors including structure and composition, the presence of optional stabilizing additives, the chosen implant site and the sample's purity and processing history. Fabrication, handling, residual solvent, sterilization method and device design are also important factors. These will be discussed separately.

1.125.3.1.1. Structure and composition: soft-segment chemistry

Various researchers recognized early on that differences in soft-segment chemistry affect biostability: polyester soft segments were found to be much more susceptible to hydrolytic degradation and attack by microorganisms than were polyethers.[52] Work that began in the 1970s after some failures of first-generation polyurethane pacemaker leads has been continued to elucidate failure modes and to screen new candidate polymers. Much of this work was done using protocols that greatly accelerate degradation rate, either through the use of highly oxidizing and hydrolyzing conditions, elevated temperature, use of intramuscular implant sites, and/or the practice of stretching the test sample to several times its initial length. Those polymers that degrade predominantly by chain scission and molecular weight reduction often show early signs of *environmental stress cracking* (ESC) under microscopic examination. These highly strained samples, often in the form of thin-walled tubing or film, may ultimately fail catastrophically as these cracks propagate under the atypical static elongation superimposed on them during the test. Soft poly*ether* urethanes degrade even faster in these accelerated *in vitro* and *in vivo* tests if they are exposed to certain metal oxides during the test. Cobalt, a commonly used metal in alloys for high-flex-life pacemaker wire and orthopedic implants is known to accelerate polyether oxidation. This has been termed *metal-oxide-induced oxidation* (MIO). As cobalt-containing metal alloys are often used in chronic implants, the use of softer grades of polyether-urethanes in close proximity to these alloys should be avoided. Even when covered by biostable, yet permeable silicone elastomer, degradation of a polyetherurethane having a durometer hardness of 80A has been observed when in contact with cobalt alloys.[53,54]

The reader should note that, the above consideration notwithstanding, with well-designed medical devices it is rare to see the extent of *in vivo* degradation that occurs in accelerated *in vitro* degradation testing. Furthermore, materials used as positive controls in these accelerated degradation tests are *softer* homologues of polyurethane that are successfully used in pacemaker leads, and many other implants. Even softer polyetherurethane-ureas can be very stable in blood pumps and vascular grafts in which MIO is not a factor.

Whereas softer (e.g., 80 Shore A) polyalkylether-urethanes are hydrolytically stable, they *are* susceptible to oxidation in accelerated testing when attacked by macrophages and foreign body giant cells *in vivo*. Analogous polyalkylenecarbonate, first thought to undergo minor surface hydrolytic degradation *in vivo*, may actually be susceptible to some surface oxidation particularly when it contains trace ether linkages introduced during polyol synthesis. Exclusion of ether linkages in the polymer appears to improve surface biostability in preliminary accelerated degradation testing. The presence of hydrophobic hexamethylene chains shielding the polycarbonate linkages protects this specific polycarbonate, in part by reducing permeability. A similar effect *may* slightly improve oxidative stability of polyhexamethyleneoxide relative to polytetramethyleneoxide, which has two less methylene groups in its repeat unit, and therefore, a higher bulk concentration of ether groups per unit volume.

As previously discussed, the *concentration* of the soft segment(s) is a major determinant of polyurethane biostability. Assuming a stable hard segment is chosen (e.g., MDI+BD or MDI+ED) the harder homologues, that is, those with the least soft segment, have the best biostability in virtually all of the polymer families studied to date. Soft segments that give tough polyurethanes but which are inherently susceptible to significant degradation by hydrolysis and/or oxidation are unsuitable for use in biostable formulations: polyadipate esters and polylactones are examples. At the other end of the spectrum are candidates that are oxidatively and hydrolytically much more stable but which give relatively weak polymers: single-soft-segment PUs and PUUs based on polydimethylsiloxane or polyisobutylene are included in this group. The most commonly used organic soft segments in biostable polyurethane(urea)s are currently aliphatic polycarbonates and aliphatic polyethers, wherein the length of the repeating alkyl chain is either four or six carbon atoms. These provide polymers having excellent initial physical–mechanical properties

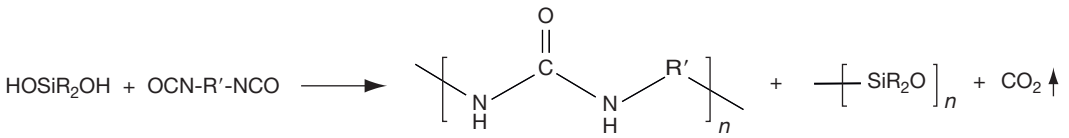

Figure 14 Reaction of isocyanate with silanol. Reproduced from Sheludyakov, V. D.; Kozyukov, V. P.; Mironov, V. F. *Russ. Chem. Rev.* **1976**, *45*(3), 227–245.

and *in vivo* stability that is more than adequate for many implant applications.

In fact, the long-term performance of biomaterials depends on both the *initial* properties of the polymer and the extent to which the initial bulk and surface properties are retained during implantation. Inherent oxidative biostability of commonly used soft segments in polyurethanes of nominal 80 Shore A indentation hardness, in decreasing order of inherent stability during accelerated testing *i*, in the author's experience is:

polyisobutylene > polydimethylsiloxane
> poly (hexamethylenecarbonate)
> polyoxyalkylene (polyether)

However, this is *not* the same order of the initial toughness of the resulting polymers, which is roughly the reverse, except that polycarbonate polyols of equivalent concentration and molecular weight often give tougher polymers than polyethers.

Studies that consider various aspects of stability continue: cross-linked poly(ether polyurethanes) based on poly (1,4-butane diol), and 4,4′-diphenylmethane diisocyanate having varied aliphatic hard segments consisting of 1,6-hexamethylene diisocyanate have been prepared having diols and triols which hydrolytically degraded in distilled water at 37 °C. The degree of degradation is dependent on the degree of cross-linking and nature of the diisocyanates and chain extenders.[55] The polyether polyurethane Elasthane 80A has been evaluated for *in vivo* cellular responses including foreign body reaction cytokines release at the site of the material implant,[56] and in T-cell-deficient mice.[57]

Specific surface modifications to polyether polyurethanes have been made via the use of *surface-modifying end groups* to modify biological response. The role of serum proteins and material surface chemistry in the formation of *Staphylococcus epidermidis* biofilm on polyurethanes (Elasthane 80A, hydrophobic) modified with polyethylene oxide (Elasthane 80A-6PEO, hydrophilic) and fluorocarbon (Elasthane 80A-6F, hydrophobic) was reported by Patel *et al.*[58]. On the hydrophilic Elasthane 80A-6PEO surface, bacterial adhesion decreased steadily over 24 h and, most notably, the polyethylene oxide surface was found to significantly inhibit *S. epidermidis* biofilm formation over 48 h *in vitro*.

Polyether urethanes based on poly(tetramethylene oxide) (PTMO, MW 2000), chain extended with butenediol and having silanol-terminated polydimethylsiloxane (PDMS, MW 2000) blocks exhibit various degrees of microphase separation that influenced their stability and biological performances *in vitro*. The combination of enhanced mechanical properties, biostability, cellular affinity as well as platelet nonadherence was improved with PDMS.[59] However, we note that the authors of this study may have unknowingly prepared an admixture of silicone fluid in polyurethane rather than the intended

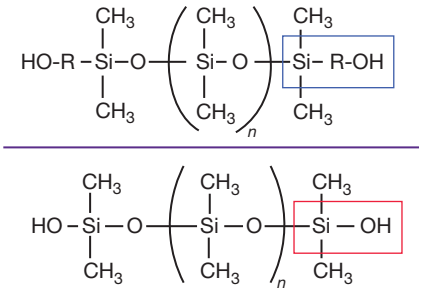

Figure 15 The synthesis of well-defined, high-molecular weight silicone–urethane(urea) copolymers requires oligomeric diols (or diamines) with the top structure. The organic R group can be a short-alkyl chain, but often includes an ether oxygen that may improve compatibility. Silanol-terminated fluids are readily available reactants used in the manufacture of RTV silicones, but they do not form silicone–urethanes in reactions with (di)isocyanates as discussed above.

silicone–urethane copolymer: hydroxyl groups bonded to silicon: also known as *silanols*, generally do not react with isocyanates to form urethane groups. Instead, isocyanates abstract water from silanols creating new siloxane bonds (–O–Si–O–) that increase silicone chain length. The condensed water *can* react with –NCO to form unstable carbamates that decompose to release CO_2 and form amines that produce *ureas* by reacting with –NCO. For example, the reaction of model monofunctional organic isocyanates with silanediols and oligosiloxanes containing terminal hydroxyls proceeds with the isocyanate acting as a dehydrating agent (Figure 14).

The polycondensation of dialkylsilanediols or polyalkylsiloxanediols with hexamethylene or tolylene diisocyanates, oligourethanes with terminal isocyanato-groups, yields insignificant amounts of organosilicon polyurethanes: these reactions result mainly in the evolution of CO_2 and water and the formation of organic polyureas in admixture with polysiloxanes (Figure 15).

1.125.3.1.2. Importance of block and segmented PUs in long-term implants

During more than 40 years of polyurethane use in chronic implants, our knowledge of polymeric biomaterials has evolved from an empirical approach to more systematic macromolecular design. The advancement of biomaterials science and the introduction of new bulk and surface analytical techniques and instrumentation have facilitated the development of biomaterials for specific applications, gradually replacing the older process of adopting commercial polymers for use in device manufacturing. The relative ease with which polyurethane bulk and surface properties can now be tailored during synthesis makes them one of the best platforms for the development of advanced biomaterials.

As previously mentioned an early and notable success with polyurethane biomaterials was in the fabrication of cardiac assist devices including balloon, sac, and diaphragm types in which available silicone homopolymers lacked sufficient flex life, toughness and thromboresistance. This remains an important application considering that these life-supporting devices must flex with the beating heart about 750 000 times per week. Federal Drug Administration (FDA) approval of sac- and diaphragm-type devices as alternatives to heart transplantation indicates the importance and reliability of certain block and segmented polyurethanes in such 'destination devices.' The earliest cardiovascular applications all used solvent-based fabrication methods including dipping, casting, spraying, and even labor-intensive pouring of viscous polymer solutions with hand manipulation of molds. This limited their early use to less cost-sensitive devices in which the material itself was 'enabling technology.'

In the mid 1970s, in response to the success of the early solvent-based polyurethanes (Biomer and Avothane-51), Upjohn Corporation offered a series of experimental thermoplastic polyether-urethanes: the Pellethane 2363X series. The first clinical use may have been an extruded catheter for AVCO's intraaortic balloon pump, followed soon after by pacemaker lead insulation from Medtronic. This pioneering development work with thermoplastic PUs led to the introduction of commercially available 'medical grade' thermoplastic Pellethanes® by Upjohn. The Pellethane 2363 Series was later acquired by Dow Chemical. Implantable applications continued to be developed until *c.*1989 when, during the so-called biomaterials crisis, Dow announced that Pellethane would no longer be sold for use in chronic implants, at the same time DuPont and Ethicon established the same policy for Biomer™ Segmented Polyurethane. At the urging of National Institute of Health (NIH), The Polymer Technology Group in Berkeley, CA (now DSM Biomedical) developed replacements for both polymers (Elasthane™ TPU and BioSpan® SPU), which became platform biomaterials for a number of more advanced biomedical polyurethanes and silicone–polyurethane copolymers (see **Figure 5**). Although the *current* trend in mechanical cardiac assistance is toward the use of 'axial flow' devices that do not use flexing polymeric components to pump blood, thermoplastic polycarbonate-urethane (e.g., Bionate® TPCU) is being used in another critical component of these devices: the insulation of electrical leads that transmit power and information to and from the implanted device.

At present the role of a small number of polyurethanes in long-term cardiovascular implants is unique and still required due to an unmatched combination of physical–mechanical properties, biostability and processability. The latter is related to the many fabrication methods available to the device manufacturer – an important consideration when specifying biomaterials during device design.

1.125.4. Composition of Important biostable PU and PUUs

Virtually all high-strength, biostable polyurethanes and silicone–polyurethane copolymers used in chronic implants are synthesized from the components listed in **Table 2**. In most polymers, the aromatic diisocyanate (MDI) is used to form the hard segments. Although they may be more easily extruded and molded, polymers based on the cycloaliphatic analogue, HMDI generally have inferior long-term biostability, reduced heat and solvent resistance and lower physical–mechanical properties at equal hard segment concentration. Biodegradable polyurethanes, on the other hand, often use aliphatic or cycloaliphatic diisocyantes to avoid aromatic degradation products resulting from their intended decomposition *in vivo*.

1.125.4.1. Chain Extenders

Commonly used chain extenders include butanediol (BD), and ethylene diamine (ED). Even-numbered chain extenders are often preferred because they can improve efficiency in hydrogen bonding and resulting physical–mechanical properties.

Sanchez-Adsuar and Martín-Martínez[60] studied the influence of the length of the chain extender using three linear chain extenders: ethylene glycol, 1,4-butanediol, and 1,6-hexanediol. Short-chain extenders produced phase separation, higher crystallinity and adequate rheological properties but did not affect

Table 2 Polyurethane and silicone–polyurethane copolymers used in chronic implants

Type	*Tradename*	*Manufacturer*	*Difunctional Isocyanate*	*Chain Extender*	*Polyol(s)*	*End Groups*
Poly-carbonate TPU	Bionate®	DSM Biomedical	MDI	BD	PHMC	NA
Surface-modified polycarbonate TPU	Bionate® II	DSM Biomedical	MDI	BD	PHMC	C_{18} alkyl

the surface properties. Improved crystallinity and a high degree of phase separation were created in the PUs by the decrease in the length of the chain extender. In addition, Bae *et al.*[61] compared dynamic mechanical behaviors of polyurethanes with different types of linear and nonlinear chain extenders and showed the T_g of the soft-segment matrix varying with the type of chain extenders.

The effects of butanediol (BD) or 2,2′-(methylimino) diethanol (MIDE) as chain extenders on the degradation, mechanical properties, hydrophilicity, and cytophilicity of polyurethanes containing (MDI) and polycaprolactone diol (PCL-diol) have been evaluated. *In vitro* degradation studies showed that PU containing MIDE has a higher degradation rate than PU synthesized using BD.[62] Adhikarir *et al.*[63] used silicone chain extenders and showed improved compatibility in PDMS soft-segment phase with the hard segment in mixed macrodiols.

Yoon and Ratner[64] used various perfluoro chain extenders in making polyurethanes. They found the perfluoro chain-extended polymers had more soft segments at the material surface than those at the same hard-segment content. Decreasing the soft-segment molecular weight increased fluorine content or hard-segment concentration in the surface region. The same fluorine content was found uniformly distributed throughout the surface region and in the bulk. Symmetric fluorine substitution in the chain-extender region generally enhances the mixing of hard and soft segments.[65]

Aromatic diamines have been used as chain extenders in reactive injection molding (RIM) for polyurethane elastomers.[66] Heterocyclic polyurethanes synthesized by the extension reaction of macrodiisocyanates with heterocyclic diamines have been shown to increase the decomposition temperature of the polyurethanes.[67] Colored or transparent materials were made elastic (based on polyethylene glycol adipate) or brittle (low molecular glycols) depending on the nature of the heterocyclic unit.

1.125.4.1.1. Diols

Linear and branched chain extenders are used (see **Table 1**). Important considerations include the molecular weight of the diol or polyol. Diols used as chain extenders are subject to similar requirements as found in those used as soft-segments: uniformity and purity, and especially batch-to-batch consistency are important parameters in maintaining reproducible consistent properties and quality of the final polyurethane product.

Aliphatic diols of varying lengths including up to and beyond C_{12} have been developed.[68] In addition, branched structures, such as 2-methyl-1,3-propane diol, and triols (glycerine (1,2,3-propane diol), trimethoylpropane (TMP)) are commonly used. The ability to bind functional organics such as heparin has also been developed using specially designed diols.[69] The trend towards developing biodegradable or resorbable diol chain extenders having multiple ester or ether linkages with applications in tissue engineering scaffolds and bioresorbables is also seen.

1.125.4.1.2. Diamines

Diamines are useful as chain extenders in polyurethane-ureas. The hydrogen-bonding ability of the resulting polyurea hard segments provides exceptional tensile strength at low hardness. Compared to low molecular weight diol chain extenders, diamines provide twice the hydrogen bonding capacity per reacted isocyanate group. Phase separation is excellent even at low hard segment content, making tough rubber-like elastomers possible. These elastomers can have extremely good flex life in blood-contacting applications in VADs and TAHs. Examples include Biomer™ and BioSpan® SPUs.

Common diamine chain extenders include ethylene diamine, and the cyclo-aliphatic primary diamine 1,3-cyclohexanediamine (Table XX) which may be used in the same polymer, and aliphatic and aromatic secondary diamines.[70] Slower reacting secondary aliphatic diamines have been studied as chain extenders in aliphatic polyurea spray applications.[71] Polyether-based polyurethane membranes have been made and characterized with chain extenders having varying lengths.[72] Permeability and diffusivity of gases increased with the increasing length of the chain extenders, as did the extent of microdomain phase separation.

Diamine chain extenders having *biodegradable* properties have been developed in tissue engineering applications. Bioresorbable components including putrescine (PUT) or branched lysine ethyl ester (LEE) diamines have been reported.[73] The products from their decomposition are seen as being more biocompatible while the polymers have properties approaching typical diamine chain extended materials.

1.125.4.2. Soft Segments

Study of polyurethane soft segments and the variety of diols available for consideration is extensive and has been recently reviewed.[74] Because it is one of the major components responsible for final material properties, selection of the soft-segment component is a critical aspect in the design of biomedical polyurethanes. The soft-segment molecular weight, distribution, (di)functionality, solubility with other reactants during synthesis, and compatibility with the hard segment are all important considerations, as is the ability to crystallize during elongation in the product polymer. Decomposition mechanisms and degradation pathways leading to bioabsorption or biostability make for tunable soft segment and provide factors that receive additional consideration in tissue scaffold and bioresorbables engineering.[75]

1.125.4.2.1. Polyester

Polyester-based polyurethanes degrade by hydrolytic degradation of ester functional groups.[76] These polyester-based urethane elastomers degrade even in moist air via acid-catalyzed hydrolysis of the ester group, and sometimes revert to viscous liquids.[77] The reaction is autocatalytic, with one acid group being generated per $-CO_2-$ group. Appreciable loss in mechanical properties can occur with only a small number of $-CO_2-$ linkages being reacted due to appreciable loss in molecular weight: each reaction of a carboxyl group generates one new molecule containing an acid group which can further react. Melting points and densities of the poly(ester polyurethanes) are strongly dependent on soft-segment (polyester) concentration.[78]

1.125.4.2.1.1. Adipate esters

Adipates are saturated polyesters that exhibit strength and durability, excellent tear and abrasion resistance, resistance to

solvents and resistance to oxidation and UV light degradation. Depending on the hard-segment content and other substitutions, hydrolytic stability can vary from good to marginal: microorganisms have been isolated that can use adipic acid-based PUs as their sole source of carbon and nitrogen.[79]

An Estane polyurethane, is a commercially available random copolymer consisting of poly(butyleneadipate) (PBA) and butane diol soft segments formed from adipic acid and MDI and BDO hard segments.[80] It has been used in a number of biomedical applications and has been evaluated for orthoplastic applications.[81] Polymers including PBA soft segments are clearly not suitable as biostable polyurethanes due to the hydrolytic instability of the soft segment. They may be candidates of use in bioresorbable polymers but appear to be less desirable than polylactones (see **Section 1.125.4.2.1.2**).

Recently, Pierce *et al.*[82] designed a series of completely amorphous poly(ester urethane) based on adipic acid and β-hydromuconic acid that has a wide range of mechanical properties. In kinetic analyses these materials were found to have extremely fast linear degradation profiles with little or no cytotoxic response.

For improving surface properties, Ming and Ping[83] treated biomedical poly(ester)urethanes based on polyester adipate soft segments with low-powered gaseous CO_2, O_2, NH_3, and SO_2 plasmas, which resulted in the incorporation of oxygen-containing groups, nitrogen-containing groups and sulfur-containing groups. They found an increase in the polar character resulting from increased wettability for all the treated surfaces.

1.125.4.2.1.2. Lactones

Lactones comprise a large portion of potential soft-segment candidates and homo- and copolymers of lactone-containing soft segments have been prepared.[84] From this class of candidates, caprolactone has been used in polyurethane-containing biomaterials, especially for biodegradation and bioresorbable properties. Polycaprolactone PUs have been extensively studied for tissue engineering and scaffolding applications.[85–87] Saccharic acid dilactones prepared from D-glucose and D-mannitol, D-glucaro- and D-mannaro-dilactones decompose easily in phosphate buffers under neutral or slightly basic conditions (pH 7 or 8), and are additional examples of novel degradable polymeric materials containing lactone soft segments.[88]

1.125.4.2.2. Polyethers

A number of different polyethers have been used[89]: segmented polyurethanes (SPUs) based on polyethylene glycol (PEG), polypropylene glycol (PPG) and a series of pluronics with different ethylene oxide/propylene oxide ratios (EO/PO) and molecular weights have been prepared.[90] Segmented polyurethanes (SPUs) based on polyethylene glycol (PEG), polypropylene glycol (PPG) and a series of Pluronics with different ethylene oxide/propylene oxide ratios (EO/PO) and molecular weights were prepared. Different diisocyanates were used for making SPUs: 4,4-diphenylmethane diisocyanate (MDI), 4,4-dicyclohexylmethane diisocyanate (MDCI), hexamethylene diisocyanate (HMDI) and isophorone diisocyanate (IPDI). Butane diol (BD) and ethylene diamine (ED) were used as chain extenders. The polymers obtained were characterized by infrared spectroscopy (IR), nuclear magnetic resonance (NMR) and differential scanning calorimetry (DSC). The microphase morphology (phase separation and phase mixing) was discussed in detail.

Grasel *et al.*[91] made a series of PTMO polyurethane block copolymers with varying levels of propyl sulfonate groups incorporated into the hard segment block. The highly sulfonated materials were found to rearrange to minimize their interfacial tension, depending on the contacting environment. They also looked at platelet deposition which was found to decrease as the level of sulfonation increased: highly sulfonated polymer showing substantially less platelet spreading and activation. Inclusion of the sulfonate in the backbone, however, increased hydrophilicity and apparently reduced interchain hydrogen bonding compared to controls. The result was a significant reduction of physical–mechanical properties.

1.125.4.2.3. Other polyalkylene oxides (also known as polyethers)

Other polyalkylene oxides such as polyethylene glycol have been extensively used and studies in polyurethanes and early reviews exist.[92] Although PEG often imparts favorable surface properties including reduced protein adsorption and enhanced thromboresistance, incorporation of PEG soft segments into the backbone greatly reduces resistance to *in vivo* oxidative degradation of polyurethanes. For this reason, it is best used in short-term implants of $\sim\leq$6 month duration, for example, for sensors or immunoisolation devices.

1.125.4.2.4. Aliphatic polycarbonates

One of the most effective methods of improving oxidative stability in polyurethanes currently used in clinical applications has come with the development of polycarbonate soft-segment chemistry: enhanced biocompatibility and biostability for poly(carbonate)urethane has been reported by a number of authors (e.g., see Shan-hui *et al.*[93]).

Synthesis of polycarbonate diols (PCD) useful for soft segments has been described by Pawlowski and Rokicki[94] and synthesis, characterization and structure property relationship of poly(carbonate polyurethanes) has been reviewed.[44,95,96] In preparing polyurethanes, the influence of molecular weight and chemical structure of several polycarbonate diols on the kinetics of condensation reaction with *p*-tolyl isocyanate was also reported.[97]

Ahn *et al.*[98] prepared a series of polyurethane elastomers varying the composition of hard-segments chain extenders (BD and Isophrone, IPDA) and similarly controlling the ratio of soft segments (poly(tetramethylene ether) glycol and poly (hexamethylene carbonate) glycol). In his study, he was able to show that most of the urea carbonyl groups were associated in hydrogen bonding, while urethane carbonyls were only partially associated, depending on the hard-segment composition. They further reported that when the composition of soft segments was varied by partially exchanging PTMO with PHC, the polar properties of carbonate groups in the PHC seemed to increase the phase mixing of hard and soft segments.

The microphase separation between hard and soft segments in segments was observed to influence protein adsorption, platelet activation, and cellular attachment and growth. In a

series of poly(carbonate) MDI-based urethanes, Hsu and Lin[99] synthesized polyurethanes having four different soft segments: two aliphatic macrodiols (poly(hexyl, ethyl)carbonate diols, and two aromatic macrodiols in different molar ratios to MDI. Higher M_w poly(carbonate) macrodiols resulted in more phase-separated structure: aromatic macrodiols had better mechanical strength and biostability. Polyurethanes synthesized with poly(ethyl-hexyl)carbonate diol in a molar ratio MDI/macrodiol/chain extender of either 3/2/1 or 4/3/1 resulted in greater microphase separation and was found to have superior biocompatibility and biostability. In this fashion, control over the different aspects of the macrodiol such as molecular weight and ratio to other components have a tunable effect on final properties.

1.125.4.2.4.1. Potential importance of purity/lack of ether contaminants

In the synthesis of polycarbonate diols from ethylene carbonate at higher temperatures, the formation of oxyethylene group incorporation is possible[94]: polycarbonate polyurethanes having such ether linkages as 'impurities' can affect physical properties and thermoplastic processing. When the polycarbonate diol having these oxyethylene groups is incorporated into polyurethane, the expectation would be a decrease in hardness, a difference in modulus at equivalent hard-segment content, and a possible decrease in biostability (oxidative stability). However, depending on the amount of oxyethylene content, these groups having ethereal linkages can be effective in modulating polyurethane properties.

1.125.4.3. General Properties of Polymers with a Single Soft Segment Chemistry

General trends exist among the different classes of polyurethane copolymers. The contributions from the hard and soft segments can be easily adjusted via compositional changes during synthesis and often vary monotonically until a *phase inversion* point is encountered. In polymers with only one soft segment chemistry and one hard segment chemistry, composition affects many bulk properties including modulus, hardness, toughness and even permeability, albeit without much control of selectivity or molecular weight cutoff. At high soft-segment concentration, for example, 60–80 wt% in TPUs and ~70–90 wt% in solution PUUs, in which the soft segment is the *continuous phase*, polymers vary from soft, sticky gels, to rubber-like elastomers, to 'snappy' elastomers (i.e., with a tensile modulus > natural rubber). As soft segment ratio is decreased to the point that it is no longer the phase with highest volume fraction, the slope of a graph of a given property versus composition may change. Polymers with intermediate composition can have co-continuous phases and may be leathery but still flexible within the body, particularly in constructs with thin cross sections. As soft segment is reduced to the point that it becomes a minor, dispersed/noncontinuous volume fraction, polyurethanes may resemble impact-modified plastics, depending on composition and soft segment molecular weight. Decreasing soft segment concentration generally *increases* biostability, tensile strength, indentation hardness, and compressive, tensile and flexural moduli. It *decreases* ultimate elongation and permeability, the latter due to the glassy or semicrystalline nature of the hard segment. In the harder grades of thermoplastic polyurethanes in which hard segment concentration *and* molecular weight are high, phase compatibility is increased by reducing soft-segment molecular weight.

1.125.4.3.1. Effect of alkylene chain length

Martin *et al.*[36] compared the effect of average soft-segment length on morphology and properties of a series of poly(hexamethylene oxide) (PHMO) MDI/ BDO elastomers. Consistent with the above discussions, they reported that as soft-segment length was increased there was an increase in microphase separation, average interdomain spacing, hard-domain order, hardness, stiffness and opacity.

1.125.4.4. Mixed Soft Segments

When tailoring PU properties for a specific application, a valuable tool for extending the property range is the use of two or more soft segments in the same polymer. This approach is particularly effective when the two soft segments possess some thermodynamic compatibility with each other. In this case properties like permeability and absorption are more likely to vary systematically with soft segment composition. For example, power law relationships often give good fits to permeability versus composition data.[100]

Mixed polyisobutylene (PIB)/poly(tetramethylene oxide) (PTMO) soft-segment polyureas containing conventional hard segments were prepared by Jewrajka *et al.*[18,19]. The PIB-containing polymers had improved hydrolytic and oxidative stability. The authors believe that the PTMO segments were better able to transfer stress from continuous mixed soft phases to the dispersed hard phase, which strengthened and made these PIB-based polyureas flexible. It was reported that this significantly improved elastomeric properties without compromising oxidative and hydrolytic stability.

1.125.4.5. Hydrophobic and Hydrophilic Polyethers

One useful example of polyurethanes having mixed soft segments is polyethyleneoxide + polytetramethylene oxide. This combination of hydrophilic and hydrophobic polyethers permits close control of the permeability of dense polyurethane membranes to gases, vapors, and many solutes, which depend on the ratio of PEG to PTMO in the soft segment. However, this approach is only effective when the (swollen) soft segment comprises the major volume fraction of the polymer; for example, when the volume fraction of the soft segments in the dry polymer, plus the water (or other permeant) it absorbs brings the soft segment to a *volume* fraction of >~50% or preferably ≫ 50%. Note that the typically higher density of hard segments means that at 50 wt% the less dense soft segment is likely to be the continuous phase. In permeability optimizations the hard segments can be considered impermeable, acting like a filler that increases the diffusion path of permeants while reducing the cross-sectional area and volume of the polymer available for transport. Keeping hard segment domains low in concentration and therefore dispersed in a permeable continuous soft segment phase permits control of overall permeability via soft segment chemical composition *and* molecular weight.[100–102]

This provides a continuous diffusion path from one surface of the membrane to the other. It may also provide a 'reservoir phase' in drug delivery applications in which the drug is dispersed within a polymer matrix optionally tailored to maximize drug solubility.

Other hydrophilic polyether copolymer mixtures such as those having PEO and PPO soft segments also have the ability to absorb water, which can be similarly adjusted by changing the soft-segment composition and thereby attenuating the physical properties. Polymers have been compared at fixed or variable MDI/butanediol compositions.[103] At constant hard-segment ratios, increasing the amount of PPO over PEO decreases water uptake as expected, however saturation water concentrations were not related in a simple manner. (This is likely to be related to the *incompatibility* of PPO with PEO.) Similarly, at constant soft-segment ratios and composition, water uptake decreases with increasing hard-segment composition, although less dramatically.

1.125.4.6. Silicone and Polyether and Silicone and Polycarbonate

Silicone polymers have a long history in biomedical applications, especially in cardiovascular applications. Pure silicone polymers in general can be hemocompatible and relatively nonthrombogenic; however, they lack mechanical integrity and physical properties such as tear and cut growth propagation, and the higher modulus required in some critical applications. Polyurethanes containing silicones have been developed as a method for enhancing not only the physical properties of the silicone polymer, but also the surface and bulk properties of silicone-free polyurethanes.

Useful combinations of soft segments include polyalkylenecarbonate + polydimethylsiloxane or polyalkyleneoxide + polydimethylsiloxane. Increasing silicone content increases biostability and (oxygen) permeability, but quickly decreases toughness. Polyurethanes with these mixed soft segments can be optimized via soft segment composition, for example, for biostability and/or permeability while maximizing physical–mechanical properties. Figure 16 demonstrates the effect of silicone content on oxygen permeability in nine polymers, including those made with mixed PTMO+PSX soft segment combinations. When the graph is extrapolated to an 'imaginary polyurethane' with 100% silicone, the literature value of oxygen permeability for pure PSX is obtained (Figure 17).

In mixed soft segments it is also possible to take advantage of synergies unavailable through the use of single soft segment. The synergistic combination of silicone and organic soft segments in enhancing biostability was first reported in 1978, and again in 1988. This led to the commercial introduction or captive use of silicone urethane copolymers by several firms who all claimed novelty for their specific compositions.

Mixing PDMS and polyether (also known as polyalkylenoxide) soft segments in PUUs, Park *et al.*[104] created selective gas permeability and diffusion in membranes. They noted that the microstructure of polyether-based PU membranes transformed into a more polyphasic structure by an incorporation of the PDMS phase.

Early on, Nyilas *et al.*[1] had shown that eliminating various impurities and surface inhomogeneities in peroxide-cured silicone rubber (Silastic 372) greatly influenced *in vitro* clotting characteristics in cardiovascular applications. Processing methods, catalyst contaminants and molding conditions were found, in addition to reinforcing silica particles in submicroscopic domains, to affect clotting. Lim *et al.*[105] reported physical properties of segmented poly(dimethylsiloxane) polyurea-urethanes and the extent of phase separation in relation to blood-contacting properties. Whereas the physical properties (tensile strength and modulus) of these materials were not significantly lower compared to polymer without PDMS, the surface properties of the materials were more hydrophobic when measured by contact angle. The key

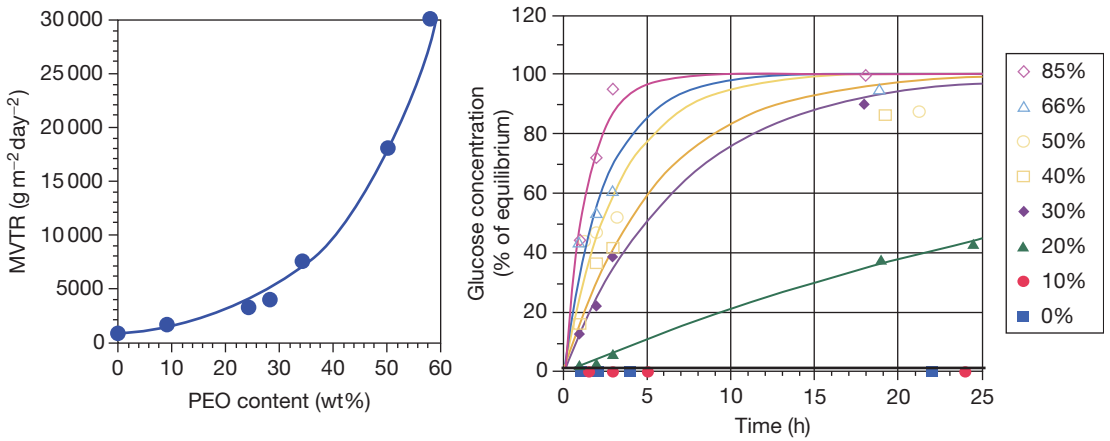

Figure 16 Permeability can be precisely controlled in nonporous polyurethane(urea)s having two soft segments, one of which is hydrophilic. Here increasing the polyethyleneoxide (PEO) content in a PEO+PTMO (polytetramethyleneoxide) polyetherurethane-urea yields increasing 'inverted-cup' moisture–vapor transmission rate (MVTR) measured according ASTM E 96-BW for 0.001 inch film thickness left. Among all classes of polymers MVTR values vary over five orders of magnitude. Hydrophilic polyurethanes are among the most moisture-permeable, high-strength polymers known. Applications include membranes, wound dressings and (biodegradable) films for postsurgical adhesion prevention. Tailoring glucose permeability (measured in diffusion cells) is also possible as shown in the right hand graph. Glucose permeability coefficients were immeasurable below about 10% PEO in this series of polymers, but increased rapidly with PEO content above that concentration.

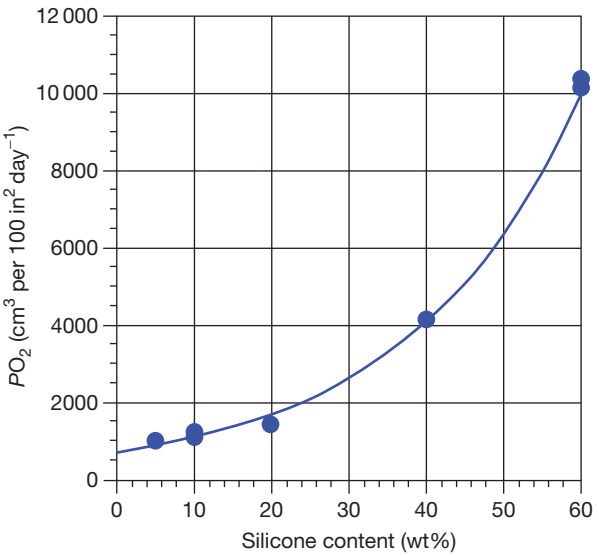

Figure 17 Oxygen permeability (Mocon) versus silicone content in a series of aliphatic and aromatic silicone-polyetherurethane: PurSil and PurSil-AL TSPUs.

realization from these findings was that surface interactions play a critical role in biointeraction and stability.[91,106]

Polydimethylsiloxane (PDMS) polyurea-urethanes based on hexane diisocyanate modified polyether-PDMS soft segments show three distinct phases: a PDMS-rich phase, a polyether soft-segment-rich phase and a hard-segment-rich phase. When evaluated for their blood-contacting properties in a canine *ex vivo* model, they had lower adherent platelet and fibrinogen deposition when compared to a polymer without PDMS in the soft segment. Varying the amount of PDMS in the soft segment of these polymers did not reveal significant differences in their blood-contacting properties.[105] PDMS incorporated into polyurethanes (as end groups, backbone or pendant groups or by admixture) is extremely surface active. The air-facing surface of configured articles may become saturated with PDMS at a bulk concentration of $\ll 1$ wt% silicone. This may explain the insensitivity of platelet and fibrinogen deposition to bulk silicone concentration in the study by Lim.

The biostability of soft-segment poly(ether urethane) (PEU) and poly(carbonate urethane) (PCU), and a material in which the soft segment was partially replaced with poly(dimethylsiloxane) (PDMS), have been compared *in vitro* using an oxidative solution of $H_2O_2/CoCl_2$.[107] Oxidative degradation of the polyether soft segment results in chain scission and cross-linking and pitting of the material surface. In addition, biaxial fatigue accelerated chemical degradation of PEU and eventually caused brittle stress cracking. Partial substitution of the polyether soft segment with PDMS enhanced oxidative stability. TPU containing polycarbonate soft segments was found to be more stable to oxidation with minimal chemical or physical degradation, even in biaxial fatigue.

Commercially, biomedical-grade thermoplastic silicone polyether urethanes such as PurSil® and Elasteon® are true thermoplastic urethane copolymers containing varying amounts of silicone as a soft segment. PurSil is manufactured using a continuous synthesis process in which polydimethylsiloxane (PDMS) comprises one of the soft segments along with polytetramethyleneoxide (PTMO). During prepolymer synthesis, intensive mixing and other conditions that favor compatibilizing the two normally immisible polyols facilitate the synthesis of polymers of any desired soft segment ratio. The hard segment of PurSil TSPU consists of an aromatic diisocyanate, MDI, with a low molecular weight diol chain extender. The copolymer chains are also terminated with silicone (or other) Surface-Modifying End Groups™ (SME). This polymer is noncytoxic, nonhemolytic, nongenotoxic, nonmutagenic, nonpyrogenic, and is the subject of an extensive FDA master file. PurSil has been shown[108,109] to have significantly better biostability than polymers with only PTMO as soft segment. However, during the development of PurSil[110] it was reported that soft homologues with only PTMO *decreased* in MW in intramuscular implants of (strained) film specimens, whereas homologues with only PDMS as soft segment *embrittled* due to apparent *cross-linking* of the polymer. This led to the conclusion that optimum silicone content existed at $\ll 100\%$ silicone soft segment. This is especially true in applications in which maximum physical–mechanical properties are required as high silicone levels generally reduce toughness, cut growth propagation, etc.

Poly(hexamethylene oxide) (PHMO) and poly(dimethylsiloxane) (PDMS)-based macrodiols and mixtures have recently been made and characterized, and they exhibit predictable hard- and soft-segment mixing characteristics.[111]

1.125.4.7. Silicone and Aliphatic Polycarbonate

In addition to the polyether polyol + PDMS soft segment combination described above, even tougher and possibly more biostable polyurethane(ureas) have been prepared in a similar manner, by combining silicone and polyalkylenecarbonate polyols as mixed soft segments, for example, CarboSil® thermoplastic silicone–urethane copolymer.

1.125.4.7.1. Polydimethylsiloxane (silicone)

Silicon-containing polymers and the science and technology of their synthesis have been reviewed by a number of authors (see, e.g., Jones *et al.*[112]). In addition, Yilgör and McGrath,[113] have surveyed polysiloxane containing copolymers and their applications.

As a biomaterial, silicones are frequently identified as one of the few materials having the low hardness and low modulus that is useful in many device applications.[114] Conventional silicone elastomers can have fairly high ultimate elongation, but only low-to-moderate tensile strengths. Consequently, as measured by the area under their stress–strain curves, the toughness of most biomedical (homopolymer) silicone elastomers is not particularly high. In addition, poor cut-growth propagation (e.g., when nicked by a scalpel) and the universal need for reinforcing fillers can also be considered as minor disadvantages in the use of silicones as biomaterials.

One of the least attractive properties of conventional silicone elastomers in device manufacturing is that the materials require covalent cross-linking *and* the inclusion of reinforcing (silica) fillers to develop useful properties. Linear or branched silicone (polydimethylsiloxane (PSX)) homopolymers are viscous liquids or gums at room temperature. Fabrication of device components must include, or be immediately followed by,

cross-linking to form chemical bonds among adjacent polymer chains. The infinite network thus formed gives the polymer its excellent rubber elasticity and characteristic physical–mechanical properties. Cross-linking of extrudable and moldable silicone stock is done via peroxide-generated free radicals adding to vinyl groups incorporated along the polymer backbone, or, more commonly, by the platinum-catalyzed addition of silane (–Si–H) to terminal vinyl groups in so-called LIM systems. Certain low-strength (RTV) silicone adhesives vulcanize at room temperature by *condensation* reactions, eliminating an acid or alcohol to generate –Si–$(OH)_2$ or silanols. This is followed by the elimination of water as silanols condense to form –Si–O–Si– (siloxane) bonds and create a three-dimensional network. Regardless of how the cross-linking or vulcanization is affected, the resulting thermoset silicone cannot be redissolved or remelted. This reduces the number of post-fabrication operations that can be used in device manufacturing with conventional silicones, relative to those possible with thermoplastic biomaterials. For instance, thermal forming, tipping, and tapering; radio-frequency welding; heat-sealing; and solvent-bonding are all useful postfabrication methods that are essentially unavailable when building devices from conventional silicone elastomers.

1.125.4.7.2. History of silicone–urethane development

Even though silicone polymer use preceded polyurethanes as biomaterials by several years, investigators recognized early on the possible advantages of combining silicone and polyurethane in a single biomaterial.[115] Since *c.*1968, combination materials have been prepared as coatings, blends, interpenetrating networks, surface-modifying additives in urethane base polymers, and, most recently, high-strength 'structural' copolymers of silicone and polyurethane.

Before 1970, polyether-based urethanes incorporating polytertramethylene oxide (PTMO) soft segments were known to be inherently stable to hydrolysis and for having excellent flex life. In the late 1970s, development continued with manufacture of segmented and thermoplastic multipolymers having two or more of these types of soft segments along the polymer backbone. The use of more than one soft segment allowed polymer properties to be optimized by controlling the concentration of each soft segment, and the total soft-segment to hard-segment ratio. The series of polymers resulting from thermodynamically compatible mixtures of the polyalkyleneoxides PTMO and PEO have a huge range of permeabilities to water, gases and solutes depending on the ratio of hydrophilic PEO to hydrophobic PTMO. These are currently used as membranes and occlusive dressings. As films or coatings they provide high moisture vapor permeability combined with liquid- and microbial-barrier properties.

In polyurethane–silicone copolymers, the silicone may be present along the polymer backbone and/or in the form of covalently bonded end groups or grafts. Because of the surface activity of silicones in organic base polymers (even when copolymerized), it is relatively easy to obtain silicone-like surface properties on polyurethanes at very low silicone content. This is particularly true when the silicone is present in the copolymer as mobile end groups that can easily 'self-assemble' at the copolymer surface. A bigger challenge has been to obtain some of the other desirable silicone properties – for example, biostability or low modulus – while preserving the bulk properties of polyurethanes such as optical clarity, thermoplastic processability, and extreme toughness (**Figure 18**).

In 1970, the solvent-cast silicone-polyurethane Avcothane-51 was specifically developed as a biomaterial and introduced by Avco Everett Research Laboratory (Everett, MA) for the first clinical intraaortic balloon. This material consisted of a hybrid/psuedo-interpenetrating network of linear polyether urethanes modified with silicone cross-linked after device fabrication (Avcothane-51 later renamed Cardiothane-51 continued to be used in IABs until about 2000). The material is best characterized as a hybrid in which a silicone–urethane copolymer (with Si–O–C bonds) formed *in situ* during solution synthesis stabilizes a blend of a larger amount of moisture-curing silicone homopolymer in a polyurethane-rich solution During fabrication, for example, by dipping, the organic solvent, a 2/1 mixture of THF and *p*-dioxane, evaporates. Atmospheric moisture then condenses on the surface and diffuses into the bulk to hydrolyze terminal diacetoxy groups on the silicone chains. This condenses acetic acid that catalyzes the next step: loss of acetic acid generating, end groups with two hydroxyl groups on each terminal silicon atom. These very reactive 'silanols' condense water to form siloxane cross-links by the same room-temperature vulcanization reaction used in bathtub caulking and silicone medical adhesives. Anhydrous conditions during processing are critical however, because moisture intrusion into the Avcothane dipping solution causes premature cross-linking of the silicone and gel formation in the liquid system, rendering it unusable (**Figure 19**).

The combination of silicone and polyurethane was first proposed to improve the thromboresistance of early cardiac-assist devices, which at the time were plagued by gross thrombogenicity. Cardiothane-51 has since been reported to have good thromboresistance, flex life, abrasion resistance and biostability. Despite excellent *in vivo* results, the Avcothane/Cardiothane system had several disadvantages that limited its use as a biomaterial. These include the need for solution processing, the tendency of the solution to prematurely react with water and coagulate, and the dependence of polymer surface properties on reaction and fabrication conditions. In addition, the polyblend nature of Cardiothane and the thermodynamic incompatibility in the high molecular weight silicone with the preformed polyurethane reactant led to the formation of silicone macrodomains large enough to scatter light. This causes Cardiothane and other hybrid systems to be opaque or translucent to visible light, depending on the actual size of the domains (e.g., see RimPlast™, a family of curable silicone containing thermoplastic compositions for injection molding produced by Huls America, Inc.).

Since the introduction of Avcothane-51, many investigators have sought to develop high-strength, *thermoplastic* silicone-polyurethane (TSPU) copolymers. The prospect of combining the biocompatibility and biostability of conventional silicone elastomers with the processability and toughness of TPUs is an attractive approach to what would appear to be a nearly ideal biomaterial. For instance, it has been firmly established that silicone acts synergistically with both polycarbonate and polyether-based polyurethanes to improve *in vivo* and *in vitro* stability – as, for example, when covalently bonded to the

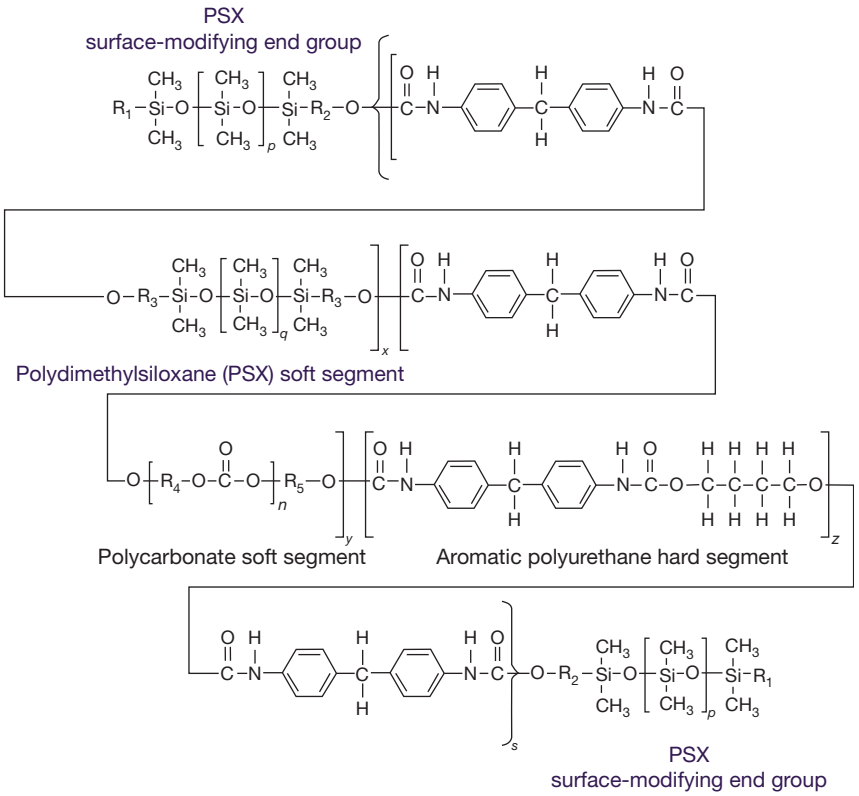

Figure 18 Structure of a thermoplastic silicone–polycarbonate–urethane copolymer with silicone surface modifying end groups. Silicone content, hard segment concentration, and end group chemistry may be easily varied during synthesis to produce a wide range of surface and bulk properties. Fluorocarbon end groups may be used, for example.

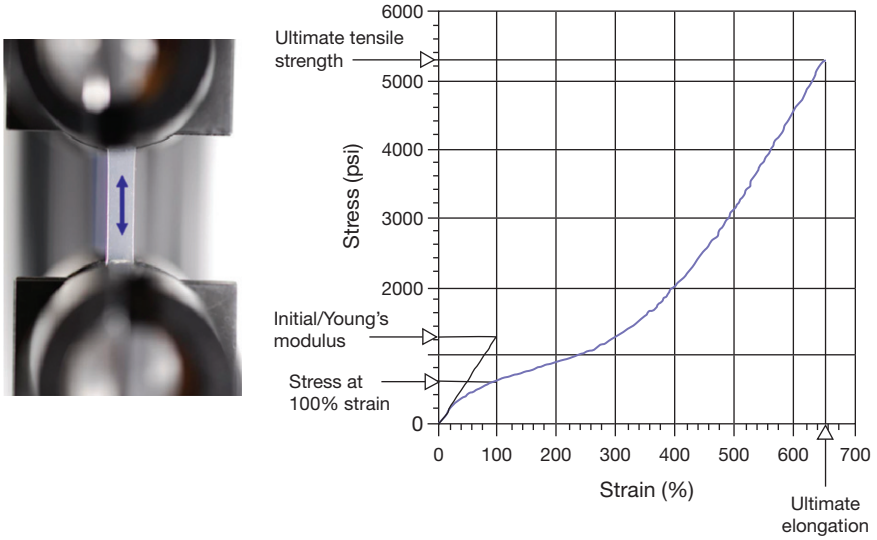

Figure 19 Typical stress versus (engineering) strain curve of a low- to medium-modulus polyurethane elastomer. It is measured in uniaxial tension on a tensile testing instrument (left). Various properties used in device design are labeled. Note the increasing slope in the upper elongation range. This is often caused by strain-induced crystallization, for example, with PTMO soft segments. The area under the stress–strain curve is the energy-to-break the sample, a measure of toughness. Except for very low strain, the nonlinear stress–strain behavior must be considered in device design, for example, when using finite element analysis (FEA).

urethane during synthesis.[109] Several copolymers have shown increased resistance to metal ion-induced oxidation and environmental stress-cracking,[43] both of which have been identified as modes of polyurethane failure in applications such as some early polyurethane pacemaker leads. In polycarbonate-based polyurethanes, silicone copolymerization has been shown to reduce degradation of the carbonate linkage (**Figure 20**), whereas in polyether urethanes, the covalently

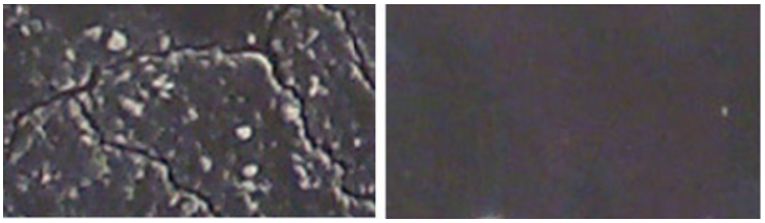

Figure 20 Scanning electron micrograph of early explants (*c*.1991) of low hardness (65A) segmented polycarbonate-urethane-ureas after 12-month intramuscular implantation in rabbits showing enhanced biostability via silicone copolymerization: (left) neat polycarbonate–urethane with environmental stress cracking; (right) silicone–polycarbonate–polyurethane copolymer with no stress cracking.

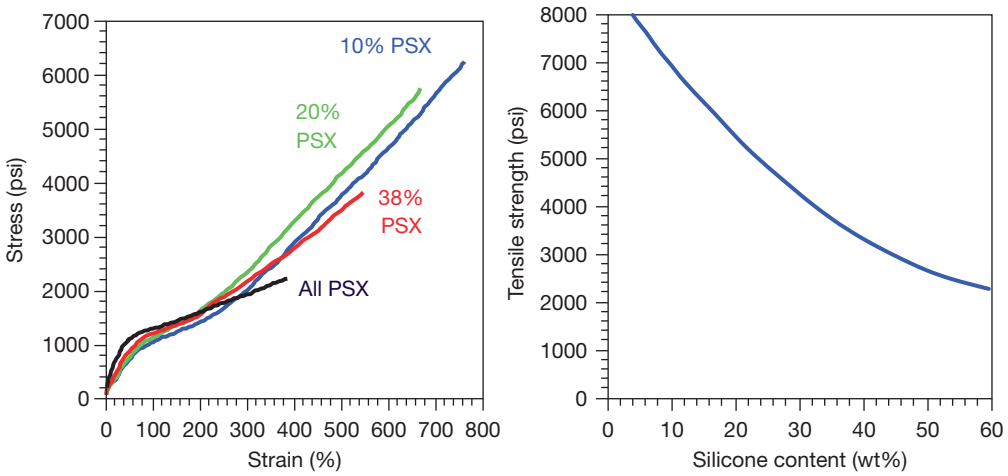

Figure 21 The relationship between tensile properties and silicone content in a series of aromatic thermoplastic silicone–urethane copolymers. Increasing silicone decreases ultimate tensile strength and energy to break, also known as toughness. Optimum silicone content for a soft elastomer often lies between 20% and 35% silicone by weight. In harder versions only 5–20% may be needed. Even at the higher silicone contents these silicone–urethanes have about 3 times the ultimate tensile strength of silicone rubber.

bonded silicone seems to protect the polyether soft segment from oxidative degradation *in vivo*.

1.125.4.7.3. Benefits of silicone modification of PU and PUU

Many of these silicone–urethane copolymers demonstrated previously unavailable combinations of properties. Aromatic silicone-polyether urethanes have a *higher* modulus at a given Shore hardness than do conventional polyether urethanes. Aliphatic silicone-polyether urethanes on the other hand, have a very low modulus and high ultimate elongation, which is typical of silicone homopolymers or even natural rubber. PTMO and polycarbonate soft segment containing polyurethanes polymers however, maintain tensile strengths 3–5 times higher than those of conventional typical silicone biomaterials.

Although less than 1% silicone can give silicone-like surface properties, higher silicone content is required to obtain silicone-like bulk properties such as biostability, permeability, or reduced water absorption. Not all the bulk properties of silicone are desirable in every application (low tensile strength is seldom desirable applications.) Thus, the more silicone that is used to replace the organic soft segment, the lower the tensile strength becomes (Figures 8 and 9). For many biomedical applications 5–25% by weight is an optimum concentration. If high permeability is required – for example, in membranes – higher silicone content may be required. The graph indicates that even when silicone content is as high as 60 wt% the thermoplastics can have tensile strength exceeding most conventional silicone elastomers at 1000–2000 psi. In addition, higher silicone content increases the ultimate raw materials cost of the polymers. Clearly, there is an incentive to determine the minimum silicone concentration that will produce a desired balance of properties (Figure 21).

1.125.4.7.3.1. Improvements in biocompatibility

Early realization that improved thromboresistance and biostability could also be achieved by combinations of soft-segment components (e.g., replacing portions of polyether with PDMS) led to studies directed towards finding this optimum level.[114,116,117] In addition, extending polyether soft segments with polysiloxane was proven to reduce corrosion of metallic parts and reduce the susceptibility to metal ion oxidation (MIO) in implanted devices such as pacemakers or neurostimulator leads.[43] In many applications polyurethanes containing 20–35% polysiloxane (PS-20 and PS-35) were found to be optimum *in vitro*. For implanted tubing samples on cobalt mandrels only traces of microscopic cracks (indicating degradation) were seen after 2 years. *In vivo* polysiloxane-polyether urethanes have also been shown to have higher resistance to biologic oxidation and stress-cracking.[42] PDMS significantly delayed MIO, while the polysiloxane-free controls were severely degraded (Figure 22).

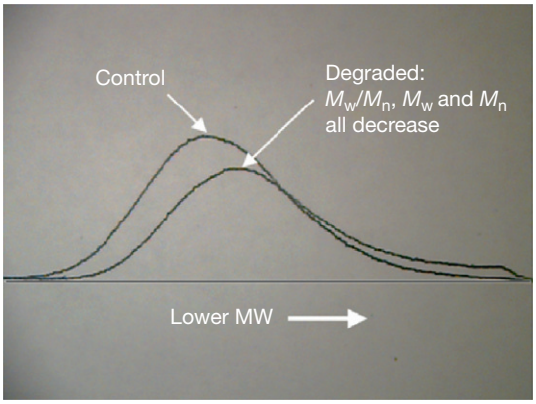

Figure 22 Environmental stress cracking and metal-ion induced oxidation of polyurethanes under accelerated conditions initially results in only surface damage. If the degradation penetrates the bulk significantly and/or if the sample has a very high surface-to-volume ratio, bulk changes may be measurable. Size exclusion chromatography of thin thermoplastic polyurethane films intentionally degraded *in vitro* reveals a reduction in both the number average and weight average molecular weights, and a narrowing of the molecular weight distribution as measured by the polydispersity index M_w/M_n consistent with chain scission.

There is a trade-off between biostability and flexibility, especially for the polyether containing polyurethanes as previously pointed out.[118] In addition, because the (oxidative degradation) reaction is initiated at the soft-segment carbons α to the ether oxygens, the softer the polymer, the more polyether is present and the more susceptible it is to degradation.[119] The harder, more rigid materials, containing the lowest percentage of polyether, are, therefore, more biostable. These have been used with success in cardiac pacing leads and in neurostimulation. The lack of very soft, highly-biostable, polyurethane based on a single soft segment chemistry has 'limits options' in the design of chronically implanted devices.

1.125.4.7.3.2. Improved processing of softer elastomers

Increasing the ratio of soft to hard segment increases the flexibility and lowers the modulus of TPUs while lowering the melt processing temperatures. However, as hardness is decreased polyurethanes derived from a single organic soft segment get increasingly sticky, particularly directly after thermoplastic extrusion or molding. Soft TPUs with some silicone in the backbone and/or as end groups are less prone to self-adhesion when processed, and therefore permit practical processing of softer grades. This allows silicone–urethane copolymers to approach the softness of cross-linked silicone homopolymers, particularly when cycloaliphatic diisocyanates are used, albeit at the possible expense of biostability in long-term implants.

In some cases, end groups have been extended to include alkane chains without the use of backbone silicone. Certain end groups' structures are capable of self-assembling into well organized monolayers which exhibit good stability once formed while also improving processability.[120] The effect of end groups on properties, M_w, and processability has been described in a number of articles.[121–123]

End groups may be incorporated during prepolymer synthesis and optimum amounts are generally determined empirically, with consideration for their effect on molecular weight.

1.125.4.7.3.3. Additives

The ability to thermally and mechanically process polyurethanes while maintaining physical and chemical properties can be improved by the addition of a variety of stabilizers, fillers, pigments, plasticizers, antioxidants and processing aids.[124] Environmental stability can also be improved with stabilizing additives, many of which are compounds with low or medium molecular weight. These additives must be used with caution in biomedical applications because of their potential for diffusion and leaching from the material *in vivo*. In some cases however, such chemicals are required for ease of processing, and their ability to leach out of the material has been tolerated. Perhaps the best example is ethylenebisstearamide wax (MW 580 Da), a multipurpose additive typically used at ~0.2–0.5 wt% to lower melt viscosity, reduce melt fracture, improve mold release, and reduce blocking (stickiness) of extruded parts. This material is extremely surface active and produces a surface layer of low-energy, close-packed C_{18} (stearyl) groups whatever is made from the polymer. As such is a determinant of biological interactions with the modified polyurethanes. However, it *may* contribute to environmental stress cracking if lost from the surface *in vivo*, and it certainly can interfere with the bonding of parts during device assembly.

Inorganic particulate fillers are used to render polyurethanes radiopaque and/or to pigment them. Barium sulphate and titanium dioxide are two examples. Their use requires attention to the quality of the compounding process that disperses them in the polymer. Good dispersion and wet out of the filler is important in minimizing exposed filler at the biological interface: silicone–urethane copolymers appear to evenly incorporate fillers better than silicone-free polymers, apparently due to improved wetting of the filler by the silicone-containing polymer. Often a pelletized concentrate of the filler is prepared on a twin-screw extruder and 'let down' with neat polymer by dry blending pellets in the feed hopper of the molding machine or extruder. Pigments and dyes are occasionally used in implantable biomedical polymers to create a contrast between the material and the surgical field or for cosmetic reasons.

When exposed to radiation, polyurethane, polyurea and polyurethane-polyurea polymers degrade at varying rates depending on temperature, structure and light intensity. Typically, stabilizers are added to preserve the useful lifetime of the materials. Hindered-light amine stabilizers (HALS) have been shown to be effective light stabilizers particularly when used with other stabilizers, such as UV absorbers: early contributions to polymer stabilization using HALS where those that had the ability to form peroxy radicals have been studied.[125] In general, radicals can be oxidized by HALS to produce nitroxides, which forms a cycle.[126]

1.125.4.7.4. Effect on surface chemistry and biological interactions

It is a fundamental assumption of biomaterials science that the chemical composition and (nano)structure of a surface are determinants of the biological interactions with that surface. In the case of tissue-contacting devices and prostheses, responses can range from passive integration with new blood vessel formation adjacent to the surface, to strong avascular fibrous tissue encapsulation or 'walling-off' of the implant.

Attack by macrophages and foreign body giant cells can degrade susceptible materials, and that degradation may produce byproducts that elicit still more inflammatory reaction, fibrous tissue formation, and/or material degradation leading to failure. Avoiding fibrous encapsulation, for example, is particularly important in implanted devices in which efficacy requires mass transport. These include drug delivery devices, sensors and (hybrid) artificial organs. Where direct blood contact is required, foreign surfaces may activate complement, bind proteins, generate microemboli or even gross thrombogenisis without some modification of the surface region and/or administration of systemic anticoagulants. Device-centered infection can also cause early device failure and/or increase patient morbidity or mortality.

For the polyurethanes, surface properties and biocompatibility have been studied by a number of authors.[127] showed that in a series of biocompatibility tests where polyether polyurethanes (chain extended by ethylene glycol) were compared with poly(tetramethylene) polyurethanes, no detectable differences were found although surface compositions varied. The polytetramethylene polyurethanes were similar to Biomer™ in biocompatibility.

1.125.5. Composition of Some Bioresorbable Polyurethanes

Biostable versus biodegradable polyurethanes are at opposite ends of the polyurethane spectrum and demonstrate the versatility of this large class of materials. The amount of work underway directed toward biodegradable polyurethane, tissue scaffolds is one notable example. A number of recent reviews are available (see, e.g., Holland *et al.*,[128] Howard,[129] Santerre *et al.*,[130] Guelcher[131]).

1.125.5.1. Comparison to Biostable Analogues

Improvements in the biostability of polyurethanes have focused on soft segments having reduced or eliminated reactive sites which are predominately ester or ether linkages. In this vein, the polycarbonate diols have exhibited notable stability over these predecessors and have demonstrated oxidative as well as hydrolytic stability in accelerated tests. Figure 23 compares loss in polymer molecular weight with time for commercially available biomedical grade polyurethanes having either polyether (Elasthane™) or polycarbonate (Bionate®) or Bionate II® (polycarbonate with octadecyl-SAM end groups) soft segments at increasing hard-segment concentrations. As pointed out previously, increasing the hard-segment concentration decreases the number of sites available for reactive degradation and increases the hydrophobicity of the polymer. Comparing the polyether-polyurethane (PEU) Elasthane™ 80A, which has a lower hardness value than Elasthane™ 55D, the oxidative stability is predictably less for the 80A sample. Predictably, both PEU's have lower oxidative stability than the polycarbonate containing polyurethanes.

Further improvements in stability have targeted complete elimination of oxygen in the soft segments by creating polyols resistant of both oxidation and hydrolysis. Polyisobutylene diol (PIBd),[132] and methods for preparing polyurethanes

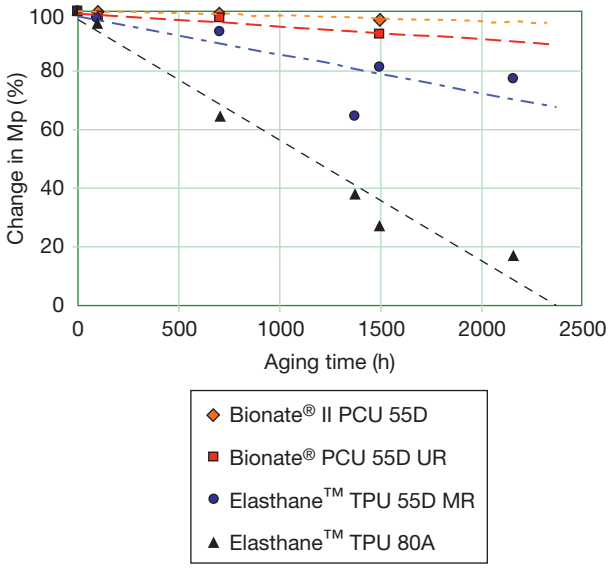

Figure 23 Accelerated *in vitro* oxidative stability of polyurethane elastomers: peak (size-exclusion) molecular weight versus time exposed to 20% hydrogen peroxide + 0.1 M cobalt chloride at 37 °C. The Elasthanes are aromatic polyether-urethanes and the Bionates have similar hard segments but use polyhexamethylene carbonate soft segments. Bionate II uses an ether-free polyol and ocatadecyl ($-C_{18}$) self-assembling monolayer end groups for improved molding and extrusion (without a leachable wax additive).

containing soft segments and multiblocks of this prepolymer[133] have been extensively studied by the Kennedy group (for additional examples see Erdodi *et al.*[134]). Polyurethanes having soft segments made using dihydroxy-polyisobutylene have been compared to polyurethanes containing polyether, polycarbonate, and silicon polycarbonate polyurethane elastomers.[134] Mechanical properties, hydrolytic, and oxidative stability have been reported as being better than comparative materials. Use in biomedical applications have been repeatedly indicated.[135] To date, only lack of a supplier of urethane-grade PIB polyols has limited use in biomedical polyurethanes applications.

1.125.5.1.1. Degradable soft segments

Due to polyurethanes ester linkages being hydrolytically unstable, (oxygen in ester linkages along the soft segment/polymer chain are sources of reactive initiations), polymeric molecules containing such linkages have been identified as suitable candidates for degradable polymers. Polymers for biodegradable medical devices have been made from poly(hydroxybutyrate)–poly(hydroxvalerate) (PHB–PHV), and copolymers of hydroxyvalerate were studied early on as candidates for biodegradable systems.[128] Many studies have included the lactones such as poly(ε-caprolactone) incorporated into polyurethane ureas.[136]

Amino acid-based polyesters have been prepared for use as biodegradable soft segments. Caracciolo *et al.*[137] compared the structure–property relationships for a series of biomedical segmented polyurethanes based on poly(ε-caprolactone) diol (PCL diol), 1,6-hexamethylene diisocyanate or L-lysine methyl

ester diisocyanate (LDI). Chain extenders containing urea groups or an aromatic amino acid derivative were used to strengthen hard-segment through either bidentate hydrogen bonding or π-stacking interactions. Although polyurethanes synthesized using hexamethylene diisocyanate (with the aromatic chain extender) exhibited the higher elongation, tear energy, and lower strain at break, and in general were stronger than those obtained using lysine methyl ester diisocyanate (LMED), the LMED containing polymers were shown to be biodegradable and possessed a range of sufficient thermal and mechanical properties.

Biodegradable polymers including polyglycolides and polylactides have been studied as tissue engineering prototypes by Gunatillake *et al.*[76]. They noted some disadvantages of these polymers including poor biocompatibility, release of acidic degradation products, along with poor processability and loss of mechanical properties during degradation.

Aliphatic diisocyantes have been used to couple lactide–PEG–lactide polyols in the synthesis of degradable polyurethanes (Cohn U.S. Patent 4,826,945). PEG-to-lactide ratio is easily changed to tailor degradation rate, which at high PEG concentration can be very rapid, giving water-soluble degradation products. Constructs using high-PEG homologues have high water absorption and need to be protected from atmospheric moisture to avoid premature degradation of the hydrolytically unstable lactide blocks.

1.125.5.1.2. Degradable hard segments

Biodegradable hard segments have been prepared by a number of methods. Diisocyanate amino acid analogs have been prepared having degradable segments,[138] and degradable ester linkages in the hard-segment and cross-linking interchanges have been prepared.[139] Methods to accelerate hard-segment degradation via degradable chain extender based on DL-lactic acid and ethylene glycol have been reported by Tatai *et al.*[140] In each of these cases, maintaining mechanical integrity and loss of material properties is always an issue when deviating from standard materials.[268–271]

1.125.6. Basic Structure–Property Relationships in Block and Segmented PUs and PUUs

A comprehensive review of the structure–morphology–property relations in segmented thermoplastic elastomers, including polyurethanes has recently been prepared.[141] Stoichiometric reactions of soft-segment oligomers and hard-segment precursors and the influence of soft-segment structure and molecular weight, hard-segment symmetry and crystallinity, and the strength of the hydrogen bonding on the morphology and properties of segmented, nonchain extended thermoplastic elastomers are key factors affecting 'physicals.' As previously discussed, the ratio of soft segment to hard segment and degree of hydrogen bonding plays a critical part of the overall development of polymer properties. The type of soft segment and the uniformity in the soft-segment distribution and the amount, type and distribution of the hard segment dictate the quantity and quality of hydrogen-bonding present in the material and allowed to form yielding ultimate structure–property relationships.

1.125.6.1. Effect of Hard-Segment Chemistry and Content

The concentration of hard-segment in PU block copolymers affects physical properties: barrier properties, indentation hardness, melt rheology, ultimate tensile properties, modulus and many other properties and processing-related variables. Control during synthesis of molecular weight and molecular weight distribution of the hard-segment component is a key factor in designing polyurethane elastomers and is crucial in producing consistent material. Elastomers having uniform hard segments are generally prepared by carefully ordered addition of components, and the resulting hard-segment chemical composition and distribution, as well as cross-linking reactions, are well controlled. As an example, lower reaction temperatures and simultaneous mixing of all reactants give the preferred size distribution of hard segments in reactions derived from an aliphatic diisocyanate when dealing with wide variations in reactivity between two isocyanate groups on the same molecule.[142]

Hard-segment composition and the effect of hard-segment segment size and molecular weight distribution have been related using dynamic-mechanical and thermal scanning behavior.[143] Detailed analysis of specific molecular motions can be explained in terms of domain perfection. Judicious ordering of the ratio of molecular weight of the soft segment and keeping hard segments crystallized and surrounded by uncrystallized soft segments has been used to produce highly efficient impact-resistant polyurethanes suitable for body armor applications.[144]

The level of phase segregation between hard and soft segments has been measured by several authors and found to depend especially upon the nature of the soft sequence and its average molecular weight, the nature of the hard sequence, and the number of hydrogen bonds established in the matrix (see, e.g., Elidrissi *et al.*[145]). In addition, for shape memory, polyurethane (PU) block copolymers composed of poly(tetramethylene glycol)/MDI/BD, 80−95% of shape recovery was obtained at 30−45 wt% of hard segment content.[146]

1.125.6.1.1. Importance of hydrogen bonding

The physical properties of polyurethanes are a result of the quality and quantity of association between the polymer chains which are chiefly developed as a result of hydrogen bonding. Early on Seymour[147] *et al.* (1970) made infrared studies of hydrogen bonding in polyether and polyester SPU elastomers and reported NH stretching vibration indicating almost all of the active NH groups form hydrogen bonds between the urethane nitrogen-hydrogen and the urethane carbonyl linkages in ester or ether prepolymer linkages. Furthermore the extent of hydrogen bonding did not change in samples stretched to over 300%. Quantifying this, Brunette[148] reported hydrogen-bonding spectral properties of polyurethane block copolymers comparing a variety of hard-segment components. He pointed out that the shift in the stretching frequency of the hydrogen-bonded X–H group (X–H. . .Y) could be used as a measure of the strength of the hydrogen bonding and that with increasing hydrogen bond strength, the X–Y distance (R) decreases and is usually accompanied by an increase in the difference between the associated X–H stretching frequency and nonassociated X–H stretching frequency.

Yilgör *et al.*,[149] compared hydrogen bonding in polydimethylsiloxane and polyether-based urethane and urea

copolymers using a variety of methods. The extent of interaction and resulting phase mixing between hard and soft segments in these copolymers was determined. Quantum mechanical calculations showed substantial hydrogen bonding between urea groups and the oxygen in the ether-type soft segments, but absence of any interaction between silicones and urea groups. Calculations were in agreement with thermomechanical behavior and mechanical properties of these copolymers.

1.125.6.1.2. Effect of soft-segment chemistry and content

The elastomeric nature of polyurethanes is due to the mobile amorphous soft-segment components in which the crystalline or glassy hard segments are dispersed. Several factors play a part in the expression of physical properties arising from this component. The molecular weight of the soft segment and the uniformity in molecular weight distribution are factors: chemical make-up, the amount and type of bonding present and compositional distribution in these long chain amorphous segments also play a critical role. These factors have been alluded to earlier and extensively studied by a number of authors (for early examples, see Takahara *et al.*[150–152]).

The three main general classes of soft-segment polyols currently used in commercial biomedical applications are (1) polyester soft segments (not susceptible to oxidation but readily undergo hydrolytic degradation); (2) polyether soft segments (oxidatively degrade under certain conditions) or (3) polycarbonate soft segments (more biostable than polyether soft segments).[153] Combinations of materials within these classes (e.g., lactones and adipates in the polyester class, polytetramethylene oxide/polyethylene glycol in the polyether class or combinations of poly(oligocarbonate diols),[154] can be mixed and matched to provide extended properties and improve biocompatibility.

Depending on the chemical composition under stress, there is a tendency in these soft segments to align. Rate-dependent stiffening and strain-hardening behavior of the microstructure can be tailored by increasing the hard-segment content resulting in improvement in barrier properties, increased stiffness and flow-stress levels.

1.125.6.1.2.1. Single soft segment

Single soft segment components can be selected over multiple segmented components to provide uniformity in compositional distribution. Single-component soft segments having narrow molecular weight distributions (i.e., a narrow molecular weight distribution in the polyol starting material depending on the method of synthesis), can produce a tailored polymer having uniform properties. Reproducibility in batch-to-batch is increased, and properties may be more consistent. However, polymers with single soft segments do not provide as much versatility in tailoring properties for specific applications as polymers having two or more soft segments in the backbone.

1.125.6.1.2.2. Mixed soft segments

Variations in composition made by including, both hydrophobic and hydrophilic prepolymers as soft-segments, are useful in tailoring permeation and absorption. Stepwise variation in average soft segment concentration gives systematic changes in the solubility and diffusivity of a wide range of permeants including gases, condensable vapors, proteins and other solutes. The hard segments can be chosen to meet specific physical–mechanical requirements but ideally constitute a minor volume fraction of the total polymer. Silicone containing prepolymers such as PDMS diol are copolymerized with 'organic' prepolymers based on polyether- or polycarbonate-diols to provide synergistic properties including controlled gas permeability and enhanced biostability.

1.125.6.1.3. Effect of end groups on surface chemistry

The surface that comprises the biological interface is often very important to implant performance. Unmodified surface may activate complement, initiate thrombosis, degrade and crack, adsorb fluids and biomolecules, bind cells, wear, and/or damage tissue. Surface properties are, therefore, equally as important as bulk properties when specifying a material for devices or prosthetic implants.

A variety of materials have been *applied* to polyurethane surfaces in order to modify biological interactions. Posttreatment of devices using a variety of techniques including plasma irradiation and deposition (see, e.g., Dejun *et al.*[155]), chemical ionization, ultraviolet irradiation (UV), gamma irradiation (GI), and interfacial modification (IM) followed by surface treatment with poly(ethylene glycol) (PEG), hydroxyl-ethyl methacrylate (HEMA) hexamethylene diamine (HMD), or chitosan (CT), have been developed, to mention a few. Alves *et al.*[156] showed that modification by GI gives high values of grafting yield and has the advantage of providing a clean modification without requiring initiators.

In modifying surface properties Takahara *et al.*[150,152] looked at MDI/BD polyurethanes having poly(ethylene oxide), poly(tetramethylene oxide), hydrogenated poly(butadiene), poly(butadiene) and poly(dimethylsiloxane) soft segments in relation to surface, bulk and *ex vivo* blood-contacting properties. Hydrophobic polyols poly(dimethylsiloxane) and hydrogenated poly(butadiene) showed distinct microphase separation between hard and soft segments with 'surface enrichment of the hydrophobic component at the air–solid interface.' This poly(dimethylsiloxane)-based segmented polyurethane had the lowest platelet adhesion among the segmented polyurethanes investigated in the study, while the platelet deposition on the poly(ethylene oxide)-based polymer increased with time. In addition, Bernacca *et al.*[157] studied parameters of blood compatibility to the response of two polyurethanes of differing primary structures and having a variety of surface modifications. Covalent attachment of heparin, taurine, a platelet membrane glycoprotein fragment, PEO, 3-aminopropyltriethoxysilane, and glucose or glucosamine were added to effect material thrombogenicity. While unmodified control polyurethanes caused platelet release and complement activation, high molecular weight (2000 Da) polyethylene oxide reduced platelet release slightly. Glucose attachment to the surface produced a significant reduction in platelet activation and was found to be the least activating. In both of these cases it was the surfaces and surface interactions that provided property improvements and increased biocompatibility.

In an additional selected example we note that Freij-Larsson *et al.*,[158] reported that hydrophilic surfaces prepared by grafting

polymer surfaces with hydrophilic polymers such as PEO lowered interfacial tension towards aqueous solutions which are known to adsorb very low amounts of proteins. They prepared and studied a number of amphiphilic polymers having backbones consisting of poly(methyl methacrylate-*co*-ethylhexyl acrylate) and poly(styrene-*co*-acrylamide), respectively, and PEO 2000 grafts combined with polyurethane and found that the modified surfaces had generally lower adsorption of blood proteins with the poly(methyl methacrylate-*co*-ethylhexyl acrylate) backbone blend modified surfaces having the lowest adsorption.

Topical treatments of preformed PU surface can certainly be effective, but they add one or more steps to device manufacturing, lowering yield and increasing cost. Modifying the polymer before component fabrication has several advantages including the seamless integration into device manufacturing. The use of covalently bonded surface-active end groups appended to the polymer during synthesis has proven to be an effective method of surface modification of polyurethanes and other step growth polymers (*vide infra*).

As the safety, effectiveness, and useful life of implants are often affected by surface properties, it follows that technology for controlling surface chemistry and structure can be useful in improving device performance. However, experimental investigations designed to determine the effect of systematic variations in surface properties on biological response do not always result in clear conclusions. In the case of polymers this may result from inaccurate assumptions about the resulting change in the surface produced by a change in the bulk. It may also be due to the lack of knowledge about the surface restructuring or relaxation that occurs upon a change in environment, or under adsorbates that interact with the surface. The use of sensitive, surface-specific methods of characterization, especially those that work within an environment relevant to the use of biomaterials is needed when developing reliable surface-structure-versus-property relationships.[272–275] Our understanding of how surfaces affect biologic interactions is far from complete, in part because of our inability to adequately characterize the surfaces before, during and after contact. On some surfaces the effect of the initial device surface chemistry and nanostructure on biological response may be blunted by the inevitable adsorption of proteins that occurs directly upon contact. However, this does not detract from the need for surface modification technology, particularly those that can be easily integrated into the routine manufacturing of medical devices (**Figure 24**).

In most condensed phases of matter (and polymers in particular) the surface is not merely a continuation or projection of the bulk onto the outer monolayer. The surface is usually very different from the bulk, and minor changes in the bulk may cause large changes at the surface. Liquids and solids spontaneously minimize their interfacial energy by a number of mechanisms including migration of species from the bulk to the surface region. Polymers with 'mobile' surfaces can also rearrange to minimize total surface area *and* their interfacial energy per unit area according to the environment in which they are immersed. They do this, by 'presenting' available chemical groups that minimize the energy gradient across the interfacial region. This can involve diffusion from the bulk, or flipping of polymer chains to expose different backbone or pendant groups, and/or by changes in packing density. These surface relaxations are favored in amorphous

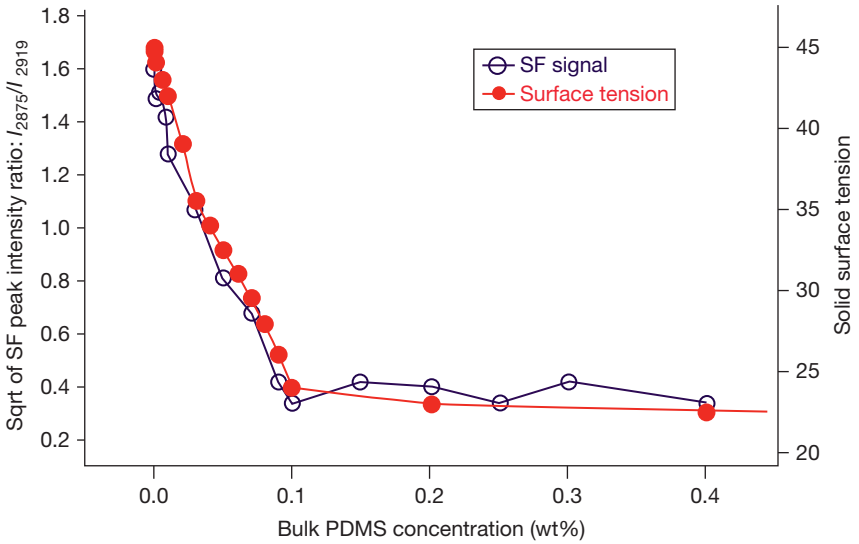

Figure 24 Surface concentration measured by sum frequency generation spectroscopy (SFG) versus bulk concentration in solid films made from a blend of silicone–urethane copolymer in high-molecular weight phenoxy resin. The base phenoxy was chosen for its high-solid surface tension and compatibility with polyurethanes. As small amounts of the PSX copolymer are added to the bulk polymer, the surface phenoxy concentration is reduced as silicone populates the surface. This decrease in surface phenoxy (and increase in surface silicone) is exactly mirrored in the reduction in solid surface tension (calculated from water and methylene iodide contact angle measurements) caused by the low-energy silicone. Only ~0.1 wt% bulk silicone is required to saturate the surface. Similar results are obtained with silicone end groups covalently bonded to polyurethanes during synthesis, making end groups useful for polymer surface modification. This behavior is quantitatively similar to conventional surfactants in liquid systems.

polymers above T_g that are free of cross-links and which are optionally plasticized by water. In softer polyurethane copolymers with soft segments that are above T_g at 37 °C, rearrangement may occur fairly rapidly. For this reason very minor amounts of *surface active* additives or impurities may produce a pronounced change in surface composition.

In addition to substances admixed with the neat polymer, polymer end groups can also be highly surface active, even though they are covalently bonded to the polymer backbone. Furthermore mobile end groups can be designed to spontaneously self assemble at high density in the surface region during and after device fabrication. Thus end groups can be designed which are chemically different from the backbone polymer and which act as permanent, built-in surface modifiers (see Section 1.125.6.1.4.1).

1.125.6.1.4. Optimizing polyurethanes for specific biomedical applications

Polyurethanes for implantable devices can be selected from commercially available biomedical polymers, that is, catalog items, or they may be custom synthesized for use in specific applications. The latter may be necessary when a complex, highly constrained property specification must be met.

Even when investigating available polymers there are considerations beyond the polymer properties listed on the data sheet, which are often measured dry at room temperature. These include immediate property changes upon implantation caused by heating to body temperature, and the absorption of water in the body. The role of water as a solvent/plasticizer is one important consideration in material selection, particularly in hydrogen bonded polymers such as PU and PUU. For example, oxidative stability of poly(carbonate urethanes) and their silicone-containing copolymers have caused them to be evaluated as a replacement for poly(ether urethanes) (PEUs) in a number of medical devices (see, e.g., Christenson *et al.*[159]). The ether groups increase equilibrium water content during implantation resulting in a different degree of softening, creep and permanent set in the polyetherurethane relative to the polycarbonate-containing analogue.

1.125.6.1.4.1. Satisfying bulk and surface property requirements

Soft-segment composition and concentration affect not only the bulk properties, but also the surface due to their ability to migrate and concentrate in the surface region. Movement from the bulk to the surface is 'surface activity.' The spontaneous ordering of like molecules in the surface is known as self assembly. In using surface activity and self assembly to modify polymer surfaces even the less restricted mobility of polymer end groups can be very useful.

Surface-modifying end groups (SMEs) add another dimension when tailoring (biomedical) base polymers and they can produce a desired surface chemistry without the use of additives. Some surface-active oligomers that have been covalently bonded to base polyurethanes during synthesis include: silicone (S), sulfonate (SO), fluorocarbon (F), polyethyleneoxide (P), hydrocarbon (H) groups, and quaternary ammonium halides. Often, very low bulk concentrations control the surface chemistry without compromising the bulk properties of the polymer (see Table 3). The result may improve a variety of surface properties, such as thromboresistance, biostability, abrasion resistance and antimicrobial properties. Surfaces of configured articles develop spontaneously once the surface is formed so the base polymer is permanently enhanced without the additional step of post-fabrication treatments or topical coatings.

Table 3 History of commercially-available silicone–urethane biomaterials

Trade name, patent date	*First soft segment*	*Second soft segment*	*Desired enhancement*
Avcothane-51 Cardiothane-51 PIPN, 1969	PTMO polyether	PSX blend	Thromboresistance biostability (1978)
Thoralon™ SPU & TPU, 1983	PTMO polyether	PSX	Thromboresistance biostability
PurSil™ w. SME TSPU, 1994	PTMO polyether	PSX	Biostability
CarboSil® w. SME TSPU, 1994	PHMC polycarbonate	PSX	Biostability
Elasteon™ TSPU, 1997	PHMO polyether	PSX	Biostability

Similar polymers with different trade names may have been used captively by device manufacturers. Avothane/Cardiothane demonstrated the benefits of combining silicone with polyurethane, albeit in an optically opaque material that was difficult to process. Progress in silicone chemistry and the availability of oligomeric silicone (PSX) diols and diamines made the manufacture of thermoplastic silicone–urethane copolymers possible.

The added mobility of end groups relative to the polyurethane backbone has been shown to facilitate the formation of uniform overlayers by the surface-active (end) blocks. The use of the surface-active end groups leaves the original polymer backbone intact so the polymer retains strength and processability. Surface-modified polymers have been made with tensile strengths exceeding 5000 psi containing only 0.5 wt% or less of end groups. This novel technology is applicable to a wide range of polymers. However, modification with highly surface-active end groups is particularly adapted to the synthesis of polymers that may incorporate low molecular weight monofunctional end-groups for molecular weight control: for example, polyurethanes and other step-growth polymers. The SME approach also allows the incorporation of mixed end groups on a single polymer. For example, the combination of hydrophobic and hydrophilic end groups gives the polymer 'amphipathic' surface characteristics in which the hydrophobic-to-hydrophilic balance may be controlled.

Self-assembling monolayer end groups (SAME®) is a related technology utilizing, second-generation surface-modifying end groups (SMEs). SAMEs are modeled after well-known SAMs, for example, alkane thiols. That is they have a self assembling alkane spacer chain and head group. Instead of a terminal thiol group used to chemisorb to a gold substrate from solution, the SAME typically has a hydroxyl or amine group which is reacted with isocyanate during polyurethane synthesis. Monofunctional SAME reactants are chain stoppers for step growth reaction so they automatically become end groups (Table 4).

Traditional SAM technology (e.g., thiols on gold or silanes on silica) has clearly demonstrated that bioactive 'head groups' can be appended to alkane chains as a method of creating model surfaces for *in vitro* research. Ideally, the chemistry used during such model studies could then be applied to actual medical devices to further improve clinical outcomes. However, SAM technologies are not easily transferred to medical device applications due to the fragility of such systems including the oxidative instability of the gold-thiol bond.[276]

SAME® technology, on the other hand, is capable of providing polymers with 'SAM-like' engineered surfaces.

Table 4 Surface-Modifying End Groups maintain bulk polymer properties while controlling surface chemistry

Surface-Modifying End Group (SME®)	*Advantages*
Silicone	Hydrophobic, nonadhesive surface, lubricious, may increase biostability under certain conditions, may increase infection resistance
Flurocarbon	Hydrophobic, nonadhesive surface, chemically-stable surface, may increase biostability under certain conditions, may increase infection resistance
Polyethylene Oxide	Hydrophilic, affects material permeability, reduces protein adsorption
Sulfonate	Hydrophilic, may be thromboresistant, can react or bind to proteins and peptides
Hydrocarbon)	Hydrophobic, may increase biostability under certain conditions, may bind albumin
Mixed SMEs	Example: Silicone (S) and PEO (P) – amphipathic structure: hydrophilic and hydrophobic polymer depending on the surrounding environment

Relative to backbone chains, polymer end groups are more mobile, in part because they are often tethered to the backbone by a single, flexible covalent bond (see Figure 3). End group mobility allows them to diffuse from the bulk and assemble in the polymer surface to affect surface composition. This occurs spontaneously if the presence of the end groups in the surface reduces system interfacial energy. Simple hydrophobic end groups may diffuse to an air interface, while purely hydrophilic end groups may enrich a polymer surface when exposed to aqueous body fluids. The self assembly of endgroups into monolayers using the SAME technology utilizes very specific hydrophobic or hydrophilic spacer groups, and a head group chemistry chosen for the particular application. The spacer groups will 'self-assemble' at the surface through either hydrophobic or hydrophilic interactions, and thus present the head group as the outermost monolayer of the polymer. One or more surface-modifying end groups give independent control of surface and bulk properties, where control of bulk properties can be extended via hard-segment composition and concentration. A variety of SME and SAME compositions have been used to modify surface properties such as antimicrobial and lubricous combinations (Figure 25).

1.125.7. Fabrication of Medical Device Components from PUs and PUUs

1.125.7.1. Solution Processing: Dipping, Spraying, Solvent Bonding, and Web Coating

Polyurethaneureas have hard segments with very high cohesive energy density and therefore may not be thermally processable. Such a high temperature may be required to liquefy the polymer so that soft segment degradation occurs. In cases where the polymer is solvent soluble, solution-processing methods can

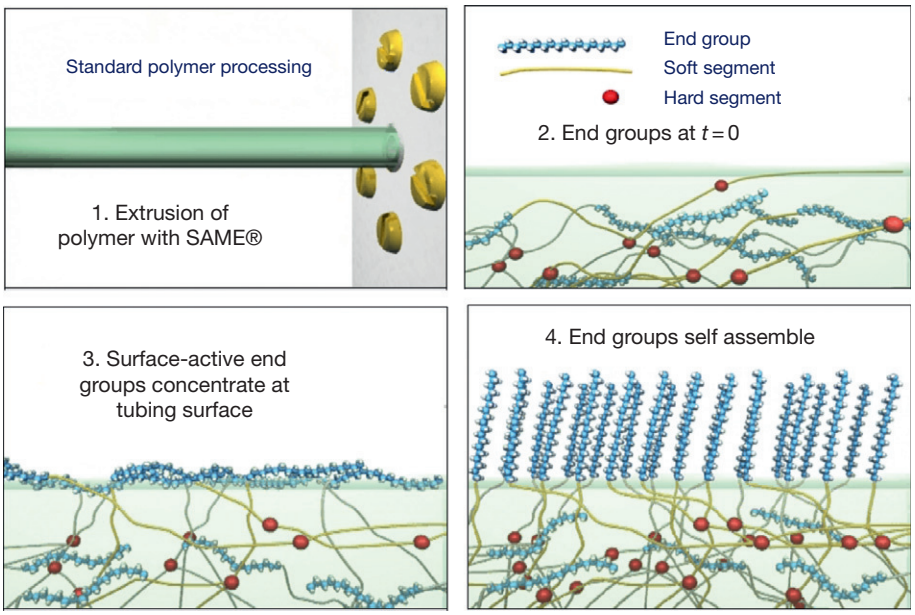

Figure 25 Self Assembling End Groups (SAME™): surface activity and self assembly produce and organized layer of close-packed end group in the surface of extruded biomedical tubing without any postfabrication coatings or surface treatments (schematic, not to scale).

Figure 26 Many sac- and diaphragm-type cardiac assist device are fabricated by solution processing. This can range from simple pouring with hand manipulation, of male or female molds, to robotic dipping. Environmental conditions must be controlled and worker safety must be considered given the evolution of toxic and flammable solvent vapors. It is vitally important to remove residual solvent from cast part to avoid negative effects on hemolysis, cytotoxicity and other biocompatibility tests.

be used. However, solution processing may also be attractive in some cases, even for linear or branched thermoplastics that can easily be molded or extruded. Use of solvent-based glues in device assembly is one example (Figure 26).

Solution processing begins with solution preparation and filtration. In solution synthesis of polyurethaneurea elastomers the *product* is often a concentrated solution, requiring dilution before use. Flammable, toxic, aprotic solvents with high boiling points are commonly used: dimethylacetamide (DMAc), dimethylformamide (DMF), dimethylsulfoxide (DMSO), and *n*-methylpyrolidone (NMP) are candidates. DMAc and DMF are commonly used in synthesis of PUUs, but the low-boiling (highly-flammable) solvent tetrahydrofuran (THF) may be used as a diluent, or even as the main solvent for more soluble TPUs. Very high-purity solvents are needed to avoid leaving nonvolatile impurities in or on the fabricated part. Prefiltered, chromatographic-grade, glass-distilled solvents are preferred. Suitable solvents are often hygroscopic and need to be protected from moisture before and after solution preparation.

Dissolution of prereacted, pelletized TPUs should be done in a fume hood in a covered vessel fitted with a high shear mixer. Safety procedures for the handling of toxic and flammable chemicals should be followed. It is best to slowly add free-flowing pellets to the stirring solvent to prevent agglomeration, which can greatly lengthen the solvent diffusion path and therefore the dissolution time. Gentle heat may be applied with a heat lamp while keeping the temperature well below the boiling point. This is difficult with THF as it boils at 66 °C, and shear heating from the mixer will raise solution temperature. The entire process of preparing a solution from pelletized TPU may take several hours, and is usually complete when the solution is clear and no undissolved polymer remains. Harder grades are much slower to dissolve than softer grades.

The starting solution *must* be filtered before device or component fabrication. Suitable filters are depth type that can remove undissolved gels *and* particulates while not sloughing off filter material into the filtrate stream. Suitable filters use sintered stainless steel fiber or polyproplylene media which have been thoroughly cleaned before use and flushed with pure solvent to prewet the pores. Absolute pore size ratings, measured by bubble point, ranging from ~<1 to 20 μM are used, but smaller pore size greatly increases pressure drop and the filtration time of viscous solutions. Filtrate is collected in precleaned glass vessels and covered using cap liners or other closures that are not attacked by the solvent. Any additional dilution required after filtration, for example, due to solvent evaporation, should be done with high-purity, prefiltered solvents (Figure 27).

Solutions may be used to fabricate device components by a number of methods. The most primitive involves simply pouring the solution over a male or female mold while manually manipulating the mold to achieve even solution coverage. Ultrasonic spraying of dilute solutions represents the other extreme, and may be useful when dimensional control of small parts is required, such as when coating stents. Other methods include dipping male mandrels into baths containing the polymer solution, or casting a solution onto a permanent substrate or a release surface. When roll goods are coated continuously in the manufacture of films or membranes the process is known as web coating and uses equipment that resembles a printing press. The delivery rate of the solution to the coating head, solids content, and web speed determine final thickness (Figures 28 and 29).

In order to produce consistent product free of pinholes and impurities, environmental controls are a necessity. Temperature and humidity controlled clean rooms *without* air recirculation are preferred as controlled evaporation rate, low particle count, dew point control and removal of toxic and flammable solvents are all required within the work space. Appropriate electrical service and environmental monitoring are important safety requirements for which professional help should be sought.

Ambient water concentration is a big determinant of the quality of solvent cast or dipped coatings and parts. Evaporative cooling during the process may condense atmospheric moisture on the drying part which mixes with the remaining solvent. As water is a nonsolvent for most polyurethanes the condensed water may act to coagulate the polymer rather than allowing it to dry to a dense film. This problem is particularly important when processing with high boiling solvents which may require either elevated temperature (ca. 35 °C) in the work space, or the use of industrial dehumidifiers capable or reducing dew point to very low levels. Note that very dry

Figure 27 Clean room dipping of simple tubes for use in a hybrid artificial pancreas. The membrane polymer in solution in DMAc is slowly pumped through a SS depth filter into the bottom of a dipping tube fitted with an overflow sump. It then returns by gravity to the reservoir tank that feeds the pump. This continuously supplies the dipping tube with particulate-free homogeneous polymer solution while 'sweeping' the surface clean.

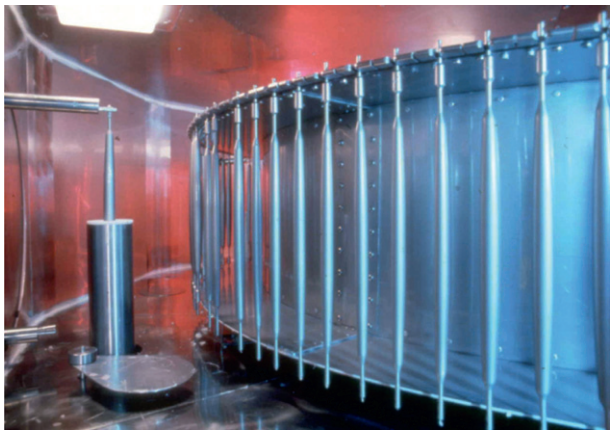

Figure 28 Automated dipping of intraaortic balloons on stainless steel mandrels *c*.1976. Dipping solution is continuously circulated and refiltered by pumps and filters located on the floor below the dipping machine. The internal environment is high efficiency particulate air (HEPA)-filtered air with controlled temperature and humidity. Mandrels are held stationary while the dipping tube moves up and down to coat the mandrel. Two dips in each direction are required per balloon.

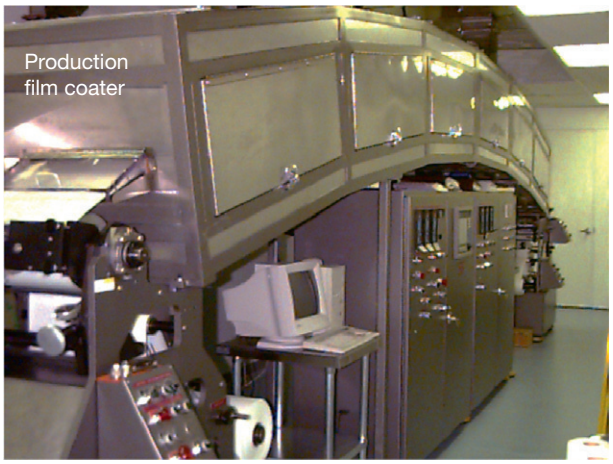

Figure 29 Continuous web coater for casting polymer films and coatings. A N_2-purged pressure pot containing the liquid coating feeds a gear pump the speed of which is automatically controlled using a noncontacting thickness gauge. Substrate roll goods ('webs') pass under the coating head enter the oven at left and emerge coated onto a take-up spool at far right. This equipment can produce large quantities of film, membranes, transdermal devices and coated fabric. Often the product is die cut prior to device assembly and packaging.

environments may increase static discharge caused by moving air, which can create a fire hazard.

Removal of trace quantities of solvent is a necessary part of all solution processing and can have a dramatic effect on the biocompatibility of the final product. Cytotoxicity and hemolysis can have consequences that are not related to the polyurethane material itself, but are only due to the residual solvent leaching out during testing or use. Thus, the removal of even trace quantities of residual solvent is important. Drying at elevated temperature ($\leq 60\,^{\circ}C$) in flowing air is often more effective than vacuum drying, as the main resistance to solvent loss at this stage may be diffusion within the polymer, not desorption from the surface. In order to reduce the residual solvent level in thick parts, water extraction may be required, for example, at 60 °C, followed by air or oven drying to remove absorbed water. Clean room particle count and inclusions in the finished device are additional issues that need to be considered when setting specifications for solvent-based processing.

As mentioned above, resolving the safety issues associated with solvent-based processes is of utmost importance. Professional engineering design input is highly advisable. Organic solvent vapors can exceed flammable limits without adequate exhaust and controls, and any sources of ignition from open flames, electrical equipment, static discharge, etc., can cause fires or explosions. Fire suppression equipment and proper grounding is vital, as is worker protective equipment including gas/vapor masks. All precautions and standard guidelines for handling flammable solvents and vapors must be rigorously followed and environmental monitoring must be routinely performed.

1.125.7.2. Thermoplastic Processing

Melt processing of the final polymer product is an engineering discipline which in itself has been extensively studied (see, e.g., Throne,[160] Lu *et al.*,[161] Erol and Kalyon[162]). It involves heating the polymer to reduce its viscosity to the point that it can be extruded or molded into a final shape followed by cooling to room temperature to 'lock in' the shape. Automated and/or continuous thermoplastic processes are capital intensive, but capable of high throughput and low cost of goods. Extrusion, injection molding, compression molding and thermal forming of polyurethanes are all standard, commercially developed methods for thermoplastic polyurethanes. Optimizing melt processing conditions for polyurethanes involves consideration of melt rheology as affected by temperature and shear rate, and the water content of the polymer fed to the process. The presence of allophonate cross-links can complicate processing due to their thermolabile nature. If present they can break during processing and reform slowly thereafter (**Figure 30**).

By using the intensive mixing and controlled temperature profiles offered in twin-screw extruders, the synthesis of pelletized TPUs can be achieved by further reacting a prepolymer with chain extender[163,164] or by metering all reactants to the throat of the extruder in the 'single shot' method. Although it is typical to collect a pelletized product for subsequent processing, it is possible to extrude tubing and profile from the extrudate of the reactor/extruder. This type of processing has also been termed reactive extrusion and is a well-studied and expanding field (see, e.g., Semsarzadeh *et al.*[165]).

For optimal results control of trace water in thermoplastic PUs prior to any melt processing is required.[166] The effect of water on the melt viscosity of certain TPUs can be dramatic: at high concentrations; foaming and thermal–hydrolytic degradation can occur. With trace amounts of moisture melt viscosities can actually be lower than for bone-dry polymer. Over drying can increase melt viscosity apparently by promoting allophonate cross-link (re)formation and/or by reducing the plasticizing effect of water. The effect of increased melt viscosity can be measured in, amperage draw on the extrusion equipment, and pressure drop across screen packs.

Drying is often done using dehumidifying hopper dryers in which air passes through one of two dessicant beds before entering the bin or hopper holding the polymer. As one bed is being used the other is regenerated with heat and the two are switched frequently. A dew point meter may be fitted to the hopper outlet to measure the approximate extent of drying via the moisture content of the exiting air stream.

Drying of TPUs can produce unwanted side effects so over drying is to be avoided to prevent yellowing of aromatic TPUs and the increased melt viscosity (decreased melt flow index) mentioned above. In all thermoplastic processing of thermoplastic polyurethane, attention to trace water levels and thermal history is advisable.

Despite the considerations unique to polyurethane chemistry, TPUs may be processed by virtually all thermoplastic processing methods used in the creation of semiconfigured like film and tubing, in the postconversion shaping of semiconfigured goods, and in the assembly of components into complete devices. Methods include rotational casting, thermoforming, vacuum forming, heat sealing, ultrasonic and RF welding, laser ablation, die cutting, and machining. Processors familiar with thermoplastic polyurethanes should be used whenever possible.

1.125.7.3. Other Fabrication Methods

In a typical reactive fabrication process, the use of solvents is unnecessary and the reacting liquid prepolymer plus chain extender and/or cross-linker is delivered to a mold before it solidifies. This can also be done on a batch or semicontinuous scale in which the reactants are hand mixed and the reaction

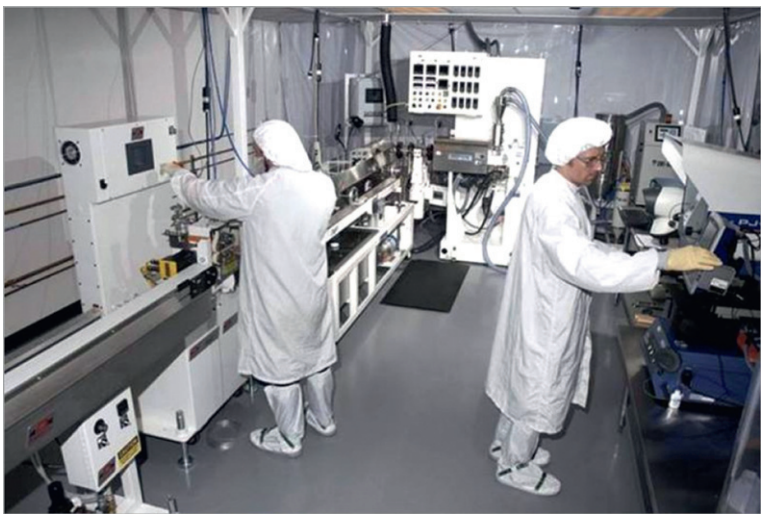

Figure 30 Clean room thermoplastic tubing extrusion line. The extruder is located at the rear at right angles to a metering pump, die, water bath, tractor-cutter and collection equipment. Predried polyurethane pellets are fed to the hopper of the extruder and are melted and conveyed by a screw within the heated extruder barrel. The homogeneous molten polymer emerges from the die inflated by air and enters a water bath. The chilled tubing is cut to size and collected.

mixture is poured or injected into a mold before it solidifies (also known as RIM). With slow reacting, hand cast systems the operator may outgas the mixture under vacuum to eliminate voids in the molded part. Reaction of the degassed liquid produces solidification in the mold. One and two-component reactive urethane systems can be useful in device prototyping or potting electrical components. They are generally referred to as '100%-solids' processes. By adjusting the stoichiometry and including water and a stabilizing surfactant in the reaction mixture CO_2 can be generated during solidification resulting in a foamed product. Additional post-foaming processing can convert closed-cell foams to open cell, so-called reticulated structures that may be useful as tissue scaffolds, filters and wound dressings.

Waterborne dispersions, mentioned previously, depend on polymer (or added surfactant) hydrophilic/lipophilic balance and its effect on the stability of the emulsion. Often the difference in reaction rates of the water–isocyanate and water–amine reactions are used to advantage in the synthesis of waterborne polyurethanes. One attractive feature is the potential to eliminate solvents that may attack substrates being *coated*, as waterbornes are seldom used to make thick monolithic components. Potential applications include multilayer sensor membranes.

1.125.8. Sterilization of Segmented and Block Copolymer PUs and PUUs

Terminal sterilization is routinely applied to virtually all implantable and extracorporeal devices made from polyurethanes, but it is not without consequences. The sterilization method chosen and the process conditions used can have a significant influence on the properties of the final device. If subjected to repeated sterilization cycles the effect on the polymer may be cumulative. Subtle, barely measurable changes may become more pronounced after multiple exposures to the same sterilization process/conditions. In rare cases the resulting change may improve certain properties: increasing cross-linking density via radiation sterilization may be useful in some applications. In others, creation of free radicals and chain scission can lead to immediate molecular weight reduction, increased extractables, and possible oxidative instabilities later. The ability of a sterilization method to induce changes in a specific material depends on process conditions, the specific polymer composition, the presence of added stabilizers, the packaging gas, and the number of cycles to which the polymer is exposed. Commonly used aromatic block and segmented biomedical polyurethanes sterilized by exposure to ionizing radiation will often appear virtually unchanged after a single cycle, but will discolor or embrittle slightly after repeated cycles, resulting in increased tensile strength and somewhat reduced elongation at break. This appears to be the result of cross-linking, although the remaining soluble phase may show a *reduction* in GPC-molecular weight and narrowing of the molecular weight distribution.

In general, sterilization by ethylene oxide and low dose, single cycle gamma radiation are the least problematic and most often used. Autoclaving is to be avoided. D*evices* that include polyurethane components can be exposed to multiple sterilization cycles to exaggerate and elucidate the effect on the polymer, and then be subjected to functional and biocompatibility testing after a more typical dose history, which is usually assumed to include at least one resterilization.

The effectiveness of sterilization techniques has been determined by a number of investigators.[167,168] In general, attention was given to perceived and measurable side reactions originating from the variety of sterilization methods. Hirata *et al.*[169] looked at the relationship between urethane components on polymer characteristics and formation of by-products such as MDA (*vida infra*). In sterilizing commercially-available dialyzers fabricated using different combinations of isocyanate and polyol, they confirmed earlier reports showing that the molecular weight of polyol (castor oil polyols were used in this study) influenced the production of MDA treated with either gamma or EtO sterilization regiments.

A number of studies have looked at changes in the physical and chemical properties before and after sterilization. For example, Abraham *et al.*[170] looked at changes in the physical and mechanical behavior induced by gamma irradiation or ethylene oxide sterilization in medical-grade segmented polyurethanes BioSpan® (a segmented poly(ether urethane urea) derived from a linear block copolymer of 4,4*-diphenylmethane diisocyanate (MDI) extended with a mixture of ethylene diamine (ED) and 1,3-cyclohexanediamine, and poly (tetramethylene oxide) glycol (PTMO), and the aliphatic ether-free polyurethane Chronoflex (a polyurethane-polycarbonate of 4,4*-dicyclohexylmethane diisocyanate (HMDI) chain extended with 1,4-butane-diol (BD) and polycarbonate-diol). Sterilized BioSpan® samples showed a decrease in the soft-segment glass transition temperature and an increase in the soft-segment crystallization heat along the quenching process. Sterilized Chronoflex materials showed the opposite behavior. Hysteresis and residual strain percent increased after sterilization and with irradiation dose and strain level. Surface analysis performed by scanning electron microscopy showed magnification of original surface defects after sterilization.

Correlations between the chemical and physical compositions of a silicone and a polyurethane and beta irradiation, ethylene oxide sterilization and steam sterilization were evaluated on polymer samples implanted in rats for 10 and 90 days.[171] Differences in the biological responses were small and independent of the sterilization method. After 10 days of implantation, the capsule thickness and the amounts of cell material adhering at the surfaces were different, and it appears that the silicone rubber induces more tissue response than the polyurethanes. The differences in the early tissue response evened out after 90 days implantation time and a steady-state situation evolved, which was found to be similar for the silicone and the polyurethane.

1.125.8.1. Ethylene Oxide

The use of ethylene oxide (EO) for sterilizing medical devices has been recently reviewed.[172] This review included EO mechanism of action and toxicity and offered a critical analysis on how it is possible to use EO sterilization for medical devices, emphasizing cycle design and validation. EO diffusion in different substrates (taking into account different environmental conditions both for sterilization and aeration), was also considered. Of the techniques that can be considered, EO

sterilization produces the least amount of MDA and other compounds. There have been studies concluding that risk posed by the amounts of MDA extracted were not significant[173] however, and residual EO gas may itself be more problematic.

1.125.8.2. Radiation

Radiation effectively interacts with biological systems in a number of ways, and only small amounts are generally required to affect sterility. The primary goal in achieving sterility should not interfere with the material properties, as is often the case. Cross-linking and oxidation due to the creation and persistence of free radicals due to radiation is/ can be problematic, but can be addressed – and in some cases used to an advantage – if cross-linking or some other property that improves device design is achieved through the radiation.

1.125.8.2.1. Gamma irradiation

The change in molecular weight, tensile strength, absorbance, and residual amount of radicals as a result of GI has been reported on Pellethane-type materials by Shintani *et al.*[174]). They observed no significant difference in molecular weight; however, the polymer chain extended with 1,4-butanediol (BU) showed degradation while linear chain extended PU showed mainly cross-linking. A linear relationship between the irradiation dose and the residual radical amount was found, but the amount of residual radical on the characteristics of the material was not significant. Elution of PU oligomers was confirmed from the GPC pattern of methanol extracts. Methanol extract at an early stage is more toxic due to abundant elution of lower molecular weight compound. Cytotoxicity of a 25 kGy sterilized polyurethane film tested for *in vitro* interaction of fibroblast cells in a culture medium containing serum samples showed no signs of cell toxicity when evaluated in comparison with control groups.[175]

Zhang *et al.*[176]) compared tensile dynamic mechanical properties and the tensile short-term static creep of five medical-grade gamma-sterilized polyurethane elastomers: (Elast-Eon E2A from AorTech, Pellethane 2363 80A from Dow Chemical, Bionate 80A UR, Bionate 90A S and Carbosil 20 90A – all from Polymer Technology Group). Results showed that (1) both the storage moduli and the damping (tan delta) of the five PU increase with the frequency; (2) gamma sterilization increases the storage moduli and decreases the creep-strain of the five PU; (3) among the five PU samples, Elast-Eon E2A has the highest storage modulus, and the lowest creep-strain under a load of 0.1 MPa; and (4) the T_g of the five PU can be determined by the peak temperature of the loss modulus curve.

Haugen *et al*[177]07) found no differences in attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR) analysis of thermoplastic polyether-urethane (TPU) when comparing steam with different gamma-radiation sterilization methods. The molecular weight (M_w) had a net increase by gamma-sterilization and the samples that were irradiated also had an increase in polydispersity index in comparison, which indicate branching. Liquid chromatography/mass spectroscopy (LC/MS) analysis showed that there was a correlation between the concentration of the breakdown product, methyl dianiline, and cytotoxicity. The concentration of this compound was found to be four times higher in the steam-sterilized sample compared with that of the polymer sample that was gamma-sterilized. The cytotoxicity of TPU was found to decrease with higher radiation doses, and was significantly higher for the steam-sterilized samples.

Citing hydrolytic instability of poly(ether)urethanes [sic] versus the stability but insufficient mechanical properties of polysiloxanes, Briganti, like others before him,[178] sought to combine these materials in the form of poly(ether)urethane-PDMS grafts for use as microfibrillar vascular grafts and porous membranes. In his study, he optimized 25 kGy of GI on these materials and found no significant changes in physical–chemical and mechanical properties of the material. Where results previously obtained with cell cultures showed material preparation and manufacturing procedures not introducing any toxicity in the products at each PDMS concentration investigated[179]; cytotoxicity evaluations performed on L929 fibroblasts showed no signs of cytotoxicity after sterilization.

Hsu *et al.*[180]6) fabricated small diameter polyurethane (Pellethane 2363-80A) vascular grafts modified by epoxy-cross-linked gelatin and an RGD-containing protein to facilitate the endothelial cell seeding on the surface. After GI, the contact angle of the irradiated PU dropped a little and the environmental stress cracking resistance (ESCR) spectra revealed oxygen bonding. There were observed increases in extractables and molecular weight distribution with only slight decreases in mechanical properties. They concluded that freeze-drying followed by GI at 2.5 Mrad was the proper way to process and store vascular grafts made from these materials.

1.125.8.2.2. Electron beam

All[181] looked at the electrical and structural properties of electron-beam irradiated 'polyurethane' films in the range 90–300 kGy. He reported an increase in electrical conductivity due to degradation products with large variations in spectral composition. Irradiation doses in the range 200–300 kGy caused branching, which reduced crystallinity and created lattice defects with significant changes in melting behavior.

Thin films of Tecoflex® (an *aliphatic* polyether PU) prepared by Guignot *et al.*[182] were irradiated under a dose-rate of 5 MGy h^{-1}, with doses varying from 25 to 1000 kGy under O_2. Chain scission and cross-linking were both found to increase with the irradiation dose. FTIR spectra showed the appearance of oxidation groups (formates, esters and carboxylic acids) with scission of chains in soft (SS) and hard (HS) segments as noted by decrease of both urethane and aliphatic ether absorbance. Coupled TG-FTIR analysis indicated the degraded molecules consisted of (i) oxidized SS fragments, (ii) long SS slightly oxidized and (iii) HS accompanied by SS.

1.125.8.3. Autoclaving

Sterilizing polyurethane using pressurized steam (autoclaving) is typically *not* recommended as many types of polyurethane can degrade under these combined thermal/hydrolytic conditions. Autoclave sterilization elutes more hydrophilic compounds when compared to sterilization using γ-ray irradiation and ethylene oxide gas (EOG). This has been shown to be especially significant for PUs produced from smaller-molecular-weight polyols.[173] Softer aliphatic polyurethanes soften and distort at the typical autoclaving temperature of

121 °C. Aromatic analogues are thermoformed in autclaves in the manufacture of some cardiac assist devices, for example, to produce precise dimensions for interfacing with metal components.

Recently, Terheyden *et al.*[183] compared sterilizing methods on dental ligatures made from polyurethane, silicone and natural rubber using an autoclave, ethylene oxide, irradiation, plasma sterilization, povidone-iodine or 70% isopropyl alcohol (for 24 h). In these tests polyurethane was most resistant to mechanical fatigue but became sticky after autoclaving. Ethylene oxide, irradiation, and plasma were also found to be better than autoclaving and disinfecting solutions. In this study, polyurethane sterilized with ethylene oxide was the material of choice.

1.125.8.4. Other Methods

A number of alternatives to the above sterilization methods have been developed, especially in light of such infectious agents as prions and viruses, which may require more rigorous treatment than steam or radiation. Surface ionization methods such as atmospheric pressure cold plasmas can be generated by various methods including dielectric barrier discharge (DBD), resistive barrier discharge (RBD), and atmospheric pressure plasma jet (APPJ).[184]

Concerned with the reuse electrophysiology catheters, Lerouge *et al.*[185,186]) compared plasma-based and ethylene oxide (EO) sterilization methods in terms of material damage and effectiveness. Using two different plasma-generating devices, they described oxidation from plasma as being limited to the near-surface layers whereas EO-induced slight but deeper alkylation. Hydrolytic stability of catheters was slightly changed by plasma-based sterilization, and they noted a small increase in released oligomers. The two different plasma-generating devices they tested had different impacts on catheters, such as the degradation of an additive and a clear difference in coloration.

1.125.9. The Issue of MDA Formation in Aromatic Polyurethanes

There has been some concern over methylene dianiline (4,4′-diaminodiphenylmethane, also 4,4′-methylenedianiline) or MDA which can possibly be found in polyurethanes made with methylene diisocyanate as a hard segment component. MDA has structural similarities to benzidine and 4-aminobiphenyl, two known human carcinogens and this may be a reason for concern; however, the carcinogenicity of MDA in humans is not clearly established. Human exposures to MDA have been covered in detail, both in the workplace and otherwise (*vida infra*), but, as we shall see, no increase in cancer or tumors have been reported.[187]

The EPA has not classified MDA for carcinogenicity although statistically significant increases in the incidence of several types of tumors, including liver and thyroid tumors have been reported in *lower* animals (rats and mice exposed to large amounts of the *dihydrochloride salt of MDA* in their drinking water). The International Agency for Research on Cancer (IARC) has classified MDA as a Group 2B, possible human carcinogen.[188]

1.125.9.1. Extreme Conditions Required to Produce MDA

In early studies, a number of authors attempted to extract or create MDA-production conditions in polyurethanes, possibly as a way of advancing polyurethanes containing nonaromatic hard-segment components.[189] Notably, after prolonged and extensive digestion with chloestrolase (enzymes) and using radio-labeled compounds to effectively enhance detection, MDA was characterized as one of the isolates from polymer decomposition.

Mazzu and Smith[190] were not able to find MDA in the aqueous extracts of polyurethane except in the case of prolonged steam autoclaving. The appearance of 3–5 ppb MDA in extracts under autoclaving conditions was attributed to hydrolysis of the polymer. They concluded that the stability of the polyurethanes under most conditions renders these materials useful in biomedical applications.

Early studies on δ-irradiation-sterilized thermoset 'potting' polyurethane materials extracted with methanol or serum led to the detection of MDA around a few parts per million in the original sample. The production of MDA increased with increasing irradiation doses and was related to the irradiation dose by a second-order equation. Interestingly, in these studies MDA was not found in autoclave sterilization materials,[191,192] and no traces of MDA could be detected in the aqueous extracts from methylene diphenyl diisocyanate (MDI) based hydroxyl-terminated polydimethyl siloxane type polyurethanes.[193]

The long-term (1- and 2-year) adverse tissue response including tumor formation by subcutaneous implantation of poly(ether urethanes) and silicone films into rats was compared by Nakamura *et al.*[194]2). In both implantation periods, the polyether urethanes gave higher incidents of the adverse responses including tumor formation when compared to silicone. No significant molecular-weight-dependent trend was found in a 1-year study; however, significant PU-dose-dependent trends were found in a 2-year study. More important, no detectable amounts of 4,4′-methylenedianiline (MDA) was found in the polyether urethanes and methanol extracts from the PUs were negative in the mutagenicity tests. The conclusion was that no relationship between the tumor formation by the polyether urethane films and the mutagenicities of the chemicals (mainly oligomers) leached from the PUs.

Polycarbonate polyurethanes synthesized with aromatic diisocyanates (MDI) are more (bio)stable than the materials synthesized with aliphatic diisocyanates. Structurally, it has been shown that the MDI molecules shield the polycarbonate segments from hydrolysis via hydrogen bonding at the carbonate sites.[195] MDA is not readily soluble in aqueous systems: it has been demonstrated to be a tremendous challenge to extract MDA for analysis in such environments (e.g., see Shintani[196]).

1.125.9.2. The Need for Aromatic Hard Segments in Biostable PUs and PUUs

In designing biomedical polyurethanes for critical applications the phase separation of the hard and soft segments provides many desirable properties of the resulting polymers. Phase separation is highly dependent on the extent of

hydrogen bonding among hard segments on adjacent polymer chains and, at this time, the properties obtained from aromatic hard segments cannot be duplicated with aliphatic or cycloaliphatic diisocyanates. The increased cohesive energy density provided by high-purity aromatic diisocyanates, and MDI in particular, gives improved chemical and solvent resistance, better flex life, creep resistance, and biostability. For example, without MDI it is very likely that the use of sac and diaphragm-type cardiac assist devices as 'destination devices' would not be possible. Here, as in many other critical device applications, the risk versus benefit analysis clearly favors the use of aromatic polyurethanes in chronic implants.

1.125.9.3. History of the Issue

Business considerations and junk science have influenced the history of MDA and biomedical polyurethanes. MDA in polyurethanes was also well addressed in an early review.[197]

1.125.9.4. The Epping Bakery Incident

In February 1965, 84 residents in the town of Epping, Essex, UK, ingested MDA-contaminated bread as a result of "a bag of flour being taken to the bakery in a van had split and mixed with the dangerous chemical diaminodiphenylmethane".[198] The case was detailed,[199] and extensively followed up at varying intervals throughout subsequent decades.

At the time of the incident, description of the presenting symptoms from ingestion included rigors, limb pains, malaise and obstructive jaundice which in some cases lasted for months. Differential diagnosis included cholelithiasis. Serum bilirubin, serum alkaline phosphatase and serum aspartate transaminase were raised to a varying and generally moderate degree. In a few cases there was blood eosinophilia. Seven patients had liver biopsies. These patients reportedly showed portal inflammation, eosinophil infiltration, cholangitis, cholestasis, and hepatocellular damage at different stages. Fibrosis appeared to be slight. Following the incident, and within 2 years afterward all patients made 'good clinical recoveries'.[200–202]

The incident is a classic example of public exposure to industrial chemicals and as a result has received extensive review. At 24 years follow-up, Hall *et al.*[203]) reported the health status of 68 (81%) of the group. The causes of death were unremarkable: there was one case of carcinoma of the biliary tract, two surviving cases had suffered retinal pathology, four surviving cases had a further episode of jaundice, including food intolerance, gastrointestinal disturbances, fatigue, and visual disturbances.[201,202] At 24 years the conclusions was that although the dose and route of administration in the epidemic differed from occupational exposure, this follow up study showed no evidence of long-term health effects. Thirty-eight-year follow up showed that mortality from all causes was close to expectation among females, and below expectation among males. Additionally, there were no observed deaths from cancer of the liver or from nonmalignant liver disease. The 38-year follow-up found no evidence to suggest that the ingestion of MDA had adversely affected mortality.[204]

Additional reports on MDA exposure, although not as dramatic, have followed similar etiology.[187] Between 1967 and 1976, 10 workers at a plant in Ontario that used MDA as an epoxy hardener developed acute jaundice. The group was followed from the date of exposure through to the end of 1991 looking specifically at cancer incidence. Remarkably, only one pathologically confirmed bladder cancer had developed, which was just above the expected number of cases predicted in the normal population.[205]

In 1997, a group of six techno-party-goers in Hanover Germany were admitted to the hospital with severe colicky abdominal pain and subsequently developed symptoms of hepatotoxicity.[206] They had ingested an alcoholic beverage that had been spiked with a powdery substance they dubbed MDA: they had mistakenly ingested MDA instead of the psychometric 'Ecstasy' drug: methylendioxyamphetamine (MDMA, *N*,α-dimethyl-1,3-benzodioxole-5-ethanamine; CAS 42542-10-9). As a result, clinical symptoms including acute jaundice developed within two days after ingestion. Enzymes indicating cholestasis increased steadily and transaminases remained moderately elevated. Between days 5 and 7, all patients became febrile for 1 day, their body temperatures rising up to 40 °C, thereafter the clinical status of all patients normalized. Laboratory values for enzymes and liver function returned to normal within 6 weeks, except for one patient, whose GGT value remained elevated due to the chronic consumption of alcohol. The long-term prognosis appeared favorable. All patients with 'Epping Jaundice' recovered and there were no further reports of recurring illnesses attributable to the 4,4′-diaminodiphenylmethane intoxication.

Additional cases of accidental and occupational exposure[207–210] can be found in the literature. Recent government publications from the State of California Office of Environmental Health Hazard Assessment (OEHHA) have extensively reviewed the literature on human and animal studies, evaluation and testing done with MDA.[211]

The possible metabolic pathways for metabolic processing of MDA have been proposed by Cocker.[212] The various metabolites included in the reaction scheme are potential candidates for monitoring exposure. Work on metabolic processes is continuing: vascular smooth muscle cells have recently been shown to be capable of converting MDA to *N*-acetyl methylenedianiline (*N*-acetyl-DAPM) and *N*,*N*′-diacetyl methylenedianiline (*N*,*N*′-diacetyl-DAPM).[213]

In addition to MDA, alternative diisocyanates and diamines such as toluene-diamine potentially formed from polyurethanes have been considered.[214] The metabolism of MDA in biological systems has been proposed by Cocker,[212] and is presented as a graphic in **Figure 31**.

1.125.10. Future of Biomedical Polyurethanes and Silicone Polyurethanes

In the immediate future perhaps the biggest growth area for implantable polyurethanes is in orthopedic implants in which polyurethanes and silicone-polyurethanes are used to create so-called compliant bearings for hip, knee, shoulder, spine and finger joint prostheses and resurfacing devices. This trend started in the mid-1990s with the successful use of polycarbonate urethane in a dynamic spinal fixation device, an application that has grown rapidly ever since.

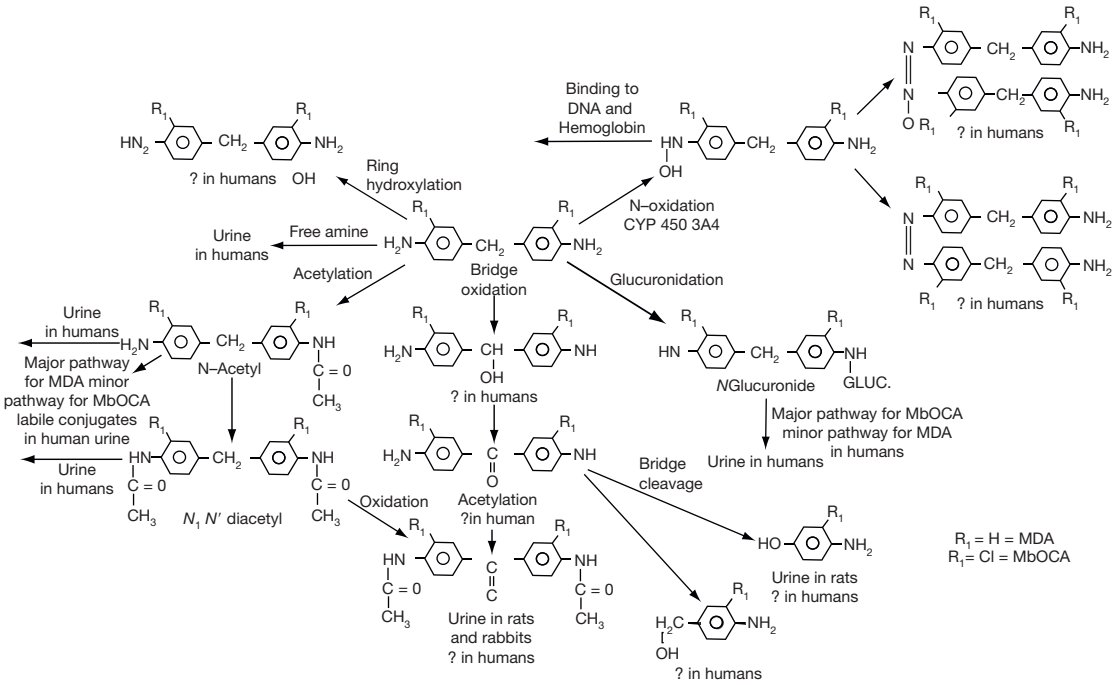

Figure 31 Metabolism of MbOCA or 4,4′-diaminodiphenylmethane in humans. Reproduced from Cocker, J. In *Biological Monitoring of Chemical Exposure in the Workplace*; Lehtinen, S., Ed.; World Health Organization: Geneva, 1996; Vol. 2, Chapter 4, pp 166–189.

Zimmer Dynesys® dynamic spinal stabilization system	Medtronic BRYAN® cervical disc	AxioMed Freedom® lumbar disc	Active Implants TriboFit® hip
• Over 14 years global experience • Over 40 thousand procedures	• 15 000 cases implanted without fracture • 3–6-year explants showed no trend of degradation	• CE Mark received • IDE pivotal study initiated	• CE Mark received • Several hundred implantations

Figure 32 Use of polyurethanes in orthopedic applications (selected examples).

As discussed in this chapter, however, polyurethanes constitute a huge class of polymers that are well suited to continued development of evermore sophisticated biomaterials. The very wide range of surface and bulk properties obtainable with the straightforward synthetic methods discussed here should maintain interest in these materials for many years. Economical, high-volume manufacturing methods, *and* easy fabrication techniques for prototyping make them attractive to device engineers, as does the ease with which custom materials can be prepared for the most materials-intensive applications (Figure 32).

The largely successful 40-year history of certain biostable polyurethanes in critical medical devices and prostheses supports the belief that they can be inherently safe, and unique in their combination of physical–mechanical properties and biostability. Continued improvements in biostability, for example, via novel combinations of polyols and/or new stabilization methods, should increase the useful life of polyurethanes in the body. This is important given the trend of implanting orthopedic implants in younger patients, and the increased prevalence of diabetes requiring sensors and artificial organs, to name just two examples.

The concept of a biomaterials toolkit based on polyurethanes has already proven to increase development efficiency by decoupling bulk and surface properties. The recognition that self assembly of polymer end groups can create the 'same' surfaces as fragile SAM thiols on gold, should allow the translation of research results to practical and stable *structural* materials. The range of surface modifications possible with end groups includes biologically active head groups

useful in diagnostic and therapeutic applications, as well as so-called passive chemistries.

More mundane developments will also increase the utility of polyurethane biomaterials including widening the property map of easily-processed thermoplastics to include materials that can replace soft thermosets like silicone, and hard engineering plastics including PAEK and PEEK. Control of macro- and micro-porosity of both biostable and bioresorbable 'urethanes' should help the development of tissue scaffolds for a number of uses, and composite biomaterials that use polyurethanes together with high-strength fibers can lead to high-performance orthopedic implants.

Considering the range of chemical compositions and physical–mechanical properties possible with polyurethanes, and their straightforward synthesis, and ease of processing, they are the most versatile biomaterials available today. This is likely to continue well into the future.

Glossary

Drug delivery system Drug delivery systems are used to control the release rate and timeframe, in which drugs become available for pharmacological effects in the body of a patient.

Implant Any medical device made from one or more materials that is intentionally placed within the body, either totally or partially buried beneath an epithelial surface.

Medical devices Products to be used with human beings for the purpose such as for diagnosis, prevention, monitoring, or treatment of diseases, injuries, or disabilities with the intended principal action being achieved by means other than pharmacological, immunological, or metabolic mechanisms; for example, by a supportive function; Council Directive 93/42/EEC Helmholtz-Zentrum Geesthacht.

Methacrylate Salts or esters from the methacrylic acid ($C H_2{=}CHCOOH$), containing reactive vinyl ($CH_2{=}CHR$) groups, which can polymerize.

Minimally invasive surgery Surgical technique which is less invasive than open surgery employed for the same clinical purpose and often involves small keyhole incisions only.

Polyurethane/polyetherurethane/ polyesterurethane A polymer consisting of polyether/ polyester units joined by urethane units.

Thermoplast A polymer which turns into liquid when heated above the highest thermal transition temperature (T_{perm}). Unlike thermosetting polymers, thermoplasts can be remelted and remolded. In general, thermoplasts are high-molecular-weight polymers.

Abbreviations

BA	*n*-Butyl acrylate
DSCP	Dual-shape creation proceure
EO	Ethylene oxide
FDA	United States Food and Drug Administration
ΔH_m	Melting enthalpy
MDI	Methylene diphenylene diisocyante
MIS	Minimally invasive surgey
NIR	Near infrared
NMRI	Naval Medical Research Institute
N-PCGDMA	Networks for poly(ε-caprolactone-*co*-glycolide) dimethacrylates
PCG	Poly(ε-caprolactone-*co*-glycolide)
PCGDMA	Poly(ε-caprolactone-*co*-glycolide) dimethacrylate
PCL	Poly(ε-caprolactone)
PCLDMA	Poly(ε-caprolactone)dimethacrylate
PDC	Multi block copolymer of PPDO and PCL
PEGMA	Poly(ethylene glycol) dimethacrylate
PEU	Poly(ether urethane)
PLG	Poly[(*rac*-lactide)-*co*-glycolide]
PPDO	Poly(*p*-dioxanone)
PTMO	Poly(tetramethylene oxide)
R_f	Shape fixity ratio
RH	Relative humidity
R_r	Shape recovery ratio
σ_{max}	Recovery stress
SMCP	Shape-memory creation process
SME	Shape-memory effect
SMP	Shape-memory polymer
T_{deform}	Deformation temperature
T_g	Glass transition temperature
T_{high}	Highest temperature in the course of SMCP
T_{low}	Lowest temperature in the course of SMCP
T_m	Melting transition temperature
TMDI	Trimethyl hexamethylene diisocyanate (isomeric mixture of 1,6-diisocyanato 2,2,4-trimethylhexane and 1,6-diisocyanato-2,4,4-trimethylhexane)
T_{perm}	Highest thermal transition temperature of a thermoplastic material at which the domains acting as physical cross links melt
T_{sw}	Switching temperature
TSCP	Triple-shape creation procedures
$T_{\sigma,\ max}$	Temperature determined at the maximum of recovery stress
T_{trans}	Thermal transition temperature

1.126.1. Fundamental Principles of Shape-Memory Polymers and of the Quantification of Shape-Memory Properties

Each biomedical application such as implants, surgical instruments, extracorporal devices, wound covers, or controlled drug delivery systems requires a specific combination of material properties and functions. Polymeric biomaterials are of high relevance for such applications, as the functions and properties can be tuned in a wide range by only small variations of their chemical structure. An important function, which, for example, implants such as hernia meshes or wound clips have to fulfill, is a function on the macroscopic level such as the mechanical function. In addition, biofunctionality is required, especially when a polymer-based device should guide a regeneration process. For medical devices that will be in contact with blood, such as artificial heart valves and tubes used in extracorporal devices, hemocompatible surfaces play a key role. Although the number of fields of applications for polymeric biomaterials is increasing steadily, the number of materials, which are applied in the clinics, is very limited. Hurdles in the development of novel biomaterials are long development times connected with financial risks, regulatory aspects, and uncertainties in the reimbursement. The rapid progress in the development of surgical techniques, especially in minimally invasive surgery (MIS) as an example, is leading to more complex requirements for modern implants. How can a bulky implant be placed in the body through a small keyhole incision or how can an implant be adapted to the individual geometry of a patient? How can a second surgery for implant removal be avoided?

The challenge associated with the first question can be addressed by smart materials, which are capable of an active on-demand movement.[1–6] In this chapter, we describe the shape-memory effect (SME) of polymers, which enables polymers to change their shape in a predefined way on demand when exposed to a suitable stimulus. At present, most investigated shape-memory polymers (SMPs) are thermally-induced SMPs, which are triggered by heat. A bulky implant having a switching temperature (T_{sw}) between room temperature and body temperature could be inserted into the body through a small incision in a compressed or elongated temporary shape. As soon as the implant is placed in the body, it is heated to body temperature and changes into its bulky application-relevant shape. The temporary shape is created by a thermomechanical process and can be adjusted to the individual needs of a patient.

A strategy to address the question of implant removal will be the introduction of hydrolytically degradable bonds into the implant material.[7] In the design of such materials, it has to be considered that the degradation products should be either fully metabolized or excretable as polymer fragments. Furthermore, degradable polymeric biomaterials enable the application of polymeric biomaterials as matrix materials for controlled drug release systems. This requires the characterization of the drug diffusion characteristics or the polymer's erosion behavior.

In the following, the fundamental principles of the thermally-induced SME as well as its characterization are discussed. Afterward, the basics of additional functionalities such as hydrolytical degradability, biofunctionality, and drug release are introduced and combinations of these functions are described as examples for multifunctional SMPs. Selected biomaterials with SME are presented, including data of the biocompatibility, whenever available. The application potential of SMP in medical devices is sketched by an overview on SMP-based medical devices being developed with a focus on general surgery, the cardiovascular system, and urogenital application. Here, a special emphasis is given on the potential use of SMPs as matrix materials in controlled drug release systems.

SMPs are different from shape-changing materials as they are able to change their shape in a predefined way on demand when exposed to a suitable stimulus, which can be heat or light.[1,8] By application of external stress, such SMPs can be deformed and temporarily fixed in a second, temporary shape. In Figure 1, a thermally-induced SMP is shown in its temporary shape. When the material is heated above a certain switching temperature (T_{sw}), the SMP recovers its original, permanent shape. The movement during recovery is predefined as it reverses the mechanical deformation which was applied for the creation of the temporary shape.

Besides this tailored thermomechanical procedure, which is also referred to as programming or shape-memory creation procedure (SMCP), the SME requires a suitable molecular

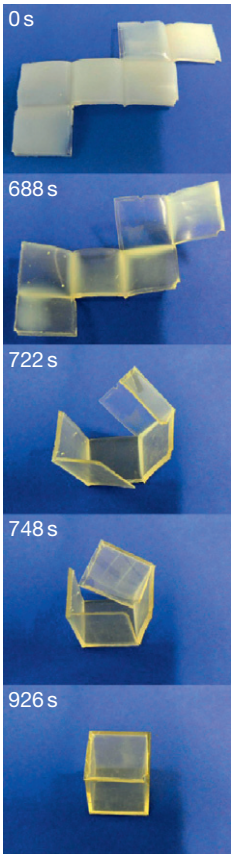

Figure 1 Time series of photographs showing recovery of a shape-memory cube when heated with an IR-lamp. Total time from start to finish of the process was 926 s. The tube was made of a poly(ε-caprolactone)dimethacrylate polymer network (the M_n of the network's switching segments was 10^4) that had been programmed to form a flat cube. architecture/morphology. Suitable polymeric materials that are capable of an SME provide a polymer network architecture consisting of netpoints, chain segments, and molecular switches, with the latter being sensitive to an external stimulus. The netpoints, interconnected by the chain segments, determine the permanent shape of the SMP. They can be of chemical (covalent bonds) or physical (intermolecular interactions) nature. While the creation of covalent bonds requires suitable crosslinking chemistry, the formation of netpoints by intermolecular interactions demands a morphology consisting of at least two segregated domains, for example, a crystalline and an amorphous phase. In such multiphase polymers, the polymer chain segments form domains. The domains that are related to the highest thermal transition temperature (T_{perm}) are called hard domains and they act as physical netpoints.

During the deformation applied when creating the temporary shape in the course of SMCP, a sufficient elastic deformability of the polymer network is required. This deformability can be reached by the chain segments, which must be capable of sustaining a certain orientation. The extent of the deformability increases with growing length and flexibility of these chain segments. Furthermore, the recoiling of the chain segments, which is entropically driven, enables the recovery of the permanent shape.

Stimuli-sensitive switches that form additional reversible crosslinks, which can be established and cleaved on demand, enable a reversible fixation of the temporary shape and prevent in this way the recoiling of the chain segments. Like the permanent netpoints, these additional crosslinks can be built by the formation of chemical (covalent) reversible bonds, intermolecular interactions of side groups, or by the solidification of domains formed by these polymer chain segments upon cooling below their correlated thermal transition temperatures T_{trans}. That is why such polymer chain segments are called switching segments; the associated domains are named switching domains. As this solidification is triggered by heat in such a thermosensitive SMP, which presently is the most prominent class of SMP, an additional classification can be performed according to the thermal transitions related to the solidification of the polymer chain segments. T_{trans} can be a glass transition temperature (T_g), a melting transition temperature (T_m), or a liquid crystalline transition. While T_gs span over a broad temperature interval, the latter ones can show a transition in a relatively small temperature interval. Melting transitions mostly extend over a temperature range between 15 and 20 K, while liquid crystalline transitions can even occur in a temperature interval between 1 and 5 K. In all cases, heating of the thermally-induced SMP above the thermal transition causes melting of the crystallites or regain of flexibility of the vitrified switching domains so that the viscous state is reached again. In a thermoplastic SMP, only the domains associated to the polymer chain segments with the second highest T_{trans} act as switching domains. Chemical crosslinks as stimuli-sensitive switches can be realized by the reaction of two functional groups under formation of a reversible chemical bond. The application of a suitable stimulus enables cleavage of these bonds on demand.

On the macroscopic level, shape-memory properties of polymers are characterized by the extent to which the temporary shape can be fixed (shape fixity ratio R_f) and the permanent shape is recovered (shape recovery ratio R_r). Further characteristic measures of SMP properties are the switching temperature (T_{sw}) obtained under stress-free recovery conditions or the temperature $T_{\sigma,max}$, determined at the maximum of the recovery stress (σ_{max}) under constant strain conditions. These shape-memory characteristics strongly depend on the polymer's structural design as well as on the parameters (e.g., heating or cooling rates or the type of mechanical deformation) applied during the SMCP.

Various different test procedures have been applied for SME quantification (e.g., determination of the material's shrinkage[9–11] or application bending tests[12] as well as three-point flexural tests[13,14]) of which cyclic, thermomechanical tensile tests[3,15,16] are the most common method for quantification of macroscopic shape-memory properties. Moreover, for biomaterials it is essential to explore the shape-memory behavior in aqueous environments similar to physiological conditions.

Cyclic, thermomechanical tensile experiments are typically performed with a tensile testing machine equipped with a thermo chamber that enables an accurate temperature control during mechanical deformation. In such experiments, the specimen is typically uniaxially deformed (e.g., elongated or compressed). In general, such test protocols or cycles consist of a SMCP where the temporary shape is generated and a recovery module where either the recovery of the original shape or the generated recovery stress is analyzed. The programming module SMCP as well as the recovery module can both be performed under stress-controlled or strain-controlled conditions. While strain-controlled procedures allow measurement of the stress on the specimen at defined thermal conditions, the change in strain is obtained in stress-controlled tests. The cyclic test protocols can be further differentiated according to the applied deformation temperature T_{deform}. In cold drawing protocols, the deformation to the temporary shape takes place at the fixation temperature $T_{low} = T_{deform}$, which is below T_{trans} of the switching domains. In a conventional heating–stretching–cooling protocol, the deformation is performed at the recovery temperature $T_{high} = T_{deform}$, which is above T_{trans}.

A strain-controlled SMCP typically consists of three steps: (1) heating of the sample to the upper working temperature $T_{high} > T_{trans}$, for elongation to a certain extension ε_m with a defined strain rate $\dot{\varepsilon}$ for a fixed time period at $T_{high} = T_{deform}$; (2) cooling to the lower working temperature $T_{low} < T_{trans}$ with a certain cooling rate β_c while ε_m is kept constant for fixation of the temporary shape; (3) unloading of the specimen to zero stress at T_{low} resulting in the fixed shape ε_u. From a σ–ε diagram as displayed in **Figure 2(a)**, the Young modulus $E(T_{high})$ at T_{high} which is also called rubber modulus E_{rubber} can be determined from the initial slope of the σ–ε curve in step (1). The corresponding Young's modulus $E(T_{low})$ at T_{low} also named E_{unload} can be obtained from the slope of the unloading path in step (3).[17] After the temporary shape is fixed, the recovery process can be initialized (step 4) as discussed below.

In the equivalent stress-controlled SMCP, the programming steps (1) and (3) remain unchanged while step (2) is adapted. After ε_m is reached, the sample is allowed to relax to a stress σ_m, which is then kept constant during cooling to T_{low}, whereby the deformation of the sample to ε_l is monitored during cooling. If the sample is cooled under constant stress σ_m, different effects have to be considered, for example, changes

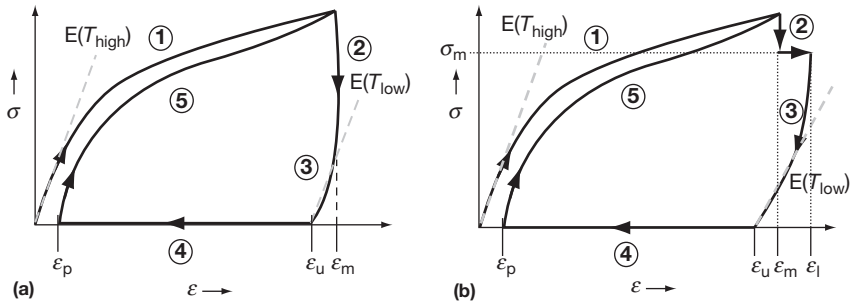

Figure 2 Schematic representation of stress–strain curve as a result of the cyclic, thermomechanical tensile tests for two different cycle types. (a) Strain-controlled programming with stress-free recovery ($\sigma-\varepsilon$ diagram) cycle type A.3: ①, stretching to ε_m at T_{high}; ②, cooling to T_{low} with constant cooling rate β_c while ε_m is kept constant; ③, unloading to zero stress while reaching ε_u; ④, heating up to T_{high} under stress-free conditions, while keeping $\sigma = 0$ MPa and ε_p is recovered; ⑤, start of the second cycle. (b) Stress-controlled programming with stress-free recovery ($\sigma-\varepsilon$ diagram): ①, stretching to ε_m at T_{high} while relaxation to σ_m is allowed; ②, cooling down to T_{low} with constant cooling rate β_c while σ_m is kept constant and ε_l is reached; ③, unloading to zero stress while reaching ε_u; ④, heating up to T_{high} under stress-free conditions, while keeping $\sigma = 0$ MPa and ε_p is recovered; ⑤, start of the second cycle. In both $\sigma-\varepsilon$ diagrams the gray dashed lines represent Young's modulus which can be determined either at T_{high} in step ① or at T_{low} during unloading in step ③. Modified from Lendlein, A.; Kelch, S. *Angew. Chem. Int. Ed.* **2002**, *41*, 2034–2057. Copyright Wiley-VCH-Verlag GmbH & Co KGaA, reproduced with permission.

of the expansion coefficient of the stretched specimen at temperatures above and below T_{trans} as well as volume changes arising from vitrification ($T_{trans} = T_g$) or crystallization ($T_{trans} = T_m$) of the switching domains. Finally, in step (3) the specimen is unloaded to zero stress at T_{low} whereby ε_u is reached (see **Figure 2(b)**).

For quantification of the applied programming, R_f is determined which describes the ability to fix the mechanical deformation ε_m. R_f is calculated by the amplitude ratio of ε_m to the total deformation ε_u. In a strain-controlled programming protocol, R_f is given by the ratio of the strain in the stress-free state after the withdrawal of the tensile stress in the Nth cycle $\varepsilon_u(N)$ and the maximum strain ε_m (eqn [1]). In the stress-controlled programming protocol, R_f is given by the ratio of the tensile strain after unloading, $\varepsilon_u(N)$, to the maximum strain $\varepsilon_l(N)$ at $\sigma = \sigma_m$ after cooling to T_{low}, $\varepsilon_l(N)$ (eqn [2]).[3]

$$\text{Strain-controlled: } R_f(N) = \frac{\varepsilon_u(N)}{\varepsilon_m} \quad [1]$$

$$\text{Stress-controlled: } R_f(N) = \frac{\varepsilon_u(N)}{\varepsilon_l(N)} \quad [2]$$

After the SMCP is finished and ε_u is fixed, the next step in a cyclic, thermomechanical test is heating from T_{low} to T_{high} with a constant heating rate β_h ((4) as in **Figure 2(a)**), allowing the recovery of the original permanent shape when performed under stress-free conditions (at $\sigma = 0$ MPa). After T_{high} is reached, a recovered shape ε_p is achieved as displayed in a strain-stress-recovery diagram (**Figure 2(a)**).

For quantification of the recovery in dual-shape tests, the R_r is calculated, depending on the applied SMCP type (stress-controlled or strain-controlled).

$$\text{Strain-controlled SMCP: } R_r(N) = \frac{\varepsilon_m - \varepsilon_p(N)}{\varepsilon_m - \varepsilon_p(N-1)} \quad [3]$$

$$\text{Stress-controlled SMCP: } R_r(N) = \frac{\varepsilon_l(N) - \varepsilon_p(N)}{\varepsilon_l(N) - \varepsilon_p(N-1)} \quad [4]$$

In a strain-controlled protocol, the change in strain obtained during the programming step in the previous cycle ($\varepsilon_m - \varepsilon_p(N-1)$) is related to the change in strain that occurs during the present cycle $\varepsilon_m - \varepsilon_p(N)$ (eqn [3]). The recovered strain in two successively passed cycles in the stress-free state before application of yield stress is represented by $\varepsilon_p(N-1)$ and $\varepsilon_p(N)$. In the case of a stress-controlled programming and stress-free recovery after cooling to T_{low} during the Nth cycle $\varepsilon_l(N)$, the shape recovery ratio R_r quantifies the ability of the material to memorize its permanent shape. For this purpose, the change in strain which occurs during the programming step in the $(N-1)$th cycle $\varepsilon_l - \varepsilon_p(N-1)$ is compared to the change in strain which occurs as a result of the following cycle $\varepsilon_l - \varepsilon_p(N)$ (eqn [4]).[3]

Further characteristic values that can be determined from recovery under stress-free conditions are the switching temperature (T_{sw}), the temperature interval of recovery ΔT_{rec}, and the recovery rate $v_{rec.}$[16] ΔT_{rec} is defined as the difference between the temperature T_{end} where the transition from the temporary to the original shape ends and the temperature T_{start} where the recovery process begins (eqn [5] and **Figure 3(a)**). The recovery rate v_{rec} is given as the ratio of the strain recovery ratio R_r over the temperature interval ΔT_{rec} (eqn [6]). T_{sw} can be determined as inflection point of the ε–T diagram representing the peak of $v_{rec.}$[15,18]

$$\Delta T_{rec} = T_{end} - T_{start} \quad [5]$$

$$v_{rec} = \frac{R_r}{\Delta T_{rec}} \quad [6]$$

If recovery takes place under constant strain conditions ($\varepsilon = \varepsilon_m =$ constant), the generation of the recovery stress can be monitored in a stress–temperature recovery σ–T diagram (see **Figure 3(b)**). For dual-shape SMPs (especially thermoplastics) in the σ–T diagram, typically a stress maximum σ_{max} is observed at a characteristic temperature $T_{\sigma,max}$ when heating to $T_{high.}$[15,16] Here, σ_{max} represents an equilibrium state between the stored forces applied during deformation and the retracting forces, driven by the entropy elasticity, which is a result of the softening of the polymer caused by the decrease in Youngs's modulus. The latter effect dominates the behavior at temperatures above $T_{\sigma,max}$.

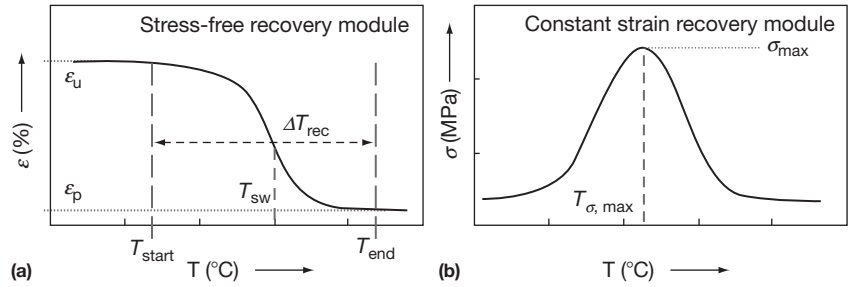

Figure 3 Schematic representation of recovery curves for thermoplastic SMPs. (a) ε–T diagram of a thermoplastic SMP recovered under stress-free conditions. (b) σ–T diagram of a thermoplastic SMP, recovered under constant strain conditions. Reproduced from Wagermaier, W.; Kratz, K.; Heuchel, M.; Lendlein, A. *Adv. Polym. Sci.* **2010**, *226*, 97–145, with permission from Springer Science+Business Media.

Several model approaches have been developed to analyze and simulate the shape-memory behavior of SMPs. Viscoelastic models, which are based on the structural concept of SMPs consisting of at least two phases (switching domains and hard domains) with different transition temperatures, considered two Maxwell models (spring and dashpot) connected in parallel.[19,20] According to a recently introduced phenomenologically thermomechanical model for SMP by Liu *et al.*,[21] the structural conformation of an amorphous SMP at a certain temperature could be described as coexistence of frozen and active volume fractions. A central assumption of this model is that only the active volume fractions were elongated in the rubbery state at $T > T_g$ and the applied deformation was fixed during cooling. In addition, specific models for crystallizable SMPs have been reported, which consider that during cooling from a melt (at T_{high}), newly formed crystals stabilize the SMP and act as physical crosslinks. Barot *et al.*[22] developed a model for the thermomechanical behavior of crystallizable SMPs within a thermodynamic framework for homogenous and inhomogeneous deformation in different geometries. In this model, four different polymer-related processes and states of the SMP are theoretically described: (i) the rubbery, totally amorphous state at $T > T_m$ of the switching segments, (ii) the semicrystalline phase at temperatures $T < T_m$, (iii) the crystallization process on cooling below T_m, and (iv) the melting process caused by heating again above T_m.

When, on the molecular level, a second switching segment is integrated into the polymer network which enables a morphology of at least two segregated domains and results in two transition temperatures $T_{trans,A}$ and $T_{trans,B}$, the capability of two subsequent shape changes can be implemented in a polymeric material.[23–29] The original shape (C) is defined by the netpoints resulting from the crosslinking reaction, while shapes (A) and (B) are created in a two-step thermomechanical programming process. The physical crosslinks associated to the highest transition temperature $T_{trans,B}$ are associated to shape (B), while shape (A) relates to the second highest transition temperature $T_{trans,A}$. Various triple-shape creation procedures (TSCP) have been investigated; the most obvious method is a twofold dual-shape creation procedure (DSCP). In this type of a TSCP, named TSCP-1, the triple-shape material of a permanent shape (C) is first heated to T_{high} where the polymer network is in the elastic state and then a deformation is applied. The cooling under external stress to T_{mid} ($T_{trans,A} < T_{mid} < T_{trans,B}$) results in formation of physical crosslinks related to $T_{trans,B}$. Shape (B) is obtained after release of the external stress. Subsequent deformation of this shape at T_{mid} and cooling to T_{low} under external stress creates shape (A). When the material is heated to T_{mid}, shape (B) is recovered; subsequent heating to T_{high} results in shape (C). In the following, a typical cyclic, thermomechanical triple-shape test consisting of a TSCP-1 programming module followed by recovery under stress-free conditions is described for an AB multiphase polymer network named MACL composed of crystallizable poly(ε-caprolactone) (PCL) segments and amorphous poly (cyclohexyl methacrylate) (PCHMA) segments (see **Figure 4**). In the first step, the specimen is heated to $T_{high} > T_{trans,B} = T_{g,PCHMA}$ where the material is in a rubber-elastic state. After equilibration at T_{high}, the sample was deformed to ε_B^0. Then, the material is cooled to a temperature T_{mid} which is in between $T_{trans,A} = T_{m,PCL}$ and $T_{g,PCHMA}$ and external stress is maintained until the physical crosslinks fixing shape (B) are established (ε_B^{load}). After releasing the external stress, shape (B), ε_B is obtained. In the second step, shape (A) is created. The sample, which presently is in shape stress, (B), is further deformed at T_{mid} to ε_A^0 (shape A). Cooling under external stress to $T_{low} < (T_{trans,A} - 20\,K)$ leads to a second set of physical netpoints related to $T_{trans,A}$ stabilizing ε_A^{load}. These new physical crosslinks fix shape (A) (ε_A), which is obtained when the external stress is released. Finally, the sequential recovery of the shapes (B) (ε_B^{rec}) and (C) (ε_C^{rec}) is triggered by reheating to T_{high} as shown in **Figure 4**.

In addition, in a procedure named TSCP-2, the material can be deformed at T_{high}, and subsequently cooled to T_{low} to fix the shape (B). Afterward, the material is heated to T_{mid} where a second deformation is applied. After cooling to T_{low}, the shape (A) is created. The recovery sequence by heating is the same as that for TSCP-1.[30] Besides three individual shapes, such triple-shape materials allow by individual choice of the transition temperatures two dual-shape effects.[26]

Indirect actuation of the thermally-induced SME broadens the applicability of SMP. Two different strategies enable the indirect actuation of the SME: the first strategy involves heating of the SMP indirectly, for example, by exposure to energy transporting radiation. Lowering of T_{trans} so that the SME is triggered while the sample temperature remains constant is the second strategy and can be realized by diffusion of a plasticizer into the polymer. Here, we will focus on the first strategy.

In a medical device based on polyurethane, the SME could be induced by illumination with light of an IR laser.[31,32]

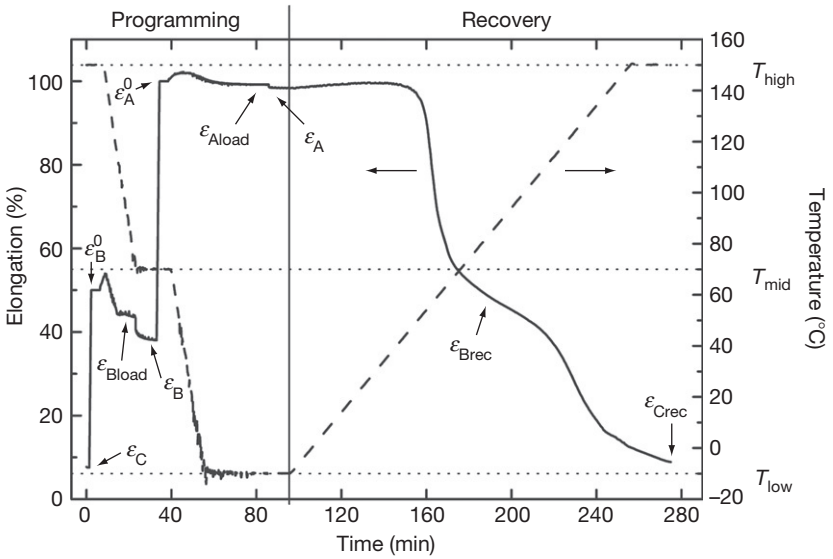

Figure 4 Cyclic, thermomechanical tensile test for quantification of triple-shape effect. Strain and temperature as a function of time taken from the fifth cycle for MACL(45) multiphase network composed of crystallizable PCL segments and amorphous poly(cyclohexyl methacrylate) segments with 45 wt% PCL content ($T_{trans,A} = T_{m,PCL} = 50\,^{\circ}C$ and $T_{trans,B} = T_g = T_{g,PCHMA} = 140\,^{\circ}C$). The solid line indicates strain; the dashed line indicates temperature. In this triple-shape experiment, the sample first is stretched from ε_C to ε_B^0 at $T_{high} = 150\,^{\circ}C$, then cooled to T_{mid} with a cooling rate of $\beta_c = 5\,K\,min^{-1}$ to under stress-control results in ε_B^{load} and after unloading ε_B is fixed. Then the sample is further elongated at T_{mid} to ε_A^0 and subsequently cooled to T_{low} under stress-control with $\beta_c = 5\,K\,min^{-1}$ whereas the elongation decreases to ε_A^{load}. Shape (A), corresponding to ε_A, is obtained by unloading. The recovery process of the sample is monitored by reheating with a heating rate of $\beta_h = 1\,K\,min^{-1}$ from T_{low} to T_{high} while the stress is kept at 0 MPa and the sample contracts to recovered shape (B) at ε_B^{rec} and finally shape (C) at ε_C^{rec} is recovered. Reprinted from Bellin, I.; Kelch, S.; Langer, R.; Lendlein, A. *Proc. Natl. Acad. Sci. USA* **2006**, *103*(48), 18043–18047. Copyright 2006 National Academy of Sciences, USA.

The principle could be extended to laser-activated shape-memory vascular stents and SMP foams for aneurysm treatment,[33,34] both of which require a light diffuser for the uniform application of light.[35] In all cases, energy absorption by the polymer for actuation is quite low.

An increase in the absorbed energy can be reached by the incorporation of conductive fillers such as heat-conductive ceramics, carbon black, and carbon nanotubes resulting in a better interconnection between the heat source and the shape-memory devices.[14,36,37] Here, it needs to be considered that besides a better heat transfer, the incorporation of particles also influences the mechanical properties.

The incorporation of carbon nanotubes into shape-memory polyurethanes enables a certain level of conductivity to be reached. Upon application of an electrical current, the sample temperature is increased as a result of the high ohmic resistance of the composite, so that electrical energy is converted into heat.[38–41] This warming can be used to trigger the SME. The addition of other conducting materials such as polypyrrole, short carbon fibers, and nickel particles increased conductivity, in case the conductivity of carbon nanotubes was not sufficiently high enough.[40–44] The addition of 2.5 wt% carbon nanotubes increased the modulus from 12 to 148 MPa, and addition of 5 wt% polypyrrole results in a modulus of 112 MPa. A composite having 2.5 wt% carbon nanotubes and 2.5 wt% polypyrrole featured a modulus of 112 MPa. The composites having nickel particles arranged in chains were prepared by curing the SMP resin containing small amounts of Ni powder in a weak magnetic field.[43,44] While the ohmic resistance is reduced so that a voltage of 20 V is sufficient for actuation, the storage modulus is increased compared to pure SMP resin or randomly distributed Ni.

A remote actuation of the thermally-induced SME in alternating magnetic fields had been realized by the incorporation of magnetic nanoparticles of iron(III) oxide cores in a silica matrix into SMP.[45–47] The sample temperature is increased by inductive heating of the nanoparticles as soon as the nanocomposite is placed in the alternating magnetic field ($f = 258$ kHz, $H = 7$–$30\,kA\,m^{-1}$). Thermoplastic materials as well as covalent polymer networks were selected as the matrix. A first material was a thermoplastic, biodegradable multiblock copolymer named PDC having poly(*p*-dioxanone) (PPDO) hard and PCL switching segments. A second thermoplastic multiblock copolymer was an aliphatic PEU from methylene bis(*p*-cyclohexyl isocyanate), butanediol (BD), and polytetrahydrofuran named TFX. In TFX, the switching domains are amorphous compared to PDC which has crystalline switching domains. Incorporation of the nanoparticles into PCL dimethacrylates and their subsequent polymerization yielded nanoparticle composite networks. The energy spectrum for the indirect actuation could be shifted to radio frequency when a near single crystal metal alloy comprising terbium, iron, and dysprosium-d of nominal composition $Tb_{0.3}Dy_{0.7}Fe_{1.92}$ was embedded in an epoxy thermoset. Here, the radio frequency triggers the magnetoelectroelastic effect, which generates the indirect heating.[48] In composites based on a matrix from thermoplastic polyurethanes derived from diphenylmethane-4,4′-diidocyanate, adipic acid, ethylene oxide, propylene oxide, 1,4-BD, and bisphenol A with $T_{trans} = T_g$, a reduction in the frequency and the magnetic field required for triggering the

SME of composites could be achieved by using magnetite particles in the range of 9 μm.[49] In addition, the indirect magnetic actuation of thermosets could be achieved by the incorporation of nickel zinc ferrite particles into a commercial ester-based thermoset polyurethane.[50]

When a second phase capable of providing domains having an additional transition temperature is introduced, a remotely actuated triple-shape effect is enabled (Figure 5).[46] This system consisted of silica-coated iron(III) oxide nanoparticles incorporated into a polymer network matrix similar to the above described MACL networks. When stimulated by increasing the magnetic field strength stepwise, a two-step recovery of shapes B and C could be obtained, whereby the best triple-shape properties were achieved for nanocomposites containing 40 wt% of PCL. In this way, the triple-shape effect could be characterized by two distinct switching magnetic strengths $H_{sw,1}(A \rightarrow B)$ and $H_{sw,2}(B \rightarrow C)$ corresponding to the switching temperatures determined in cyclic, thermomechanical tensile tests for thermally-induced triple-shape polymers.

SMPs, which can be controlled independently from heat, were obtained by incorporating light-sensitive reversibly reacting molecular switches into polymer networks resulting in the light-induced SME.[51] Suitable light-triggered molecular switches are cinnamic acid (CA) or cinnamyliden acetic acid (CAA). A 2 + 2 cycloaddition reaction occurs between two of these light-sensitive moieties, forming covalent crosslinks by formation of cyclobutane rings upon irradiation with UV light of $\lambda > 260$ nm. When irradiated with UV light of $\lambda < 260$ nm, these crosslinks can be cleaved again. The permanent shape of these photoresponsive SMPs is determined by the amorphous permanent polymer network.

The light-induced SME could be realized in two kinds of polymer structures: a grafted polymer and an interpenetrating polymer. In the first one, the CA molecules were grafted onto the permanent polymer network by copolymerization of *n*-butylacrylate, hydroxyethyl methacrylate, and ethyleneglycol-1-acrylate-2-CA using poly(propylene glycol)-dimethacrylate ($M_n = 560\ g\ mol^{-1}$) as a crosslinker. The interpenetrating polymer network was formed by loading a permanent polymer network consisting of *n*-butylacrylate with 3 wt% poly(propylene glycol)-dimethacrylate ($M_n = 1000\ g\ mol^{-1}$) as the crosslinker with 20 wt% star-poly(ethylene glycol) endcapped with CAA terminal groups (SCAA). The loading of the polymer was achieved by swelling in a 10 wt% SCAA chloroform solution, obtained as an opaque yellow film after removal of the solvent. The permanent shape of both light-sensitive SMPs, the grafted and the interpenetrating polymer networks, is determined by the permanent network (Figure 6).

In the DSCP, the polymer network is stretched first, resulting in a strain of the coiled polymer segments. Afterward, the polymer network is irradiated with UV light $\lambda > 260$ nm, whereby additional crosslinks are created, which fix the elongated form in a temporary shape. When irradiated with UV light of $\lambda < 260$ nm, the crosslinks are reversibly cleaved and the permanent shape is recovered. The grafted polymer featured in the fifth cycle R_fs of max. 52% and R_rs of max. 95%. The interpenetrating network showed in the third cycle 33% R_f and 98% R_r. As light-induced SMPs circumvent the constraints of external heating, they have a high application potential in the medical field.

1.126.2. Synthesis and Properties of Selected Examples of SMP Intended for Biomedical Applications

In covalently crosslinked polymer networks, the general parameters for controlling the shape-memory behavior are the nature of the switching segments influencing the characteristics of the SME such as T_{sw} and the crosslink density influencing the mechanical properties.

A common strategy for the synthesis of SMP networks with covalent crosslinks is subsequent crosslinking of linear

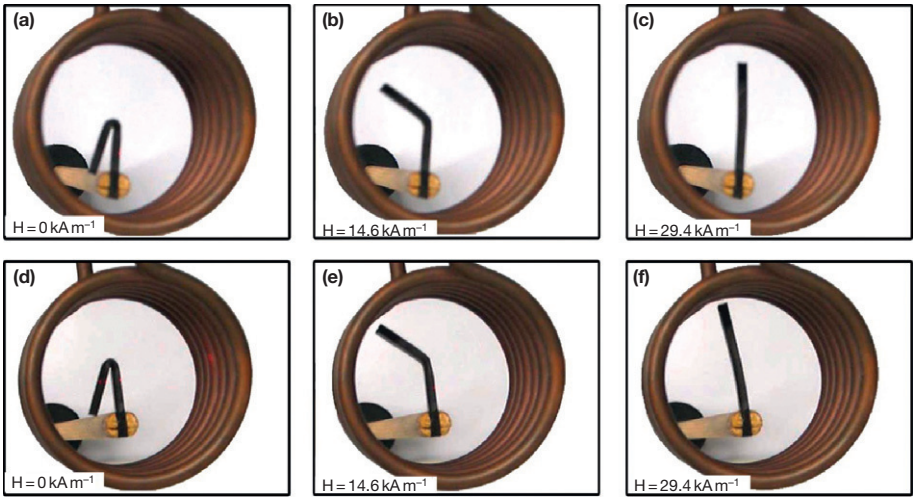

Figure 5 Images obtained for a triple-shape composite polymer network obtained from cyclohexylmethacrylate, poly(ε-caprolactone) dimethacrylate, and 12.5 wt% silica-coated iron(III) oxide nanoparticles during recovery at magnetic field strength *H* of 0, 14.6, and 29.4 kA m^{-1}. (a-c) TSCP-1: (a) shape A at 0 kA m^{-1}, (b) shape B at 14.6 kA m^{-1}, and (c) shape C at 29.4 kA m^{-1}. (d-f) TSCP-2s-II: (d) shape A at 0 kA m^{-1}, (e) shape B at 14.6 kA m^{-1}, and (f) shape C at 29.4 kA m^{-1}. Figure 6 Molecular mechanism of shape-memory effect of the interpenetrating polymer network: the chromophores (open triangles) are covalently connected to star-shaped oligomers, which are loaded into the permanent polymer network (filled circles, permanent crosslinks), forming photoreversible crosslinks (filled diamonds); fixation and recovery of the temporary shape are realized by UV light irradiation of suitable wavelengths.

polymers by postprocessing methods. Crosslinked poly(ethylene-*co*-(vinyl acetate)) (PEVA) is produced by curing linear PEVA with the radical initiator dicumyl peroxide, enabling a thermally-induced crosslinking reaction.[52] A second strategy comprises the one-step synthesis of polymer networks by (co) polymerization of monomers or oligomers with monomers having three or more reactive groups. Examples for this synthesis strategy are SMPs based on polyesters, which are obtained from ring-opening polymerization with the addition of crosslinking dilactone.[53,54] The most important approach to covalently crosslinked SMP networks involves the crosslinking of linear or branched polymeric precursors in a second step either by crosslinking precursors having three or more reactive groups ('star-shaped' precursors) with a crosslinker having two reactive groups or by crosslinking linear precursors with crosslinkers having three or more reactive groups. The shape-memory characteristics of these polymer networks can be controlled by parameters such as the number of polymer chain segments originating from netpoints (arms), the length of the chain segments, the thermal transition of the domains provided by the switching segments, and the number of phases. The mechanical properties are determined by the crosslink density, which is controlled by the chain segment length and the functionality of crosslinks as predefined in the polymeric precursors and the crosslinker. Switching segments can be amorphous or crystallizable. In addition, the nature of the switching segment influences the hydrolytic degradation and determines the trigger of the SME.

The copolymerization of diethylene glycol dimethacrylate (DEGMA) or poly(ethylene glycol) dimethacrylate (PEGMA) with low-molecular-weight acrylates yielded AB copolymer networks with $T_{trans} = T_g$ having covalent crosslinks. The choice of the acrylate enabled control of the elastic properties as well as T_{trans}. Furthermore, the elastic properties could be controlled by the molecular length and by the weight amount of the crosslinker.[13] When *t*-butyl acrylate (tBA) was copolymerized with DEGMA, AB copolymers with T_g around 55 °C were obtained. The rubbery modulus of the SMP networks could be adjusted between 1.5 and 11.5 MPa by the variation of the crosslinker content which was varied between 0 and 40 wt%. When methacrylate was used in such AB copolymer networks instead of tBA, the T_g could be varied between 56 and 92 °C while values of the rubbery modulus between 9.3 and 23.0 MPa were obtained.[55] *In vitro* biocompatibility tests are published for a PEGMA-*co*-methyl methacrylate SMP including tests for cytotoxicity, sensitization, irritation, acute and subchronic toxicity, and genotoxicity of sample extracts according to the 10993 GLP guidelines and have shown highest passing scores possible for all tests.[56]

Covalently crosslinked SMPs with $T_{trans} = T_m$ were created from semicrystalline polycyclooctene having unsaturated carbon bonds by ring-opening methathesis and which was subsequently crosslinked by the addition of dicumyl peroxide.[57]

Linear multiblock copolymers enable SMPs, in which the permanent crosslinks are replaced by physical crosslinks, to allow reshaping of the permanent shape when necessary. A necessity in these thermoplastic SMPs is the formation of at least two segregated phases forming hard domains and switching domains, respectively. The hard domains determine the permanent shape by physical crosslinks, which can be removed only by overstepping the thermal transition of the hard domains. T_{trans} of the switching domains is related to T_{sw} and therefore is applied to trigger the SME. Thermoplastic SMP can be synthesized by direct coupling of presynthesized polymer blocks with a linker, by applying the prepolymer method, or by melt blending.

A widely used method for the synthesis of multiblock copolymers is the coupling of the different oligomeric building blocks with a reactive linker.[4,58–60] A straightforward coupling method of hydroxytelechelic polymer blocks (diols) is the application of diisocyanates. The polyaddition reaction leads to urethane bonds without other reaction products. Frequently used diisocyanates are 2,4-diisocyanatotoluene (TDI), 1,6-diisocyanatohexane (HDI), and 1,6-diisocyanato-2,2(4),4-trimethylhexane (TMDI).

In the process called the prepolymer method, isocyanate-terminated prepolymers are obtained by reaction of hydroxytelechelic oligoesters or -ethers with an excess of a low-molecular-weight diisocyanate. Low-molecular-weight diols or diamines are added as so-called chain extenders to further couple these prepolymers. In this way, shape-memory polyurethanes or polyureas can be obtained as phase-segregated block copolymers having the prepolymer as switching domains. The hard domains contain highly polar urethane and urea bonds exhibiting high values of T_{trans}. The length of the hard segment blocks can be adjusted by the ratio of the prepolymer to diisocyanate/chain extender.[61]

Blending is a way to obtain thermoplastic SMP rather by processing than by synthesis. In this type of thermoplastic SMP, the component providing the hard segment and the component forming the switching segment are located in different linear multiblock copolymers.[62] While the mechanical properties could be varied systematically by the blend

composition, T_{sw} was nearly constant. The principle of shape-memory blends is of high interest as the segments in general can be selected according to the requirements of specific applications.

The polyaddition of polytetramethyleneoxide (PTMO) precursors with HMDI and 1,4-BD by the prepolymer method leads to phase-segregated PEUs with $T_{trans} = T_g$.[45,61,63] Here, the polyaddition of the HMDI with 1,4-BD forms the segment providing the hard domains, while the PTMO segment provides the switching domains. In a commercially available PEU synthesized from methylene bis(*p*-cyclohexyl isocyanate) (H12 MDI), BD, and PTMO diol T_g is at 74 °C. Determination of shape-memory properties revealed R_f of 100% and R_r of 80% after the third cycle at ε_m 50%. Remote actuation of the thermally-induced SME in alternating magnetic fields was realized by the incorporation of silica-coated magnetic nanoparticles of iron(III) oxide core into a polymer matrix of the described polymer.[45]

A polyether-based SMP with a T_{trans} of about 55 °C exhibited no cytotoxic effects on the adhesion and proliferation of human skin fibroblasts and gingival fibroblasts. In addition this PEU limited the adhesion of platelets.[64] The cytocompatibility and hemocompatibility made this PEU useful for artificial hearts, wound dressings, and pacemaker leads.[61] Plasma sterilized noncytotoxic PEU foams with T_gs of 35 and 55 °C could be used as a material for endovascular procedures.[65,66] In dogs with lateral aneurysms on both carotid arteries, the PEU-based SMP foams were able to occlude the aneurysms (test period: for 3 weeks) and to cause neointima formation at the neck of the aneurysm.[66] However, variations in PEU blood compatibility have been observed, with improved thromboresistance correlating to more alkylated soft segments,[67] higher soft-segment content on the surface,[68] well-developed microphase separation, and surface treatments such as grafted sulfonate groups.[69,70] On polyurethane-derived SMPs based on methylene diphenylene diisocyanate (MDI), PTMO, and *N*,*N*-bis(2-hydroxyethyl)isonicotinamide, effective nonleaching biocidal properties could be shown.[71] It was found that this polyurethane SMP possessed good bactericidal activity against *Staphylococcus aureus* and bacteriostatic activity against *Escherichia coli*. Also PCL-based shape-memory polyurethane ionomers with quaternarized pyridine moieties proved to be suited to reduce the bacterial activity of *Klebsiella pneumoniae* (− 96.2%) and *S. aureus* (−100%). Cytotoxicity testing by use of the agarose overlay assay with L929 mouse fibroblasts revealed no adverse effects of the materials on these cells.[72]

Polyurethane-based shape-memory block copolymers having $T_{trans} = T_m$ are synthesized by coupling of crystallizable hydroxytelechelic precursors with diisocyanates. Switching segments can be polyethers such as PTMO or polyesters such as PCL exhibiting a T_m near body temperature. A polyesterurethane consisting of hard segments based on 4,4′-MDI and 1,4-BDO and soft segments of PCL (PU/PCL, 70/30) and with T_{trans} at body temperature was blended with the PCL, which provided the switching segment. The blended SMP supported adhesion and proliferation of human bone marrow mesenchymal stem cells (MSCs). This gives the possibility to use the material for cardiovascular stents with an MSC coating on the blend for possibly better tissue compatibility.

1.126.3. Multifunctional SMPs by Integrating Hydrolytic Degradability or Controlled Drug Release Capability

Besides different ways of stimulation and the application driven adjustment of thermal and mechanical properties, a challenge in the development of SMP is the addition of novel functions resulting in multifunctional materials. Multifunctionality is the targeted combination of material functions, which are not linked with each other.[73,74] Multifunctional materials can be created by the integration of various functions in multimaterial systems on the nano- or micro-level. Single material systems combining the different functions on the molecular level[73] were reached as well, for example, by combining the shape-memory capability with hydrolytical degradability. This combination of functions is advantageous when devices or implants are only temporarily required, as a second surgery for the removal of the implant can be avoided. Another function that can be created in SMP is the controlled release of drugs. This function aims at ensuring constant levels of a drug over an extended period of time by simultaneously reducing the frequency of administration of the drug.[75] Often lower dosages of drug are effective in this way compared to oral administration, thereby possibly leading to reduction of drug side effects. SMP matrices as drug carrier would allow implanting of bulky devices by MIS and fixation of such devices in the body, combined with the above-mentioned advantages. Such a combination of functions is demanded by biomaterial-assisted therapies, for example, for vascular and urinary stents or as scaffold material for reconstructive or esthetic surgery (e.g., breast remodeling), and in tissue engineering applications (e.g., bone regeneration).

Degradation of SMP devices *in vivo* involving breakdown of macromolecules is mainly designed to utilize hydrolytic bond cleavage. However, it needs to be considered that breakage of bonds *in vivo* can be enhanced by enzymatic processes. The hydrolytic degradation rate is determined by the hydrolysis rate of the cleavable bonds and by diffusion processes: the diffusion of water into and of small degradation products out of the polymer matrix. In general, two mechanisms of hydrolytic degradation can be differentiated, which are determined by the relation between hydrolysis rate and diffusion rate.[76] If the hydrolysis rate is high compared to the diffusion rate, the degradation is confined to a thin layer on the surface. This 'surface erosion' (**Figure 7(a)**) is directed from the surface to

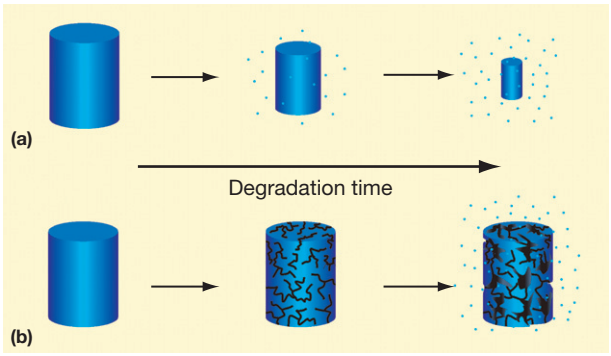

Figure 7 Mechanisms of hydrolytic degradation: (a) surface erosion; (b) bulk degradation.

the center of the polymeric implant reducing it permanently in size and mass, while the material which is distant from the surface sustains its original properties. On the other hand, 'bulk degradation' (**Figure 7(b)**) is a nondirected process. Here, diffusion is fast compared to the hydrolysis and allows degradation to take place all over the polymer matrix. First, mechanical properties change without size reduction of the polymer matrix. Randomly distributed bond breaks lead to the generation of larger degradation products. After a material-specific induction time, the degradation products become soluble and small enough to diffuse out of the matrix and the implant disintegrates with a fast mass loss. Depending on diffusion rate, hydrophilicity, and homogeneity of the implant material, the effective degradation behavior often shows characteristic elements from both degradation mechanisms.[77,78]

Biodegradability of SMP was realized by the introduction of hydrolyzable bonds, which could be easily cleaved under physiological conditions.[79] However, if biodegradable polymers are used in medical devices, the compatibility of the polymer and its degradation products to the surrounding tissue has to be considered.[80] In polymers, the chemical nature of the polymer itself determines the hydrolyzation rate: orthoesters hydrolyze faster than ester bonds, which in turn hydrolyze faster than amide bonds. Another influencing factor is the steric accessibility of the hydrolyzable bonds. The degradation is slower if bulky substituents hinder the access of the medium to the cleavable bonds and in this way the hydrolysis. The diffusion rate of water and water-soluble degradation products within the material depends on hydrophilicity and morphology of the polymer. When the hydrophilicity is comparable, the hydrolyzation of amorphous polymers is favored compared to semicrystalline polymers. Unlike semicrystalline polymers, they show a more homogeneous degradation which is advantageous for application in implants as the diffusion processes are significantly reduced in crystalline domains resulting in slow surface erosion on the microscopic level. Furthermore, the macroscopic shape of a material needs to be considered. Porous materials degrade faster than solid materials because of the higher surface/volume ratio as well as the shorter distances for diffusion within the polymer matrix.

The most widely applied class of biodegradable SMP is the class of aliphatic (co)polyesters. The ester bond is a suitable target for hydrolytic cleavage. In general, the more an ester bond is activated by electron-accepting substituents, the faster it is hydrolyzed. In polyesters from monomers with long aliphatic hydrocarbon chains, the ester bond is not activated. Therefore, hydrolyzation of these polymers is slower than of that of polyesters based on hydrophilic monomers with short hydrocarbon chains and acceptor substituents (**Figure 8**).

In aliphatic (co)polyesters from lactone monomers such as the cyclic diesters diglycolide and dilactide resulting in poly(α-hydroxy acids), bulk degradation could be observed. Polyglycolide (PGA), polylactide (PLA), and copolymers are established biomaterials in clinical application. But hydrophilic (co)polyesters incorporating poly(ethylene oxide) (PEO) or PPDO also showed bulk degradation.[81] Here, ether bonds enhanced the hydrophilicity and could activate adjacent ester bonds for hydrolyzation. A frequently applied method to increase the rate of degradation of polyesters exhibiting a slow degradability was the introduction of easily hydrolyzable ester bonds by copolymerization. Here, the incorporation of glycolide units, especially glycolide–glycolide diads, leads to copolymers with enhanced degradability, whereas the rate of the hydrolytic degradation could be controlled by the glycolide content and distribution in the polymer chain.[82–86]

Hydrolyzable polymer chain segments retained their biodegradability when they were incorporated into multiblock copolymers or copolymer networks by coupling thermally with short linkers or photochemically with unsaturated end groups. In polymer networks, the degradation properties could be

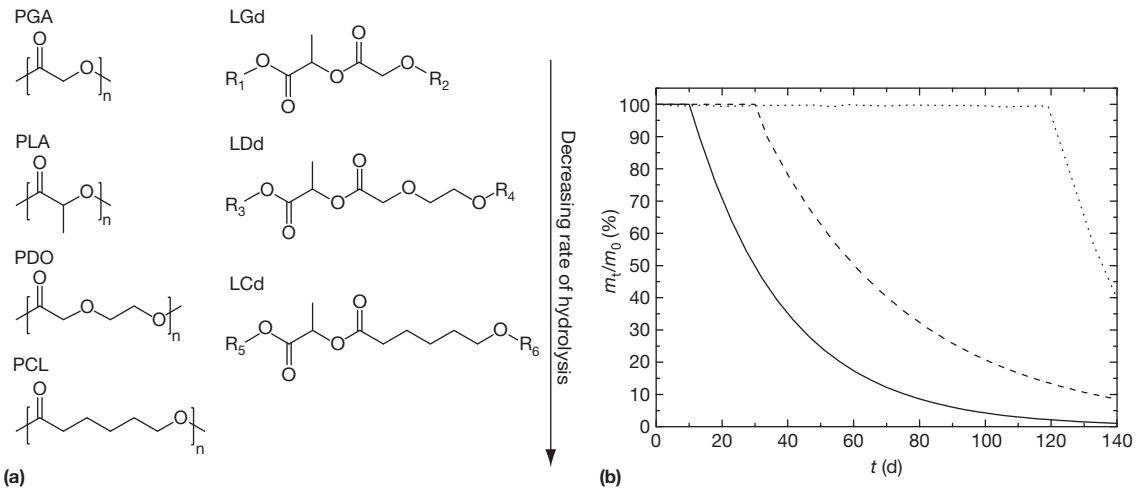

Figure 8 Comparison of the rate of hydrolysis of polyesters applied in SMP. influenced by the crosslink density. Most SMPs were phase-segregated block copolymers or copolymer networks being composed of two or more different polymer segments. These segments differed substantially in their rate of hydrolysis leading to a faster degrading part and a residual part, which remained in the body until fully degraded (enzymatically or by slow hydrolysis) or eliminated by other physiological mechanisms.

In the following, specific approaches will be discussed, which led to hydrolyzable SMPs. Hydrolyzability was realized, for example, in thermoplastic SMPs, which have been obtained as linear multiblock copolymers with PCL blocks, PPDO blocks, and diisocyanate as junction unit.[81,87] The M_n of the switching segment as well as the composition of the SMP have an influence on T_m of the switching domains and consequently on T_{sw}.[88,91] These multiblock copolymers named PDC displayed a linear mass loss *in vitro*, resulting in continuous release of degradation products. In contrast to the hydrophilic PPDO, the PCL exhibited a very slow degradation rate. In *in vivo* and *in vitro* experiments, the degradation behavior of biodegradable multiblock copolymer SMPs, PDC containing PPDO hard segments, and crystallizable PCL switching segments, which were synthesized via cocondensation of two oligomeric macrodiols with an aliphatic diisocyanate as junction unit,[89,90] was tested.[81,91] The study showed that the *in vivo* degradation process of PDC is characterized by a release of microparticles, which were supposed to primarily consist of PPDO, and which did not negatively affect a strong integration of the SMP in the subcutis of rats[89] and mice.[92] This might be explained by the angiogenic effect of the PDC, which was shown in the hen's egg chorioallantoic membrane test (HET-CAM test)[93] and also after subcutaneous implantation in rats[89] (**Figure 9**) and mice.[92]

In multiblock copolymers having a PCL switching segment and a polyurethane hard segment, an increased elasticity above T_{trans} could be achieved by incorporating polyhedral oligosilsesquioxane (POSS) sequences.[94]

Another example of biodegradable SMP is multiblock copolymers containing poly(L-lactide) (PLLA) and poly(glycolide-*co*-(ε-caprolactone)) (PGCL).[95] The degradability of the PGCL segment was improved by incorporation of easily hydrolyzable glycolic acid ester bonds. The change of shape-memory properties during hydrolytical degradation was investigated in a biodegradable shape-memory polyesterurethane from poly (adipate)diol. The poly(adipate)diol provided the segments forming the domains acting as switching domains while hard domains were built by the reaction between MDI and BD using the applied prepolymer method.[96] The degradation process could be divided into three phases: an induction phase, a phase of continuous degradation, and a phase of accelerated degradation. R_r remained fairly constant during phase one and decreased slowly during phase two. The increase in crystallinity in phase two was accompanied by an increase in R_f.

In addition to the polyesters, other classes of hydrolyzable polymers were used to combine shape-memory capability with biodegradability, including polydepsipeptides which are alternating copolymers of α-amino acids and α-hydroxy acids and are known to be nontoxic and degradable. Biodegradable SMPs were obtained as thermoplastic multiblock copolymers by coupling of oligodepsipeptide diols and PCL diols using TMDI.[97,98] The PCL domains had the function of the switching domains, while the polydepsipeptide segments provided the hard domains.

Glassy switching domains based on a copolymer segment are frequently utilized for the adjustment of T_{sw} to a specific temperature as it is necessary for SMPs in medical applications. Depending on the ratio of the comonomers during polymerization of the copolymer block, the T_g can be altered within the temperature range defined by the T_gs of the two related homopolymers. An example is a polyesterurethane having switching domains based on copolymers from L-lactide and ε-caprolactone, and polyurethane hard domains from BD and TDI.[99] In this thermoplastic SMP, T_{sw} could be adjusted between 28 and 53 °C. It was shown that the degradation rate of the copoly(ether)esterurethanes depended not only on the hydrolysis rate of their ester bonds, but also on the materials' hydrophilicity and on the molecular mobility, which was significantly different at temperatures above or below T_g.

SMP networks with a certain degradability having $T_{trans} = T_m$ could be obtained by initiator-free photopolymerization of PCL-based macrodimethacrylates, which were created by an esterification reaction of PCL macrodiols with methacryloyl chloride. The shape-memory properties of the polymer networks, named N-PCLDMA, were excellent, with R_r between 92 and 97% and R_f between 86 and 97% after five cycles. Recently, the *in vitro* degradation of SMP network nanocomposites consisting of crosslinked PCL and Fe_3O_4 nanoparticles had been investigated.[100]

AB polymer networks with $T_{trans} = T_m$ were prepared from linear PCL or PGCL which were functionalized with methacrylate end groups and were copolymerized with *n*-butyl acrylate (BA), yielding the polymer networks N-PCLDMA-BA or N-PCGDMA-BA. The networks with BA as comonomer contain an amorphous poly(*n*-butyl acrylate) phase exhibiting a very low glass transition temperature ($T_g = -55$ °C) and provide additional elasticity to the polymer network.[101] Molecular parameter for controlling T_{sw} was the molecular weight of the used macrodimethacrylate crosslinker while the mechanical properties were a function of the BA comonomer content. With increasing BA content, the values of the elastic modulus, the tensile strength ε_m, and the tensile stress at break σ_R decrease by approximately an order of magnitude. In biocompatibility tests, the SMP N-PCLDMA-BA, which was made sterile using ethylene oxide,[102] was able to induce angiogenesis and strong tissue integration in male Naval Medical Research

Institute (NMRI) mice already one week after subcutaneous implantation.[92] The same SMP also proved its capability for auto-induced regeneration of a radical stomach wall defect in rats.[103,104] No gas leakage after gas insufflation could be detected and fast and unfavorable degradation of the polymer did not occur. A tight connection between the polymer and the adjacent stomach was found, resulting in adequate mechanical stability under the extreme pathophysical conditions of the stomach milieu (**Figure 10**).

Incorporation of additional easily cleavable ester bonds increases hydrolytic degradability of polyester-based SMP networks substantially.[105] By UV-curing of poly((ε-caprolactone)-*co*-glycolide)-dimethacrylates (PCGDMA), crystalline, hydrolytically degradable, covalently crosslinked SMP networks (N-PCGDMA) with an increased hydrolytical degradation were obtained. The precursors had a glycolide content of 14 mol% and M_n of 4900 or 12 800 g mol^{-1}. While T_{sw} of N-PCGDMA using PCGDMA of 4900 g mol^{-1} was at 30 °C, N-PCGDMA built from PCGDMA of 12 800 g mol^{-1} had a T_{sw} at 38 °C. N-PCGDMA using PCGDMA of 4900 g mol^{-1} displayed R_r of 86% and $R_f > 96\%$ after five cycles with $\varepsilon_m = 150\%$. With increasing molecular weight of the precursors, R_r and R_f increased, so that R_f of >97% and R_r of >99% were obtained.

ABA triblock polymers with hydrolytically degradable switching segments and with $T_{trans} = T_g$ were prepared by a ROP of *rac*-dilactide with poly(propylene oxide) (PPO)-diol as macroinitiator in the presence of dibutyltin oxide (DBTO) as catalyst. Here, the poly(*rac*-lactide) (PLA) block represents the switching segment in the polymer network. The PPO B-blocks exhibit a T_g well below ambient temperature, which cannot be used as T_{trans} but provided additional elasticity to the SMP networks. The ABA triblock copolymer diols with a middle block of PPO were end-group functionalized with methacrylate groups and photochemically crosslinked using UV light to obtain polymer networks.[101]

However, methacrylate networks were relatively brittle and therefore difficult to handle. Copolyesterurethane networks prepared from star-shaped macrotriols or macrotetrols and a diisocyanate as a junction unit resulted in well-defined SMP networks. These precursors were synthesized by ROP utilizing initiators having more than two initiating reactive groups. ROP of *rac*-dilactide and diglycolide with a hydroxytelechelic three-armed PPO macroinitiator led to diblock star-shaped precursors, which were crosslinked in a second step with TMDI. The tailored crosslink density led to amorphous polymer networks containing poly((*rac*-lactide)-*co*-glycolide) (PLG) switching segments with more favorable elastic properties.[106] The elastic properties in such PLG-derived polymer networks could be further improved by the incorporation of a PPO segment contributing to the elasticity.[107] However, these PLG-derived polymer networks with a glycolide content between 15 and 18 wt% are limited in their applicability because of their relatively high T_{sw} between 48 and 66 °C. The synthesis of star-shaped macrotetrols by copolymerization of *rac*-lactide with *p*-dioxanone (PLD), or ε-caprolactone (PLC), or glycolide (PLG) yielded SMP networks, in which T_{sw} could be varied between 14 and 56 °C (**Figure 8**).[88]

Biodegradability involves hydrolytic degradability as well as enzymatically supported degradability. Enzymatic degradation becomes more important when slowly or nonhydrolyzable polymer segments are incorporated into biodegradable SMPs.[108] In contrast to water, the availability of specific enzymes can differ locally in the body and their diffusion capabilities are limited. However, in some cases the degradation of hydrolyzable bonds can be substantially accelerated by enzymes. Hydrolytic degradation of polymer monolayers by Langmuir—Blodgett techniques was shown to be a useful tool for the investigation of enzymatic degradation processes.[109] The enzymatic degradation of PCL and PCL-diol monolayers displayed degradation by random chain scission, which could be fitted by computer models.[110] In multiblock copolymers from PCL and PPDO, the enzymatic degradation rate decreased with increasing content of PPDO blocks, which was in contrast to hydrolytic degradation.[111] Furthermore, it was shown that the enzymes could penetrate into the PCL domains of thin films of this multiblock copolymer, whereby the penetration depth was a function of the PCL content resulting in a selective degradation of PCL blocks.[112]

Conclusively, a possible contribution to degradation by enzymatic processes is hardly predictable without *in vivo* tests and depends on several factors specific for the respective application. Biodegradability of SMP is mainly determined *in vitro* by exposure to aqueous buffer solutions under physiological conditions. The time dependence and extent of deterioration of the characteristic properties can be determined as well as the identity and quantity of degradation products. Within the SMP class of polyesters, degradation products are mainly the hydroxycarboxylic acids or oligomers thereof, which are expected to have no physiologically harmful influence, as long as their concentration is low enough to avoid a significant decrease in pH.

In multifunctional SMPs that involve controlled drug release, specific processes in synthesis, processing, and programming have to be applied to enable each of the functionalities. Key for a release of bioactive molecules is their incorporation into the polymer matrix. Drug incorporation into the matrix can principally be achieved by soaking of the synthesized matrix in a drug solution and a subsequent drying step, or alternatively by mixing of defined amounts of drug with polymer network precursors and subsequent crosslinking. The latter method often allows higher drug loading but is limited by the chemical stability of the drug under

the crosslinking conditions.[113,114] Drug release from polymer matrices is most often ruled either by diffusion or by degradation of the matrix. Although these mechanisms can occur at the same time, it is advisable to design the polymer matrix in a way that one mechanism predominates in order to better control the release pattern. Diffusion-controlled release from a degradable matrix can, for example, be achieved for small water-soluble molecules from bulk-degrading materials (such as polyesters, e.g., PLG),[115–117] in which monomer composition and polymer architecture can be used to prolong the induction time for degradation of the matrix till the time point when basically all of the drug has been released.[118] Alternatively, the use of surface-eroding materials such as polyanhydrides[119] or poly (orthoesters)[120] allows an erosion-controlled drug release.

Figure 11 depicts three functions of a multifunctional implant, that is, the SME, drug release by diffusion, and degradation of the polymer matrix. In the given example, these three independent functionalities are given in the consecutive order which is likely to be important for applications. After implantation of a medical device, the SME can allow a fixation of the device at the site of implantation. Subsequently, a diffusion-controlled drug release for treating infections, reducing inflammatory responses, or, potentially, supporting regeneration processes, takes place. Finally, the degradation of the matrix after completed drug release can avoid a second surgery for removal of the implant.

One of the biggest challenges in the design and formation of a multifunctional polymer is to ensure that the different steps in the formation or recall of the functionality do not erase one of the other functions. For the drug releasing, degradable SMPs, it is important that (i) the incorporation of hydrophilic or hydrophobic drugs does not influence the shape-memory functionality, (ii) an either diffusion- or degradation-controlled release is enabled, and (iii) the programming process and shape recovery, which a device experiences during implantation, do not change the drug release kinetics. Therefore, an evaluation strategy for drug releasing, biodegradable SMPs was introduced.[113,121] Four steps were identified, which need to be analyzed for usage of drug-loaded SMPs in a physiological environment, which include traditional assessments of drug release matrices such as the determination of the drug loading and release profile as well as the interdependence of matrix functionalities. Drug-loaded implants for long-term treatments contain a large amount of drug compared to the daily dose. Therefore, it is an important safety aspect to ensure that no dose dumping, that is, an uncontrolled fast release of possibly toxic drug levels occurs.

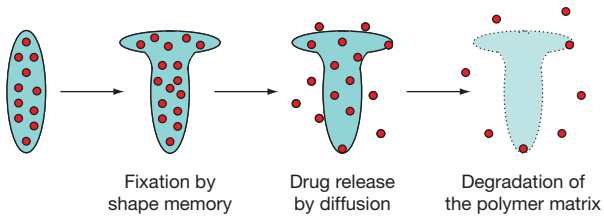

Figure 11 Consecutively initiated functionalities of a multifunctional material: SME for fixation of the device, diffusion-controlled drug release, and degradation of the matrix.

So far, only a few systems representative for triple functional materials combining biodegradability, SME, and controlled drug release have been published. All of them belong to the bulk-degrading polyesters with a diffusion-controlled release. However, monomer type and ratio as well as network architectures resulted in quite different capabilities of the networks which will be discussed in more detail to highlight common characteristics and individual advantages and shortcomings. In the following, several semicrystalline matrices and an amorphous matrix will be compared regarding drug loading, thermomechanical and shape-memory properties, and release profiles.

The first example for triple functional SMPs was N-PCGDMA polymer networks. In these semicrystalline networks, hydrophobic and hydrophilic drugs could be incorporated either by swelling (up to 0.72 wt%) of the final networks in an organic solvent saturated with the respective drug, or by mixing defined amounts of the drug (in this case, 0.2–5.7 wt%) with the network precursors followed by irradiation (*in situ* incorporation).[114,122] A semicrystalline polymer network was chosen so that the crystalline phases of the networks were used for fixation of the temporary shape, while drug molecules should predominantly be incorporated in the amorphous phases without having a too strong influence on the melting point of the polymer crystallites or the shape fixation and recovery.[113] Drug incorporation did have some influence on crystallite formation and, therefore, on T_m and T_{sw}. However, this was only the case in networks with a high glycolide content (>14 mol%) or small precursor M_n (<6900 g mol^{-1}), as these networks only form crystallites to a small extent even in the drug-free state. The same was observed when large amounts of drug were incorporated by *in situ* loading (>4.8 wt%). In these cases, the formation of crystallites was inhibited leading to a decrease of T_{sw} and/or low shape fixity. Large amounts of drug furthermore decreased the elongation at break of the networks, which reduced their programmability. In materials with high crystallinity, in the drug-free state (i.e., glycolide contents ≤14 mol% and precursor $M_n \geq 6900$ g mol^{-1}), no effect of drug loading on the thermomechanical properties and shape-memory functionality was observed.

Drugs loaded by swelling were released from the selected materials in three phases, that is, an initial burst release (34–39 wt%), a diffusion-controlled subsequent release (cumulative release >80 wt%, over 120–140 days) that linearly correlated with the square root of time,[123] and a final nonlinear phase. Drug-loaded networks which were shown to have high shape fixity and shape recovery were subjected to hydrolytic degradation and compared with drug-free samples. The induction time for erosion as observed by the onset of mass loss of the matrix was about 120 days. This illustrates that a diffusion-controlled release was realized before erosion of the matrix would have led to changes in drug release. Furthermore, independence of polymer functionalities could be demonstrated. However, alterations in polymer network composition are typically limited for semicrystalline SMPs by the need to form crystallites for shape fixation. In addition, only limited amounts of drug could be incorporated by swelling (<1 wt%), which was theoretically high enough to ensure pharmacological efficiency of the model drugs, but might be necessary to be increased for other drugs.

By introducing an additional amorphous phase by incorporation of 60 wt% *n*-butyl acrylate, AB polymer networks were obtained in which the PCGDMA copolyester chains served as degradable crosslinkers.[101] With increasing glycolide molar content χ_G, that is, increasing hydrophilicity of the material, more of a hydrophilic model drug could be incorporated by the swelling technique. At the same time, larger hydrophilicity of the polymer networks also favors water uptake and rapid initial drug release. Therefore, tailoring the material's hydrophilicity by adjusting χ_G is suitable to control the drug release rates from the AB networks.[124]

Oligo(ε-caprolactone)octols crosslinked by low-molecular-weight aliphatic diisocyanates also form degradable semicrystalline SMPs.[125] Defined amounts (10 and 20 wt%) of theophylline as model drug were mixed with the oligomers followed by crosslinking, a methodology which potentially could result in drug modification. Drug incorporation increased T_m and ΔH_m, which indicated improved crystallization of ε-caprolactone segments. Drug loading did not affect shape fixity. Remarkably, the temperature interval for shape recovery was very small for this network, in both the drug-free and drug-loaded materials. No major burst release was found in this system, and a complete linear release was achieved within 35 days.

It was assumed that a higher drug loading by swelling can be achieved in fully amorphous SMPs such as the star-shaped PLG networks described above. In contrast to semicrystalline materials, the entire matrix is amorphous and therefore accessible to drug.[121] Furthermore, crystallization is not required for shape fixation thus allowing a wider variability for network composition (monomer type and ratio) and network architecture.[113] Also, loading may not impact shape fixation. However, drug molecules may act as softeners and reduce the T_g of amorphous SMPs which could result in an unwanted shift in T_{sw}.

The star-shaped PLG networks loaded by swelling showed loading levels up to 2.6 wt%. Drug loading did not impede the thermomechanical properties or the shape-memory functionality after synthesis. Interestingly, it could be demonstrated that the uptake of water as a softener reduced the T_g from 54 to 36 °C, that is, into a physiologically relevant temperature range. Depending on the type of drug, different phases of drug release were observed to be present at different levels, that is, a burst release of up to 25 wt% of the drug, a linear diffusion-controlled release, and a final nonlinear release that timely overlaps with erosion. Drug release was completed after 4 months. During degradation, drug-loaded polymer networks exhibited lower Young's moduli than the drug-free network. However, the rate of degradation was not influenced by the incorporation of drugs.[121] On the basis of that, it may be expected that future work on drug-loaded SMPs will explore, for instance, in larger detail (i) alterations in the SMP structure to obtain higher drug loadings by swelling; (ii) the effect of the drug loading methodology on release, SME, and biodegradation; (iii) the extent of possible changes in covalent SMP network architecture to control release rates without impairing the SME; (iv) the types of drugs, which can be released from SMPs, and whether the programming technology for thermosensitive SMPs is compatible with thermal stability of therapeutic peptides and proteins; or (v) important issues of prototype development and translation into clinical use including aspects like sterilization, shelf-life, etc.[126]

1.126.4. Biomedical Applications of SMPs

The trend in the clinics toward MIS[127] will allow complicated treatment procedures with a strongly reduced risk of iatrogenic infections. This is because MIS in contrast to open surgery avoids major incisions in the body. Also, patients often recover faster from MIS interventions compared to open surgery and hospitalization costs may be significantly reduced. At the same time, MIS sets new requirements for materials to be used as matrix of medical devices, that is, the capability to be inserted through keyhole incisions and afterward gain full functionality. The advantages of SMPs as candidate matrices rely on two unique properties to fulfill these requirements, that is, their capability to undergo controlled, predefined changes in shape and to generate forces during shape recovery. Both are required to allow adoption of the functional implant shape in a tissue environment.

Depending on the respective application, implants should provide a supportive function and mechanical strength over a long period of time (e.g., stents[55,128]) while for other tasks mechanical forces may only be required initially for deploying the implant (e.g., neuronal electrodes[129]). Furthermore, there are suggested applications where mechanical forces are temporarily useful, but the material should then biodegrade and disappear from the site of application, for example, for self-tightening suture materials.[81] Such specific requirements can be fulfilled by selecting a material from the growing number of different SMP platforms (see **Section 1.126.3**). So far, the suggested SMP medical devices only base on thermosensitive SMPs. Besides triggering the shape recovery by direct exposure to heat (e.g., body temperature; flushing with warm water), indirect heating by light absorption of near infrared (NIR) dyes loaded into the material[31] is an intensively evaluated approach particularly for intravascular applications.

Grouping of medical devices from SMPs may be conducted based on the aspects of (i) the involved material (polymer macromolecular chemistry, degradable, nondegradable); (ii) the engineered implant shapes (e.g., threads for sutures, rods for fixation plugs, hollow fibers for stents, foams for aneurysm closure); or (iii) their indication. In order to illustrate the variety of targeted clinical applications, the latter approach was used in **Figure 12** for a graphical summary of the so far suggested SMP devices as recently discussed in more detail.[130]

According to the trend to MIS and the requirements for new materials, SMP devices for intravascular interventions represent the most intensively studied application. However, it should be noted that device failure in such indication can be of life-threatening consequences. In addition, the induction of shape recovery by local intravascular hyperthermia is a complex and challenging procedure. Therefore, a significant amount of research may still need to be conducted to further improve the set-ups and rule out safety concerns associated with SMP-based medical devices for intravascular applications. However, other applications, for example, as ureteral stents, suture material, or devices for soft tissue fixation to bones,

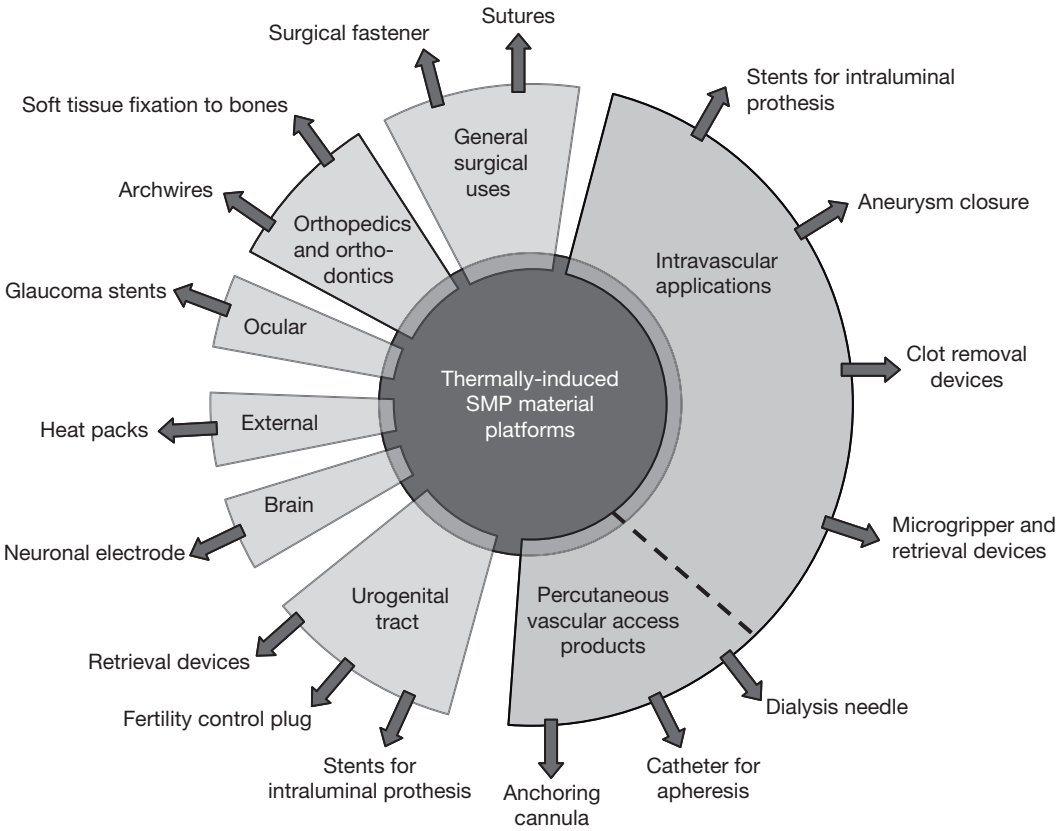

Figure 12 Summary of suggested clinical applications of SMP-based medical devices as published in the scientific and patent literature. A comprehensive list of references as well as a more detailed description of the involved principles can be found in. Lendlein *et al*.[130]

may not be associated with such risks and thus be accepted by clinicians for clinical evaluation. Therefore, such applications may possibly be the first fields of SMP usage in the clinics.

For optimal healing with minimal scar formation, wounds have to be closed by applying a defined pressure to the wound lips. This can be realized by shape recovery of SMPs whose thermomechanical properties have been tailored to the clinical need. Moreover, since biodegradability of sutures is generally well accepted by patients, efforts were made to design biodegradable SMPs. Such polymers have first been described by Lendlein *et al.* and were suggested as suture materials.[81] As illustrated in **Figure 13**, loops of suture threads first loosely connect the wound lips, which subsequently are closed upon heating to moderate temperature.

Stents are used to eventually keep open the internal lumen of flow pathways where local flow constrictions were removed by cardiovascular intervention. Stents have to be inserted in a shape with a small outer diameter, to subsequently expand and apply pressure against the surrounding tissue. In the United States, coronary stents cover about two-thirds of an expected revenue of $5 billion solely for stent devices in 2010, but peripheral applications including renal and biliary stents are also of high relevance.[127] Despite the clinical need and intensive usage, stent technology requires further improvement. This is clearly shown by common restenosis of bare-metal stents, and, in the case of drug eluting stents, by safety concerns due to, for example, late thrombosis with a mortality rate of up

Figure 13 Degradable SMP suture for wound closure that shrinks upon heating in order to bring together the edges of the wound with a defined pressure for optimal healing. Reproduced from Lendlein, A.; Langer, R. *Science* **2002**, *296*, 1673–1676, with permission from AAAS.

to 45% as recently summarized.[131] Therefore, fully degradable stents are believed to be the future in stent technology.[132] However, so far most studies on SMPs as stent matrices have been conducted with nondegradable SMPs. For example, often materials based on acrylate chemistry with polyethylene glycole dimethacrylate crosslinkers[55] or polyurethanes[33] were used. Only in some cases, partially degradable materials employing degradable polyester segments were evaluated.[25]

SMP matrices were shown to be feasible for the required expansion of polymeric stents in vessels and resistance against intravascular pressure.[133] It has been suggested that suitable expansion sizes can be achieved by unrolling and unfurling from a compact shape which can by administered by a 18 Fr. catheter (**Figure 14**).[55] Formerly suggested concepts that involve changes in implant length upon shape recovery have not been followed any further, possibly because of lower feasibility for intravascular placement.[128,134] As shape recovery of

the thermosensitive SMP matrix must be avoided before proper adjustment of the stent, the T_{sw} of the employed materials was typically up to 20 °C above body temperature. Local heating was achieved by loading the SMP with an NIR absorbing dye and heating by laser light with an optical fiber.[33] This technique is challenging at least at flow rates relevant for intravascular conditions because of cooling of the device down to body temperature by the blood stream.

As mentioned before, because of possible interoperative or postoperative risks from potential stent failure in cardiovascular applications, the field of renal or biliary stent applications might be easier to be entered by novel SMP devices. Recently, a demonstrator of a ureteral stent has been designed from a biodegradable material. As illustrated in a model set-up in Figure 15,[122] the device can be anchored at elevated temperatures, for example, as a result of flushing with warm water.

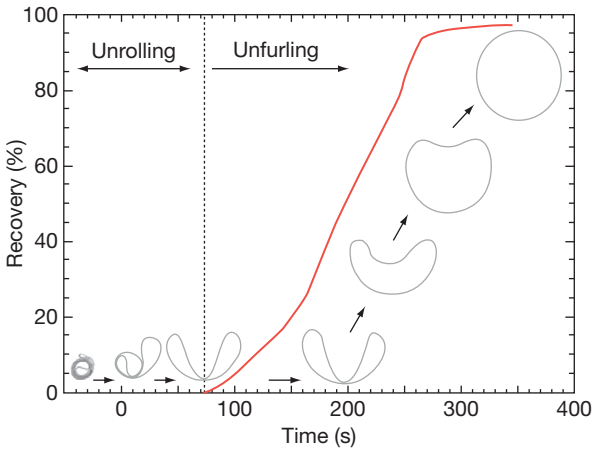

Figure 14 Example of a stent's shape recovery from a furled and rolled temporary shape. Reproduced from Yakacki, C. M.; Shandas, R.; Lanning, C.; Rech, B.; Eckstein, A.; Gall, K. *Biomaterials* **2007**, *28*, 2255–2263. Copyright 2007, with permission from Elsevier.

Moreover, as a controlled drug release could be established from the polymer matrix used in this study, and generally is advantageous for ureteral stents to avoid infections, this stent exemplarily illustrates the advantageous combination of three functionalities in one device – shape-memory, controlled drug release, and biodegradability.

Fixation of ruptured tendons or ligaments to bones is conventionally done with the help of metal screws that are drilled into the bone, possibly damaging the ligament or getting loose over time. On the contrary, cylindrical SMP plugs that are inserted into predrilled cavities together with the end of a ruptured ligament or ligament graft may transfer the mechanical load more homogeneously against the wall of the bone tunnel. The principle of such SMP plugs is shown in Figure 16.[56]

In the literature, a brief report can be found on a successful functional evaluation *in vivo* of an SMP plug in the reconstruction of knee ligaments (anterior cruciate ligament) in a sheep model.[135] Moreover, an FDA clearance was recently obtained for an SMP anchor with attached suture material for ligament fixation to the bone.[136] This strongly shows that the SMP technology is moving forward toward biomedical applications and that some products may be launched in the near future.

Overall, SMPs as a technology platform can be envisaged to have a high potential for transfer into biomedical applications requiring biodegradable, multifunctional materials because of the generality of the underlying fundamental principles of the SME and the synthetic preparation of SMP network architectures as polymer systems, in which functions and properties can be tuned in a wide range by only small variations of their chemical structure. While basic research in SMPs is progressing rapidly, broadening the application potential of the SMP platform besides biomedical applications, the polymer system approach enables existing SMPs to be tailored to the challenging demands of the medicinal sector. This included the investigation of suitable sterilization techniques as well as their interaction with the SMPs. In the last few years, these efforts have been crowned with success when first pilot trials toward a

future translation of the materials into clinical applications have been conducted. SMP devices that progressed farthest toward an FDA clearance are for nonintravascular use. Stent technology as one of the most intensively studied fields of SMP applications will certainly remain a major focus of research because of the enormous revenues in this medical field. Although several challenges of SMP stents for intravascular applications will still have to be addressed, biodegradability as one feature of stents from multifunctional SMPs might advantageously overcome clinical complications like late thrombosis. Furthermore, controlled drug release capability as another feature of multifunctional SMPs may open up new opportunities for SMP applications beyond the medical device act.

Glossary

Advection A mechanism of transport with the net flow of the fluid.
Constitutive equation An equation relating the stress accumulated in a material to the history of deformation that the material experiences.
Debye length The length scale over which mobile charge carriers screen out the effect of electric fields.
Elastic modulus The tendency of an object to deform elastically with applied force.
Electrohydrodynamics Study of the dynamics of electrically charged fluids.
Electrostatics A branch of science that deals with stationary or slow-moving charges.
Extensional viscosity The resistance provided by a fluid to extensional deformation (like stretching). Typically measured as a ratio of the stress to the strain rate experienced in extensional flow.
Inviscid Devoid of viscosity. Typically pertains to material with very low viscosity.
Metastability A system is considered metastable when it is susceptible to fall into a lower energy state by the slightest interaction, although it experiences a condition of equilibrium in its present state
Newtonian and non-Newtonian fluids A fluid is said to be Newtonian when the stress in the fluid scales linearly with the strain rate. The proportionality constant is called the viscosity of the fluid. Fluids that deviate from this simple relationship between stress and strain rate are called non-Newtonian fluids.
Phenomenological model A mathematical model that expresses the results of observed phenomena without detailing their fundamental significance
Rheology Study of deformation and flow of matter
Strain hardening A condition where the extensional viscosity of a fluid increases with increasing strain.
Viscoelasticity A phenomenon by which a material demonstrates both viscous and elastic characters when deformed.
Zero-shear-rate viscosity The constant viscosity of a fluid measured at vanishingly small shear rates.

Abbreviations

De Deborah number
Fr Froude number
Oh Ohnesorge number
Pe Electric Peclet number
TR Trouton ratio
We Weber number

Symbols

a	Tube diameter (m)
b	Kuhn step length (m)
b_{max}	Finite extensibility parameter in the FENE-P model
c	Concentration of polymer in solution ($kg\,m^{-3}$)
D	Radius of curvature of the jet (m)
D_c	Curvilinear diffusion coefficient ($m^2\,s^{-1}$)
d_g	Distance between the electrodes (m)
E	Local electric field ($V\,m^{-1}$)
E_∞	Applied electric field strength ($V\,m^{-1}$)
h	Instantaneous jet diameter (m)
h_0	Nozzle diameter (m)
h_t	Terminal diameter of the jet (m)
I	Current flowing through the jet ($C\,s^{-1}$)
I_0, I_1	Modified Bessel functions
K	Conductivity of the solution ($\mu S\,cm^{-1}$)
k_B	Boltzmann constant ($J\,K^{-1}\,mol^{-1}$)
L_c	Characteristic length scale of flow in the conical meniscus (m)
l_{cap}	Capillary length (m)
L_N	Characteristic length scale at which transition from charge conduction to charge advection occurs (m)
M_c	Critical molecular weight for entanglements ($g\,mol^{-1}$)
M_e	Molecular weight between entanglements ($g\,mol^{-1}$)
M_w	Molecular weight ($g\,mol^{-1}$)
N_e	Number of Kuhn monomers between entanglements
N_K	Number of Kuhn monomers per chain
Q	Flow rate ($m^3\,s^{-1}$)
s	Separation distance between fibers (m)
T	Absolute temperature (K)
t_e	Charge relaxation time (s)
t_f	Characteristic times of fluid flow (s)
u, v	Velocity ($m\,s^{-1}$)
V	Voltage (V)
z	Distance along the direction of propagation of the jet (m)
Z	Number of entanglements per chain
δ	Kronecker delta function
ε	Dielectric constant of the fluid
$\bar{\varepsilon}$	Dielectric permittivity of vacuum ($C^2\,N^{-1}\,m^{-2}$)
$\dot{\varepsilon}$	Strain rate (s^{-1})
γ	Surface tension coefficient ($N\,m^{-1}$)
$\dot{\gamma}$	Shear rate (s^{-1})
$[\eta]$	Intrinsic viscosity ($m^3\,kg^{-1}$)
η_0	Zero-shear-rate viscosity (Pa s)
η_E	Extensional viscosity (Pa s)
λ_{max}	Stretch ratio
η	Viscosity of a Newtonian fluid (Pa s)
ν	Solvent quality parameter
ρ	Density of the fluid ($kg\,m^{-3}$)
σ	Surface charge density ($C\,m^{-2}$)
ζ	Monomeric friction coefficient
Σ	Volumetric charge density (Cm^{-3})
τ	Relaxation time of polymeric fluid (s)
τ_d	Reptation time (s)
τ_e	Entanglement relaxation time (s)
τ_p	Polymeric stress (Pa)
τ_R	Rouse relaxation time (s)
χ	Aspect ratio
ω_{max}	Growth rate of the fastest-growing mode of the surface-tension-driven Rayleigh instability (s^{-1})

1.127.1. Introduction

The electrospinning process has been extensively used in recent times for producing very fine fibers from a wide variety of materials, easily and inexpensively. The fibers that are produced through electrospinning span almost 4 orders of magnitude in their diameters, ranging from tens of micrometers down to only a few nanometers, and are essentially unlimited in length. Thus, the process has generated much interest among scientists and engineers. Electrospun fibers are finding widespread application in the emerging areas of nanotechnology.[1–3] The technique also holds much promise in enriching biomedical research and industry through contributions to biomaterials,[4,5] drug encapsulation and delivery,[6–8] tissue engineering,[9–13] etc. Thus, there is much to be gained by understanding the underlying physical principles that allow control of various aspects of the process by which such novel materials can be fabricated. Uncovering the physics that govern electrospinning is a formidable task, however. The technique presents a rich variety of challenges that arise from the interactions among a large number of physical processes acting in tandem. However, concerted effort on the part of the scientific community has succeeded in generating robust understanding of some critical aspects of the process. Our aim here is to outline these so that engineers and scientists can find some assistance in designing electrospinning processes. In this chapter, we start by discussing the electrospinning process in general and also discuss the problems associated with scaling up the process. A discussion on the electrostatic, hydrodynamical, and rheological aspects associated with electrospinning is provided next. In this part we also provide an overview of the leaky dielectric model that is used to describe the electrical properties of the fluids used in electrospinning. Furthermore, we summarize major concepts associated with the mechanics in various regions of the electrospinning jet and review the physics that eventually lead to the formation of fibers. Thereafter, we consider the morphologies of the fibers formed in electrospinning and also review some properties of the electrospun fabrics, especially those associated with porosity, which is of particular relevance in the consideration of many biomaterials. The scope of the chapter restricts our discussion to major concepts and results only. Readers are, nevertheless, encouraged to consult the many references that are listed for further information on the details of the subjects of their interest.

1.127.2. Process Description

A schematic of the electrospinning process is shown in Figure 1. In the laboratory, typically a small amount of fluid is extruded out of a capillary using a syringe pump and is subjected to a high potential difference with respect to a grounded counter electrode. As a result of electrification, charge accumulates on the surface of the fluid, subsequent repulsion among the charges leads to the destabilization of the meniscus, and a jet ensues. The electrified jet accelerates downfield, usually more or less in a straight line at first, but eventually this steady jet becomes unstable with respect to transverse bending perturbations, and takes on a whipping-like motion. The instability is hence called the 'whipping instability.' It is believed that the whipping instability imposes the final drawdown usually responsible for the formation of the very small diameter fibers in electrospinning. The fluids used in electrospinning typically contain a volatile solvent that evaporates as the jet propagates downstream, leading to the formation of solid fibers that are eventually deposited on the counter electrode in the form of a nonwoven mat. The morphologies of the fibers formed in electrospinning vary, depending on the processing conditions and fluid properties. The most common occurrences are those of homogeneous uniform fibers and morphologies that resemble beads on strings. However, other morphologies, such as flat ribbons,[14] fibers with wrinkled surfaces,[15,16] porous fibers, etc., have also been reported. Some examples of these structures are shown in Figure 1.

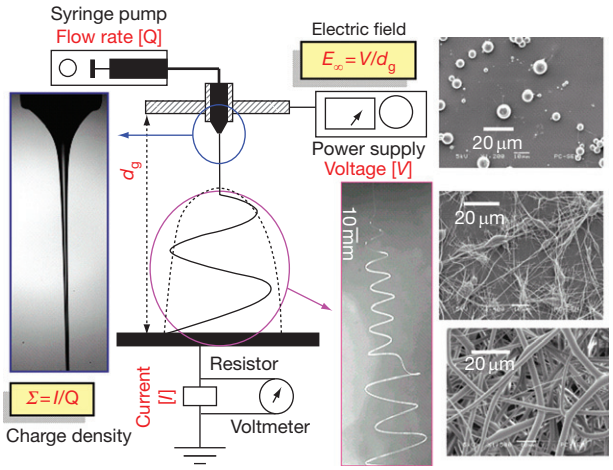

Figure 1 Schematic diagram of electrospinning showing details of the jetting processes, the whipping instability, as well as the fiber morphologies that can be obtained. The flow rate (Q), the voltage (V) and the distance between the electrodes (d_g) are set, and the current (I) flowing through the jet is measured. The electric field strength is calculated as $E_\infty = V/d_g$. The quantity $\Sigma = (I/Q)$ is the volumetric charge density. The photograph on the left hand side shows the straight section of the steady jet immediately after it ejects from the conical meniscus. The photograph on the right shows the whipping instability, where the centerline of the jet bends at a characteristic wavelength. These photographs were obtained using a digital SLR camera (Nikon D60) and by backlighting the jet. The micrographs on the extreme right show products that can be obtained by electrospinning the same polymer (a polyurethane) at different concentrations. As the concentration is increased, the product changes from drops to beads-on-string morphologies and finally to homogeneous fibers (top to bottom).

The controlling variables in electrospinning are the infusion rate Q, the applied accelerating voltage V, and the distance between the electrodes d_g. Also important are the properties of the fluid, most notably the electrical conductivity (K), dielectric constant (ε), surface tension (γ), and the viscoelastic properties (e.g., viscosity η and relaxation time τ, or storage modulus G' and loss modulus G''). Each of these quantities has to be adjusted, either individually or in tandem, to obtain desirable results. The electrospinning process constitutes an electrical circuit, and the current flowing though this 'circuit' is significantly influenced by the control parameters, the flow rate for instance. This makes electrospinning a challenging problem to analyze. The extent of the challenge can be appreciated by studying Figure 2, which shows the different ways in which the fiber size can be manipulated empirically in electrospinning.

Electrospinning, however, is simple to set up. Therefore, a variety of configurations have been reported. These can be broadly categorized into two groups: (a) those using a spinneret (capillary tubes/nozzles/emitters) and (b) those that use 'nozzleless' configurations, based mainly on the electrification of free surfaces of fluids. In most laboratory experiments, however, a configuration using a single needle is used for simplicity, and the apparatus resembles the one shown in Figure 1, sometimes referred to as a 'parallel-plate' configuration. More commonly, the plate on the high voltage electrode is discarded, in what is then referred to as a 'point-plate' configuration. Gravitational forces are relatively weak compared to the electrical ones, so different orientations of the nozzle and collectors (vertical, horizontal, and at a specific angle) have also been reported, with similar results. Variations in nozzle design, for example, nozzles having a coaxial structure for fabricating compound core–shell electrospun fibers[18,19] or nozzles that allow fluids to flow side by side during electrospinning,[20] have also been incorporated within the process. Even scanning probe tips have been used to serve as emitters of jets in electrospinning.[21] An early example of a nozzleless configuration is that reported by Yarin and Zussman.[22]

The practicality of scale-up for industrial production is a persistent concern in electrospinning, because the production rate of fibers from a single spinneret is often very low, and the smallest fibers are frequently obtained using the lowest flow rates. To increase production rate, multiple emitters/nozzles have been introduced in electrospinning.[23] The latter arrangements not only increase the overall production rate significantly, but also allow the production of multicomponent mats of fibers. However, the arrangement of nozzles is complicated by the electrostatic interactions between neighboring charged jets. Scale-up has also been achieved using the free surface configuration.[22] One advantage of using this configuration is that the difficulties associated with pumping of viscous fluids can be mitigated. Furthermore, maintenance aspects associated with large-scale production involving multiple jets are simplified. Figure 3(a) shows a photograph of an arrangement that uses a rotating cylinder or mandrel as the source of the electrospinning jets. In Figure 3(b), the rotating cylinder is replaced by a pair of wheels with wires strung

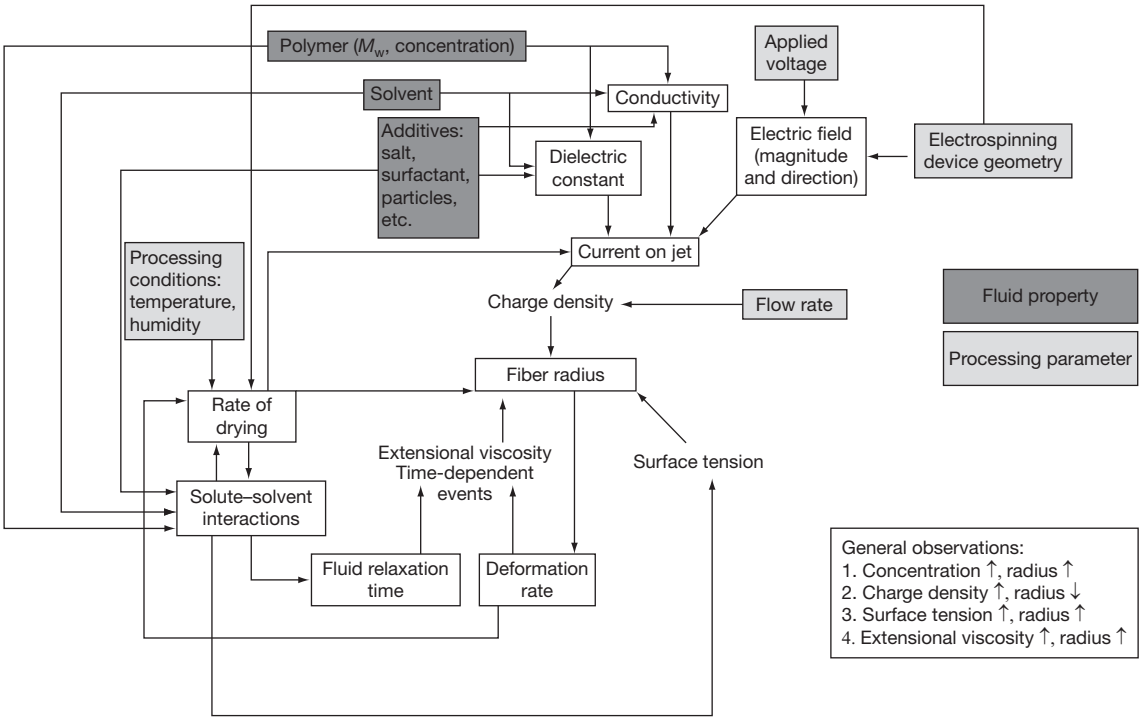

Figure 2 Flow diagram demonstrating the manner in which the properties of the fluid and process variables affect the diameter of the fibers obtained from electrospinning. Diagram from Yu and Rutledge.[17]

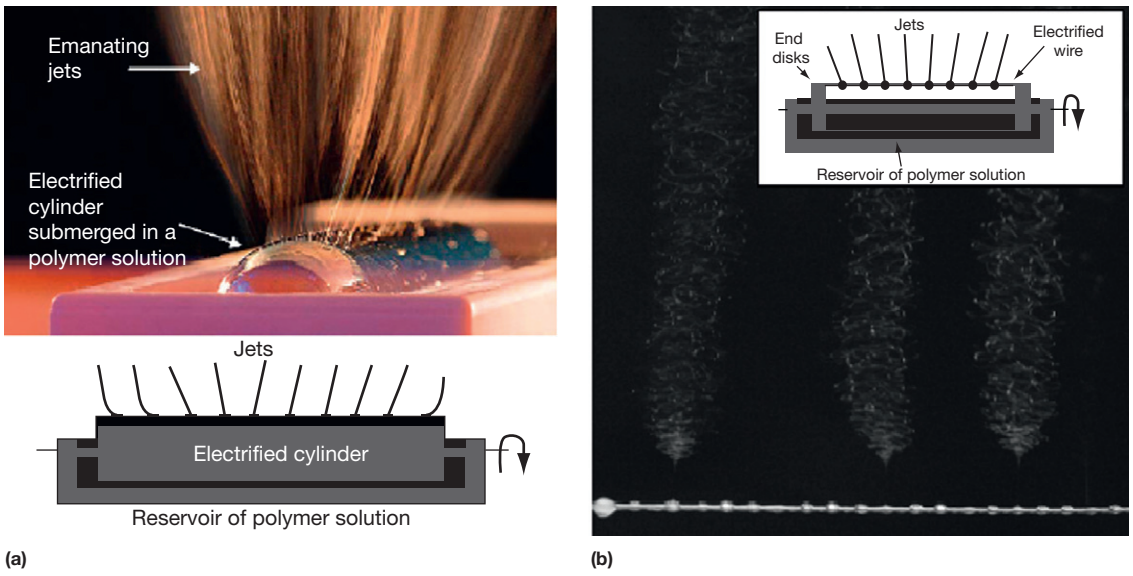

Figure 3 Examples of nozzle-free configurations used in electrospinning. (a) Jets arising from an electrified cylinder immersed in a polymer solution. Image courtesy Elmarco Company, Liberec, Czech Republic. A schematic is shown in the bottom panel. (b) Multiple jets arising from liquid drops on an electrified wire as shown in the schematic diagram in the inset. The wire periodically dips into a polymer solution, which then breaks up into droplets that serve as sites for the eventual jetting process. Image courtesy of Dr. R. M. Hill, Institute for Soldier Nanotechnologies, MIT Cambridge, USA.

between them; in this case, the jets arise from droplets on the electrified metallic wire, which form as the wire dips into and rises out of a solution bath. Both arrangements shown in Figure 3(a) and 3(b) allow for reasonably easy scale-up, with the additional advantage that the spacing among the jets is chosen naturally rather than imposed, as in the case of arrangements using multiple nozzles. The electrical interactions between jets results in repulsion among the jets and affects the deposition density of the fibers on the substrate.[24] On the other hand, with the rotating cylinder source the jets

are no longer truly continuous, resulting in fibers of finite (albeit quite long) length. Nonetheless, these arrangements demonstrate the ease with which electrospinning can be set up to generate nanofibers. Some of these configurations now serve as the basis for commercial electrospinning equipment designed for manufacture of nanofibers. However, control of the process is commensurately challenging. In the following sections, we discuss some aspects of the process that are fairly well studied and understood.

1.127.3. Mechanics: Electrostatics and Hydrodynamics

1.127.3.1. The Leaky Dielectric Model

Two advantages of electrospinning are that it is very easy to implement, and a wide variety of materials can be processed through the technique. Since electrospinning is predominantly an electrically driven process, it is important to consider the electrical characteristics of the fluids used. The dynamics of the fluids under the influence of an external electric field are generally discussed in the framework of the leaky dielectric model, which was first proposed by Melcher and Taylor.[25] A leaky dielectric differs from a perfect conductor or a dielectric material in that free charges accumulate on the surface of the material in the presence of an external electric field and modify the local field. Under these conditions, two components of the electrical field develop, one tangential to the interface and another normal to it. The presence of a tangential component on the surface prevents the interface from being in an equilibrium condition and provokes it to deform. In contrast, the electrical stress in perfect dielectrics and conductors is always perpendicular to the interface. Electromechanical coupling occurs at the fluid-fluid interface alone; forces resulting from charges in the bulk are negligibly small. As the fluid accelerates, the tangential component of the electrical stress is largely balanced by the viscous, or viscoelastic, response of the fluid. Thus, both the constitutive behavior and the electrical properties of the fluid determine the condition of the process. It is common practice in electrospinning to include ionic salts that increase the conductivity of the fluid or surfactants that decrease its intrinsic surface tension. However, it is important to bear in mind that if the changes in conductivity resulting from these additions are large enough to alter the behavior of the fluid from that of a leaky dielectric to that resembling a conductor, then the tangential component of the electrical stress that accelerates the fluid is likely to diminish and the flow process be stopped. In this limit the electrical stress will be balanced by the alteration of the shape of the interface and surface tension only. These aspects are discussed in detail in a separate review.[26]

Electrohydrodynamic processes, including electrospinning, are often discussed in the 'quasi-electrostatic' limit, in which the charge distribution on the surface is unaffected by translocation or alteration of the shape of the interface. For a fluid of large enough electrical conductivity there is a layer of charge carriers on the surface, of thickness on the order of the Debye length, that is in a perfect equilibrium state. This charge layer is described by the well-known Poisson–Boltzman equation. When the liquid moves, it disturbs the equilibrium charge distribution on the surface as some of the charges are swept away by flow. However, the surface layer is maintained if the charges are replenished faster than the rate at which they are removed. The 'quasi-electrostatic' condition is valid in this limit. It is realized when $t_f \gg t_e$, where t_f and t_e are the characteristic times of fluid flow and charge relaxation, respectively. The latter is given by $t_e = \varepsilon\bar{\varepsilon}/4\pi K$, where ε is the dielectric constant of the fluid, $\bar{\varepsilon}$ is the dielectric permittivity of vacuum, and K is the conductivity of the solution. In general, the choice of t_f depends on the process of interest. For momentum transfer to a viscous fluid, for instance, the hydrodynamic time $t_f = (\rho h_0^2/\eta)$ can be considered. For polymeric fluids the viscoelastic relaxation time might be more relevant. It has been observed for fluids where these time constants become comparable that the jetting process becomes unstable and chaotic. However, for cases where $t_f \gg t_e$, stable flow conditions are obtained.[27]

1.127.3.2. Governing Equations and Major Results

The equations that describe the dynamics in electrospinning constitute, at a minimum, those describing the conservation of mass, momentum and charge, and the electric field equation. Additionally a constitutive equation for the fluid behavior is also required. Assuming the simplest Newtonian fluid properties, the governing equations take the following form:

$$h^2 v = 1 \quad [1]$$

$$Eh^2 + Pehv\sigma = 1 \quad [2]$$

$$vv' = \frac{1}{Fr} + \frac{3}{Re}\frac{1}{h^2}\left(\eta h^2 v'\right)' + \frac{1}{We}\frac{h'}{h^2} + \Omega\left(\sigma\sigma' + \beta EE' + \frac{2E\sigma}{h}\right) \quad [3]$$

$$E = E_\infty - \ln\chi\left[(\sigma h)' - \frac{\beta}{2}\left(Eh^2\right)''\right] \quad [4]$$

The above equations were invoked originally in Hohman *et al.*[28] within the Slender Thinning Jet approximation and describe the steady-state conditions of the jet. These were subsequently put in the nondimensional form shown above by Feng.[29] Similar derivations are also available in other reports.[30] In the above equation, the primed quantities signify spatial derivatives. The variables v, h, σ, and E signify the velocity, the radius of the jet, the surface charge density, and the local electric field, respectively. The variable $E_\infty = V/d_g$, where V is the imposed driving potential, and d_g is the distance between the electrodes. Nondimensionalization is carried out based on characteristic values at the nozzle: the radius of the nozzle, h_0, for length, $v_0 = Q/\pi h_0^2$ for velocity, $E_0 = I/\pi h_0^2 K$ for electric field, and $\sigma_0 = \bar{\varepsilon}E_0$ for surface charge density. The dimensionless groups that represent the comparative strength of various forces are as follows:

Electric Peclet Number: (charge convection/conduction) $Pe = 2\bar{\varepsilon}v_0/Kh_0$
Froude Number: (inertia/gravity) $Fr = v_0^2/gh_0$
Reynolds number: (inertial force/viscous force) $Re = \rho v_0 h_0/\eta$
Weber number: (inertia/surface tension) $We = \rho v_0 h_0/\gamma h$
The charge induction parameter: $\beta = (\varepsilon/\bar{\varepsilon}) - 1$
Aspect ratio: $\chi = D/h_0$
Electrostatic force parameter: $\Omega = \bar{\varepsilon}E_0^2/\rho v_0^2$

The subscript '0' in these equations signifies the relevant quantity at the nozzle. Reneker *et al.*[31] also considered the gravitational and aerodynamic conditions and concluded that these are inconsequential to the electrospinning process.

The equations listed above assume that the fluid involved is Newtonian. Newtonian fluids exhibit a linear relationship between the applied stress and the rate of deformation, characterized by a constant viscosity. However, in most electrospinning experiments polymeric fluids are used, and these demonstrate significantly nonlinear behavior. In these fluids, the viscosity remains constant only up to deformation rates that are of the order of the inverse of the longest relaxation time (τ_d) of the fluid. In shear flows, this feature of polymeric fluids leads to a definition of the zero-shear-rate viscosity (η_0), which essentially is the constant viscosity observed in polymeric fluids at low shear rates ($\dot{\gamma}$). At high shear rates, the shear viscosity (η) typically decreases rapidly. This phenomenon is commonly known as shear thinning. In extensional flows such as that observed in electrospinning, the 'extensional' viscosity (η_E) becomes important. In Newtonian fluids, $\eta_E = 3\eta_0$. In viscoelastic fluids, the extensional viscosity also remains constant at a value of $3\eta_0$ up to the point where the imposed extensional strain rate ($\dot{\varepsilon}$) is of the order of the inverse of the longest relaxation time of the fluid. Higher extensional strain rates elicit a response where η_E may increase over 2–3 orders of magnitude above the base value of $3\eta_0$, a phenomenon known as extensional strain hardening. This response is generally observed in solutions having low concentration of polymers and where the polymer coils are isolated from each other.[32] For polymer melts or concentrated solutions, where significant overlap among polymer chains occur, η_E first decreases for $\dot{\varepsilon} \geq 1/\tau_d$, and again starts to increase when $\dot{\varepsilon} \geq 1/\tau_R$, where τ_R is the Rouse relaxation time of the polymer chains in the fluid.[33] For systems where the overlap is significant, τ_d and τ_R are related through the equation $\tau_d = 3Z\tau_R$, where Z is the average number of entanglements per chain. Z is dependent on the concentration (number of chains per unit volume, c) and the length of the chains (molecular weight M_w). Procedures for estimating the number of entanglements and time constants are available.[34]

Since the flow properties of polymer solutions vary dramatically with changes in solution concentration and molecular weight, it is useful to review briefly some of the relevant methods that are used to characterize polymer solutions. It is well known[35,36] that there exists, for a given molecular weight, a critical concentration, c^*, below which the polymer coils do not overlap each other. A polymer solution is considered dilute when the $c < c^*$. In this regime the characteristic properties of the polymer solutions are significantly influenced by the interaction of the polymer with the solvent. For instance the intrinsic viscosity, defined as $[\eta] = (\eta - \eta_s)/(c\eta_s)$, where η and η_s are the solution and the solvent viscosities respectively, and c is the polymer concentration, scales with molecular weight, M_w, as $[\eta] \sim M_W^{(3\nu-1)}$. Similarly, there exists another concentration c^{**} above which the solvent ceases to affect the properties of the solution. For $c > c^{**}$, the solution is considered concentrated. For entanglements to occur in these solutions, the molecular weight of the chains should typically be about twice a critical molecular weight, M_c. Thus, it is possible to have a concentrated but unentangled solution if the molecular weight is small enough, even though the concentration in solution is large. For unentangled, concentrated solutions, $\eta_0 \sim cM_w$. For those solutions where entanglements dominate, $\eta_0 \sim c^4 M_w^{3.4}$.[37] In between these two regions, there are zones denoted 'semidilute,' where both solvent effects and the effects of entanglement density become important. The quantities c^*, c^{**}, and M_c can be established using theoretical arguments, and polymer solutions can be effectively classified into regimes based on the concentration of the polymer in solution and its molecular weight. A plot showing these regimes is known as the Graessley diagram, named after W. W. Graessley who first introduced it.[38] An example is shown in Figure 4, along with data from a group of representative solutions of poly(ethylene oxide) in water (PEO–water) that have been used in electrospinning.

In Figure 4, the line demarcating the limits of the dilute region is obtained from the relationship $c^* \approx 1/[\eta]$, where the intrinsic viscosity is given as $[\eta] \propto M_w^{\alpha}$ and $\alpha = 3\nu - 1$. Here ν is the solvent quality parameter, which ranges from 0.5 to 0.7, approximately. For the current purpose, we follow the experimental work of Daga and Wagner[48] and use $\alpha = 0.67$ for demarcating this limit. The above dependence of the $[\eta]$ on M_w holds at low concentrations ($c < c^*$) and at low values of M_w. As M_w is increased, there exists a value of c at which the dependence of $[\eta]$ on M_w deviates significantly from that noticed at low concentrations. The concentration at which the crossover from the dilute solution to the concentrated solution occurs is theoretically given by $c^{**} = 0.77/[\eta^{**}]$, where $[\eta^{**}]$ is the value of the intrinsic viscosity at which the first deviation from the dilute solution behavior of the intrinsic viscosity is observed.[38] For purposes of illustration in Figure 4, we again follow Daga and Wagner[48] and estimate

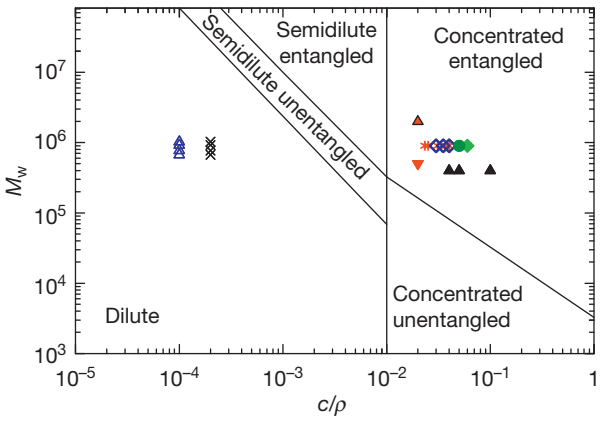

Figure 4 The Graessley diagram showing the various regimes for PEO–water solutions. The markers correspond to systems reported in the literature that have been used for electrospinning and yielded uniform fibers. The dilute solutions shown are those reported in Yu *et al.*[39] These correspond to PEO–water solutions having two different concentrations whose background viscosities are increased by addition of polyethylene glycol having shorter length of chains. Other markers correspond to PEO–water solutions used in Shin *et al.*[40,41] (red up triangle), Daga *et al.*[42] (red star), Zhou *et al.*[43] (green diamond), Deitzel *et al.*[44] (black up-triangle), Uyar and Besenbacher[45] (blue open diamonds), Liu and He[46] (red down triangle), and Panda and Ramakrishna[47] (green circle).

c^{**} as $c^{**} \approx 8c^*$. The line demarcating the semidilute unentangled and semidilute entangled solutions is given by $M_w = (c^{**}/c)^{1/\alpha}(\rho/c^{**})M_{c,melt}$, where $M_{c,melt}$ is the critical molecular weight for onset of entanglements in a melt.[37,49] Typically, $2 \le M_{c,melt}/M_{e,melt} \le 5$, where $M_{e,melt}$ is the entanglement molecular weight, defined below. For the current calculations we have taken the lower bound, so that $M_{c,melt} = 2M_{e,melt}$. $M_{e,melt} = 1624\ g\ mol^{-1}$ for PEO.[50] In the concentrated region the decrease in the number of entanglements per chain with decreasing concentration leads to a linear variation of the critical molecular weight for entanglements. The line demarcating the crossover from unentangled to entangled in the concentrated solution region ($c^{**} \le c \le \rho$) is given by $M_{c,soln} = (\rho/c)M_{c,melt}$.[33,37] It is immediately apparent that most experiments with PEO–water systems have been conducted in the concentrated entangled region; the work of Yu *et al.*[39] is a notable exception. All these experiments resulted in homogeneous fibrous products. The diagram is unique to a given polymer–solvent system and provides a valuable aid to the design of solutions used in electrospinning and rheology.

In general, the constitutive behaviors of polymer solutions vary with the concentration and the molecular weight. A large number of models are available for describing these. Excellent texts are now available that provide details of the models.[36,51] However, since concentrated entangled solutions are frequently used in electrospinning, a brief description of the behavior of these solutions in extensional flow fields is warranted here.

The dynamics of entangled polymeric fluids are usually studied within the framework of the Doi–Edwards theory.[35] The theory envisages an isolated chain in a concentrated entangled solution to be confined within a 'tube of constraints' set by its neighboring chains. The average diameter of the tube 'a' is determined by the average amplitude of fluctuation of the position of a chain segment between entanglement points separated by a number of Kuhn monomers (N_e). For melts and concentrated solutions $a \approx b\sqrt{N_e}$, where b is the Kuhn step length of the chains concerned. For a chain containing N monomers, the tube can be thought of as being composed of N/N_e segments of diameter a. Lateral motion of the chain beyond the 'walls' of the tube is energetically unfavorable. However, within the tube itself (i.e., on a length scale smaller than a), the dynamics of the chain is governed by the monomeric friction coefficient ζ, which arises due to thermodynamic interactions between chains. The time taken for N_e monomers to move a distance of the order of the tube diameter is $\tau_e = (a^2/D_c) = (b^2N_e)/(k_BT/\zeta N_e) = (\zeta b^2/k_BT)N_e^2$. Here D_c is the curvilinear diffusion coefficient along the chain contour, k_B is the Boltzman constant and T is the absolute temperature. One can also write $\tau_e = (\zeta b^2 N_K^2/k_BT)(N_e/N_K)^2 = \tau_R/Z^2$, where $\tau_R = (\zeta b^2 N_K^2/k_BT)$ is the Rouse time for a chain containing N_K monomers, and $Z = (N_K/N_e)$, is the number of entanglements per chain. Following deformation, the entire chain relaxes stress through a snake-like motion along its backbone, called 'reptation.' The reptation process is completed in a timescale τ_d, which constitutes the longest relaxation time of the chain. In entangled melts, the longest relaxation time of the chains is related to the timescale of segmental motion (τ_e), through the relationship $\tau_d = 3Z^3\tau_e = 3Z\tau_R$.[34] In general, the dynamics of entangled solutions are also governed by these timescales. The relevant length scale is the equilibrium length of the tube, which is related to the radius of gyration of the chain. Watanabe provides an excellent review on the subject.[52]

The original Doi–Edwards model has been subsequently modified and extended. Ianniruberto and Marrucci[53] have suggested a relatively simple model, popularly known as the 'double constraint release with chain stretch' (DCR-CS) model, that is capable of capturing qualitatively the important dynamical features associated with flow of entangled solutions. In Figure 5, predictions of the model in extensional flows are provided to illustrate the influence of polymer molecular weight and the number of entanglements per chain on the extensional viscosity. The figures are plotted in terms of Trouton ratio, $TR = \eta_E/\eta_0$, and Deborah number, $De = \dot{\varepsilon}\tau_d$. Figure 5 illustrates the universal behavior that the Trouton ratio remains constant at a value of 3 for $De < 1$ and starts to decrease rapidly between $1 \le De \le (\tau_d/\tau_R)$, due to orientation of the molecular coils in the direction of flow.

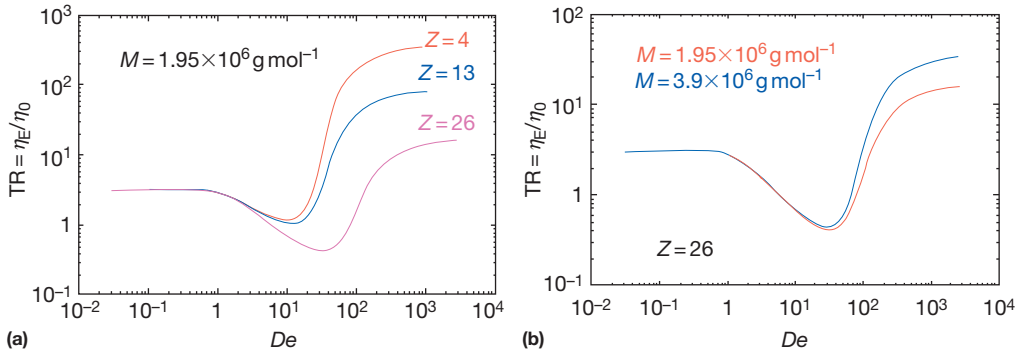

Figure 5 Theoretical predictions of the DCR-CS model for the extensional flow behavior of an entangled polymer solution, plotted as the steady-state Trouton ratio, $TR = (\eta_E/\eta_0)$ versus Deborah number (De) based on the longest relaxation time (τ_d). $De = \dot{\varepsilon}\tau_d$, where $\dot{\varepsilon}$ is the imposed strain rate. The predictions are based on polystyrene ($M_{e,melt} = 13\,300\ g\ mol^{-1}$) in diethyl phthalate. (a) Predictions of extensional flow behavior for solutions having the same molecular weight (M_w) but different entanglement numbers (Z). As the entanglement number increases, the upturn in the TR is delayed to higher values of De. Also the maximum achievable TR, shown by the dotted lines, decreases with increasing values of Z. (b) Predictions of extensional flow behavior for solutions having the same Z but different values of M_w. The maximum achievable TR increases as M_w increases. Also, the rate of increase of the TR is greater for longer lengths of chains.

For $De \geq (\tau_d/\tau_R)$, however, the Trouton ratio increases rapidly due to the onset of stretching of the chains and reaches a value much larger than the Newtonian limit of TR = 3. The Trouton ratio ultimately saturates at very large values of *De*, when the finite extensibility limit is reached and the polymer chains are completely stretched out.

Figure 5(a) illustrates the effect of the number of entanglements per chain, $Z = N_K/N_e$, on the Trouton ratio. In the melt phase, each polymer is characterized by a number of Kuhn segments between entanglements, $N_{e,melt}$, or equivalently the entanglement molecular weight $M_{e,melt} = M_w\ (N_{e,melt}/N_K)$. Fetters *et al.*[50] have tabulated these values for a large number of polymeric species. In concentrated solution, as the concentration of the polymer is decreased, Z also decreases since the degree of overlap among the chains goes down. In the concentrated, entangled region, the M_e of the solution can be related to $M_{e,melt}$ through the relationship $M_e = M_{e,melt}(c/\rho)^{-1}$, where c is the concentration of the polymer in solution and ρ is the bulk polymer density; this assumes that the solvent is approximately a θ-solvent for the polymer. The maximum Trouton ratio achievable by a given polymer solution can be derived using asymptotic analysis of the equations of the DCR-CS model. When $De \to \infty$, $TR \to 6\lambda_{max}^2/(1 + 1.5Z)$, where $\lambda_{max} = \sqrt{N_K/Z}$ is the stretch ratio and $N_K \sim M_w$, the molecular weight of the polymer. Thus, as concentration in solution decreases (for a given molecular weight of polymer), Z decreases and λ_{max} increases so that the limiting Trouton ratio at high strain rate becomes larger. Also as M_e decreases, the λ_{max} decreases concomitantly (since N_K is directly proportional to M_w). Consequently, the maximum Trouton ratio also decreases. In effect, the chains become 'stiffer' and 'less extensible' with respect to flow. **Figure 5(b)** illustrates the same effect arising from a change of molecular weight: as M_w decreases (at constant Z), λ_{max} decreases, resulting in a decrease in the limiting Trouton ratio.

Meanwhile, **Figure 5(a)** also shows that the solutions with larger concentrations (larger Z) demonstrate an upturn in the Trouton ratio at a larger Deborah number. The upturn in the extensional viscosity is expected to occur for $\dot{\varepsilon} \approx 1/\tau_R$. For Deborah number based on the longest relaxation time, this criterion translates to $De = \dot{\varepsilon}\tau_d \approx \tau_d/\tau_R = 3Z$. Thus, the critical Deborah number at which the upturn in the Trouton ratio occurs shifts to the right. However, since τ_R is also larger, the critical strain rate at the upturn, $\dot{\varepsilon}_c$, is actually lower. Further details of this analysis can be found elsewhere.[54]

In the context of electrospinning, several models have also been used to describe the non-Newtonian behavior of the fluid. In one such model, called FENE-P (finitely extensible nonlinear elastic dumbbell model with Peterlin's approximation), the polymeric stress contribution depends on the average of the polymer configuration tensor and the finite extensibility of the polymer chain. For the FENE-P model, the polymeric stress can be obtained as follows:

$$\tau_p = nk_BT\left(\delta - \frac{\langle QQ\rangle}{1 - \mathrm{tr}\langle QQ\rangle/b_{max}}\right) \qquad [5]$$

In the equation above, $\langle QQ\rangle$ is the polymer chain configuration tensor and b_{max} is the finite extensibility parameter. The term δ is the Kronecker delta function. Also, n is the monomer density, k_B is the Boltzmann constant, and T is the absolute temperature. The details of the physics leading to the FENE-P model are available elsewhere[51] and are not discussed here. For the purposes of this review, it suffices to state that this model has been successful in predicting the rheological behavior of polymer solutions. Other models that have been used in the study of electrospinning include the linear Maxwell,[55] the Oldroyd-B,[30] and the neo-Hookean[56] models. In addition, Feng[29] has used an empirical nonlinear model representing fluid behavior in his work. Apart from FENE-P, the other models that have been used are 'phenomenological' in nature. One shortcoming of phenomenological models is that their predictions depend strongly on the numerical values of certain 'adjustable' model parameters. The adjustable parameters might or might not have a physical or molecular significance. The accuracy of the predictions of these models depends on how good the estimates of the parameters are. The parameters are often estimated by elaborate 'fitting' procedures over a limited range of experimental rheological data. Extrapolating the predictions beyond the range of conditions used to estimate the parameters can become problematic. On the contrary, the molecular models, like DCR-CS or FENE-P, relate rheological phenomena to the dynamics of the polymer chain and its interactions with the surroundings (solvents, for instance). This is advantageous because flow properties of the fluids can be designed by suitably tailoring the polymer chain architecture or the properties of the solvent. For this reason, we have chosen to illustrate the behavior of entangled fluids using the DCR-CS model in this section. However, such models have not, thus far, been widely used in the electrospinning literature.

1.127.3.3. Electrospinning Zones

The electrospinning process has been studied in terms of three distinct zones: namely, the conical meniscus region, the straight thinning jet region, and the 'whipping jet' region, which constitutes the zone where the jet bends and a nonaxisymmetric convective instability sets in. In the following sections, we discuss each of these regions briefly.

1.127.3.3.1. The conical meniscus

As the fluid exits from the spinneret and enters the electric field, it assumes a conical (or nearly conical) shape, from the apex of which a thin jet emerges. In inviscid fluids, the shape that the meniscus attains depends on the interplay between the electric field and the surface tension and has been studied extensively since the early 1900s. Zeleny first demonstrated that a drop of liquid having surface tension γ, held at the end of a capillary tube of radius r_0, and raised to a potential difference of V disintegrates into a spray. He also demonstrated that at the point of disintegration the ratio $V^2/r_0\gamma$ remained approximately constant.[57,58] Taylor[57] elaborated upon this analysis and suggested that the critical half angle of the meniscus approaches a value of 49.3° close to the disintegration event. This condition of the meniscus is well known as the 'Taylor cone.' However, Yarin *et al.*[59,60] showed that the Taylor cone represents a specific self-similar solution, whereas there exist other, non-self-similar solutions that do not tend to the semivertical angle of 49.3° near criticality. In this way, Yarin *et al.*

Figure 6 Various shapes of the meniscus observed for three solutions of poly(methyl methacrylate) ($M_w = 540$ kDa), having different concentrations (10, 12, 15 wt% in dimethyl formamide), and hence, different zero-shear-rate viscosities (0.5, 1.1, and 10 Pa s respectively). The solutions were subjected to conditions where the electric field and infusion rates are identical.

demonstrated that the electrified meniscus can assume a wide variety of shapes that are different from that of the Taylor cone. Figure 6 shows some examples of such shapes. Here, three solutions of polymethyl methacrylate having identical polymer molecular weights but at different concentrations in dimethylformamide and also differing in the zero-shear-rate viscosity are considered. The solutions were subjected to identical electric field strengths and infusion rates during electrospinning. Clearly, the shape of the meniscus changes as the concentration of the polymer in solution and the solution viscosity increases. Collins *et al.*[61] have shown that such changes in the shape of the meniscus can be brought about by altering the conductivity of the fluid. In the limit of high fluid conductivity, the Taylor cone shape is dominant. As mentioned previously, tangential stresses are generally insignificant in highly conducting fluids. Typically, in fluids with high conductivity, the charge relaxation time is small, and charges are made available instantaneously to the surface. In this way, the capillary pressure that continually rises in a sharpening meniscus is always balanced by the electrostatic pressure. Also, as a consequence of high conductivity, the electric field in the fluid vanishes. The lack of an internal electric field prevents the development of significant tangential (or shear) components along the surface. These conditions preserve the spherical symmetry of the flow and lead to the Taylor cone geometry in conducting fluids. However, as conductivity of the fluid decreases and the dielectric character increases, a deviation from the conical shape predicted by Taylor's theory is observed. The change in the shape is attributed to the development of tangential (shear) stresses on the surface of the meniscus in fluids with low conductivity. These tangential stresses couple with the viscous nature of the fluid to accelerate the fluid near the apex, deforming the meniscus and causing its shape to deviate from that of a perfect Taylor cone. This process is reflected in the menisci shown in Figure 6. Since the mobility of the charges in a fluid scales approximately inversely with viscosity,[26] higher-viscosity fluids are likely to be less conductive (more dielectric) and thus deviate from the Taylor cone shape the most. From left to right in Figure 6, a change in behavior is observed from that characteristic of fluids with low viscosity and high conductivity, where a jet appears abruptly from the apex of a conical meniscus, to that typical of viscous, dielectric fluids, where a more gradual transition from the conical meniscus to a steady jet occurs.

The motion of the fluid within the conical meniscus can also be quite complicated. For liquids of low conductivity and viscosity, Hayati *et al.*[62] discovered intense meridional circulation of liquid toward the apex along the surface of the conical meniscus and away from the apex along the axis of symmetry within the conical meniscus. The motion inside the conical meniscus occurs due to the existence of the tangential component of electrical stress on the surface of the meniscus. The stable jet is essentially maintained by the shearing flow on the surface of the cone that supplies material to the jet. The balance of the viscous and electrical forces on the surface of the meniscus establishes a velocity scale for flow into the jetting region.[63] Recirculation within the meniscus occurs when $u \geq Q/L_c^2$ approximately.[63] The meridional circulation decreases with increasing conductivity of the solution, as the tangential electric stress diminishes in magnitude. For sufficiently high conductivity, the flow within the fluid is not much different from a sink flow corresponding to the imposed flow rate Q. In a sink flow, the fluid moves radially inward to a point where it disappears at a constant rate. As mentioned earlier, in this limit, the meniscus approaches the shape of the Taylor cone.

While the work of Collins *et al.* provides some qualitative insight into how the viscosity and conductivity can affect the shape of the meniscus, it does not explain how the viscoelasticity of the fluid is likely to affect these shapes. Using the neo-Hooken model[56] for a purely elastic fluid, Yarin *et al.*[59,60] showed that the critical angle at the apex of the cone decreases from the value predicted by Taylor's theory as the influence of elastic forces increases. By contrast, using numerical simulations with the FENE-P constitutive model, Carroll and Joo[30] demonstrated that fluids with increasing elastic character adopt larger critical apex angles, even when possessing the same viscosity and conductivity and subjected to the same electric field. Around the same time, Yu *et al.*[39] reported similar trends, observed experimentally. Both the FENE-P model and the results of Yu *et al.* apply to dilute polymer solutions, where the isolated polymer molecules remain in a coiled state for strain rates that are less than the inverse of the longest relaxation time of the polymer. In this limit the stress accumulated in the fluid is borne mostly by the solvent and is directly proportional to rate of strain imposed by flow. However, at higher strain rates, the polymer chains unravel, and the subsequent loss in entropy manifests as an elastic stress in the fluid. In effect, a single time constant, the polymer relaxation time, governs the separation between regions of linear (viscous) and nonlinear (viscoelastic) fluid behavior. Ultimately, at very large strain rates, the elastic stress saturates as the polymer molecule is stretched to its maximum length. Meanwhile, the solutions represented in Figure 6 fall in the category of semidilute or entangled polymer solutions. These fluids are typically much less extensible than dilute polymer solutions. Thus, the complexities arising from elastic effects are less evident in these experiments than in the work of Yu *et al.* Moreover, the slow motion near the nozzle is likely to be dominated by the viscous response of the fluid, which explains why a qualitative explanation of the shape of the meniscus can be provided following the arguments of Collins *et al.* These complexities arising from the rheological behavior of the fluid thus make the prediction of the shape of the meniscus in electrospinning an ongoing challenge. Further attention to these aspects is warranted.

1.127.3.3.2. The thinning jet

The conical meniscus eventually gives rise to a slender jet that emerges from the apex of the meniscus and propagates downstream. An example of the jet emanating from a conical meniscus region is shown in Figure 7. The jetting process can be studied using the mathematical framework described in Section 1.127.3.2. Hohman *et al.*[28] first reported this approach for the relatively simple case of Newtonian fluids. This suggests that the shape of the thinning jet depends significantly on the evolution of the surface charge density and the local electric field. As the jet thins down and the charges relax to the surface of the jet, the charge density and local field quickly pass through a maximum, and the current due to advection of surface charge begins to dominate over that due to bulk conduction. The crossover occurs on the length scale given by eqn [6][64]:

$$L_N = \left[K^4 Q^7 \rho^3 (\ln \chi)^2 / 8\pi^2 E_\infty I^5 \bar{\varepsilon}^2\right]^{1/5} \quad [6]$$

This length scale defines the 'nozzle regime' over which the transition from the meniscus to the steady jet occurs. Sufficiently far from the nozzle regime, the jet thins less rapidly and finally enters the asymptotic regime, where all forces except inertial and electrostatic forces cease to influence the jet. In this regime, the radius of the jet decreases as follows:

$$h = \left(\frac{Q^3 \rho}{2\pi^2 E_\infty I}\right)^{1/4} z^{-1/4} \quad [7]$$

Here z is the distance along the centerline of the jet. This equation was first derived by Kirichenko *et al.*[65] and was later verified experimentally by Shin *et al.*[40,41] Between the 'nozzle regime' and the 'asymptotic regime,' the evolution of the diameter of the thinning jet can be affected by the viscous response of the fluid. Indeed by balancing the viscous and the electrostatic terms in the force balance equation it can be shown that the diameter of the jet decreases as $h = (6\mu Q^2 / \pi E_\infty I)^{1/2} z^{-1}$.

The mathematical framework of Section 1.127.3.2 has also been used to study the effect of nonlinear (e.g., viscoelastic) fluid behavior on the thinning that takes place in the straight section of the electrospinning jet, as represented by the works of Feng[29] and Carroll and Joo.[30] In fact, the straight jet section has been studied extensively to understand the influence of viscoelastic behavior on the axisymmetric instabilities[28,66] and crystallization[67] and has even been used to extract extensional viscosity of polymeric fluids at very high strain rates.[68] For highly strain-hardening fluids, Yu *et al.*[39] demonstrated that the diameter of the jet decreased with a power-law exponent of $-1/2$, rather than $-1/4$ or -1, as discussed earlier for Newtonian fluids. This $-1/2$ power-law scaling for jet thinning in viscoelastic fluids has been explained in terms of a balance between electromechanical stresses acting at the surface of the jet and the viscoelastic stress associated with extensional strain hardening of the fluid.[69] Additionally, theoretical studies of viscoelastic fluids predict a change in the shape of the jet due to non-Newtonian fluid behavior. Both Yu *et al.*[39] and Han *et al.*[68] have demonstrated that substantial elastic stresses can be accumulated in the fluid as a result of the high strain rate in the transition from the meniscus into the jetting region. This elastic stress stabilizes the jet against external perturbations. Further downstream the rate of stretching slows down, and the longitudinal stresses relax through viscoelastic processes. The relaxation of stresses following an extensional deformation, such as those encountered in electrospinning, has been studied in isolation for viscoelastic fluids.[54,70] Interestingly, Yu *et al.*[39] also observed that, elastic behavior notwithstanding, the straight jet transitions into the whipping region when the jet diameter becomes of the order of 10 μm.

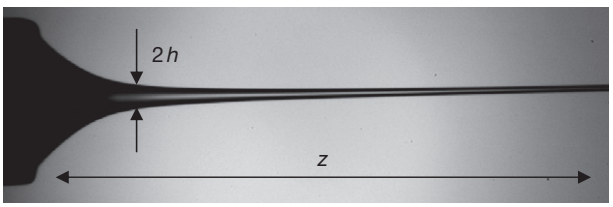

Figure 7 The jet that emerges from the meniscus steadily tapers down at a rate that is dependent on the properties of the fluid. The strain rate in the tapering jet is given by $\dot{\varepsilon} = -(2Q/h^3)(dh/dz)$.

1.127.3.3.3. The whipping jet

While it is in principle possible to draw out fibers of small diameter by electrospinning in the cone-jet mode alone, the jet does not typically solidify enough *en route* to the collector and succumbs to the effect of force imbalances that lead to one or more types of instability. These instabilities distort the jet as they grow. A family of these instabilities exists, and can be analyzed in the context of various symmetries (axisymmetric or nonaxisymmetric) of the growing perturbation to the jet. Some of the lower modes of this instability observed in electrospinning have been discussed in a separate review.[64] The 'whipping instability' occurs when the jet becomes convectively unstable and its centerline bends. In this region, small perturbations grow exponentially, and the jet is stretched out laterally. Shin *et al.*,[40,41] Fridrikh *et al.*,[71] and Fridrikh *et al.*[72] have demonstrated how the whipping instability can be largely responsible for the formation of solid fiber in electrospinning. This is significant, since as recently as the late 1990s the bifurcation of the jet into two more or less equal parts (also called 'splitting' or 'splaying') was thought to be the mechanism through which the diameter of jet is reduced, leading to the fine fibers formed in electrospinning. Despite some evidence of the splitting of the jet in 'postmortem' micrographs of fibers, it has been demonstrated that conditions that lead to the splitting of the jet are difficult to sustain in ordinary electrospinning experiments.[73] Thus, these events are in fact quite rare. Nevertheless, diagrams that suggest this relatively rare form of instability to be operative during electrospinning continue to appear in the literature. In contrast to 'splitting' or 'splaying,' the appearance of secondary, smaller jets from the primary jet have been observed more frequently and in situ.[59,60,73] These secondary jets occur when the conditions on the surface of the jet are such that perturbations in the local field, for example, due to the onset of the slightest bending of the jet, is enough to overcome the surface tension forces and invoke a local jetting phenomenon. Figure 8(a) shows the whipping event observed in a polymer solution. Figure 8(b) demonstrates the growth of the amplitude attained during whipping in a series of time-lapse traces.

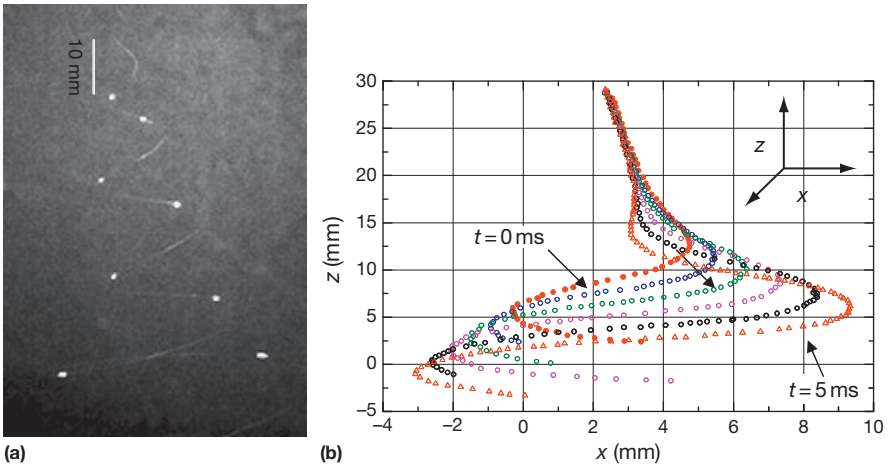

Figure 8 The whipping motion observed in a jet of a 2% (w/w) solution of polyethylene oxide ($M_w = 1.25 \times 10^6$ g mol^{-1}) in water. (a) Photograph shows the convective nature of the whipping instability that propagates downstream with an approximately constant wavelength. The growth in the amplitude of the instability with distance can also be observed from the photograph. The photograph was taken using a digital SLR, which was backlit by a flash that could be remotely triggered. The flash was triggered once with the shutter speed held at 1/100 s. (b) Traces of the growing amplitude observed through time-lapse photography performed using a high-speed camera (Phantom V5, Vision Research) at 1000 frames per second. Traces were extracted from individual images using digitization software. A calibrated grid placed in the plane of focus provided the spatial reference. The evolution of the jet immediately following the onset of the whipping instability is shown.

The conditions necessary for the transition of the straight jet to the whipping jet has been discussed in the works of Gañán-Calvo,[74] Yarin *et al.*,[59,60] Reneker *et al.*,[31] and Hohman *et al.*[28] Gañán-Calvo has analyzed the transition in terms of propagation speeds of surface disturbances, the upstream component of which is delayed by convection of surface charge. His analysis reveals that the transition occurs at a point where the net propagation speed (downstream) of surface perturbations becomes imaginary, and the straight jet ceases to be convectively stable. Yarin *et al.*,[59,60] Reneker *et al.*,[31] and Hohman *et al.*[28] however, adopt a more microscopic viewpoint and conjecture that charges arranged in a straight line and interacting with each other through Coulomb's forces are intrinsically unstable, and that the perturbation caused by these interactions leads to the bending of the jet.

Following the onset of the whipping instability, small perturbations grow exponentially, and the amplitude of the instability increases convectively as the jet thins down. Hohman *et al.*[28] and Fridrikh *et al.*[72] have calculated the growth rates and the wave numbers associated with the jet undergoing a whipping instability by extending the equations of motion (eqns [1]–[4]), which have also been derived for curvilinear jets,[28] into the nonlinear regime. In developing the dispersion relationship, the surface charge repulsion, surface tension, and inertia were considered more important than the effects of Maxwell's stress, which arises due to the electric field and finite conductivity of the fluid. Using the equations reported by Hohman *et al.*, and under similar restrictions, Fridrikh *et al.*[72] obtained an equation for the lateral growth of the jet excursions arising from the whipping instability far from the onset and deep into the nonlinear regime. These developments have been summarized in the review article of Rutledge and Fridrikh.[64]

The whipping instability is postulated to impose the stretch necessary to draw out the jet into fine fibers. As discussed previously, the stretch imposed can invoke an elastic response in the fluid, especially if the fluid is polymeric in nature. An empirical rheological model was used to explore the consequences of nonlinear behavior of the fluid on the growth of the amplitude of the whipping instability in numerical calculations.[72] There it was observed that the elasticity of the fluid significantly damps the amplitude of oscillation of the whipping jet. The elastic response also stabilizes the jet against the effect of surface tension. This effect is well known and is a topic of current research in nonelectrified viscoelastic jets. In the absence of any elasticity, the jet eventually breaks up and forms an aerosol. However, the presence of a polymer in the fluid can arrest this breakup if the factor $\tau/(\rho h^3/\gamma)^{1/2} \gg 1$, where τ is the relaxation time of the polymer, ρ is the density of the fluid, h is a characteristic radius, and γ is the surface tension of the fluid.

1.127.3.4. Discussion on Current Carried by Electrospinning Jet

The current carried by the jet plays a critical role in various aspects of electrospinning. The current in the jet consists of two contributions, one due to Ohmic conduction and another due to the advection of the surface charge with the flow. Rewriting eqn [2], the current can be expressed as follows:

$$I = \pi h^2 K E_z + 2\sigma Q/h \qquad [8]$$

As before, I is the current carried by the jet of radius h subjected to an electrical field with an axial component E_z. The variables Q and σ represent the flow rate and the surface charge density, respectively. The first term in the above equation is due to the conduction current, and the second is due to advection of surface charge. As the jet thins down, the conduction component becomes smaller and the advection component dominates. The electrospinning process is in

large part driven by electrostatic interactions among the charges that appear on the surface of the fluid following electrification. Since it is difficult to determine directly the surface charge density on the thinning jet in experiments, the current is usually measured instead. Numerous investigations have reported the nonlinear dependence of the current on the applied driving voltage and fluid flow rates. Demir *et al.*[76] and Theron *et al.*[77] determined a power-law dependence of the current on the applied voltage, V, with exponents of 2.17 and 2.7 respectively. Similarly, a power-law dependence of the measured current on the flow rate, Q, has also been reported,[71,76,77] with the exponent ranging from −1.04 to +1. The nonlinear behavior of the current has been difficult to rationalize analytically. The observed nonlinear behaviors have been attributed to the onset of fluid instabilities[40,41,44] as well as to the limitation on the mobility of charge in the equipment concerned.[77] Recent measurements have shown that $I \sim E(QK)^{0.5}$ for a large number of experimental systems reported in the literature.[78] This compares with the power-law behavior observed in electrospray systems, where the current scales as $I \sim (QK)^{0.5}$ but does not depend on electric field, E.[79] The similarity between the two systems is conspicuous. A careful study of the jet current has led to the proposal that secondary electrosprays may form on the whipping jet in some cases.[78]

Having measured the current carried by the jet, the surface charge density is then estimated using the relation $\sigma = (h/2)(I/Q)$, which follows from eqn [8] in the limit where the radius of the jet is small enough to neglect the contribution from Ohmic conduction (the first term in eqn [8]). However, other sources of current may interfere with such measurements unless appropriate precautions are taken. One of these is the plasma current, which is most noticeable at high voltages and in equipment configurations of the point-plate type. The secondary jetting processes previously mentioned[78,80] lead to aerosols that also carry a measurable current not associated with the main jet; in such cases, the existence of the aerosol contribution makes it difficult to estimate the amount of charge that is carried by the main jet. A third source of current can arise from the partial ionization of the surroundings (particularly when the humidity is high) near the surface of the electrified jet, leading to free ions that also discharge on the grounded counter electrode.[81] These processes can make the measurement of the actual current carried by the main jet extremely complicated, and prone to overestimation. These complications have impeded efforts to accurately measure current and the surface charge density. Better methods to make such measurements are certainly needed.

1.127.4. Products of Electrospinning

1.127.4.1. Electrospun Fibers: Diameter and Morphology

As mentioned in the introduction, the electrospinning technology is capable of generating fibers with diameters spanning about 4 orders of magnitude, from tens of microns down to tens of nanometers. Much effort has gone into determining to what extent the morphology and the size of the fibers in this range influence the properties of the products formed. For instance, Ma *et al.*[82] and Tuteja *et al.*[83] have shown that the capacity of electrospun mats to repel oil or water strongly depends on the fiber size, the spacing between the fibers, and the morphology of the fibrous products. Ma first showed that the apparent contact angle, θ^*, of a fluid with an electrospun mat increased with decreasing fiber diameter, and that the introduction of the beads-on-string morphology provided a significant enhancement in liquid repellency over the simple, uniform fiber morphology; these results were understood in terms of relative spacing between fibers or beads, s/d, where s is the separation distance between fibers (or beads) and d is the diameter of fibers (or beads).[82] Tuteja *et al.*[83] subsequently proposed two dimensionless design parameters by which to understand the repellency of fluids on various surfaces: the spacing ratio, $D^* = (1+s/d)$, and the robustness $H^* = 2(1-\cos\theta)\, dl_{cap}/s^2$, where $l_{cap} = (\gamma/\rho g)^{0.5}$. Here, θ is the intrinsic contact angle that the liquid forms on a smooth flat film of the same material. The robustness parameter in particular introduces for the first time a length scale, l_{cap}, and provides insight into the significance of small fiber size to enhance the metastability of a liquid drop on a mat of fibers comprised of material with an intrinsic contact angle less than 90°. It was demonstrated that for conditions where $D^* \gg 1$ and $H^* \gg 1$, wettable surfaces can be made repellant to a given liquid. The robustness concept was later embellished to include both a robustness height, H^* and a robustness angle, T^*; both robustness parameters quantify the sagging of the vapor–liquid interface between fibers (or beads) as a result of a pressure difference across the interface.[84] In short, these works demonstrated that with the control of the fiber size, fiber spacing, morphology, and chemical composition, it is possible to tailor repellency of electrospun surfaces to organic and inorganic fluids. These aspects have been highlighted in a recent review.[85] The mechanical modulus of electrospun fibers has also been shown to deviate from the bulk value of the polymer as a consequence of fiber size in a number of instances. Arinstein *et al.*[86] reported an increase in the elastic modulus of individual electrospun fibers with decreasing diameter, and argued that the enhancement of the modulus results from confinement effects arising from the decreasing lateral dimension of the fibers. These aspects have generated substantial interest in understanding the physics that govern the morphologies and diameters of the fibers obtained via electrospinning.

Predicting the morphologies and diameters of electrospun fibers has been a challenge, however. The difficulties arise because the hydrodynamic, viscoelastic and electrical stresses cannot be directly measured in an electrospinning jet. The rapid evaporation of the volatile solvent further complicates the analysis. Nevertheless, neglecting the effects of evaporation during jet thinning, Fridrikh *et al.*[71] proposed a relation for fiber diameter by balancing the surface charge repulsion force acting on the jet with surface tension, in the limit where gradients in the velocity subside and the effects of viscosity are unimportant. This so-called 'terminal' diameter (h_t) of the jet can be expressed as follows:

$$h_t = \left(\frac{2\gamma\bar{\varepsilon}}{\pi(2\ln\chi - 3)}\right)^{1/3}\left(\frac{I}{Q}\right)^{-2/3} \qquad [9]$$

In the above equation, $\chi \sim D/h$ is a dimensionless measure of the wavelength of the instability, D being the radius of

curvature of the jet. The final solid fiber diameter is then determined from h_t through an appropriate volume correction for solvent removal. These assumptions were tested and found to be valid for a number of polymer solutions.[71] However, many studies in the literature[69,87] highlight the apparent correlation of fiber diameter with solution viscosity, which is not captured by eqn [9]; presumably, under many conditions of electrospinning, the assumptions behind eqn [9] are not met before the jet solidifies, either due to premature solvent removal or viscoelastic hardening of the jet. Thus, while eqn [9] may be viewed as a valuable lower bound, the quantitative prediction of fiber diameter in general remains a substantial challenge.

Besides fiber diameter, the fiber morphology can vary from smooth fibers with near-uniform diameter to those resembling 'beads on a string,' depending on the fluid properties and processing conditions. Even droplets can be obtained under suitable conditions. A large body of work that discusses these effects (occurrences of droplets, beaded fibers, or smooth fibers) in terms of the nonlinear viscoelastic behavior of polymeric fluids exists.[44,88] Shenoy *et al.*[89] offered an appealing physical interpretation, in terms of entanglements between polymer molecules in solution required to obtain smooth, uniform fibers. Helgeson and Wagner,[87] on the other hand, emphasized the role of shear viscosity, through the use of the Ohnesorge number $Oh = \mu/(\rho\gamma r_0)^{0.5}$. However, using a set of well-characterized fluids, Yu *et al.*[39] demonstrated that neither the entanglement density nor the Ohnesorge number provide a reliable predictor of uniform fiber formation. Instead, they argued that the elastic stress invoked in the fluid during electrospinning is of fundamental importance. Such elastic stresses can be induced through increased entanglement density in the solution or by the more efficient transfer of stress from the surface of the jet to the jet interior, as a consequence of viscosity, but they can be induced by other mechanisms as well. For the formation of fibers with a uniform morphology, sometimes referred to as 'electrospinnability,' it suffices that the elastic stress generated during processing is much greater than the capillary pressure that would cause breakup of the fluid filament. Yu *et al.* provided a criterion based on the Deborah number (De), which relates the characteristic process timescale to the relaxation time of the fluid, to predict the formation of uniform fibers. According to this criterion, the relevant Deborah number is given by $De = \tau\omega_{max}$, where τ is the relaxation time of the polymeric fluid and ω_{max} is the growth rate of the fastest-growing mode of the surface-tension-driven Rayleigh instability; to a good approximation, ω_{max} can often be estimated using the conventional formula for an uncharged, Newtonian fluid filament, $\omega_{max} = \left[\rho R_0^3 I_0(x_R)/\gamma I_1(x_R)\left(1 - x_R^2\right)x_R\right]^{-1/2}$, where ρ is density, R_0 is the initial radius of the jet, γ is the surface tension, and $x_R = 0.697$ is the reduced wave number of the fastest-growing mode; I_0 and I_1 are modified Bessel functions. When $De < 1$, breakup of the jet into a spray of droplets results; for $De > 1$, beaded fibers are obtained. For $De > 6$, uniform fibers are routinely observed. Significantly, Yu *et al.* used experimental measurements of extensional viscosities and strain hardening of the fluids to explain the influence of elastic stresses on electrospun products. Prior to this, explanations had depended largely on measurements of rheological response in shear flow, which frequently becomes weaker with increasing shear rate. However, their experiments were restricted to a rather narrow range of field strength, and it was not clear whether significantly higher electric fields could also serve to retard the development of the Rayleigh instability, as suggested by the work of Hohman *et al.* (cf. equation [20] in Hohman *et al.*[28]).

In addition to beading along the fiber, the morphology of electrospun fibers can be varied, for example, in the shape of their cross-section. For example, electrospun fibers with wrinkled surfaces[16,90] and those resembling flat ribbons[14] have been reported. In these cases, the effect of the skin that forms due to rapid evaporation of the solvent from the surface has been emphasized. This phenomenon can be understood as arising from the formation of a skin layer on the surface of the fiber, which subsequently buckles as the core of the fiber continues to shrink. In order to explain these observations qualitatively, Wang *et al.*[90] and Pai *et al.*[16] correlated the observed wrinkled and porous morphologies with the ratio of a drying time, $t_D = R_0/2W_{E0}$, which gives an order of magnitude of time for the drop to solidify by evaporation, and a buckling time, $t_B = D_2(\phi_{pg} - \phi_{p0})^2/W_{E0}^2$, which characterizes the onset of the buckling instability, as proposed previously by Pauchard and Allain[91,92] and Pauchard and Couder[93] for liquid drops. Here, W_{E0} is the initial evaporation rate, R_0 is the radius of the drop or jet, D_2 is the mutual diffusion coefficient of the solvent–polymer system, ϕ_{pg} is the volume fraction of polymer undergoing vitrification at the surface of the jet, and ϕ_{p0} is the initial volume fraction of the polymer in the solvent. Using these characteristic times, qualitative predictions for the fiber morphologies could be obtained. In general, it was observed that larger fibers tend to buckle due to the larger drying time associated with the reduced surface area (relative to volume) for evaporation; polymer solutions made from higher-molecular-weight polymer tend to buckle due to a shorter buckling time associated with the smaller mutual diffusion coefficient; and polymer solutions with larger concentration tend to collapse due to the smaller difference between the polymer concentration at the fiber surface and at the core.

In addition to the competition between drying and buckling, many electrospun fibers exhibit either superficial or internal porosity, which arises due to a temperature- or nonsolvent-induced liquid–liquid phase separation prior to solidification of the fiber. The works of Casper *et al.*[15] and Megelski *et al.*[94] provide some excellent examples of the wide variety of porous surface morphologies that can be obtained by varying the solvent, humidity, and polymer molecular weight. Surface pores are typically obtained when processing from highly volatile solvents. The evaporation of the volatile solvent can lead to a significant decrease in the surface temperature. The lowering of temperature induces phase separation at the surface of the jet or condensation of liquid from the ambient air, through a mechanism discussed by Srinivasarao *et al.*[95] By contrast, processing from less volatile solvents in the presence of a nonsolvent vapor typically allows for internal phase separation and the formation of pores internally or throughout the fibers. Pai *et al.*[16] demonstrated that electrospun fibers obtained by electrospinning a solution of a polymer in a hygroscopic solvent and in a humid atmosphere contain internal pores or

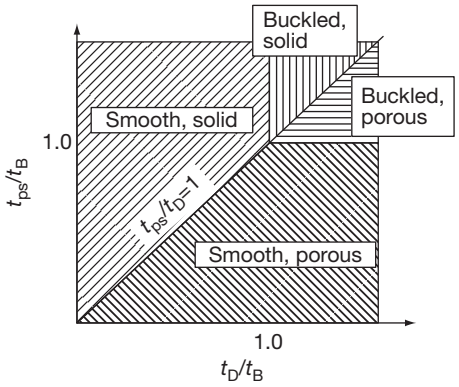

Figure 9 Phase diagram demarcating areas where fibers with different surface morphologies and internal structures can be expected. See Pai *et al.*[16] for details.

voids. In their case, the water vapor from the ambient permeated into the hygroscopic solvent and acted as a nonsolvent for the polymer. This caused the polymer to phase separate during processing and led to the formation of voids within the fiber, which amounted to as much as 30% of the volume of the fiber, depending on the molecular weight of the polymer used. This phase-separation process competes with the buckling and drying processes mentioned earlier. To understand this new competition, one can introduce a phase-separation time, t_{PS}, corresponding to the time required for sufficient cooling or exchange of solvent and nonsolvent to induce phase separation within the jet, as described by Dayal and Kyu[96] or by Pai *et al.*[16] For processes that satisfy the conditions where the $t_D/t_B > 1$ and $t_{PS}/t_B < 1$, fibers with smooth external morphologies can be expected. Based on the competition between the several processes of drying, buckling, and phase separation, one can construct a diagram such as that shown in **Figure 9**, demarcating regions where the various fiber morphologies can be expected. Lastly, hollow fibers or those having a core–shell morphology can be obtained by electrospinning two fluids simultaneously in a coaxial configuration.[18,19,97,98] Similar core–shell morphologies have also been obtained by spinning from an emulsion.[99] Such morphologies are thought to be promising for a variety of applications, including drug delivery.[100,101] Coaxial electrospinning can also be used to encapsulate a block copolymer as the core within a more thermally stable outer shell; upon subsequent annealing of these fibers, novel ordered morphologies are found to occur.[102–105] These ordered morphologies are significantly different from those that are observed in the same copolymers in bulk. For example, copolymers that are known to form lamellar morphologies in the bulk are prone to form a novel, 'concentric lamellar' morphology under confinement within a fiber whose diameter is on the order of 1–10 periods of the bulk lamellar morphology. Radial confinement also leads to novel defect structures, such as the recently identified radial edge dislocation loop.[105]

1.127.4.2. Properties of the Electrospun Mat

In addition to the liquid repellency and mechanical properties of the mats, discussed earlier in the context of fiber size, two other properties of the electrospun mat probably deserve mention in the context of biomaterials applications. These are (1) the organization of fibers within the mat and (2) the porous structure of the mat. In the absence of special efforts to control the deposition of fibers on the grounded electrode, the dynamics of the whipping process are responsible for the formation of the seemingly random array of fibers within a two-dimensional (2D) network that is usually observed in scanning electron micrographs. The deposition area can be controlled somewhat, through the use of focusing rings[106] or environmental conditions.[81] Rotors,[107,108] patterned electrodes,[109] parallel bars,[110] and disks[12,13] have all been used to alter the deposition, fiber alignment, and collection of electrospun mats. Liquids have also been used as collectors.[111–114] The fibers can also 'weld' at points of contact between fibers, depending on the amount of solvent remaining in the fiber at deposition, or by subsequent thermal or chemical treatment[115,116]; such welding has been shown to improve electrical properties of the mat.

While much attention has been devoted to the characterization of fiber diameters, far less attention has been directed to the characterization of the porous structure of the fibrous mat. Nevertheless, the overall porosity and the distribution of void space within an electrospun mat are crucially important for applications such as composites and tissue engineering. Characterization of the void space, however, is problematic. The overall pore volume fraction, or porosity, can be measured gravimetrically, for sufficiently thick samples. However, characterizing the distribution of the void volume within the mat, and the interconnectivity of these pores, remains a challenge. Eichhorn and Sampson[117] have developed models that relate the characteristic pore size and the available surface area to the length, width, and linear density (mass per unit length) of fibers, the porosity, and the mean coverage of the network; the mean coverage corresponds to the mean number of fibers that would project down onto a common point in the 2D plane of the mat. The fiber diameter plays an important role in determining the pore dimensions in the network. Interestingly, these models indicate that the available surface fraction for a given value of porosity does not strongly depend on the mean coverage.

On the experimental side, a number of techniques have been used to characterize the porosity of the electrospun mats.[118–120] Most popular among these are mercury intrusion porosimetry, liquid extrusion porosimetry, and capillary flow porosimetry. Recently microcomputed tomography has been utilized to characterize electrospun mats.[121] Scanning electron microscopy (SEM) is also routinely used for the purpose. However, SEM provides only qualitative information of pore structure, unless appropriate image analysis techniques are employed to account for the 2D projection of 3D structure. Of these techniques, perhaps the most common method of characterization is mercury porosimetry. However, this method is known to introduce artifacts, such as the 'ink-bottle effect,' in the characterization of complex porous geometries. For compliant materials like aerogels and electrospun mats, deformation of the sample under measurement conditions also leads to systematic errors in the characterization of pore sizes. Recently, a method for correcting such liquid intrusion data for deformation of the sample, by either buckling or elastic compression, has been reported, and the method

has been applied to several materials used for cultivation of human dermal fibroblasts.[122,123] These and other studies[11] confirm the nearly linear correlation between fiber diameter and characteristic void size in electrospun mats. Several empirical efforts to exert some control over the packing density and patterning of the mat have been reported. These include the use of special collectors, for example, coated vitreous enamel substrates with tailored dielectric properties and coating thicknesses,[124,125] the variation of composition of mixed solvents,[126] and the introduction of sacrificial components such as salts, ice crystals, beads, an extractable blend component, or a second extractable fiber type.[122,127,128] The results of such methods are mixed, however. Removal of sacrificial components has been reported to either decrease or increase porosity and pore size, depending on such factors as capillarity and the thermal transitions of the polymer component left behind.

1.127.5. Summary and Conclusion

In this review, we have attempted to summarize some of the important results from ongoing research into the fundamental physics that govern the electrospinning process. The idea has been to provide a few guiding principles for those who would use electrospinning to fabricate materials for biological or biomedical applications, and to instill an appreciation for the richness and complexity of the phenomena that are responsible for the formation of such materials. We have outlined the flow processes involved in the electrified meniscus and those associated with the jetting process. The relevant processes are the steady thinning jet, whose behavior can be understood quantitatively using continuum equations of electrohydrodynamics, and the ensuing fluid dynamical instabilities that give rise to whipping of the jet. The current carried by the jet is of critical importance to the process, and some scaling aspects concerning the total measured current have been discussed. The resulting materials are equally rich in their diversity of structure and morphology. Solvent evaporation and solidification of the jet into a fiber, and arrest of the filament-stretching process, are areas that merit further attention. These processes play a role in setting both the diameters and the textures of the ensuing material. Since electrospun materials are frequently used as scaffolds in biomedical applications, a discussion of some aspects of the electrospun mats thought to be particularly relevant to such applications, such as fluid repellency, mechanical properties, and pore size distribution, has been included. We hope that, armed with such guiding principles, the biomaterials community may be better prepared to advance the applications of electrospun material in this field.

Glossary

Catheter An intraluminal medical device, typically tubular in design, inserted to gain transient access (minutes–days) to tissues, blood, or organs within the human body; can be single or multiple lumen.

Emulsion A dispersion of one immiscible liquid phase within another, stabilized by interfacial surfactants; microdroplet suspensions.

Fluoridated Ionic or electrostatic association of fluoride anion with a cation in a metal or ceramic salt or material.

Fluorinated Covalent attachment of fluorine to another element (e.g., C, S, P) in a molecule or material.

Microporous Open pore structure within a bulk solid of a scale of one to several hundred microns in pore diameter.

Perfluorinated Complete replacement of C–H bonds with C–F bonds.

Perfluoropolymer A polymer where hydrogen has been replaced completely by fluorine (e.g., PTFE).

Plasma Two very distinct meanings with contextual differentiation: (1) the complete milieu of blood but without the cellular fraction (i.e., all soluble, noncellular components), or (2) a highly excited and extremely reactive gaseous phase containing many reactive species used for cleaning or etching surfaces, or depositing chemical coatings, depending on the chemistry and excitation energies.

Plasma expander A therapeutic nontoxic material with high intrinsic oxygen-carrying capacity used to supplement blood volume and function *in vivo* in cases of acute blood loss.

Surface energy The free energy resident at a solid surface or liquid interface (typically with gas or air) that drives adsorption events, surface rearrangement of molecules, and physical and chemical reactions at this surface.

Abbreviations

ACL	Anterior cruciate knee ligament
A-V	Arteriovenous
CTFE	Chlorotrifluoroethylene (monomer or repeat unit)
ECM	Extracellular matrix
ePTFE	Mechanically expanded, porous PTFE
ETFE	Ethylene tetrafluoroethylene, a copolymer of non-fluorinated ethylene monomer and perfluorinated ethylene monomer
FDA	US Food and Drug Administration
FEP	Fluorinated ethylene propylene, a copolymer of tetrafluoroethylene (TFE) and hexafluoropropylene (HFP)
HDPE	High density poyethylene
HFP	Hexafluoropropylene
IOLs	Intraocular lenses
MRI	Magnetic resonance imaging
PCTFE	Polychlorotrifluoroethylene polymer homopolymerized from the chlorine-fluorine-containing CTFE monomer
PE	Polyethylene
PET	Poly(ethylene terephthalate) polyester
PFA	Perfluoroalkoxy
PTFE	Poly(tetrafluoroethylene)
PVDF	Poly(vinylidene fluoride)
RGDS, PHSRN, YIGSR, IKVAV	Cell adhesion peptide motifs
RGPs	Rigid gas permeable contact lenses
TIPS	Trans-jugular intra-hepatic porto-systemic shunt
TMJ	Temporomandibular joint

1.128.1. Introduction

Materials that contain substantial amounts of covalently attached fluorine are classed as fluorinated or perfluorinated materials. These fluorinated liquids and solids are chemically and physically distinct from fluoridated hydroxyapatites, bioactive glasses and ceramics, dentifrice compounds, cements, and other ceramics where fluoride ion (F^-) is complexed into the material using salt or ionic formulations. Fluorinated biomaterials have a substantial history in various medical device applications and their use and development is important currently. As with other materials, structure–property relationships are critical to why fluorinated biomaterials offer distinct properties of interest to medical device applications. Understanding these properties requires some introduction to the chemistry of fluorinated compounds and why chemical attachment of high amounts of fluorine atoms produces beneficial biomaterials properties. As primary materials of biomedical interest, fluoropolymers comprise a family of highly fluorinated thermoplastic carbon-based polymers analogous to polyethylene (PE) in which some or all of the hydrogen atoms attached to the carbon polymer chain are replaced by fluorine or pendant fluorinated alkyl groups. Other halogen atoms such as chlorine are also included in some polymers.[1] Interests in and applications for fluorinated materials have increased significantly as DuPont scientist, Roy Plunkett, first serendipitously discovered polytetrafluoroethylene (PTFE) in 1938 as a pioneering perfluorinated polymer: a slippery white powder inside a canister of tetrafluoroethylene (TFE) gas, now well-recognized as Teflon™. Prior to 1937, only three pure perfluorocarbons were known, and none was solid: carbon tetrafluoride, hexafluoroethane, and TFE. However, numerous fluorochemicals and fluoropolymers have since been invented and commercialized, and now used in excess of 90 kt annually: primarily PTFE, but also poly(vinylidene fluoride) (PVDF) and other minority fluoropolymer chemistries. Notably, fluoropolymers show unique properties distinct from other polymeric materials, including chemical inertness, extreme hydrophobicity and solvent resistance, low coefficients of friction, and temperature resistance.[1] These properties facilitate their wide use in certain biomedical applications where most hydrocarbon-based materials fail. However, fluoropolymers are often considerably more expensive.

In 1949, shortly after PTFE's commercial launch as DuPont's Teflon™ product, fine Teflon™ shavings were implanted into the canine peritoneal cavity and found to produce no observable acute inflammatory changes or overt tissue reactions in the peritoneum.[2] Thin fibrous sheaths containing fibroblasts were observed to surround the plastic pieces, but the Teflon™ surface was apparently not biologically reactive to their eyes. On the basis of this initial promising outcome, the first practical biomedical applications for Teflon™ mesh were proposed.[2] However, fabrication processes to alter this material proved (and continue to prove) challenging and limiting to its use. In 1963, Oshige (Sumitoma Electric Industries, Osaka, Japan), discovered a process for expanding PTFE films to produce highly uniform, continuous fibrous porous structures. These materials retained their microstructure but with vastly improved mechanical strength after thermal processing.[3] In 1972, this expanded fibrous material was first used experimentally as a venous graft substitute[4] and as an arterial bypass implant 1 year later.[5] In 1976, expanded PTFE (now generally referred to as ePTFE) was refined to production scales by Gore (USA), allowing expanded access and clinical use in commercialized biomedical products.[6] This allowed this interesting, unique fluorinated biomaterial to be developed for many biomedical applications, both inside and outside the living host. While fluorinated polymers are expensive raw materials and often exhibit challenging processing conditions, their device fabrication properties, namely, intrinsic lubricity and broadly observed biocompatibility in certain conditions, resulting from fluorinated chemistry, are two key properties sought in their biomedical technologies. Understanding certain aspects of fluorinated chemistry is important to appreciate their value to biomedical products.

1.128.2. Fluorinated Polymer Chemical and Physical Properties

1.128.2.1. Fluoropolymer Properties Derived from Chemistry, Molecular Structure, and Bonding

Replacing large amounts of hydrogen in C–H bonded materials with fluorine to create C–F chemistry produces dramatic changes to the material's physical and chemical properties. Fluorine's highest electronegativity polarizes the C–F bond, facilitating irregular hydrogen bonding patterns with other materials. The C–F bond is the strongest carbon bond, some 25 kcal mol^{-1} stronger than C–Cl.[7] This, with fluorine's intrinsically poor leaving group ability, makes alkyl fluorides 10^2–10^6 times less reactive than the corresponding alkylchlorides in certain solvolysis and displacement reactions, improving chemical stability.[7] Adjacent aliphatic bonds are also strengthened by fluorination (the CF_3–CF_3 bond is 10 kcal mol^{-1} stronger than the CH_3–CH_3 bond).[7] Extraordinary thermal and chemical stabilities of perfluorinated materials result from this chemistry. Fluorine's high ionization potential and low polarizability support a tendency for relatively weak intermolecular forces, low interfacial energies, and low refractive indices in fluorinated materials. Partially fluorinated commercial polymers, polyvinylidene difluoride (PVDF) and ethylene tetrafluoroethylene copolymer (ETFE), have zig-zag polymer chain conformations with different C–F dipole alignments along the chain,[7] while perfluorocarbons with only C–F bonds assume helical chains orientations with C–F dipoles distributed axially around the backbone helix.[8–14] PTFE, for example, as a model of very high molecular weight perfluorocarbon chain, is known to have a rich phase diagram of several distinct helical chain solid phases (Figures 1 and 2).[15]

1.128.2.2. Perfluorinated Surfaces

High levels of materials fluorination from this same C–F bonding chemistry presented at surfaces show unique molecular structure–property relationships, imparting specific, technologically attractive interfacial properties. Perfluorinated surfaces

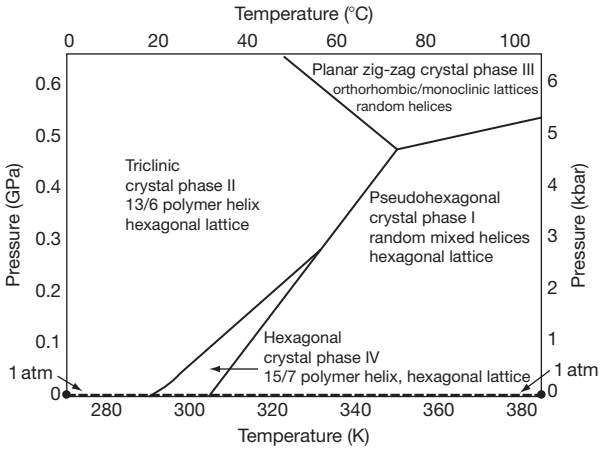

Figure 2 Polytetrafluoroethylene (PTFE) pressure–temperature solid phase diagram. PTFE's phase behavior first reported in 1954 and further refined exhibits two crystalline transitions at 19 °C (phase II) and 30 °C (phase IV) at atmospheric pressure (dashed line indicated as 1 atm). Substantial polymer chain molecular motion within these crystals is observed in this temperature range far below PTFE's melting point (~340 °C). A first-order phase transition at 19 °C between phases II and IV unravels the polymer crystal helical conformation from a well-ordered triclinic structure with 13 atoms/180° turn to a partially ordered hexagonal phase with 15 atoms/turn. Heating phases II and IV above 30 °C produces further rotational helical disordering and untwisting to yield a pseudo-hexagonal structure I with dynamic conformational disorder but retaining long-range positional and orientational order. These phase changes in PTFE solid structure affect PTFE's mechanical stability and use at body temperature (37 °C), particularly under pressure or stress in device applications. Three unique PTFE crystalline phases possible at ambient pressure near both room and body temperature influence PTFE's solid properties, relevant to many applications dependent on its solid-state phase mechanics under those conditions. [b]$mN\,m^{-1}$, from Smart, B. E. In *Organofluorine Chemistry: Principles and Commericial Applications*; Banks, R. E., Tatlow, J. C., Smart, B. E., Eds.; Plenum: New York, 1994 ($\gamma_{l/v}$ values).

often demonstrate low solid-state surface free energy (or surface tension), lubricity, and chemical resistance and durability. Perfluorocarbon liquids exhibit the lowest interfacial free energies, designated $\gamma_{l/v}$, (also known as surface tension[7]) – see values comparing hydrocarbon and perfluorocarbon liquids, **Table 1** – spreading spontaneously ('wetting') over nearly all solid surfaces, a result of perfluorocarbons' intrinsically low intermolecular forces. **Table 1** also shows that fluorinated liquids always exhibit lower surface free energies than their hydrocarbon (shown) or partially fluorinated liquid analogs (data not shown). **Table 1** data evidence solid perfluorinated PTFE exhibiting lower interfacial free energy (consistent with its Zisman critical surface tension γ_c values)[7,8,15] than its PE analog or partially fluorinated copolymers (e.g., PVDF, ETFE), correlating directly with PTFE's recognized utility as a low energy, low adhesion, low friction surface. Substituting either hydrogen or another halogen for fluorine along the polymer backbone results in significant increases in solid-state interfacial free energy values (as seen by comparing PTFE with high density polyethylene (HDPE), PVDF, and ETFE in **Table 1**). For further details, please refer to **Chapter 6.603, Ultrahigh Molecular Weight Polyethylene Total Joint Implants**.

Lowest solid surface free energies[1] are generally attributed to ambient, organized exposure of $-CF_3$ groups: a very low γ_c or $\gamma_{s/v}$ value is measured for close-packed, organized monolayers of nearly vertically aligned $CF_3(CF_2)_{10}COOH$ molecules coated on a solid, closely packing the ambient-exposed terminal CF_3 groups.[16,17] Substituting only one hydrogen for one fluorine in this terminal, exposed CF_3 group increases the surface free energy to a less impressive value of $15\,mN\,m^{-1}$.[17] Maximizing the surface density of exposed CF_3 groups reduces solid surface tension by exploiting CF_3 group orientation/organization/presentation. In fact, several coating strategies have sought to place and then orient CF_3 groups on surfaces using various means without a perfluorinated base material or perfluoropolymer matrix. Because adjustments of the surface density and organization of these groups are necessary to achieve low surface tensions, presenting the CF_3 group alone at surfaces is insufficient to reduce solid surface free energies to useful levels. Alignment of alkyl chains terminating in this perfluorochemistry at the surface is required: surface tension reduction proceeds to a minimum as chain length approaches $n = 8–10$.[18] Coupling this with surface chain organization can often change this requirement: organized monolayers comprising long-chain surfactant $CF_3(CF_2)_n(CH_2)_{16}COOH$ reduce surface free energy over that observed for oriented monolayers of shorter $CF_3(CF_2)_nCOOH$ when $n{\sim}6$.[17] Additionally, orienting side chains in polymer films comprising perfluoroalkyl side-chain acrylates and methacrylates to enrich surfaces with side-chain terminal CF_3 groups[17,19–21] achieves low interfacial energies. Perfluoroalkyl-grafted polysiloxanes also exhibit side-chain orientation to reduce surface tension via presentation of their perfluorinated chemistry, sometimes with spontaneous perfluorinated group organization.[22–26]

1.128.3. Fluoropolymers

Fluoropolymers can be classified into homopolymers and copolymers on the basis of the monomer(s) used in their respective polymerizations. These can be either completely (perfluorinated) or partially fluorinated on the basis of the amount of fluorine in the main chain. **Table 2** lists some currently available commercial fluoropolymers and manufacturers. Although most fluoropolymers share general properties (e.g., thermal and chemical stability, lubricity), their mechanical properties are slightly different, depending on whether they are fully fluorinated or contain fractional hydrogenation. Generally, fully (per)fluorinated polymers exhibit greater elongation and higher maximum service temperatures than partially hydrogenated fluoropolymers, with latter also exhibiting higher stiffness. **Figure 3** compares some mechanical properties for different fluoropolymers.[15]

1.128.3.1. Polytetrafluoroethylene

PTFE (DuPont trade-name Teflon™) is perhaps the most typically cited fluoropolymer. As described for its chemistry above, size and mutual repulsion of adjacent fluorine atoms, PTFE macromolecular chains exhibit a twisting helix comprising 13 CF_2 groups per 180° turn, distinct from the classic PE hydrocarbon's planar zig-zag chain.[21] **Figure 1** shows this important chain conformational distinction that imparts certain fluoropolymer physical properties. Helical PTFE chains (often of very high molecular weight from the polymerization of the gaseous monomer TFE) pack into solid crystallites (see phase diagram, **Figure 2**) comprising long parallel rods where individual molecules can slip over each other as quasicylindrical masses under shear stress. Mutually repulsive forces of adjacent fluorine atoms keep the PTFE chain backbone rigid, with low energy barriers to chain slip events due to low chain–chain cohesive energies. Tight helical presentation of fluorine atoms in highly crystalline PTFE polymers (**Figures 1** and **2**) lowers the surface free energy, giving PTFE a low coefficient of friction and low adhesion properties.[1,7,15] Its very high bulk solid

fractional crystallinity in all solid state phases, means that the PTFE polymer scatters light of most visible wavelengths, resulting in PTFE's characteristic opaque white color. Importantly, Figure 2 also indicates that solid PTFE exhibits two crystalline helix-based transitions at 19 °C (phase II) and 30 °C (phase IV) at atmospheric pressure, altering the polymer crystal's helical conformation from a well-ordered triclinic structure with 13 atoms/180° turn[21] to a partially ordered hexagonal phase with 15 atoms/turn between 19 and 30 °C. Heating both phases II and IV above 30 °C produces further helical disordering and untwisting, producing a pseudohexagonal structure I. These changes in PTFE solid structure alter PTFE's solid-state mechanics. Three unique PTFE crystalline phases possible at ambient pressure near both room and body temperature indicate that PTFE's mechanical properties, including cold creep, in many applications depend on its phase transitions under those conditions.

As a result, PTFE is the most lubricious polymer available, with a low coefficient of friction (0.1). This property is a major selection criterion for manufacturing fluoropolymer tubing used in medical devices. Unfortunately, this also makes PTFE solids very susceptible to cold flow (creep) under stress – a major reason for their poor performance in mechanical and repetitive wearing applications (i.e., poor bearing and joint surfaces). For examples, the original Teflon hip prosthesis cup developed by Sir John Charnley in 1956,[27] and the proplast-Teflon temporomandibular joint (TMJ) implant, developed formerly and sold by Vitek (USA) more recently, represent such failed biomedical mechanical PTFE applications. Furthermore, mechanical failure and tribological wear can break down PTFE into particles that can induce intense foreign-body reactions and also prompt bone resorption around the implant. Because of the increasing number of clinical reports of implant failure of Vitek's devices, the US Food and Drug Administration issued a nation-wide safety alert in 1990, and subsequently recalled Vitek's devices. Even after Vitek declared bankruptcy from rising litigation costs, it continued to market the TMJ implants, and surgeons still used them, until eventually the FDA seized all products from Vitek as well as its subsidiaries.[28,29] For further details, please refer to **Chapter 5.517, Tissue Engineering of the Temporomandibular Joint**.

Lastly, PTFE's extremely high molecular weights (e.g., $>10^6$) and rigid helical chain conformation manifest themselves in PTFE's high melt viscosities (e.g., 10^{12}–10^{12} Pa s^{-1}) that are ~6 times higher than that for most thermoplastic polymers. This is excessive for conventional melt processing methods used to fabricate thermoplastic medical devices (e.g., extrusion and injection molding). PTFE's high melt viscosity requires a high continuous service temperature (i.e., ~260 °C) for its processing into devices. Processing technologies for PTFE are similar to those of powder metallurgy, involving form-casting of prepolymerized PTFE granulated powders or latex formulations, followed by compression and sintering. PTFE's high thermal stability is key to success in processing under these conditions.[1,7]

1.128.3.2. ePTFE (Gore-Tex™)

When extruded under conditions of anisotropic loading, PTFE solids can be fabricated into highly porous solids with fabric-like properties. Using a series of mechanical operations – extrusion, rolling, and stretching – a biaxially stretched PTFE microporous membrane is produced, first by stretching in the longitudinal direction parallel to the rolling direction, and second by stretching perpendicular to the axis of the initial

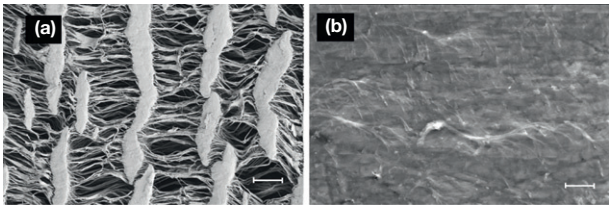

Figure 4 (a) Scanning electron micrograph (SEM) of expanded PTFE (ePTFE) showing regular node-fiber open materials structure (scale bar, lower right corner = 10 μm; we kindly acknowledge B. Wagner, W. L. Gore & Associates, Flagstaff, AZ, USA, for the ePTFE micrograph). (b) SEM of solid surface of Teflon™ (P. Hogrebe is acknowledged for these SEM micrographs) showing the cross-sectional porous structure from the compressed sintering of PTFE particles and dense continuous top surface (scale bar = 10 μm).

stretch. The resulting expanded Teflon™ microarchitecture (called ePTFE) exhibits pores axially aligned along the direction of stretch, resulting in a unique material with an oriented microporous architecture, eventually commercialized as Gore-Tex™.[6] ePTFE (initially Gore-Tex) is a porous structural material characterized by consistent PTFE nodes interconnected by PTFE fibrils (**Figure 4(a)**). The morphological characteristics of ePTFE compared to solid PTFE are contrasted in **Figure 4(a)** versus **4(b)**, respectively. ePTFE internodal spacing or distance (i.e., PTFE fibril length between solid PTFE nodes) is often used to describe and control biological behavior.[30] ePTFE exhibits high strength, a smooth external surface, and billions of continuous superfine interconnected fibrils per square centimeter. Pore size can be controlled by mechanical processing from 1 to 100 μm[31] while retaining properties similar to PTFE, for example, biological adsorption, low tensile strength, low modulus of elasticity, chemical stability, and ready sterilizability. Porous ePTFE structures also provide versatile options to mechanically modulus-match this material to tissue sites better than other polymers for many soft biological tissue applications.[32] Porosity also importantly encourages in-growth of tissue and hence moderate levels of tissue fixation, even when bulk PTFE does not exhibit this property.

1.128.3.3. Fluorinated Ethylene Propylene

Fluorinated ethylene propylene (FEP) is a copolymer of TFE and hexafluoropropylene (HFP), first produced by DuPont in 1956 (Teflon™ FEP) to reduce PTFE's high crystallinity and melt viscosity, and thereby improve its processing characteristics. Bulky FEP perfluoromethyl groups produce defects in solid polymer FEP crystallites, reducing the polymer melting point, impeding chain slip, and reducing solid cold flow.[33] FEP combines the unique mechanical and chemical properties of PTFE with the melt-processability of more conventional polymers. FEP has a maximum service temperature of 204 °C and a slightly higher coefficient of friction.

1.128.3.4. Other Fluoropolymers

Besides PTFE, ePTFE, and FEP, other fluoropolymers have not been commonly accepted for use as biomedical materials. They are more typically used in nonmedical industry. ETFE is a copolymer of monomers TFE and ethylene, first produced by

DuPont in 1970 (Tefzel™), with a higher tensile strength and lower creep than PTFE, FEP, or perfluoroalkoxy (PFA) as a result of ETFE's planar zig-zag chain configuration and strong electronic interactions between the bulky CF_2 units on one chain and smaller CH_2 groups of adjacent chains.[1,15] PVDF is a homopolymer of vinylidene monomer (CH_2CF_2), and sold as Kynar™. PVDF has the highest flexural modulus of all fluoropolymers because of interpenetration of larger CF_2 groups crystallizing with adjacent smaller CH_2 groups on adjacent chains. Unlike other fluoropolymers, PVDF is soluble in highly polar solvents (e.g., dimethylformamide, tetrahydrofuran), acetone, and esters.[1] PVDF's high dielectric constant, high dielectric loss factor, and interesting piezoelectric behavior under certain conditions result from this chemistry and resulting solid state structures. Fluorine' shielding effects to all neighboring CH_2 groups provide PVDF with good chemical resistance and thermal stability[15,33] PCTFE (polychlorotrifluoroethylene) is homopolymerized from the chlorine-fluorine-containing chlorotrifluoroethylene (CTFE) monomer. Regular introduction of Cl atoms along the polymer chain promotes chain–chain attractive forces. This lowers PCTFE's melting point and reduces its electrical and chemical resistance properties.[34] Removal of chlorine is more facile than fluorine, leading to some chemical, thermal, and photo-stability issues. PCTFE is melt-processed with difficulty because of its high melt viscosity but has improved mechanical properties with greater hardness, tensile strength, and better resistance to cold flow compared to PTFE.

1.128.3.5. Fluoropolymer Processing

Fluoropolymers are commonly processed into products by solid melt extrusion, where polymers develop flow upon melting in normal extrusion equipment. This technique exposes fluoropolymers to very high temperatures in order to reduce viscosity and improve flow characteristics for extended production runs and product lengths. Owing to its high crystallinity and processing problems, PTFE is often processed by a more complex, multistep treatment termed 'paste extrusion.' Fluoropolymers such as FEP, PFA, and PVDF will readily melt-flow when heated, typically above 260 °C. This permits uninterrupted feed of polymer resin into the extruder to produce long continuous lengths of product (i.e., tubing). By contrast, PTFE extrusion is limited by the requirements for its paste handling, size of the polymer stock preform, and tubing. Nonetheless, because PTFE is not melt-processable like other polymers, this presents an important opportunity: PTFE tubing important for several biomedical applications can be manufactured to tighter size tolerances, with wall thicknesses as small as 25 μm and tolerances of ±10 μm. This benefit is largely due to PTFE's inability to melt flow, allowing more precise control over its use in extrusion forms. This property is essential for producing medical products requiring tight tolerances such as small-diameter and multilumen tubing with multiple precision passages (i.e., for advanced catheters). Because fluorinated polymers are generally expensive, their appropriate or unique properties must justify their applications for biomedical use over less expensive materials. For further details, please refer to **Chapter 4.406, Protein Interactions with Biomaterials** and **Chapter 1.122, Structural Biomedical Polymers (Nondegradable)**.

1.128.3.6. Fluorinated Coatings[35]

In many fluid matrices, low interfacial energies for most perfluorinated liquids and solids drive partitioning of this material to interfaces with air to minimize surface energies, a process commonly called 'blooming' in the coatings industry. This means that desirable low surface tension, lubricity, durability, and chemical inertness associated with perfluorinated species might be imparted to surfaces selectively without requiring the entire bulk material (where such properties may not be needed) to be fluorinated. This reduces the expense of using perfluorinated materials, exploits the intrinsic fluid properties for many lower molecular weight fluorinated precursors for coating applications, and allows many modes of application (i.e., dipping, coating, spraying, painting) over prefabricated components of complex shape. Perfluorinated chemistry is known to migrate to surfaces spontaneously if permitted kinetically (i.e., in liquid coatings that are cured into films).[35] Film formation and coatings from perfluorinated components take place readily, both as applied over layers as well as when bloomed from bulk liquid mixtures, because of their surface energy-lowering properties. This has significant cost advantages as materials bulk fluorination costs and associated processing are quite expensive. Additionally, coatings-only properties are often preferred as bulk fluorinated materials mechanical properties are less than ideal (e.g., creep and flow in PTFE), despite intrinsic interfacial mechanical and wear limitations in these coatings. Emphasis on surface-fluorinated coatings and films has therefore increased as technological drivers provide impetus for new, improved, and less expensive methods to put this value-added chemistry on surfaces. Plasma-deposited fluorinated coatings (i.e., from gaseous precursors reacted under high energy excitation) are well developed for this purpose as well,[36] representing a mature industry and biomedically relevant materials treatment (e.g., for intraocular lenses, IOLs).[37] Lastly, while several different methods are reported to deposit PTFE-like thin overlayers onto surfaces as coatings (i.e., e-beam/laser sputtering from solid PTFE targets, vacuum evaporation) pulsed laser deposition of fluorinated chemistry has been shown to yield higher quality PTFE-like coatings.[38]

1.128.4. Biomedical Applications of Fluorinated Biomaterials

Table 3 provides a list of fluoropolymers applied as biomedical materials. Fluorinated solids, liquids, and coatings find widespread biomedical applications, particularly popular as transient clinical interventional and luminal access devices (i.e., catheters in many forms), more permanent implants (cardiovascular,[39] dental,[40] ocular,[41] craniofacial,[42] urological,[43] and abdominal[44] applications), and in biotechnology *in vitro* components (reagent dispensing tubing, protein blotting and filtration membranes). Annually, millions of perfluorinated polymer components are used worldwide in biological milieu both *in vitro* and *in vivo*. PTFE (e.g., Teflon™) and ePTFE (e.g., Gore-Tex™) are widely used in medical tubing, advanced catheters, vascular grafts, meshes, sutures, and other medical implants. For further details, please refer to **Chapter 1.122, Structural Biomedical Polymers (Nondegradable)**. PVDF is used for biotechnology blotting/separation membranes.

Table 3 Fluoropolymer biomedical application chronology

Decade	*Fluorinated materials medical applications*
1970s	Implantable vascular grafts, peripheral catheters, and introducers
1980s	Guiding catheters, protein blotting membranes, tissue meshes, dialysis shunts
1990s	Stents, perfluorinated oxygen carriers, lens cores, IOL coatings
2000s	Perfluorinated imaging/targeting microparticles, combination drug delivery

Fluoropolymer surface properties desired in these biomedical applications appear to be divided into two distinct behaviors, specifically seeking to exploit claims that fluoropolymer surfaces (1) resist microbial colonization and cell attachment, and (2) readily adsorb, transfer, and filter proteins from aqueous-based gels and milieu for bio-separations and analysis. Both biomedical performance goals result from common inseparable consequences of the strong interactions of low-energy fluoropolymer surfaces with soluble proteins in physiological systems. While fluoropolymers are often regarded as chemically inert, their surfaces are not inert to protein adsorption, either *in vitro* or *in vivo*. In fact, extremely tight binding of serum albumin to fluoroplasma-deposited surfaces,[45] high levels of fibronectin and hemoglobin on PVDF,[46] various serum proteins,[47] significantly adsorbed fibrinogen,[48] and high levels of both fibronectin and albumin[49] on PTFE are observed *in vitro*. Importantly, protein adsorption to fluoropolymers is also observed *in vivo*[50,51] and correlated with platelet activation responses often observed on ePTFE vascular graft materials *in vivo*.[50,52,53] Importantly, nonspecific serum protein adsorption is significant and often irreversible on fluoropolymer surfaces, leading to their utility as blotting membranes, deliberately protein-masked assay components, and chemically cleanable surfaces in biotechnology batch reactors. For further information, please refer to **Chapter 4.406, Protein Interactions with Biomaterials**.

Nonetheless, because of high uptake of proteins not conducive to engaging most cell receptors, general cell attachment for numerous cell types and clinically observed host endothelialization are recognized as poor on *nonporous* solid fluoropolymer chemistries[41,47,50,53–55] with the apparent exception of macrophages[56] and neural cells seeded onto preadsorbed albumin on chemically modified patterns on PTFE.[57] In contrast, porous fluoropolymers with 60–80 μm voids, including ePTFE, promote cell and bacterial in-growth by porous, physical integration and infiltration despite protein adsorption.[58,59] While adsorbing proteins and activating platelets in blood, fluoropolymer's plasma protein conditioning film[60] does not support ready cell attachment, mandating preclotting with fibrin, or treatment with an adhesive over layer of protein matrix (e.g., collagen or fibronectin) to promote reliable cell adhesion.[61,62] For further details, please refer to **Chapter 2.207, Extracellular Matrix: Inspired Biomaterials** and **Chapter 4.411, Peptide- and Protein-Modified Surfaces**.

Serum albumin, the largest mass fractional protein component in blood, is known to hinder cell attachment and block nonspecific binding,[63,64] while fibronectin, collagens, and other subtle trace matricellular proteins (e.g., osteopontin, laminin, vitronectin) – as important components of extracellular matrix (ECM) – enable integrin receptor-based cell attachment and proliferation on surfaces. Hence, observed fluoropolymer inability to support cell attachment is plausibly related to ratios of nonadhesive (e.g., albumin) to adhesive (e.g., fibronectin) proteins selectively adsorbed to fluoropolymer surfaces from multicomponent solution (e.g., plasma or serum).[49] A critical adsorbed density of ECM proteins in a mixed adsorbed protein layer must be readily recognized by cell-resident adhesion receptors (e.g., integrins). For further details, please refer to **Chapter 2.207, Extracellular Matrix: Inspired Biomaterials**; **Chapter 4.411, Peptide- and Protein-Modified Surfaces**; and **Chapter 4.414, Molecular Biomimetic Designs for Controlling Surface Interactions**.

In addition to surface *density*, adsorbed ECM protein structural *conformation* on surfaces must also permit cell receptor access to putative cell binding motifs on these surface-adsorbed proteins (e.g., RGDS, PHSRN, YIGSR, IKVAV peptide motifs)[65,66] *in situ* in order to facilitate ready cell attachment and spreading. For further details, please refer to **Chapter 4.414, Molecular Biomimetic Designs for Controlling Surface Interactions**. Commercial bioadhesive cell culture protein formulations (e.g., Pronectin™, Biocoat™, or Matrigel™) artificially bias these ECM density requirements for adhesive proteins in order to overcome deficiencies in surface chemistry to successfully adhere cells independent of surface chemistry. However, direct fluoropolymer *in vivo* exposure to blood plasma containing thousands of soluble proteins simultaneously cannot ensure such cell-adhesive protein adsorption bias. Because all fluoropolymer surfaces adsorb substantial amounts of these proteins irreversibly, both amounts and conformations of adsorbed ECM proteins (e.g., collagens, fibronectin), competing with the majority nonadhesive serum proteins, determine subsequent cell attachment behavior on fluoropolymer surfaces. Therefore, while fluoropolymers can become 'passivated' by non-ECM protein coating, there is little evidence showing that fluoropolymers are intrinsically 'biologically inert' or passive to classical biological reactions (i.e., adsorption, blood activation, microbial attachment). In fact, the opposite is true: fluoropolymers are intrinsically reactive and adsorptive to almost every protein studied. Implanted device interfacial response to fluoropolymers is then a product of its adsorbed protein conditioning film. As most host protein content comprises albumin – a non-ECM plasma protein with little intrinsic cell interaction capability – under most serum- or blood-contact conditions, fluoropolymers are rapidly coated with a matrix mostly comprising albumin. This is then modified over time with continuous host protein and cell exposure, producing the clinical performance observed and attributed to fluoropolymers. As albumin often passivates surfaces against blood contact activation, highly stable adsorbed albumin correlates with some nonthrombogenic interfacial properties attributed to ePTFE *in vivo*. For further details, please refer to **Chapter 4.406, Protein Interactions with Biomaterials** and **Chapter 4.411, Peptide- and Protein-Modified Surfaces**.

1.128.4.1. PTFE (Teflon™) and ePTFE (Gore-Tex™) Vascular Implants

A 1951 innovation facilitated the spinning of PTFE paste into PTFE fibers for weaving or knitting into fabrics or meshes.[67]

Attracted by PTFE's alleged consistent nonthrombogenicity demonstrated in early animal studies, PTFE weaves were applied in vascular grafts.[68] However, these early woven vascular grafts exhibited both high early failure rates and substantial late failure rates. Graft thrombosis was the most frequent early complication, accompanied by a high mortality rate.[69] ePTFE vascular graft designs supplanted these early PTFE weaves in blood-contacting applications (initially as Gore-Tex™ ePTFE), now with over 40 years of innovation in medical implants. An interesting long-standing legal controversy over the original inventorship of and rights to patent privileges for the synthetic vascular graft, centered largely on Gore's marketing of Gore-Tex for this application, is only recently settled in court.[70]

Microporous ePTFE graft prostheses were used initially for major thoracic venous and abdominal vein repair in 1972,[4] and shortly followed for use in arterial bypass.[5] The first commercial ePTFE vascular graft device (e.g., first as Gore-Tex™ and later as Impra™ brands) was clinically approved in the 1970s for vascular grafting and has since become a major device application for fluoropolymers in medicine. ePTFE fabrics have been used in tens of millions of implants in cardiac, vascular, and endovascular surgeries, neurosurgery, hernia repair, and thoracic reconstruction. Hemodialysis access and vascular by-pass and replacement applications represent the major ePTFE applications (detailed in **Section 1.128.4.3**). Implant performance is highly variable compared to other prosthetics and autologous vascular grafts, depending on many factors, including patient co-morbidities, anatomical site of placement, the surgical team and medical center, and human versus animal model.[71] For further details, please refer to **Chapter 6.628, Vascular Grafts**.

ePTFE's porous inner surface is often proposed as essential to promote formation of a beneficial host 'pseudo-intimal lining' that is thought to passivate the graft material against extended host thrombosis and inflammatory responses. Its porous outer surface promotes perigraft tissue infiltration that stabilizes the prosthesis in place, preventing kinking.[72] Another important role advocated for ePTFE's porous structure is natural promotion of transmural endothelialization (e.g., implant cell colonization and growth) by encouraging angiogenesis, first demonstrated in a nonhuman primate model[58] decades ago. This cell colonization strategy is also reported effective in rats,[73] sheep,[74] and dogs,[75,76] but with very limited success to date in humans.[77] Unlike most animal models, humans do not readily form neointimal endothelium in these grafts. However, host cell–ePTFE responses can be enhanced, at least *in vitro*, by introducing exogenous protein growth factors (e.g., fibroblast growth factor) to the graft surface.[73,78,79] Additionally, microporosity geometries can influence results: Higher graft patency rates were achieved for ePTFE prostheses with internodal distances below 22 μm placed in both canine carotid and femoral sites. Patency rates for prostheses with average microfiber lengths of 34 μm or longer were lower. In animal models, ePTFE prostheses with a microfiber length of 30 μm improved fibroblastic in-growth producing a thinner neointima than 90-μm long fibrial ePTFE prostheses, showing substantial host fibrotic response.[4] More recent studies of ePTFE vascular grafts of different internodal porosities (i.e., 10–90 μm) showed optimal intermodal distances of ~60 μm: the 10–30 μm fibril grafts failed to achieve luminal endothelial cell coverage, and 90 μm grafts showed pseudointimal endothelial cell loss in animals.[80–82]

Improving ePTFE vascular graft endothelialization remains a major strategy to improve ePTFE vascular device implant performance both *in vivo* and *in vitro*.[83–85] Host native endothelium plays a major role in inhibiting thrombosis and controlling intimal hyperplasia. Various strategies therefore seek to induce and retain host endothelialization of ePTFE graft surfaces either prior to implantation (preseeding with cells *in vitro*) or by accelerating host *in situ* graft endothelialization *in vivo*. Early clinical trials using ePTFE preseeding were disappointing and remain controversial. Limitations for graft preendothelialization methods are long recognized and challenging, specifically as they (1) are not practical for acute or emergency interventions, and (2) require preharvest of host venous endothelial cells to obtain sufficient endothelial cells to completely cover the graft luminal surface prior to implantation. The approach currently requires a two-stage procedure with technical skills and facilities for patient cell harvest, cell expansion, and cell seeding on-graft: an initial surgical intervention before cell-seeded graft placement by a second surgical procedure. Most importantly, while animal studies demonstrate efficacy of this method, human seeding does not yet result in a reliable neointima on vascular grafts. Human performance is distinct from animal models in this regard.[83]

To overcome these issues, *in vivo* endothelialization of the implanted graft *in situ* in the host is sought.[85] To facilitate host endothelial cell colonization of the implanted ePTFE surface, grafts must rapidly and reliably select host endothelial cells (and not, e.g., host macrophages or other leukocyte cells) from circulating blood. To encourage host cell adhesion, ePTFE surfaces are chemically modified prior to implantation with cell-specific adhesion synthetic peptides[85] to attract and engage circulating endothelial cells, endothelial progenitor cells,[86] and other less well-defined progenitor cells.[87] Endovascular PTFE-covered stents are reported to reduce in-stent restenosis – a major drawback of bare metal stents.[88,89] PTFE coating also improves trans-jugular intrahepatic porto-systemic shunt (TIPS) patency and decreases clinical failures for TIPS use.[90] Nonetheless, these PTFE-covered grafts still report high incidences of hepatic or portal vein stenosis.[91,92] PTFE-coating alone cannot improve this device: further improvements in stent design and insertion techniques are necessary.[93] For further details, please refer to **Chapter 4.411, Peptide- and Protein-Modified Surfaces** and **Chapter 6.628, Vascular Grafts**.

ePTFE (Gore-Tex) is currently used most widely to fabricate medium-size (4–10 μm internode) vascular grafts for use when autogenous saphenous vein grafting is not possible, or to replace damaged vessels,[94] bypass blocked arteries and veins,[95] and for vascular access in hemodialysis.[96,97] ePTFE vascular prostheses are most clinically successful in high blood flow, low resistance conditions (i.e., large peripheral arteries $>5\sim6$ mm diameters). However, to date ePTFE is not suitable for smaller arterial reconstructions (e.g., coronary circulation and peripheral vascular placements) under high-resistance, low-flow conditions. Typical ePTFE suffers from thrombosis, poor healing, lack of compliance, and excessive intimal hyperplasia leading to stenosis.[83] Surface biofunctionalization of ePTFE (and PTFE) seeks to improve ePTFE graft *in vivo* behavior by modifying the ePTFE surface with

diverse chemistry such as coatings, plasma treatments, and immobilization. For further details, please refer to **Chapter 4.414, Molecular Biomimetic Designs for Controlling Surface Interactions**

Anticoagulant (e.g., heparinized) coatings,[98,99] or local antiplatelet drug release or systemic therapy (e.g., platelet surface glycoprotein IIb/IIa inhibitors) and locally delivered antiproliferative agents (e.g., rapamycin) attempt to overcome intrinsic materials performance issues with varying success.[100,101] These modifications improve thrombosis and healing, and prolong graft patency in short-term animal studies.[85,102] Efficacy in human patients is not clear to date. For further details, please refer to **Chapter 4.411, Peptide- and Protein-Modified Surfaces** and **Chapter 6.628, Vascular Grafts**.

1.128.4.2. ePTFE and Teflon™ Tissue Meshes

Teflon meshes have been used to repair abdominal wall defects[103] and hernias.[104–106] Despite some success, original Teflon™ mesh does not reliably integrate into body tissues, is not infection-resistant, and manifests a rate of wound complications too high for routine use in hernia or abdominal repair. Early clinical failure of PTFE meshes in hernial applications prompted a switch to ePTFE meshes that remain the primary material clinically used to repair ventral hernia, incisional hernia, laparoscopic inguinal hernia, and other laparoscopic hernia repairs.[107] These mesh materials minimize risks of postoperative intestinal obstruction and bowel fistula.[108,109] As in the case of PTFE meshes in these applications, infection complications and intestinal obstructions remain for ePTFE mesh. However, they are better controlled with systemic antibiotic therapies without mesh removal. ePTFE meshes have also been used as abdominal surgery barriers against adhesions.[110,111] For further details, please refer to **Chapter 6.638, Biomaterials for Hernia Repair**.

ePTFE has been FDA-approved for use in facial plastic surgery for facial defect reconstruction and augmentation, including rhinoplasty,[112] mentoplasty, forehead defects, auriculoplasty, reconstructive lip augmentation, orbital repair, facial folds, for facial slings, and for cosmetic reconstruction in the nasolabia folds and glabellar creases. It is contraindicated in cosmetic lip augmentation, temporomandibular joint reconstruction, cardiovascular defects, and dermal placement.[113] Nonetheless, Gore and Advanta have discontinued marketing of their products for plastic surgery.

1.128.4.3. Arteteriovenous ePTFE Grafts for Dialysis Access

Hemodialysis – essential for patients with end-stage renal disease – often requires regular, repeated (weekly) access to large blood vessels capable of producing high flow rates through an external artificial kidney device. Hemodialysis patients typically undergo cannula puncture of skin, underlying tissue, and vasculature to provide this access to the external artificial kidney. Repeated trauma to patient skin, tissue, and blood vessels from 13- to 17-gauge access needles produces notable complications including hyperplasia, thrombosis, hematoma, occlusion, infection, and other morbidities. Vascular access complications remain the main reason for hemodialysis patient hospitalization. Synthetic ePTFE arteriovenous (A–V) grafts are surgically placed across the basilic vein and brachial artery to permit cannula access and reduce tissue trauma complications. A–V prosthetic graft failure rates are substantial (>50%), leading to increasing use of native fistulas and catheters.[93,114] However, synthetic grafts reliably provide high blood flow rates shortly after placement, as they do not require maturation before use. In A–V ePTFE grafts, stenosis occurs most commonly at the graft-venous anastomosis. Histologically, macrophages are seen in large numbers in the adventitial and medial layers in the anastomotic tissues from AV ePTFE grafts.[86,114] For further details, please refer to **Chapter 6.628, Vascular Grafts**.

1.128.4.4. Multilumen Catheters

Fluoropolymer multilumen medical-grade tubing is central to many new minimally invasive catheters that permit surgeons to perform several different invasive procedures through several lumens offered in a single inserted catheter device without removing one entire catheter to insert another. These *in vivo* exposures are short term, typically using endo-luminal femoral access, and increasingly minimally invasive. PTFE's unique processing properties facilitate multilumen precision manufacture, offsetting their higher materials expense.

1.128.4.5. Guiding Catheters

A work-horse interventional tool with a well-established history, the guiding catheter is used to deliver stents and other devices endoluminally. Central to the guiding catheter is a PTFE inner liner with its superior lubricity and low friction coefficient that slides within an outer lumen. Lubricity is so critical to this device function that FEP as the second-most lubricious (and perfluorinated) material available is insufficient as a catheter liner. During catheter construction, PTFE is chemically etched onto the tube's outer diameter to promote PTFE bonding to the outer diameter of the liner and enable slip. Bonding is accomplished by using an FEP heat-shrinkable fusing sleeve. The FEP mold can then be removed from the device, leaving a smooth outer PTFE jacket.

1.128.4.6. PTFE Introducer

With over 30 years of use, the PTFE introducer facilitates catheter clinical insertion into a patient's vein, taking advantage of PTFE's endo-luminal lubricity and precision tubing processing. Once the catheter is inserted, the PTFE sheath can be removed from the patient. The introducer exploits PTFE processing that molecularly orients the fluoropolymer material in the tubing-based sleeve over the device. When this is used, PTFE tubing can be readily split and torn longitudinally from the catheter *in situ*. This allows a surgeon to remove a PTFE introducer from a patient while the primary device remains in place.

1.128.4.7. Perfluorocarbon Liquids, Surfactants, and Emulsions as Oxygen-Carrying Blood Substitutes

Perfluorofluid and/or fluorinated surfactant properties valuable for biomedical applications include high specific gravity, spreading coefficient, high contact angle and low solubility with water, low refractive index, absence of protons, and

concentration of sufficient ^{19}F nuclei useful in magnetic resonance imaging (MRI). Low molecular weight perfluorinated fluids can be aspirated into the lungs directly or injected as submicron-sized emulsion droplets into the blood to facilitate oxygen transport, exploiting their high oxygen-carrying capacities.[87,115] Liquid perfluorocarbons in the lung eliminate the gas–lung interface, acting to reduce tension in the lung alveolus and reducing mechanical work required to breathe during respiratory distress and pathologies involving lung surfactant deficiency. Liquid perfluorofluids can be inspired into the lung in large volumes (i.e., filling the lungs) without adverse effects.[115] Dispersion of perfluorofluids in aqueous media using surfactants creates submicron emulsified perfluorodroplets much smaller than red blood cells. These liquid carriers provide enormous additional oxygen carrying capacity in blood supplementing normal oxygenation in microcirculation. Several clinical trials on various perfluorinated fluid oxygen carriers as 'plasma expanders' have been conducted, most recently on Oxygent™ (Alliance Pharmaceuticals, USA), but none has been approved for human use. This microemulsion formulation comprises two different perfluorocarbon fluids stabilized with egg phospholipids. Figure 5 compares the distinct oxygen carrying capacity of this perfluorinated fluid micronized emulsion versus whole blood.

Fluorocarbon emulsion-based injectable image contrast agents to enhance ultrasound *in vivo* imaging are already commercialized (e.g., Optison®, Definity®).[116–120] Perfluorinated emulsions are eliminated from blood after parenteral injection by macrophage/monocyte clearance and exhaled eventually from the lung largely unchanged chemically. Fluorinated surfactants, while generally much more surface-active than their hydrogenated analogs, are generally much less hemolytic.[115] As a testament to their relative safety, the US Food and Drug Administration has approved the ingestion of liquid perfluorinated octyl bromide ($C_8F_{17}Br$) in large volumes (l) as a contrast agent for intestinal imaging by ^{19}F-MRI.

1.128.4.8. Other Fluorinated Material Biomedical Applications

1.128.4.8.1. Fluorinated (meth)acrylates and (meth) acrylated perfluoroalkylated silicones as cross-linked polymer cores for soft contact lenses

Exploiting the intrinsic high oxygen permeability well known for perfluorinated materials, rigid gas permeable contact lenses (RGPs) have used many variations of cross-linked perfluorinated acrylates and perfluorinated silicone gels as lens cores to improve extended-wear lens' on-eye performance. Multiple patents describe diverse materials in this regard, with several major lens manufacturers developing these lens materials. For further details, please refer to **Chapter 6.633, Development of Contact Lenses from a Biomaterial Point of View – Materials, Manufacture, and Clinical Application**.

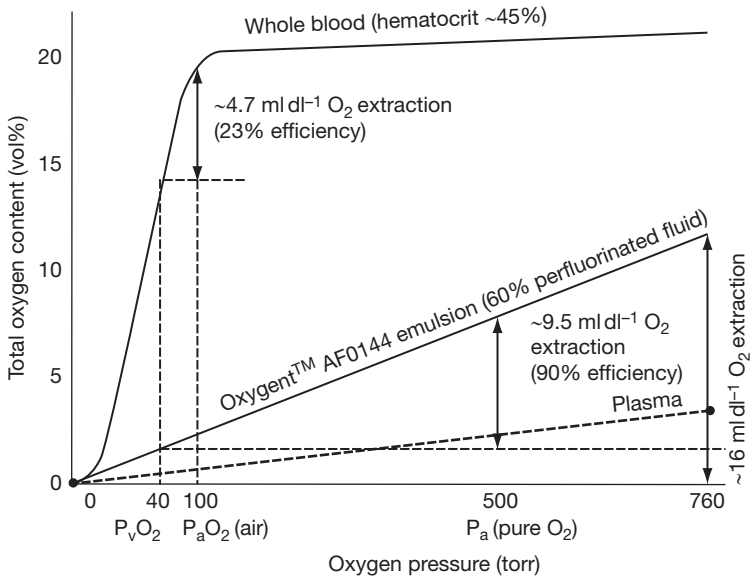

Figure 5 Comparison of efficiency of oxygen transport by a commercial emulsified fluorocarbon liquid (Oxygent™, phase III clinical trials) versus hemoglobin (Hb) in whole blood, and intrinsic oxygen solubility in plasma. In perfluorocarbon liquid dispersions, oxygen solubility is characterized by van der Waals interactions, following Henry's Law: oxygen solubility is linearly and directly proportional to oxygen's partial pressure. Oxygent™ is a 60 w/v% concentrated submicron perfluorofluid emulsion comprising primarily F-octyl bromide ($C_8F_{17}Br$, *perflubron*) with a small mass fraction of longer chain F-decyl bromide ($C_{10}F_{21}Br$). F-octyl bromide used as the perfluorofluid bulk phase is the empirical compromise between required emulsion stability in blood and a clinically acceptable physiological excretion rate. Emulsion stability increases with decreasing perfluorofluid water solubility (i.e., increasing molecular weight), while excretion diminishes exponentially with increasing molecular weight. By contrast, Hb as the oxygen carrier in blood exhibits specific coordinate bonding into the heme porphyrin iron atom and associated Hb amino acid stabilizing ligands as is well established. Successive binding of four oxygen molecules to all four hemes in each Hb is cooperative, and Hb saturation occurs when all four iron atoms bind oxygen. This results in the well-known sigmoidal shape of the oxygen saturation curve for blood that plateaus when the oxygen partial pressure in the atmosphere is attained. Lower total oxygen carrying capacity observed for perfluorinated fluid emulsions is balanced by their much higher oxygen extraction efficiencies. Adapted from Krafft, M. P.; Riess, J. G. *J. Polym. Sci. A Polym. Chem.* **2007**, *45*(7), 1185–1198.

1.128.4.8.2. Fluorinated coatings as antifouling coatings for IOLs

Cell adhesion to implanted polymer IOLs can produce complications with optical visual interference. To prevent occular cells from migrating onto and coating the implanted IOL device optical surface, thin optically transparent plasma-deposited fluorocarbon films, or layers of other fluorinated polymers are deposited on the IOL back surface. Several patents describe this approach and the IOL application. For further details, please refer to **Chapters 4.406, Protein Interactions with Biomaterials**.

1.128.4.8.3. PTFE paste injectable bulking agent

Teflon™ particles formulated into an injectable paste are reported for urological treatment of vesico-ureteric reflux (VUR)[121] in a large animal model, as it is corrected by subureteric injection of a PTFE paste.[122] Subureteric paste injection by endoscopy has successfully addressed primary and secondary VUR in children for nearly two decades.[123–125]

Similarly, PTFE paste is also used for decades to treat female stress urinary incontinence[126–128] with promising short-term results. However, this treatment does not have regulatory approval because of the associated high risk of PTFE microparticle migration and granuloma induction, especially in lymph nodes, kidneys, lungs, and brain.[129] Teflon™ paste injection nonetheless remains clinically effective and convenient in this application,[130–132] but its side effects concerns limit clinical use.[126]

1.128.4.8.4. Ligament replacement

The Gore-Tex™ ligament prosthesis comprises a single long fiber of ePTFE woven into multiple loops. Mechanical testing shows that the resulting ultimate tensile strength is ~3 times that of the human anterior cruciate knee ligament (ACL). Creep and bending fatigue testing validate this ePTFE device as a strong synthetic ACL replacement material.[133] *In vivo* in humans, 129 out of 130 patients implanted with a high strength ePTFE ACL ligament devices exhibited improved knee stability up to 15 months.[133] But initial improvements were followed by progressive prosthetic loosening.[134] Longer term follow-up of Gore-Tex ACL implant reconstructions showed a similar pattern of early improvement postoperatively with deterioration over time. Clinical failure rates of 33% were reported at 3-year follow-up.[135] Another study showed a 90% success rate at 2 years versus only a 76% success rate at 3 years or more.[136] The Gore-Tex ACL prosthesis is currently FDA-approved for use in patients with failed autogenous intraarticular graft procedures.[137]

1.128.4.8.5. Sutures

PTFE is also applied in suture fibers in various forms. Both PTFE monofilament and ePTFE fibers are surgically proven with desirable surgeon handling and lubricity properties. Additionally, PTFE is blended into other common surgical sutures used for myocardial heart valve prostheses fixation. Poly(ethylene terephthalate) (PET polyester) braided sutures are impregnated with PTFE polymer to limit wrinkling of the braid and consequent swelling. PTFE hydrophobic properties likely limit water uptake by the polyester braid, slowing its degradation by hydrolysis.[138]

1.128.5. Conclusion and Perspectives

Perfluoropolymers as solid and liquids, and perfluorinated coatings and films all offer unique properties to benefit certain biomedical devices and applications. High degrees of material fluorination produce unique chemical and thermal stability, very low interfacial energies and hydrophobicity, and low chain cohesion energies not only facilitating surface lubrication but also producing cold flow and poor solid mechanical properties. They also produce physical solid state properties that, while intractable for typical device processing applications, can be exploited using specialized approaches to yield very unique materials forms and dimensions benefiting catheters and tubing. Some of these properties are interesting and beneficial for biomaterials, both *in vitro* and *in vivo*. Fluorinated materials' reputation for 'biological inertness' is not supported by many *in vitro* assays that show substantial irreversible protein adhesion to surfaces of several perfluorinated materials chemistries. Poor cell adhesion generally characteristic of perfluorinated surfaces is instead attributed to surface binding of proteins nonadhesive to cells (e.g., albumin, lipoproteins) from blood, serum, plasma, and biological fluids that hinder cell–surface interactions. This 'tight' protein-surface adhesion is an important property for molecular biology's *in vitro* PVDF blotting membranes and other surface-protein 'masking' techniques. PTFE has played an important role in many minimally invasive medical devices, mostly intended for interventional luminal access (e.g., multilumen catheter fabrication) because of its high viscosity/high temperature paste extrusion requirements that impart high size/design tolerances in small dimensions with long production runs. Permanent *in vivo* fluorinated materials use is dominated by ePTFE in most implant applications, primarily in cardiovascular and hemodialysis. ePTFE's unique, variable expanded node-fibrillar microporous morphology permits mechanical control, processing, tissue integration, and clinically accepted biocompatibility in certain applications. Despite a rich history of biomedical development and practical utility, fluoropolymers are still developed for new biomedical opportunities. *In vivo* implant cell endothelialization within the host (discussed in **Section 1.128.4.1**) is a critical area for performance breakthroughs for implanted vascular graft fluorinated materials. Imaging and drug delivery are other areas of opportunity that extend fluorinated materials' previous extensive development as microparticle-based blood oxygen carriers. Both ultrasound contrast imaging and ^{19}F-MRI exploit perfluorofluid emulsions in tissue and will see continued development. As exploited in current imaging emulsions, fluorinated amphiphiles also produce highly stable colloids and particles capable of surface modification for utility as drug carriers.[139–143] While fluorocarbon-based targeted drug delivery vehicles are only in limited preclinical clinical testing, recent progress in DNA,[144] cytolytic peptide,[145] and pulmonary drug delivery[146] shows promise for modifying such vehicles to provide a 'see-and-treat' therapeutic modality where both fluorinated agent-based imaging and triggered drug release can be combined in a single vehicle.[116,141] Lastly, a new everolimus-releasing cardiovascular endoluminal drug-eluting stent (Xience V®, Abbott Vascular, USA) is reportedly designed to overcome some limitations of

first-generation drug-eluting stents. This design uses a thin fluoropolymer coating over the metallic stent struts to elute the antirestenotic drug, everolimus, to effectively suppress neointimal tissue and promote rapid reendothelialization above and between stent struts, as shown in preclinical studies.[70] For further details, please refer to **Chapter 4.406, Protein Interactions with Biomaterials**.

Glossary

Basement membrane Specialized extracellular matrix that separates the basal layer of epithelial or endothelial cells from the stroma.

Biochemical cues Specific biochemical motifs of the soluble and/or extracellular matrix that are presented to cell-surface receptors which induce intracellular signaling pathways.

Biophysical cues Specific characteristics of the physical extracellular matrix (ECM), such as ECM stiffness, topographical structure, and applied mechanical force, which induce intracellular signaling pathways.

Compliance A measure of the ability of a material to yield to an applied force.

Contact guidance The elongation or morphological alteration of a cell in response to physical structures of the extracellular environment.

Elastic modulus Ratio of stress to strain that relates to the relative stiffness of an elastic material.

Nanofabrication The practice of making nanometer scale features and patterns on a substrate.

Topography Description of the features of the surface of a substrate, both in scale and geometry.

Abbreviations

AFM	Atomic force microscopy
BHK	Baby hamster kidney
BM	Basement membrane
DNA	Deoxyribonucleic acid
E	Young's elastic modulus
EBL	Electron-beam lithography
ECM	Extracellular matrix
EUV	Extreme ultraviolet
FGF	Fibroblast growth factor

GLAD	Glancing angle deposition
HCEC	Human corneal epithelial cell
HUVEC	Human umbilical vein endothelial cell
IL	Interference lithography
LADI	Laser-assisted direct imprint
MDCK	Madin–Darby canine kidney
NGF	Nerve growth factor
NGL	Next generation lithography
NIL	Nanoimprint lithography
PC12 cells	Pheochromocytoma (tumor) of the rat adrenal medulla
PLLA	Poly(L-lactic acid)
RGD	Arginine-glycine-aspartic acid
RIE	Reactive ion etching
RNA	Ribonucleic acid
SCC	Squamous cell carcinomas
SV40-HCEC	Simian virus 40-transformed human corneal epithelial cell
TCPS	Tissue culture polystyrene
THF	Tetrahydrofuran
UV	Ultraviolet
VEGF	Vascular endothelial growth factor

1.129.1. Introduction

Great effort is being expended in the design and fabrication of biomaterials for tissue engineering aimed at best approximating the chemical and biophysical cues provided by the native extracellular matrix (ECM). A growing number of reports have focused on characterizing the extracellular environment and elucidating the specific elements that have the greatest impact on cell behavior. These elements are then incorporated into the design and fabrication of synthetic biomaterials with the hope that they will provide biomimetic cues to support formation and maintenance of fully functional self-regenerating healthy tissue.

Cells receive cues from their extracellular environment from multiple sources which include soluble factors in the extracellular milieu as well as the protein matrix in which they reside. It is well recognized that the biochemical components of the soluble factors and ECM have a substantial impact on cell behavior. Recent reports have now demonstrated that the biophysical attributes of the ECM, which include both nanotopography and elastic modulus, are also key regulators of cell behavior. Understanding how these biophysical cues affect cellular behavior will directly impact *in vitro* cell culture methods, the design of materials for tissue-engineering applications, and the development of improved prosthetics.

To understand and exploit the influence of biophysical cues, we must first determine the biophysical attributes of the native ECM. The focus of this chapter is on epithelial and vascular endothelial cells that are basally anchored to the ECM through a highly organized specialization of the ECM known as the basement membrane (BM). Because of its essential function within tissues throughout the body, several groups have investigated and quantified the biophysical attributes of BMs from different species and anatomic locations.

1.129.2. Basement Membrane

The BM serves as structural support as well as an interface through which cells that line organs, cavities (epithelium), and the interior of blood vessels (endothelium) interact with the underlying stroma.[1,2] BMs have also been found to line muscle and fat cells and are associated with Schwann cells surrounding peripheral nerve axons.[3,4] This specialized structure supports the overlying cells and demarcates tissue compartmentalization between the connective tissue and the epithelium or endothelium.[5] Among the primary and most studied functions of the BM are serving as the structural interface for the attachment of the overlying epithelium or endothelium, provision of ligands for binding of cell membrane-associated integrins, and serving as a reservoir for soluble cytoactive factors such as polypeptide growth factors.

Cell–substrate adhesion provides strength and integrity and is critical in the formation and maintenance of the overlying epithelial or endothelial tissue. The adhesion of cells through the underlying BM is a dynamic process *in vivo*. For example, in many epithelial-lined structures such as the skin and the cornea, a population of basal epithelial cells within the stratified squamous epithelium will undergo differentiation wherein cells will lose their cell–substrate attachment in order to physically migrate toward the surface. This continuous movement and reorganization of cells requires dynamic but regulated changes that will allow for the normal homeostasis of the tissue.

Other functional attributes of the BMs include their ability to provide a source or 'trap' for growth factors, hormones, and ions that are essential for cell function.[5–8] For example, vascular endothelial growth factor (VEGF) is released during vascular BM remodeling and is sequestered by heparin-binding proteoglycans in the BM. The sequestered VEGF is 'stored' for use in blood vessel formation at the site of injury.[9] In some cases, the BM acts as a semipermeable barrier for blood filtration, specifically in mammalian kidneys.[7] These examples, among others, demonstrate that BMs and their components play essential roles in normal organ development and function.

1.129.2.1. Biochemical Composition of BMs

The complex meshwork of proteins that comprises BMs includes glycoproteins and proteoglycans.[10–12] Type IV collagen, laminin, nidogen/enactin, and perlecan are ubiquitously expressed in all BMs.[10,12] Other minor components of the BM include agrin, type XVII and XV collagen, fibulin, and BM-40 Sparc.[13] These macromolecules are excreted from cells and subsequently self-assemble into a dense heterogeneous matrix. Although the four main constituents are present in all BMs, it is the unique combination of the macromolecular isoforms that distinguishes, for example, a corneal BM from a

glomerular BM.[10] In addition, differences in the concentrations of each biochemical component may account for biophysical differences including those in thickness, stiffness, and topography that have been reported between BMs of different tissues.[14] For example, the thickness of the BM can range from 50 nm to tens of micrometers depending on anatomic location within the tissue, age, and pathological conditions.[14–22] The macromolecular composition provides specific and necessary environmental cues for epithelial and endothelial cells in close proximity to the BM, which consequently lead to proper cell function and homeostasis within the tissue.

The most abundant macromolecule within the BM is type IV collagen, typically making up about half of the total protein composition. Type IV collagen is a nonfibrillar collagen that confers structural integrity[23] and flexibility to the BM network. It is excreted from cells as protomers (protomers are composed of three alpha chains) and a total of six protomers of type IV collagen have been identified.[24] Collagen 1V combined with the other main component laminin provides the structural mesh-like framework which allows for binding of other protein components.[2,11]

Laminin, another major constituent of the BM, has been shown to influence fundamental cell behaviors including attachment,[25,26] proliferation, and differentiation.[27] Two distinct areas of the laminin molecule have a high affinity for cell binding. Laminin molecules are heterotrimers assembled from alpha, beta, and gamma chain subunits with a semblance of a three pronged fork. Different combinations of various alpha, beta, and gamma subunits define a laminin isoform. In total, 15 isoforms of laminin have now been identified.

Nidogen (also known as enactin) stabilizes the BM as it binds to and bridges laminin and type IV collagen.[23,28,29] Nidogen has also been shown to recruit collagen into the assembly of the BM. Two isoforms of nidogen have been identified, and it has been shown that at least one of the isoforms must be present for proper BM development and function.[30] Results from these studies indicate that nidogen is essential for development, maintenance, and function of the BM.

The fourth main constituent of the BM, perlecan, is a heparan sulfate proteoglycan. The presence of heparan sulfate allows these molecules to aid in charge-dependent filtration[31] through the membrane as well as to sequester growth factors.[32,33] Similar to nidogen, perlecan also binds laminin and type IV collagen in the ultrastructure of the BM.

The coordination of the assembly of these four macromolecules, in addition to other minor components, is a complex combination of intermolecular self-assembly and network bonds, which ultimately results in the formation of the BM. Type IV collagen self-assembles into a flexible, highly cross-linked network stabilized by covalent, noncovalent, and disulfide interactions.[34] Similarly, laminin self-assembles into a honeycomb-like structure in the presence of calcium.[35] Laminin, disparate from the other major BM macromolecules, is necessary for initial basement formation.[23,36,37] Perlecan and nidogen are secreted and incorporated into the BM network individually. They bridge the two suprastructure networks of laminin and type IV collagen[10,38] (**Figure 1**).

1.129.2.2. Cellular Adhesion via Macromolecules of BMs

Cells attach to the underlying substrate through adhesion complexes which include focal adhesions. Focal adhesions were first identified as electron dense areas localized to areas of cell attachment to the BM.[39] These complexes are composed of transmembrane glycoproteins that link the cytoskeleton of the overlying cell to the extracellular environment through the BM components. Each type of adhesion involves its own set of interacting proteins and molecules to achieve adhesion to the BM and allow for cell mobility. Both mechanical and key cellular signals are transmitted through the focal adhesion complex, which ultimately impact essential cell behaviors.

Focal adhesions provide a link from the cell to the external ECM and recruit and concentrate signaling receptor molecules at integrin-binding sites. The transmembrane glycoproteins known as integrins have been characterized as one of the main family of receptor molecules involved in formation of adhesion complexes with the BM.[40] Integrins are heterodimers that can bind to several BM proteins, including collagen, laminin, vitronectin, and fibronectin.[41] Integrins are expressed most intensely in basal cells that lay adjacent to BMs.[42–44]

Cell-surface receptors, such as integrins, have two distinct roles: (1) anchor cells to the extracellular environment and (2) activate signal transduction pathways. For example, upon anchoring to the components of the BM, integrins on the cell-surface cluster and signal for the assembly of actin filaments; this suggests a close link between integrin activation and cytoskeleton assembly. This clustering and rearrangement of the cytoskeleton is evident in the formation of focal adhesions.[40] The second role of the cell-surface receptor, namely the activation of signal transduction pathways, occurs from outside-in signaling where a cell-surface receptor binds to a ligand. These signaling events ultimately regulate gene expression and phenotypical responses, such as proliferation or differentiation.[40,45]

Cell-surface receptors interact with well-defined binding sites of the ECM proteins. These specific interactions can be mimicked by fabricating small oligopeptides derivatives of the original protein sequence that are recognized by cell-surface receptors. The tripeptide arginine-glycine-aspartic acid (RGD) has been used widely as an adhesive motif to mediate cell adhesion to synthetic materials (for complete reviews, please refer to Hersel *et al.*[46] and Shin *et al.*[47]). Although it is an oversimplification of the dynamic interface provided by the combination of the BM proteins, RGD can encourage cell adhesion,[48] spreading, and migration.[49] Synthetic incorporation of adhesive ligands with subsequent study of cell behaviors can provide useful information including minimum required ligand density,[50] the relationship between cell–substratum adhesion strength and cell motility,[51] and spatial organization of ligands[49] that encourage desired cell phenotypes (for further review, see Lutolf and Hubbell[52]). In addition, integration of ligands into synthetic matrices enables researchers to understand synergistic interactions between the biochemical and biophysical attributes of the BM.

1.129.2.3. Diseases Associated with BMs

Deviations from normal BM thickness and composition have proven to be important indicators of several disease states.

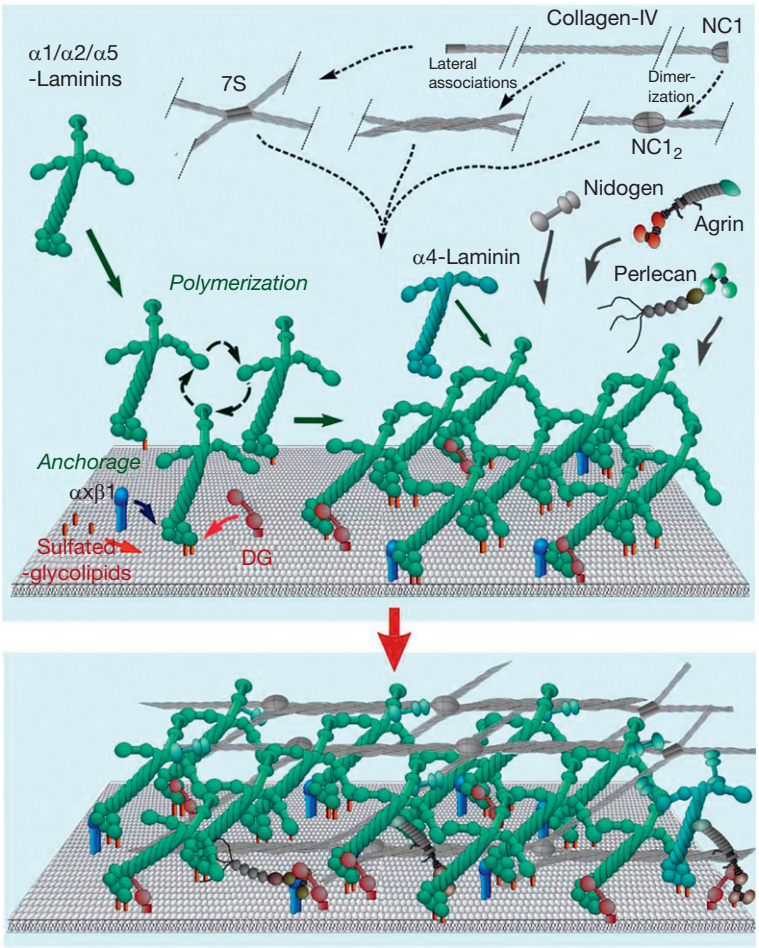

Figure 1 Assembly of basement membrane components. Laminin and type IV collagen self-assemble into covalently cross-linked networks. Nidogen and perlecan incorporate into the networks and provide stability to the matrix. The basement membrane matrix presents specific ligands that interact with cell-surface receptors, such as integrins ($\alpha \times \beta 1$) and dytroglycans (DS), and anchor cells to the BM. Reproduced from Yurchenco, P. D.; Patton, B. L. *Curr. Pharm. Des.* **2009**, *15*, 1277–1294.

Alterations in the BM component amounts and mutations within BM components have been associated with many different diseases including diabetes mellitus,[19,53–56] hyperlipemia, hyperglycemia and other vascular diseases,[57,58] corneal epithelial BM dystrophy,[59] keratoconus,[60–62] autoimmune disorders affecting the epidermal surface, cancer, and many others. Several examples of the importance of the homeostasis of the BM tissue are illustrated below.

Diabetic patients have provided one of the most studied examples in the published literature demonstrating significant alterations of BMs in a wide range of epithelial and endothelial tissues. A thickened endothelial BM in the kidney glomerulus was originally reported in diabetic patients as early as the 1960s[19,63] measuring up to 5 μm in width.[64,65] The increased thickness of BM has now been reported in many different tissues, including cornea (see **Figure 2**). Changes in levels of specific BM components including nidogen and laminin have also been observed when compared to the BM of healthy corneal membranes.[53,66] Disruption of the normal homeostasis of the BM leads to pathogenesis related to cardiovascular and microvascular complications and the development of corneal defects due to retinopathy in the microvasculature of the eye, resulting in blindness.

Mutations in specific BM components have also been shown to disrupt BM function leading to diseased states. One example is Alport syndrome which is a genetic disease that can affect multiple tissues including the kidney, inner ear, and eye. The syndrome is characterized by mutations in the collagen synthesis genes including *COL4A3*, *COL4A4*, and *Col4A5*, which ultimately result in the improper production and assembly of type IV collagen.[67–69] Mutations in the production of type IV collagen eventually result in defects in the normal filtration process of the BM. Further progression of the disease results in a thickened BM that can eventually lead to kidney failure, hearing loss, deterioration of vision, and development of corneal erosions.

The biophysical attributes of the BM and other extracellular matrices have recently been shown to play a direct role in tumor development. Early studies on the role of the microenvironment and tumors focused on specific structural alterations in BMs and how they correlate with tumor growth and prognosis.[70] For example, differentiated squamous cell carcinomas (SCC) retain the ability to deposit BM, whereas

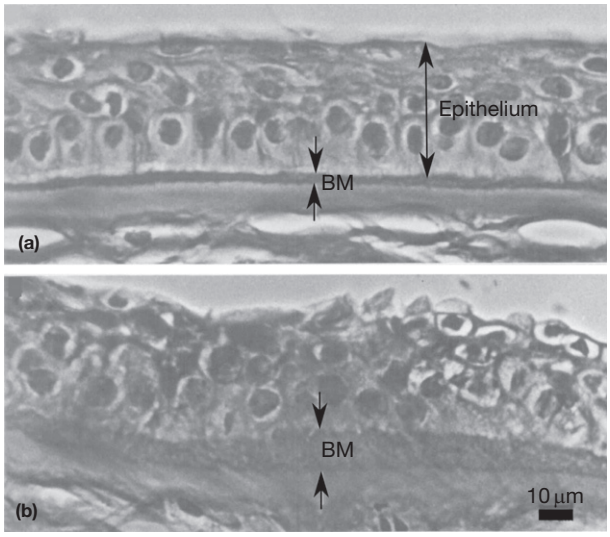

Figure 2 Diabetic cornea exhibits thickened basement membrane. Light micrographs of (a) the basement membrane of normal thickness and (b) thickened basement membrane of a diabetic patient. Tissues were stained with periodic acid-Schiff (PAS). Adapted from Taylor, H. R.; Kimsey, R. A. *Invest. Ophthalmol. Vis. Sci.* **1981**, *20*, 548–553, with permission from IVOS.

undifferentiated SCC have only minimal BM deposition.[71] Tumors exhibiting changes in the protein composition, organization, and integrity of their associated BMs ultimately may lead to alterations in the biophysical properties including topography and stiffness. This has been demonstrated in several different cancers, such as breast cancer, where there is a stiffening of matrix by an increase in collagen deposition and ECM cross-linking.[72–74] Even so, each type of tumor will need to be analyzed individually to determine the optimal biophysical properties to inhibit the tumorigenic phenotype. Neuroblastoma cells cultured on ECM of increasing stiffness exhibited decreased proliferation as well as inhibition of transcription factors involved in oncogenic proliferation.[75] These and other reports have now demonstrated that changes in the biophysical properties of the tumor microenvironment can inhibit or induce the formation of tumors and even impact the response to treatment.[76–79]

In summary, changes in the thickness and composition of the BM most likely impact the physical attributes including topography and stiffness, which then in turn impact the behavior of the overlying cells. On the basis of these observations, recent reports have sought to characterize the normal biophysical attributes of both epithelial and endothelial BMs in order to better understand how these properties influence cell function. Characterization of the biophysical attributes of normal BM is therefore essential to begin to elucidate the impact of changes in the BM as it is related to normal tissue homeostasis for both tissue-engineering applications and the development of novel therapeutic strategies.

1.129.2.4. Biophysical Cues of BMs: Elastic Modulus

As previously described, the extracellular microenvironment including the BM provides essential cues that impact cell behavior. Recent developments have now emphasized the importance of examining the biophysical cues and the impact on essential cell behaviors. Biophysical cues include mechanical forces, electrical stimuli, and other physical properties including topography and elastic modulus.[80] Although each of these parameters is important, the elastic modulus and topographic features of the BM and ECM are the focus of many ongoing studies in the field because they are definable biomaterial properties.

The elastic modulus is a measure of the relative stiffness of a material. One commonly reported elastic modulus is Young's modulus which measures the tensile elasticity of a material. Young's modulus (E) is calculated as the extent of deformation, or relative change in length (strain) for an imposed stress (force/area). Elastic moduli, including Young's modulus, can be measured using macroscopic methods (disk rheometer, tensile testing, bulge testing, ultrasonic elastography, and tomography), or microscopic methods (atomic force microscopy (AFM), microindentation, and nanoindentation).[81–83] With increasing frequency, especially in biology, the relative stiffness of a material is described in terms of compliance rather than elastic modulus. Compliance is the degree to which an elastic body is deformed by an applied force and is inversely proportional to the elastic modulus. Soft, or compliant, materials have low modulus values. For example, gelatin has a reported range of moduli of 15–20 kPa.[84] Hard or stiff materials have higher modulus values, such as high-density polyethylene, which has a modulus of about 7 MPa.[85] Some representative elastic modulus values for tissues are brain (500 Pa), muscle (10 kPa), collagenous bone (100 kPa),[86] and trabecular bone (5–15 GPa).[87] See **Table 1** for more examples.

Much of the literature has focused on 'bulk' modulus measurements of whole tissues as opposed to local modulus of individual layers within the tissue. Although the modulus of whole tissues provides information that aids in understanding how mechanical properties affect cell behavior, it does not necessarily represent the local mechanical cues presented to epithelial or endothelial cells. Therefore, current studies have examined and characterized the local elastic modulus of the supporting BMs in order to provide a biologically relevant range of modulus values that can be incorporated into synthetic matrix design. For example, in the human cornea, a bulk modulus of 0.2–1 MPa has been reported.[93] However, local modulus measurements using AFM have demonstrated that each layer within the cornea has a unique modulus value. Specifically, the human anterior corneal BM has a modulus of 7.5 kPa.[100] Studies have also incorporated *in vivo*-like conditions during measurement of the elastic modulus to more closely replicate the natural cellular environment. Using a bulge test, which applies pressure to the cornea, Danielsen[92] reported the modulus of human Descemet's membrane as 2.57 MPa. Other reported BM modulus measurements highlight the range of modulus values associated with BMs spanning tissue and species: chick inner limiting membrane 1–3 MPa,[15] mouse retinal inner limiting membrane 3.8–4.1 MPa,[15] and tectorial membrane 24–210 kPa.[97] These values indicate the heterogeneity of elastic modulus values between species and tissues indicating that the biophysical features may be involved in extracellular signaling cues to the cells which ultimately lead to downstream signaling events.

Table 1 Compilation of measured elastic modulus for various tissues

Species	*Tissue*	*Method*	*Modulus (kPa)*	*References*
Chick	Chick inner limiting membrane	AFM	950–3300	15
Fish	Lamellipodia of fish epidermal keratocytes	AFM	10–55	88
Human	Platelets	AFM	1–50	89
Human	Endothelial cells	AFM	1.4–7	90
Human	Normal breast tissue	Indentation	3.25	91
Human	Fibrodenoma breast tissue	Indentation	6.4	91
Human	Descemet's membrane	Bulge test	2570	92
Human	High-grade IDC tumor breast tissue	Indentation	42.5	91
Human	Cornea	Bulge test	200–1000	93
Human	Normal trabecular meshwork	AFM	1–34	94
Human	Glaucoma trabecular meshwork	AFM	110	94
Monkey	Monkey lens	AFM	0.4–3.2	95
Mouse	Skeletal muscle cells	AFM	25	90
Mouse	Edges of motile 3T3 fibroblasts	AFM	12	96
Mouse	Retinal inner limiting membrane	AFM	3810–4070	15
Mouse	Tectorial membrane	AFM	24–210	97
Porcine	Gelatin (pork skin)	AFM	20 in water 1800 in 85% propanol	84
Porcine	Cartilage	AFM	2600	98
Rabbit	Cardiac cells	AFM	100	90
Rat	Hippocampus	AFM	0.137–0.308	99

Pelham and Wang are the first known group to initiate studies incorporating varying modulus substrates (10–80 Pa) and their impact on cell behavior. Significant differences in cell spreading motility and phosphorylation pathways were observed with murine fibroblasts and rat kidney epithelial cultures on substrates with varied elasticity. They observed significant differences in cell spreading, motility, and phosphorylation pathways.[101] Since then, the effects of elastic modulus on different cellular fates, such as cytoskeletal organization, differentiation, migration, and proliferation, have been demonstrated. In general, cells show increased adhesion, spreading, and cytoskeletal organization when the stiffness of the substrate is increased. This behavior has been observed with various cell types, such as fibroblasts,[102–104] smooth muscle cells,[105–108] endothelial cells,[109] and chondrocytes.[110] Maximized spreading and adhesion may not be the desired cell behavior depending on the application. For example, Engler *et al.* hypothesize that cell spreading equal to half of the maximum spreading is optimal for cell attachment and migration. They demonstrated that the half-maximum spreading of smooth muscle cells occurs when the modulus of the substrate mimics the native tissue,[111] further signifying the importance of the native mechanical properties of tissues.

Cell differentiation has been reported to be directly affected by modulating the elastic modulus of the substrate on which the cells reside. Working with mesenchymal stem cells (MSCs), Engler *et al.*[86] showed that MSCs' ability to differentiate is highly dependent on the stiffness of the substrate: on soft matrices with modulus close to brain tissue cells differentiated into neural lines, on stiffer surfaces that mimic muscle tissue cells differentiated into muscle lines, and on rigid matrices that mimic bone cells differentiated into osteoblasts. Georges *et al.*[112] tested the influence of stiffness *in vivo*, by showing the differentiation of MSCs into fibrogenic myofibroblasts when the stiffness of the liver is altered after injury. Other examples that demonstrate how differentiation is modulated by the stiffness of the substrata include neurogenesis,[113] tubulogenesis,[111,114,115] angiogenesis,[116,117] and spheroid formation.[118]

The modulus of the substrata has also been reported to influence cellular migration.[119] Experiments with neutrophils demonstrated that their migration is optimal on substrates of biologically relevant stiffness of 4 kPa.[120] They hypothesized that, on softer surfaces, the low level of cellular adhesion prevents traction forces, and on stiffer substrates, the adhesion is stronger and more established, preventing migration.[120] Cell directed migration through durotaxis has also been observed toward areas of increased stiffness.[121,122] In addition, remote cell–cell sensing of the underlying substrate has been reported in response to the strain created by migrating neighboring cells when cultured on soft substrates.[123]

Proliferation of the cells is also influenced by the modulus of the matrix.[124] Experimenting with neuron–astrocyte cocultures, Georges *et al.*[125] observed that, on stiff substrates, astrocytes significantly outnumber neurons, overtaking the culture, while neurons exhibited enhanced growth when cultured on softer substrates with a modulus within the range reported for brain tissue (several hundred Pascals). These studies provide evidence to support the importance of elastic modulus as an essential component in the design of biomimetic artificial BMs for the design of prosthetics, wound healing applications, and the creation of improved *in vitro* culture models.

1.129.2.5. Biophysical Cues of BMs: Topography

In addition to the elastic modulus of the BM and ECM, cells also receive biophysical cues from the topographic features, or structure, on which the cells reside. The BM has a three-dimensional (3D) topography composed of fibers, pores, and elevations on the order of tens to hundreds of nanometers.[126]

Table 2 Compilation of basement membrane feature dimensions for various tissues

Species	*Tissue BM*	*Mean feature height (nm)*	*Mean fiber diameter (nm)*	*Mean pore diameter (nm)*	*References*
Bovine	Glomerulus	–	3–15	9.8 ± 3	127
Bovine	Tubular	–	3–15	11.4 ± 4	127
Canine	Cornea	150 ± 41	18 ± 9	32 ± 18	126

[b]Values reported as 95% confidence interval rather than standard deviation.

In comparison, a single cell can average 10–100 μm in length depending on the cell type. Thus, a cell is approximately two to four orders of magnitude larger than the topographic features on which the cell resides *in vivo*. This size difference enables a single cell to interact with hundreds to thousands of individual nano- and submicron-scale features.

Across different species, tissues, and anatomic locations, the scale of features of the BM is relatively consistent with a few notable exceptions (Table 2). The BM of the bovine glomerulus has significantly smaller fiber and pore sizes (3–11 nm fiber diameters[7,135]), which are most likely involved in the specific function of the tissue which involves filtration. Also, in both porcine[134] and rhesus[14] blood vessels, the pore and fiber diameters (~24–63 nm) are significantly less than pore and fiber diameters found in BMs of the bladder, foreskin, and anterior BM of the cornea. Differences have also been reported within a tissue. The human cornea topographic features vary in scale between the anterior BM and Descemet's membrane. On average, Descemet's membrane has smaller average pore (38 nm) and fiber (31 nm) diameters than the anterior BM (92 nm pore and 44 nm fiber diameters).[129] These structural differences may have important effects on the ultimate function of the overlying epithelium and endothelial cells in the human cornea.

Understanding the impact of this range of topographical features on cellular behavior has the potential to impact many biological applications within tissue engineering. It is critical to first examine how a wide range of topographic feature sizes modulate cell behavior. Initial steps have been taken to examine how BM range topography to micron-scale topography affects cellular behavior. Examples highlighted in Section 1.129.4 are categorized by the scale of the topography which accentuates the differences in cell behavior depending on the scale of the underlying topography. To fully appreciate how the scale of the topography influences cell behavior, we must first understand how topographical features are fabricated and the advantages and limitations associated with different fabrication techniques. In the following section, we highlight some of the main nanofabrication methods used in bioengineering and briefly discuss current methods under development that will contribute to advancements in the field of tissue engineering.

1.129.3. Nanostructure Fabrication

Nanofabrication processes have historically taken cues from the microelectronics industry. From classical processes such as photolithography and electron-beam lithography (EBL) to next generation lithography (NGL) such as nanoimprint lithography (NIL), the bioengineering field has exploited a multitude of fabrication techniques to develop topographically patterned substrates for cell studies.[138–140] A spectrum of topographical patterns with a wide range of lateral dimensions, from tens of nanometers to hundreds of micrometers, and various geometries, such as pores and fibers, have been successfully fabricated. Although the microelectronics industry has the capability to produce nano- to micron-scale features over very large areas (several square centimeters and larger), the availability of current industrial lithographic techniques are not accessible to most bioengineering research groups. Bioengineering research is limited to more modest nanofabrication methods that require researchers to use some creativity in the design of nanopatterned substrates. Depending on the substrate design needs, one fabrication technique may produce samples faster or have more flexibility in the composition compared to another technique. In addition to patterning processes, steps are often taken to transfer the pattern into the underlying substrate or into an alternative material. Pattern

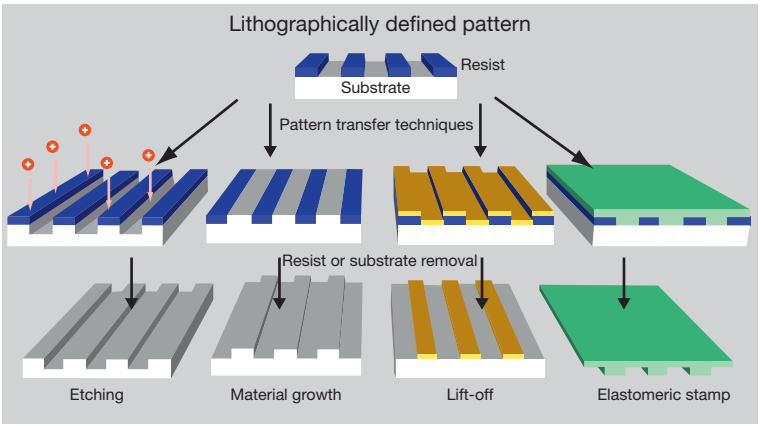

Figure 3 Schematic highlighting some of the options in pattern transfer using lithography. The pattern can be directly etched into the underlying substrate, or used as a mask for substrate regrowth, or used as a template for metal deposition and subsequent lift-off, or used as a master for fabrication of elastomeric stamps. Adapted from Chen, Y.; Pepin, A. *Electrophoresis* **2001**, *22*, 187–207.

transfer can be achieved through different processes including etching, substrate material regrowth, inorganic deposition and lift-off, and elastomeric molding (Figure 3).

Choosing the lithography and pattern transfer techniques from among the many options available is dependent on the biological application and available resources to produce the substrates. Each cell study may require different substrate design criteria in order to confirm a hypothesis. Additionally, there are a number of different nanofabrication options available to meet those design parameters. Some general design parameters and an array of nanofabrication processes are discussed below.

1.129.3.1. Design Parameters

One quality of nanofabrication that makes it useful for cell studies is its high fidelity and reproducibility for making nano- to micron-scale patterns. How best to take advantage of this quality depends on the intended bioengineering application. A few simple guidelines in substrate design can eliminate or reduce uncertainty in cell data due to uncertainty in the substrate itself.

First, the substrates must have controlled topographic feature dimensions, such that the resulting cellular observation can be attributed to a narrow range of sizes within a low percentage of error (<10%). For example, SV40-transformed human corneal epithelial cells (SV40-HCECs) demonstrate increased adhesion when cultured on 220 ± 21 and 453 ± 18 nm ridges (400 and 800 nm in pitch) compared to 680–2150 nm ridges (1200–4000 nm in pitch).[141] This observation was elucidated by using well-defined topography. In contrast, a substrate with large variations in feature dimensions, on the order of several hundred nanometers, would not have allowed for the observed quantifiable differences in adhesion. There is some criticism in using well-defined and ordered structures, mainly because this does not necessarily mirror the biophysical attributes of the native BM. *In vivo*, cells encounter a wide range of topographic length scales; however, by using a reductionist approach, we can better understand how each topographic length scale individually and in combination affects cellular response. Understanding how a specific lateral dimension modulates cell behavior will prove useful in design of improved cell culture environments and ultimately design of improved prosthetics.

In addition to well-defined lateral dimensions, the vertical dimension (or depth) of the topography needs to be well defined, with enough depth to optimally elicit a cellular response. Several studies have indicated the importance of depth on contact guidance and how this acts to amplify the cellular response to lateral dimensions.[142–147] In contrast, shallow features with limited depth can inhibit cellular response to topography.[144] Fabricating features with small lateral dimensions (replicating the range of nanoscale features quantified from BMs) with appreciable depths has been logistically difficult to obtain. As the lateral scale decreases and the aspect-ratio increases, problems occur with patterning (such as collapsing of features), etching, speed of production, and overall cost. In some cases, compromising on the overall design or substrate throughput is necessary in order to produce usable topographically patterned substrates for thorough cell studies. To address some of these problems, techniques are being used to easily produce nanotopography with more structurally reliable geometries, such as wave-like structures and 3D porous scaffolds.

The third critical design parameter is presenting large enough patterned areas to include a robust number of cells within each study. For example, surface area of the topographic patterns must be large enough to collect data from thousands to millions of cells for protein or RNA studies. Other phenotypical responses such as migration and morphology do not require as many cells, and therefore do not require as large a patterned surface area. As a cell is typically on the order of 10–100 μm, well-defined topographic features must cover a range from a square millimeter to several square centimeters, depending on the intended application. Patterning large areas can limit the fabrication techniques used for substrate production as several processes including EBL and AFM direct write are time consuming when fabricating at the multiple square millimeter scale. In addition, facile and rapid fabrication processes are desirable in order to produce many substrates for large-scale cell experiments.

As nanolithographic techniques improve (mainly driven by the microelectronics industry's objective to produce smaller transistors), so do the techniques for production of nanobiomaterials. Discussed below are some traditional lithographic fabrication processes and some techniques devised specifically for tissue-engineering applications.

1.129.3.2. Classical Lithography

Two types of classical exposure methods are commonly used for patterning of nano- to micron-scale structures and determining which method to use is dependent on production speed and expense. The first method is a serial method where a scanning focused beam patterns individual 'pixels' and is typically used in making masters and masks for other lithographic techniques. The slow speed of the serial method limits the productivity of the process and makes it cost prohibitive for mass production purposes.[148] On the other hand, serial methods typically can produce smaller feature dimensions and allow for patterning of complex designs. A second type of exposure process is a parallel replication method where substrates are exposed to irradiation through a mask. This method has increased throughput and is routinely used for mass production. One disadvantage to the parallel lithographic techniques involves the high cost of the equipment (such as radiation sources).[149]

1.129.3.2.1. Electron-beam lithography

EBL was first reported as a technique for patterning substrate materials as early as the 1960s[150,151] and has been used for patterning nano- to micron-scale features for cell studies for the past 20 years.[145,152–154] Pattern transfer using EBL is achieved through a focused electron beam which serially exposes a polymeric resist pixel-by-pixel to form a custom pattern.

The advantages of EBL include precise control over lateral dimensions down to the 5–7 nm level,[155–157] and flexibility in patterning of complex geometries. However, with a patterning speed of approximately 10^7 pixels s^{-1},[158] EBL is a very slow process making it too expensive for mass production. Additionally, stitching errors (discontinuities) can create problems when patterning large areas.[159] With its ability for precise control of patterning nanometer length scales, EBL is a principal technique used for producing master templates that are subsequently used in higher-throughput nanofabrication processes, such as photolithography and NIL.

1.129.3.2.2. Photolithography

Similar to EBL, photolithography includes identical fabrication steps with one important difference: instead of an electron beam 'writing' a pattern, in photolithography, a mask is used to expose a polymeric resist to light in specific areas simultaneously. Early applications of photolithography were limited by the wavelength of the light used for exposure: several hundreds of nanometers. In order to fabricate substrates with topographic features in the nanometer range, new techniques that parallel traditional photolithography have been developed. Extreme ultraviolet (EUV) lithography uses radiation with wavelengths of 10–120 nm (typically around 13.4 nm,[160]) to pattern sub-100 nm features.[161,162] Combining EUV with interference lithography (IL) can achieve even smaller line widths (38 nm and below,[163] see review Solak[164]). X-ray lithography also uses small (0.5–4 nm) wavelength radiation from synchrotron radiation or laser-induced plasma sources to pattern high aspect-ratio structures into resists.[149,165]

Photolithography has been used since the 1980s[166] to define micron-scale topographically patterned substrates for cell studies. It is still used today as one of many techniques that can fabricate nano- and micron-scale features. The major advantage of photolithography is the rapid substrate production (great for producing many substrates for cell studies). However, the expensive equipment including masks are drawbacks to these processes which have pushed the development of new, inexpensive lithographic techniques.

1.129.3.3. Next Generation Lithography

In order to circumvent some of the cost and production speed problems associated with classical lithographic processes, a number of 'NGL' processes are in development to provide inexpensive alternatives while maintaining the high rate of substrate fabrication.[149] A few examples of NGL approaches are NIL, soft lithography, and self-assembly of biological, organic, and inorganic molecules. Many of these approaches are already being used for fabrication of nano- to micron-scale topography for biological applications.

1.129.3.3.1. Nanoimprint lithography

NIL is a nanoscale analog of micron-scale compression molding (used in industries such as compact disc manufacturing,[167]). Briefly, NIL is a high-throughput process whereby a polymeric resist layer is patterned using a master template as a stamp. The master is commonly fabricated by EBL or other high resolution processes. The master is then used to imprint under conditions such as (1) elevated temperatures and pressures (so that the resist can flow into the spaces of the master) or (2) UV light (to photo-activate polymerization of the resist). In some cases, the molded resist or polymer can be used directly for cell studies.

Chou *et al.* were pioneers of NIL, demonstrating dot and line arrays down to tens of nanometers in dimension.[167,168] They continue to make strides in production of high-throughput NIL techniques such as laser-assisted direct imprint (LADI) where no resist is needed to directly pattern silicon substrates.[169]

1.129.3.3.2. Soft lithography

Soft lithography (also known as micro-contact printing) uses an elastomeric stamping technique to print an 'ink' onto either a surface or a mold and shape a polymeric film. Replica molding using a silicone-based stamp has been used to fabricate submicron features[170] and sub-100 nm features (using a composite stamp).[171] Recently, perfluoropolyethers, an alternative to silicone, have been used to create sub-200 nm features with higher aspect ratios than conventional silicone.[172] These soft lithography systems show promise in producing inexpensive nanostructures of high quality with speed.

1.129.3.3.3. Colloidal lithography

Colloidal lithography is a type of 'bottom-up' approach to patterning nano-, submicron-, and micron-scale arrays. Colloidal crystals are assembled through many different processes

including sonication,[173] spin coating,[16,174] and epitaxial growth.[175] The colloidal templates are then used for metal deposition,[16] or used as masks for etching into substrate materials such as silicon. Facile fabrication of sub-500 nm 3D patterns can be done using polystyrene colloids.[176,177]

1.129.3.3.3.1. Electrospun fibers

Electrospinning of collagen or other polymeric materials is a useful process to fabricate nano- to micron-scale fibers for cell culture. This method has recently gained prominence, as biologists are investigating methods to incorporate topography or biophysical cues and may not have access to alternative nanofabrication processes. The common electrospinning fabrication technique includes a syringe from which a polymeric base material is secreted, a collector onto which the fibers are spun, and a bias voltage that attracts the polymeric stream to the collector. By varying solution concentration, flow rate, applied voltage, needle size, distance between needle and collector, and collector rotation speed, the fiber size and orientation can easily be manipulated (**Figures 4** and **5**).

Electrospinning is a simple, cost-effective process that can produce fibers with diameters from tens of nanometers to several microns. Calfskin type I collagen has been electrospun into fibers with diameters of 100 ± 40 nm and been used to show that smooth muscle cells can fully infiltrate the porous scaffold. The orientation, either random or ordered, can be controlled with an array of biocompatible polymers.[178] In addition, many biologists argue that electrospun fibers more closely mimic the natural topography of the ECM to which cells are exposed, making this nanofabrication technique widely used and accepted.

1.129.3.3.3.2. Molecular self-assembly

Molecular self-assembly is the spontaneous arrangement of molecules into well-defined nanostructures that are stabilized by noncovalent interactions.[179] In nature, DNA alpha helixes and protein crystal structures are just some examples. For instance, type I collagen forms fibrils with diameters on the order of 5–500 nm.[180,181] Organic compounds, such as block copolymers, will also self-assemble into nanostructures such as lamellae, spheres, or cylinders depending on the composition of each block and the interactions between blocks. Self-assembled molecules can be used on an as is basis, or modified to be used as masks or templates for further fabrication processing (**Figure 6**).

1.129.3.3.3.3. Phase separation

Phase separation uses the temperature-sensitive nature of dissolved polymers to form polymer rich and pore phases. Removal of solvent solidifies the polymer into polymeric islands or fibrils.[140] Different morphologies and porosities can be produced by varying the polymer concentration, types of polymers and solvents, and phase separation temperature.[140] For example, poly(L-lactic acid) (PLLA) dissolved in tetrahydrofuran (THF) was phase separated, solvent exchanged with water, then freeze-dried to yield a highly porous material with fibers on the order of 50–500 nm in diameter.[182] In some cases, pH can induce phase separation and form nano- to micron-scale topography.[183] Hajicharalambous *et al.*[184] used pH-induced phase separation to form nano- and submicron porous structures for cell migration and proliferation studies.

1.129.3.4. Other Methods

There are many additional methods that are used or are in development for use in tissue engineering. Some examples include sub-100 nm wave-like features called wave-ordered structures (WOS) that are formed by low-energy ion bombardment. The method is a simple and rapid parallel process that can pattern large areas for statistically robust cell

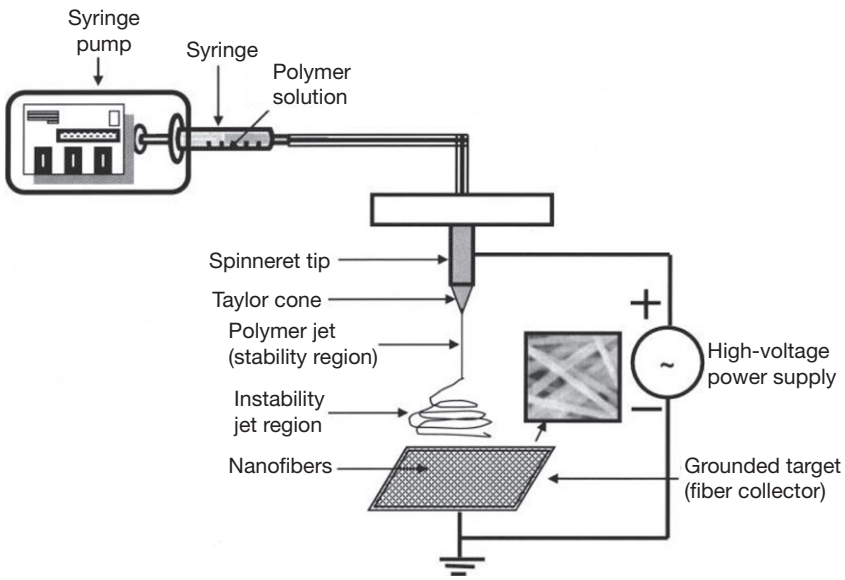

Figure 4 Schematic of the electrospinning process for making fibers. A syringe extrudes a polymer dissolved in a solvent through a tip. The voltage applied across the tip and target helps to produce a jet stream of polymer. While the polymer jet is stretched, the solvent evaporates quickly and forms the ultrafine fibers. Reproduced from Murugan, R.; Ramakrishna, S. *Tissue Eng.* **2006**, *12*, 435–447.

experiments[185–187] (Figure 7). Physical vapor deposition, specifically glancing angle deposition (GLAD), can produce nanocolumn arrays.[188] Direct writing techniques (such as with an AFM) of polymeric materials can form well-defined micron-scale features with irregular and/or custom geometries.[189] Even techniques using native tissues can produce nanotopography. Soft tissue protein extraction and gelation (pH-induced or temperature-induced gelation) show topographical features similar to dimensions found in ECMs of multiple tissues.[190]

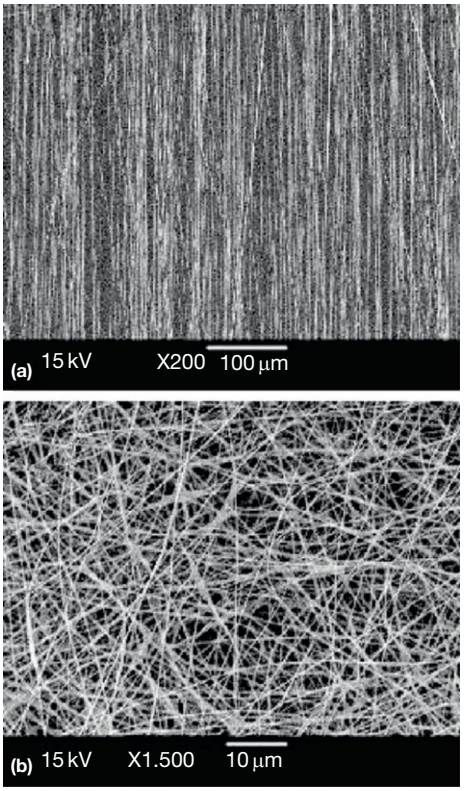

Figure 5 Both (a) ordered nanofibers and (b) random nanofibers can be produced using electrospinning techniques as shown above in these SEMs. Reproduced from Yang, F.; Murugan, R.; Wang, S.; Ramakrishna, S. *Biomaterials* **2005**, *26*, 2603–2610, with permission from Elsevier.

1.129.4. Cellular Response to Topographic Cues with Dimensions from Nano- to Micron-Scales

It has been well established over the past 100 years that cells exhibit contact guidance to structural and topographic elements in their environment. Contact guidance is defined as the elongation or morphological alteration of a cell in response to physical cues. This response is typically measured in the total number or percentage of cells elongated and aligned in a defined direction with respect to the underlying topography.[191,192] Cell guidance by substrate features has been studied as far back as the early 1900s when Harrison[193] reported cells aligning along spider web fibers. In the past 20 years, the impacts of both the shape and scale of topographic cues have been more closely examined.[143,194–204] As fabrication and substrate design techniques have improved, researchers have developed surfaces ranging from micron down to the nanoscale with the goal of more closely mimicking the biophysical environment that the cells are exposed to *in vivo*. One particular area of intense interest for both epithelial and endothelial tissues is the characterization and replication of the topographic features of the BM.

Several groups have successfully characterized and measured the topographic features of the BM from different species, tissues, and even different locations within the same tissue.[11,14,128,129,131,134,136,137,205,206] Using techniques such as transmission electron microscopy (TEM), scanning electron microscopy (SEM), and AFM, it has been observed that the BM is composed of a complex 3D environment consisting of both pores and fibers. Overall, the average dimensions of the topographic features of the native BM are similar in that they encompass both the nano- and submicron-scale range. However, in some tissues, significant variations occur, such as the pore size in both porcine heart valve and rhesus macaque vascular tissue.[14,134]

These small but significant differences in BM topography may have a profound impact on the phenotypic response of the overlying cells and may account for variations observed between or within the same tissue *in vivo*. For example, the differences in pore and fiber size reported in vascular tissues may partially account for the heterogeneity in endothelial cell function. Other significant findings include the variations observed in pore size within the two BMs in the human cornea.

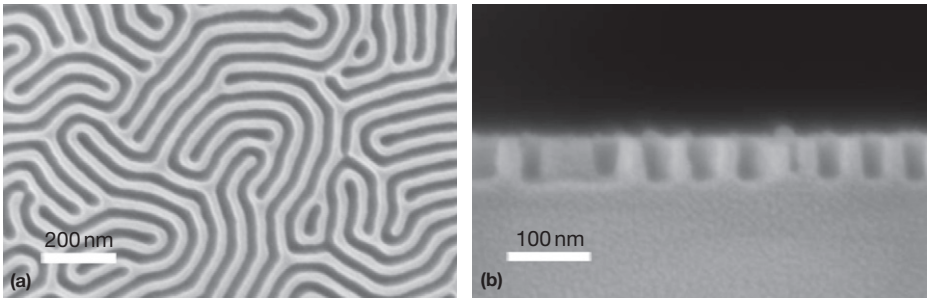

Figure 6 Self-assembly of block copolymers can be used to fabricate nanoscale structures over larger areas. In this example, the block copolymer poly (styrene)-*block*-poly(methylmethacrylate) (PS-*b*-PMMA) self-assembles into lamellae structures with a pitch of 48 nm. The PMMA block can be selectively removed to leave the PS block behind, which can be used as a mask to etch into the silicon substrate. SEMs show the top-down (a) and cross-sectional views (b) of the resulting lamellae pattern in silicon.

The average anterior BM (epithelial cells) contains pores with an average size that is double than that of the Descemet's BM (endothelial cells), which also suggests that topographic cues from the BM may be involved in guidance of cell function. These *in vivo* BM measurements have allowed the measured features to be incorporated into substrates to further examine specific cell behaviors.

Although early work focused on large micron-scale topography, recent studies have investigated smaller topography that falls into the range of measured features within the BM. A wide range of reports in the literature have observed that modulation of fundamental cell behaviors including proliferation, adhesion, morphology, and differentiation is subject to the dimensions, geometry and feature size of the topographical cues. Historically, studies involving substrates with micron size features were reported first, and as fabrication techniques have improved, more recent studies have focused on impact of cell behavior at the nanoscale.

Figure 7 Nanofeatures known as wave-ordered structures (WOS) can be fabricated with dimensions in the range of the smallest features measured in the basement membrane. WOS are formed by low-energy ion bombardment and can be patterned over large areas. Surfaces were kindly provided by Wostec, Inc. (Moscow, Russia).

To examine the impact of topographical cues, we have described in detail how the scale of topographic features can significantly modulate cell phenotype. Additionally, we consider the possible impact that the incorporation of relevant biophysical cues may have on the future design of improved tissue-engineering scaffolds.

In addition to the scale of topographic cues, the shape or geometry of the topography is also presented to the overlying cell. Although relevant, only limited studies have specifically investigated the impact of the geometry on cellular behavior. Notably, HCEC adhesion strength was tested by applying a shear force to cells that were seeded on topographically patterned ridge–groove features and pores of similar pitch. Cells on anisotropic ridges and grooves compared to cells cultured on pores with the same size pitch demonstrated similar adhesion strength.[141,207] Human umbilical vein endothelial cells (HUVECs) have also been utilized in studies investigating whether the shape or scale of features is relevant for changes in proliferation rates. HUVEC proliferation is significantly decreased on substrates containing features 800 nm or smaller regardless of the geometry,[208] suggesting that the scale rather than the geometry of the underlying topography is the most influential factor on cell behavior. On the basis of these observations, we have focused on the scale (lateral and vertical dimensions) rather than the geometry (**Figure 8**).

1.129.4.1. Micron Range (>1000 nm Widths)

There are some notable examples of micron-scale topography significantly influencing cellular function in comparison to flat controls. Some of the earliest work looking at micron-scale topographical effects on cellular behavior examined fibroblasts,[209] neuroblastoma cells,[210] and neutrophil leukocytes.[211] Brunette *et al.* began investigations into how epithelial cells would be affected by micron-scale ridge–groove features. They observed cell contact guidance along ridges and outgrowth of human gingival explants in the direction of the long axis of the topography.[166] Other studies have used similar

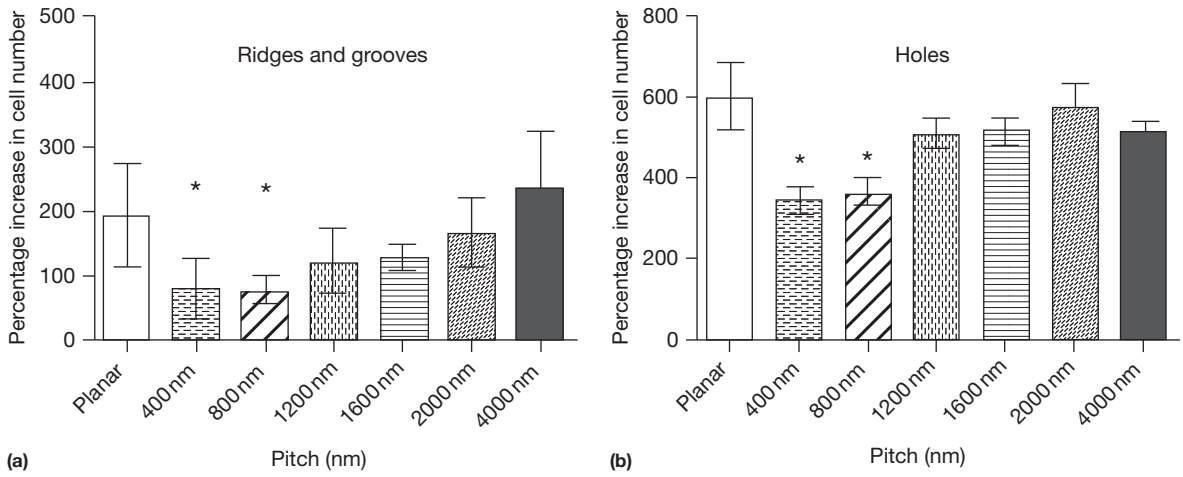

Figure 8 HUVECs demonstrate reduced proliferation rates on sub-1200 nm pitch features compared to micron-scale features and flat controls. The proliferation response was only dependent on the scale of the features: similar proliferation rates were observed for cells cultured on both ridge–groove (a) and pore (b) structures of the same pitch. Reproduced from Liliensiek, S. J.; Wood, J. A.; Yong, J.; Auerbach, R.; Nealey, P. F.; Murphy, C. J. *Biomaterials* **2010**, *31*, 5418–5426, with permission from Elsevier.

micron-scale ridge–groove features, including investigation into proper functioning macrophages, which are white blood cells that encapsulate (phagocytose) and digest debris and pathogens.[212] P388D1-macrophages showed increased cell attachment and phagocytosis when cultured on micro-grooved silicon surfaces (2–10 μm widths) compared to flat controls. In addition, as depth increased, so did phagocytosis.[212] This suggests that the addition of topographical cues aids in proper cell function of macrophages and by controlling the scale of the features (in this example, depth), the cell response can be modulated.

Other cell types cultured on micron-scale topographically patterned substrates also have demonstrated improved cell function and expression of characteristic protein markers. For example, osteoblasts, like many cell types, exhibit increased cell attachment to micron-scale topography (pores of 10–100 μm in diameter) compared to flat controls.[213] Osteoblasts also express increased levels of osteocalcin and alkaline phosphatase, two indicators of normal osteoblast phenotype, when cultured on micron-scale pores with submicron roughness compared to smooth micron pores and flat controls. This suggests that the submicron scale has an important role in proper osteoblast phenotype, and the combination of micron and submicron-scale topography has synergistic effects on cell behavior.[213] These studies show the impact that substrate topography can have on cell behavior and have encouraged researchers to probe the effects of even smaller feature sizes.

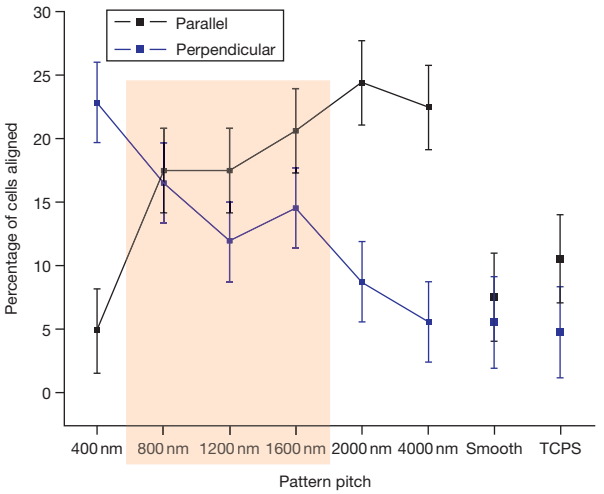

Figure 9 Human corneal epithelial cells in EpiLife® basal medium demonstrate transitional response to the underlying topographically patterned substrate when the feature dimensions increase from the submicron scale to the micron scale. HCECs align preferentially perpendicular to the 400 nm pitch groove–ridge features but prefer to align parallel to 2000 and 4000 nm pitch features. Cells align both parallel and perpendicularly on intermediate features of 800–1600 nm pitch. Adapted from Teixeira, A. I.; McKie, G. A.; Foley, J. D.; Bertics, P. J.; Nealey, P. F.; Murphy, C. J. *Biomaterials* **2006**, *27*, 3945–3954, with permission from Elsevier.

1.129.4.2. Submicron (400–1000 nm Widths)

With an abundance of data showing the impact of micron-scale topography on cellular behavior, numerous studies have taken one step closer to BM scale topography and have explored the effects of submicron features. Although these substrates do not directly mimic the scale of topographical features measured within the normal BM, they do provide insight into the importance and possible function of other topographic cues presented to the cell *in vivo*. For example, the BM can have a different topographical make-up during states such as wound healing or as a result of disease. Recent studies that use submicron and micron features have observed a transition zone in the range of 600–800 nm where differences in fundamental cell behaviors are observed. For example, HCECs cultured in media without serum have a significant population of cells that align perpendicular to ridge topography with widths of 70–400 nm. HCECs on substrates with ridge widths of 1–2 μm orient preferentially in the direction of the topographic cues. On topography with ridge widths in between the two ranges noted above (i.e., 600–800 nm), HCECs demonstrate populations of cells that align both parallel and perpendicular to the underlying ridge–groove structures[214] (**Figure 9**). It should be noted that this 'transition' in cell behavior from nano- to micron-scale may be cell-type specific and dependent on the culture environment. When a transition in cell behavior is observed, understanding how the behavior changes as a result of changes in the scale of topography may help in identifying the mechanistic pathways behind cell response to topography.

Other fundamental cell behaviors including proliferation, adhesion, and migration of HCEC cells also demonstrate a significant transitional response from the submicron to micron range. HCECs on submicron topography exhibit reduced rates of proliferation below submicron wide ridges compared to cells on micron and planar control.[215] Transformed SV40-HCECs also demonstrate modulation of cell adhesion strength in the submicron-scale range. On both 222–453 nm wide ridge structures (400–800 nm pitch) and 255 and 455 nm pores (400 and 800 nm pitch), SV40-HCECs demonstrate increased adhesion and resistance to shear flow compared to that on micron-scale topography.[141,207]

Cell migration rates are dependent on the scale of the topography and show significant differences between the submicron and micron ranges. Migration rates were high for SV40-HCECs on topography around the transition zone of 600–1000 nm wide ridges. Reduced rates were observed for cells on substrates with topography of 200–400 nm ridges (400–800 nm pitch) and on 2 μm ridges.[216] In a similar study, SV40-HCECs showed increased migration rates on 600 nm porous surfaces compared to nonporous controls.[184] What these and other reports have shown is that the submicron-scale topography can elicit a markedly different cell response compared to both micron-scale topography and flat controls. These findings provide more incentive to continue probing smaller and smaller features, specifically, feature sizes that better represent the scale of topography found in normal BMs (**Figure 10**).

1.129.4.3. Upper BM Range (100–400 nm Widths)

The upper range of topographical features, including elevations and diameters of fibers and pores, found in native BMs is 100–400 nm. Fabrication techniques to produce well-defined

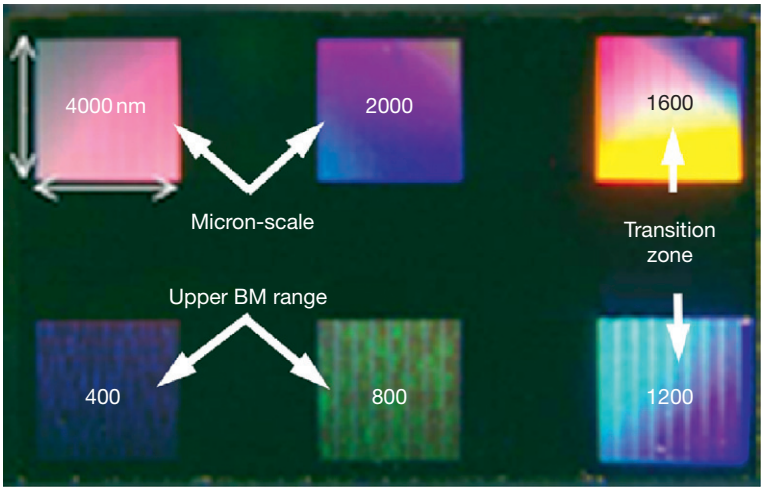

Figure 10 Three significant ranges of lateral dimensions, micron-scale, micron 'transition zone,' and submicron, are all represented on one silicon chip for cell studies. Studies have shown that certain cells exhibit different response (such as contact guidance, proliferation, and adhesion) to each scale. Adapted from Foley, J. D.; Grunwald, E. W.; Nealey, P. F.; Murphy, C. J. *Biomaterials* **2005**, *26*, 3639–3644, with permission from Elsevier.

topography in the upper BM range (in comparison to the lower BM range) are more advanced and highly employed in academia. The ease by which large patterned areas can be fabricated has created a wide breadth of research focusing on this range of topography. Examples of different cells and their characteristic responses to upper BM topography are presented below.

Topography in the range of 100–400 nm features influences cellular behaviors, such as adhesion,[141,207] contact guidance,[214] proliferation,[208,215] and migration[216] differently than submicron and micron features. HCECs have demonstrated increased adhesion when cultured on BM range topography compared to submicron, micron, and flat controls.[141] This finding suggests that the scale of the normal BM topography may play a role in cell adhesive strength and resistance to shear forces that may arise (as in blinking, blood flow, etc.). The strength of adhesion of corneal epithelial cells to 200–400 nm wide topography most likely directly impacts the ability of the cell to migrate. HCECs migrate along 200–400 nm ridges (400–800 nm pitches) at slower rates than cells on larger topography and flat controls.[216] In contrast, bovine corneal epithelial cells showed increased migration (as observed by cell outgrowth from a central button) on 100–800 nm pore substrates compared to micron-scale pores.[217] Together, these observations highlight the differences that arise between different cell types and their responses to topographical cues.

Cell protein expression and secretion are affected by topography with dimensions in the upper BM range and ranges found in other extracellular matrices. In bone, collagen fibers are organized in alternating parallel orientation with feature dimensions spanning from nano- to micron-scale.[218,219] Many studies have looked at the impact of nano- and submicron-scale topography on bone-specific cell types. For example, osteoblasts align and secrete collagen matrix parallel to 150 nm grooved (300 nm pitch and 60–70 nm deep) surfaces.[220] In addition, calvarial osteoblastic cells demonstrate increased proliferation rates and alkaline phosphatase activity on submicron rough surfaces compared to flat controls.[221] This range of topographic features may be essential for proper osteoblast phenotype.

Neurons are another example of cells that preferentially elongate in a particular direction in their native state. When cultured on topographical ridge features with submicron and micron-scale widths, PC12 (neuron) cells will align and elongate in the direction of the topography. When nerve growth factor (NGF) is present in high concentrations (50 ng ml^{-1}), PC12 cells will form neurites (a projection from a neuron cell body).[222] In the presence of both topography and NGF, PC12 cells demonstrate a threefold enhanced neurite formation on 200–400 nm (400 and 800 nm pitch) grooved surfaces compared to micron-scale grooved and flat surfaces when cultured in suboptimal concentration of NGF (5 ng ml^{-1} compared to 50 nm ml^{-1}).[223] Fibril topography with diameters in the range of 100–300 nm also elicits significantly longer neurite length and fibroblast growth factor (FGF-2) production from astrocytes.[224]

Topographic features in the upper BM range may also inhibit cell proliferation. On 200–400 nm ridge features (400–800 nm pitches), HCECs show decreased proliferation rates compared to larger topography and flat controls.[215,225] When taken collectively, the data presented for HCECs suggest that topography in the upper range of dimensions found in the BM have markedly different effects on cell phenotype than topography with larger dimensions and, most important, flat surfaces. One application for upper BM range topography is for improved *in vitro* cell culture systems. Most *in vitro* studies use tissue culture polystyrene (TCPS) for basic biological experimentation and development of therapeutics. The smooth surface of TCPS that does not replicate the native physical environment to which these cells are exposed could play a critical role in how cells respond to different chemical inputs, and possibly be a major contributor to inconsistencies between *in vitro* and *in vivo* studies.

1.129.4.4. Lower BM Range (10–100 nm Widths)

One of the major challenges researchers have faced when examining the effects of BM size topography on cellular behavior is the fabrication of nanometer (sub-100 nm wide) features. With the advancements of lithographic techniques designed primarily for the semiconductor industry, it is possible to produce surfaces with nanoscale features over large enough areas on which to culture cells. In general, most BMs have pore and fiber diameters ranging from 10 to 100 nm.[14,127–129,131,133–137,205,226] These dimensions constitute the lower size scale of topographical cues to which the basal layers of epithelial cells or endothelial cells are exposed.

To successfully mimic the smaller dimensions found in the BM, several studies have fabricated substrates with wave-like structures, lines, nanowires, fibers, islands, and pores with sub-100 nm features. These substrates have been used to determine the smallest feature width to which cells will exhibit a morphological response. Measured endpoints of the response have included both contact guidance and degree of filopodia extension. For example, Loesberg *et al.* investigated the lower topographic size range that would elicit cell contact guidance. They reported that rat dermal fibroblasts align to shallow 100 nm ridges (200 nm pitch, 77.4 nm depths), but do not significantly align to ridge widths below 100 nm.[145] In another study, immortalized human fibroblasts demonstrated a decrease in cell area and an increase in total number of filopodia when seeded on pit-defined topography with 75 nm pits (200 nm pitch and 100 nm depth) in comparison to flat controls. However, human fibroblasts did not exhibit significant differences on 35 nm pits (100 nm pitch, 50 nm depth) compared to flat controls.[227] These two studies suggest that fibroblast cells cannot sense topographic cues below a range of 75–100 nm features (or about 200 nm in pitch). In contrast, HCECs have been shown to increase alignment in response to wave-like structures with widths down to 30 nm (60 nm pitch and 200 nm depth)[187] (**Figure 11**). There are several differences between the studies including those in cell type, depth, and geometry of features, and the materials of substrates. These differences can contribute significantly to the responsiveness of the cells to topographical cues and may account for dissimilarities in a cell's ability to recognize sub-100 nm features. What all of these studies show is that there is a minimum feature dimension (given a specific depth and cell type) that will elicit a macroscopic cell response. This can be viewed as a given cell's tactile acuity limit. Understanding this lower scale of topographic features (in comparison to larger features and flat controls) will ultimately be beneficial in the design of improved prosthetics.

Other essential cell behaviors including adhesion, migration, and proliferation of cells in the presence of the smallest nanotopography fabricated have also been investigated. HUVECs

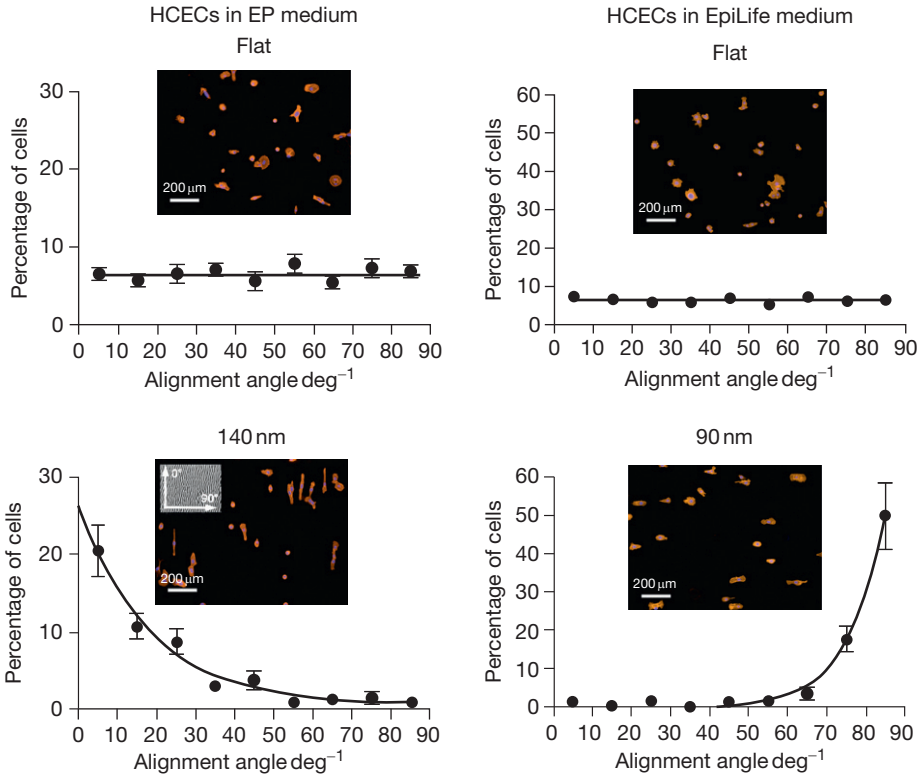

Figure 11 Human corneal epithelial cells demonstrate contact guidance to features with dimensions in the lower range of those characterized in basement membranes. HCECs in epithelial (EP) medium preferentially align parallel to 70 nm ridges (140 nm pitch), while cells in EpiLife® medium preferentially align perpendicularly to features as small as 45 nm (90 nm pitch). This example highlights the synergistic effects of topographical and soluble cues on cellular behavior. Adapted from Tocce, E. J.; Smirnov, V. K.; Kibalov, D. S.; Liliensiek, S. J.; Murphy, C. J.; Nealey, P. F. *Biomaterials* **2010**, *31*, 4064–4072, with permission from Elsevier.

exhibit enhanced adhesion and proliferation rates when seeded onto rough ($R_a = 30–40$ nm) surfaces compared to smooth controls.[228] Likewise, Hajicharalambous *et al.*[184] report increased SV40-HCEC attachment and migration on 100 nm porous surfaces compared to 600 nm porous and nonporous surfaces. In contrast, human fibroblasts demonstrate decreased attachment to 100, 200, and 300 nm pitch pits (35, 75, and 120 nm hole diameters) compared to flat controls.[229] These studies highlight the importance that experimental conditions (cell type, topographic scale and geometry, chemical make-up of the substrates, and method for collecting adhesion data) can have on observed cell outputs.

Most reports investigating how the range of topographical cues of the BM affects cellular behavior analyze cells in an undifferentiated single monolayer state. While results from these experiments are extremely insightful, they do not always represent how the cells will respond to similar cues *in vivo*. *In vivo*, epithelial cells are not organized into a single monolayer, but form multiple differentiated layers of cells. For example, the corneal epithelium is composed of several layers which include a basal layer of proliferating cells that adhere to the BM and six to eight layers of stratified superficial cells that have been induced to undergo differentiation. To investigate whether topographical cues impact the differentiation process, Evans *et al.*[230] observed bovine corneal epithelial cell proliferation and differentiation on substrates with pores ranging from 100 to 3000 nm in diameter. They observed the formation of a continuous basal lamina and a regular pattern of hemidesmosomes, similar to those observed in intact tissue, when cells were cultured on 100 nm pore surfaces. This indicates that BM relevant scale topography is possibly important for native basal lamina formation. In comparison, discontinuous basal lamina and interrupted hemidesmosome patterns were observed on 400–2000 nm pores, while neither a basal lamina nor hemidesmosomes were observed on 3000 nm pores.[230] Also, bovine CECs showed more stratified layers when cultured on 100 and 400 nm pore surfaces compared to 800–2000 nm pores and flat controls.[231] These observations reemphasize that the scale of topographical cues is important in eliciting cellular response and that topography with dimensions in the range of those found in the BM may play an important role in proper tissue development.

There are limited studies looking specifically at topographical cues with dimensions in the range of the smallest dimensions quantified in the BM (10–100 nm). However, the observations that have been reported are exciting and help us narrow down the range of sizes that should be tested. It is also critical to acknowledge that a 'one size fits all' approach is not going to work. Small changes to the environment to which the cells are exposed can have huge impacts on the cell response. Therefore, careful investigation of each cell type will be necessary to determine the best attributes to incorporate into substrate design.

1.129.4.5. Importance of Depth

For several cell types investigated, the depth is a critical factor involved in the cell's ability to respond to the lateral topographic features. In a study examining the influence of depth on HCEC contact guidance to 200–2000 nm ridges (400–4000 nm pitch), HCECs did not show significant levels of cellular alignment until the depth of the features exceeded 150 nm.[144] In another study, HCECs significantly aligned to 150 nm deep features compared to flat controls, but showed an increased percentage of cellular alignment when the depth was increased to 600 nm.[146] Together, these studies imply that the minimum depth needed to elicit HCEC contact guidance on 400 nm pitch features and larger is around 150 nm (Figure 12).

Research has also shown that the minimum depth necessary to elicit contact guidance is cell-type dependent. In a parallel study with HCECs, human stromal fibroblasts were examined to determine if depth played a significant role in eliciting contact guidance on 200–2000 nm ridged (400–4000 nm pitch) features. The stromal fibroblasts showed alignment to features with depths as low as 75 nm, which is significantly less than the depth needed to elicit contact guidance from HCECs.[144] Another study showed fibroblasts aligned to 2000 nm wide features with depth down to 50 nm depth.[142] In the same study, human endothelial cells and smooth muscle cells did not show significant alignment to 50 nm deep features. A minimum depth of 100 nm was necessary to elicit contact

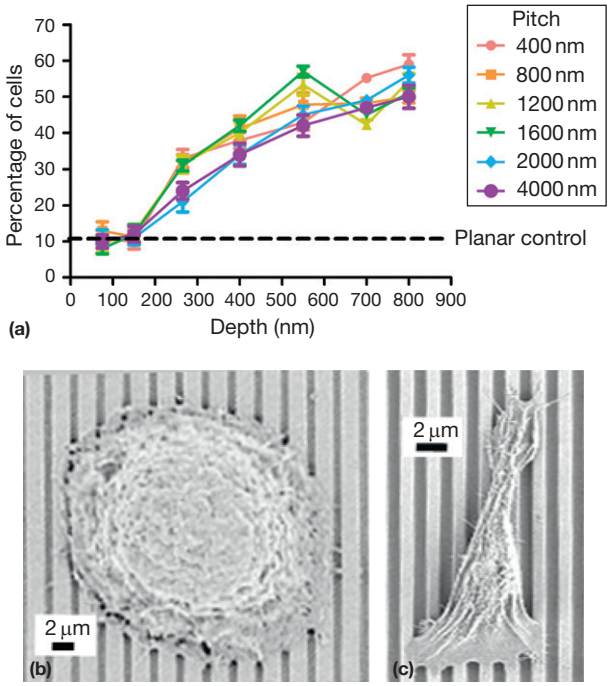

Figure 12 Cell contact guidance increases as depth of features increases. (a) Primary human corneal epithelial cells demonstrated increased alignment and elongation response when the depth of groove–ridge features increased from 70 to 900 nm. Similar cell response was observed for all groove and ridge features with pitches from 400 to 4000 nm. (b) If the depth was too shallow, cells did not show preferred elongation and alignment to the underlying topography, as represented by this cell on 4000 nm pitch features with a depth of 75 nm. (c) With depths of 265 nm and greater, cells elongated and aligned to all lateral pitches, including this cell on features with 1600 nm pitch and a depth of 265 nm. Adapted from Fraser, S. A.; Ting, Y. H.; Mallon, K. S.; Wendt, A. E.; Murphy, C. J.; Nealey, P. F. *J. Biomed. Mater. Res. A* **2008**, *86*, 725–735, copyright Wiley Periodicals, Inc., 2007.

guidance of endothelial and smooth muscle cells. Both studies highlight that cell response to topographical features is both depth and cell type-dependent. These are critical parameters to take into consideration when designing topographically patterned substrates for cell phenotype regulation.

Depth is not an 'on–off' switch for cellular response to lateral dimensions; rather, it is a factor that controls the extent to which cells respond to the lateral dimension. The fraction of baby hamster kidney (BHK) and Madin–Darby canine kidney (MDCK) cells aligning parallel to micron-scale grooved substrates increased as the depth increased (from 0.2 to 1.9 μm). The fraction of cells aligning was less affected by the lateral pitch (from 4 to 24 μm), showing similar fractions across all pitches for a given feature depth.[143] Similarly, incremental changes in depth from 75 to 800 nm resulted in gradual increases in aligned HCECs and stromal fibroblasts to 200–2000 nm ridge features. Other studies also have demonstrated that increasing depth of nano- and micron-scale lateral features significantly increases contact guidance of bovine aortic endothelial cells,[147] rat dermal fibroblasts,[145] and human fibroblasts.[142] Depth is a major factor in controlling cell response to topographical features and should play a role in the design of biomaterials.

1.129.4.6. Overview

The BM constitutes the native physical environment on which epithelial and endothelial cells reside and is composed of a compliant protein fibrous network that provides specific cues to the cells. A variety of BMs, across tissues and species, have been well characterized in terms of their protein composition, degree of stiffness (i.e., elastic modulus), and size of fibril features (i.e., topography). These biophysical cues help to regulate cell phenotype *in vivo*, but the mechanisms behind the regulation are largely unknown.

To answer some of the questions about how biophysical cues, specifically topography and elastic modulus, affect cell behaviors, researchers have fabricated an array of materials for *in vitro* cell culture. Many studies have shown that biomimetic elastic modulus alone can regulate cell behaviors and expression. Additionally, with the use of substrates containing nano- to micron-scale features, researchers have shown the impact that topography has on cell response. The nano- and microfabrication techniques used for these purposes have been widely employed in the semiconductor industries and adapted for cell culture. With the improvement of nanofabrication techniques over the past 50 years, it is now possible to produce small enough features to mimic those found in the native BM.

Topographical cues have been shown to have a significant impact on a variety of cell behaviors. Proliferation, differentiation, protein expression, migration, and cell morphology are affected by micron, submicron, or nanoscale features. Researchers have used a wide range of lateral dimensions, from tens of nanometers to hundreds of micrometers, to show that (1) topography plays an important role in cell function, (2) the scale of topography can modulate cell response to the topographical cues, (3) topographical cues work synergistically with other environmental factors (such as the soluble composition) to elicit controlled cell responses, and (4) cell responses to topographical cues are cell-type dependent.

The next step is to understand how biophysical cues regulate cell behaviors and to examine combinatorial effects of substrate topography and elastic modulus. By modulating these two substrate parameters, a clearer picture of how these specific biophysical attributes of the native BM influence cell behaviors can be drawn. In conclusion, the ultimate goal is to provide the necessary extracellular cues, through the incorporation of both biochemical and biophysical cues into the design of biomaterials, to initiate and maintain healthy tissue regeneration, create improved cell cultures systems that better approximate the *in vivo* environment, and inform the design and fabrication of improved prosthetics.

Acknowledgments

The authors would like to thank Julie Last and Jennifer Brockman for their helpful discussions. This work is supported in part by the NIH-National Eye Institute (1RO1EY017367-01A and 1RO1EY016134-01A2) and the Heart Lung and Blood Institute (R01HL079012-01A), and its contents are solely the responsibility of the authors and do not necessarily represent the official views of the National Eye Institute or the NIH.

S-EDOT	Sulfonatoalkoxy-3,4-ethylenedioxythiophene

1.130.1. Introduction

The development of conjugated polymers, also referred to as π-conjugated or semiconducting polymers, has established a new class of materials that can interface electrically active devices with living tissue. These devices include neural probes for recording[1,2] and stimulating neurons,[3,4] prosthetic devices that can record from or stimulate peripheral nerves,[5,6] cochlear implants,[7] retinal implants,[8] and cardiac pacemakers.[9] Typical device electrodes are made from electrically conductive materials such as gold, platinum, stainless steel, and iridium oxide. These materials produce flat, hard electrodes that do not integrate well with soft, ionically conducting tissue. In addition, there is an increasing need for smaller electrodes in order to record or stimulate localized areas of tissue for greater device specificity. Reducing a metal electrode surface area will result in an increase in electrical impedance and will produce a device with decreased recording and stimulating capabilities. On the other hand, conjugated polymers are a softer class of organic materials that can be synthesized with much higher surface

area and drastically reduced impedance compared to metal electrodes. Also, conjugated polymers can be chemically tailored with specific functional groups and can incorporate biological molecules either through covalent modification or entrapment during polymerization. These biological molecules could help reduce the inflammatory response and scar formation that occur upon implantation of a device in living tissue.[10] Consequently, the development and optimization of conjugated polymers for interfacing devices with biological tissue has been the focus of research groups around the world.[11–16]

Conjugated polymers have π-conjugated backbones that facilitate the movement of electrons or holes when the polymers are reduced or oxidized, resulting in conductivity.[17,18] The types of conjugated polymers used for electrode coatings have monomers with low oxidation potentials and include polypyrrole, polythiophenes, polyanilines, and derivatives of these polymers (Figure 1). An especially important derivative of polythiophene is poly(3,4-ethylenedioxythiophene) (PEDOT). This polymer and its derivatives have produced promising bioelectrode materials and will be discussed in depth in this article. Many other types of conjugated polymers exist, but they cannot all be easily synthesized as films on electrodes via electrochemical oxidation of the monomer. Electrochemical polymerization is the most common method for preparing conjugated polymer electrode coatings since it produces films grown directly off an electrode surface. In this synthesis route, a monomer and electrolyte solution are placed in a cell with a working electrode, a counter-electrode, and a reference electrode. Upon application of an electric potential or current, the monomer is oxidized and forms radical cations at the electrode surface (Figure 1). If conditions are suitable, the radical cations react to form polymer chains that precipitate onto the electrode surface.[19] As-polymerized polymer chains have charged backbones and thus must incorporate counterions from the electrolyte in order to create a neutral, stable film. Doping with counterions allows the positive charge or hole to move throughout the conjugated backbone and provides substantial charge capacity to the material. In addition, if the polymer films are oxidized or reduced, mobile anions or cations can move in and out of the film to compensate for changes in backbone charge. Many different types of anions have been used as dopants including small molecules, such as perchlorates, chlorides, and sulfonates, polymers with anionic pendant groups, and anionic biological molecules.

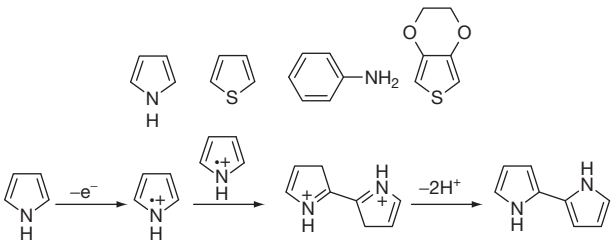

Figure 1 Monomer structures for commonly electrochemically polymerized polymers (top): pyrrole, thiophene, aniline, and 3,4-ethylenedioxythiophene. Electrochemical dimerization scheme for pyrrole (bottom). The same radical cation process continues until precipitation of the polymer.

In this chapter, we will discuss the different types of conjugated polymers used to interface devices with tissue. The material properties and biological interactions of polypyrrole and PEDOT will be discussed in detail, along with novel derivatives of these polymers and the potential use of a natural conjugated polymer, melanin. Also, other material processing techniques including gel encapsulation and nanotube formation will be included. In addition, we will review *in vivo* testing of conjugated polymers on devices, drug delivery through conjugated polymer actuation, and the possibility for *in situ* polymerization of conjugated polymer in living tissue.

1.130.2. Conjugated Polymer Electrode Coatings

1.130.2.1. Polypyrrole

The extensive study of electrochemically polymerized polypyrrole (PPy) films began in the 1980s, although there are reports of chemically polymerized PPy as early as 1963.[20–22] Since it was demonstrated that PPy could be easily deposited on metal electrodes,[23] its chemical, electrical, mechanical, and structural properties have been studied in detail. These properties, however, are highly dependent on the conditions during electrochemical polymerization, including the solvent, dopant, pH, current or voltage, and temperature.[24,25] Most importantly, it has been shown that the dopant used can affect the morphology of PPy films and, consequently, the electrical impedance of the material.[26,27] Cui *et al.* demonstrated that PPy films doped with small peptide fragments have fuzzy morphologies with high surface area.[28] As a result, the films have impedance magnitudes that are 1–2 orders of magnitude lower than bare gold at a frequency range from 10 to 10^4 Hz.

The interactions between PPy and living cells have also been examined, along with any potential toxicity. Williams and Doherty showed that electrochemically polymerized PPy doped with p-toluene sulfonate and washed with methanol is not cytotoxic to 929 mouse fibroblast and neuro2a neuroblastoma cells.[29] Additionally, a small current was applied through the PPy films and the cells continued to proliferate. Other studies using primary neural cells and tissue explants have shown similar results and indicate that unfunctionalized PPy is biopassive *in vitro*, meaning the polymer does not influence cell behavior.[30] However, the ability of PPy to facilitate electrical current has been used to change cellular morphology. Schmidt *et al.* subjected primed PC-12 cells to electrical stimulation on PPy and the cells produced longer neurites and spread out more on the substrate compared to control samples.[31] Although the cells could be electrically stimulated using the bare indium tin oxide (ITO) electrode, the cells did not adhere well to ITO, demonstrating that the cells prefer the rough, organic surface of PPy. Numerous *in vivo* studies have been performed using PPy as well. These studies are discussed in detail in the device section since most of the studies performed have implanted electrode-coated devices in animals.

Shimidzu *et al.* established that PPy can be doped with polyanions such as sodium poly(styrene sulfonate) (PSS).[32] These negatively charged polymers become entangled with PPy as electrochemical polymerization occurs and provide additional mechanical integrity to the films. Since the anionic polymer is trapped in the conducting polymer film, the cation,

sodium, is the mobile species. PPy has also been polymerized with polyanions that are biologically active such as growth factors,[33] polymers with extracellular matrix protein fragments,[28] enzymes,[34] peptide fragments,[28] heparin,[35] and hyaluronic acid.[34,36] Biological molecules can be incorporated with a co-dopant to improve the quality of the conjugated polymer films. In addition, these molecules may be physically trapped by the growing PPy film, rather than simply acting as the dopant. Unlike the passive nature of polypyrrole, the addition of bioactive molecules to electrode films can provide a means for directing cellular behavior. Importantly, it has been shown that biological molecules retain their biological activity after being trapped in conducting polymer. Kim *et al.* demonstrated that nerve growth factor (NGF) can be incorporated in PPy through electrochemical polymerization and the resulting films promote neurite outgrowth in PC-12 cells.[33] Also, the conducting polymer still has low impedance and high charge capacity. Interestingly, it has also been shown that live cells can be trapped in conducting polymer during electrochemical polymerization. Campbell *et al*. incorporated erythrocytes into PPy to create immunosensors. The erythrocytes can bind to specific antibodies, which changes the electrical resistance of PPy, thus providing a sensing mechanism.[37]

The main problem with using PPy for biomedical applications is its chemical and electrical instability.[38,39] Since pyrrole is unfunctionalized at both its α and β carbon positions, it has four available reactive sites during electrochemical polymerization. In an oxidative environment α–β′ coupling can occur and water or other nucleophilic compounds can react at the β carbon, creating defects in the polymer backbone. This type of reaction can also occur in the polymer during electrical stimulation. Yamato *et al*. compared the electrical stability of PPy and PEDOT, both with PSS counterion.[39] After holding the polymers at a constant potential in phosphate buffered saline for 16 h, the authors found that PPy lost 95% of its original electrochemical activity, whereas PEDOT only lost 11% of its original activity. It was predicted, based on previous literature, that hydroxide ions attack the β-position on the pyrrole repeat unit and break the conjugation of the polymer backbone (**Figure 2**). PEDOT, on the other hand, does not react with hydroxide ions since it has diethoxy functionalization at the β position. This study and other similar results have demonstrated that PEDOT is more suitable than PPy for devices that require long-term implantation and consistent electrical activity.

1.130.2.2. Poly(3,4-ethylenedioxythiophene)

The electrochemical polymerization of EDOT was first published in 1992 and the polymer PEDOT quickly became of interest as an electrode coating for its low oxidation potential and high chemical and electrical stability.[40,41] Similar to polpyrrole, it was shown that PEDOT has a high charge capacity and low impedance compared to the electrodes used for deposition. High surface area morphologies and tailored microstructures have been created that lower the impedance even further, making the polymer even more suitable for small bioelectrode coatings.[42–44] Although not necessarily an important property for biological applications, PEDOT films are also electrochromic, changing from dark blue to sky blue as the polymer is oxidized.[45]

In vitro toxicity and biocompatibility experiments have demonstrated that PEDOT, like PPy, is not cytotoxic to cells. Hep-2 human epithelial cells were shown to adhere better to PEDOT doped with perchlorate counterion than stainless steel electrodes and exhibited normal morphology and proliferation.[46] When treated with bovine serum albumin and other cell culture medium proteins the PEDOT samples adsorbed quantities of protein similar to polystyrene cell culture wells and stainless steel. Extracellular matrix protein adsorption allows cells to adhere to substrates *in vitro* but protein adsorption *in vivo* may result in foreign body recognition followed by an inflammatory response. To further examine the cytotoxicity of EDOT and PEDOT and to create hybrid conducting polymer-live cell electrodes, Richardson-Burns *et al*. polymerized EDOT around living SH-SY5Y neuroblastoma cells.[47] EDOT monomer was not significantly toxic to the cells over the time period needed for polymerization and the cells were able to survive the polymerization process. This finding has led to the polymerization of EDOT in tissue and the possibility of *in vivo* polymerization,[48] which is discussed at the end of this article.

Like other electrochemically polymerized conjugated polymers, PEDOT can incorporate anionic polymers and biomolecules as dopants, including peptides,[49] hyaluronic acid (HA), heparin, fibrinogen,[50] collagen,[33] and adenosine 5′-triphosphate (ATP).[51] Asplund *et al.* incorporated HA, heparin and fibrinogen into PEDOT as dopants and investigated the electrical and surface properties of the films.[50] These biomolecules are abundant in the human body and may be more suitable counterions for *in vivo* applications when compared to PSS. HA is a glycosaminoglycan found in the extracellular matrix of neural tissue, heparin is a polysaccharide anticoagulant, and fibrinogen is a glycoprotein involved in coagulation and thrombosis. PEDOT:HA and PEDOT:heparin films polymerized in a manner similar to PEDOT:PSS. On the other hand, PEDOT:fibrinogen was difficult to polymerize due to adherence of fibrinogen on the metal electrode surface prior to polymerization. In order to overcome this problem, a layer of PEDOT was deposited first, followed by PEDOT:fibrinogen. PEDOT:HA and PEDOT:heparin films have impedance and capacitance behavior similar to PEDOT:PSS, but PEDOT:fibrinogen did not produce films with adequate electrical and ionic conductivity. Additionally, it has been shown that PEDOT:heparin and PEDOT:HA films are not cytotoxic to L929 fibroblasts and SH-SY5Y neuroblastoma cells.[52] The incorporation of ATP, a nucleotide

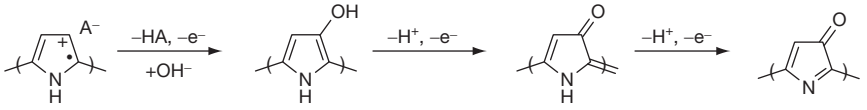

Figure 2 Side reactions during electrochemical stimulation of PPy. Hydroxide ions react at the β position and break the conjugation in the polymer.[39]

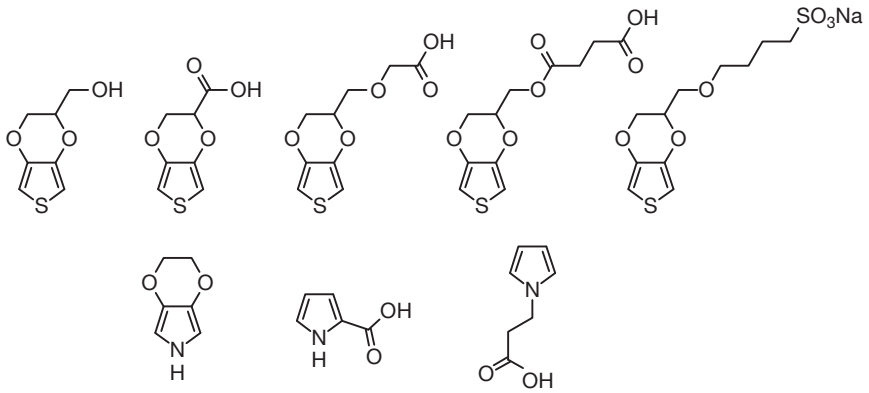

Figure 3 Example functionalized monomers for conjugated polymer electrode coatings (from top left): EDOT-OH,[54] EDOT-COOH,[55,56] C_2-EDOT-COOH, C_4-EDOT-COOH,[54] S-EDOT,[57] EDOP,[58] Py-α-COOH,[59] and PyCOOH.[60]

involved in multiple cellular functions including neural communication, also has interesting implications.[51] PEDOT:ATP films have a rough morphology, low impedance and promote adhesion of PC-12 cells. In addition, ATP is small enough to be released from conducting polymer films through electrical stimulation, resulting in an ATP delivery system.[53]

1.130.2.3. PPy and PEDOT Derivatives and Copolymers

Derivatives of PPy and PEDOT have been synthesized to produce conducting polymer films with additional chemical or biological functionality (**Figure 3**). Monomers with charged functional groups such as sulfonatoalkoxy-EDOT (S-EDOT) have been synthesized and can be used as self-dopants during electrochemical polymerization.[57] Another EDOT derivative that has been synthesized incorporates the hydroxymethyl functional group, which improves the solubility of EDOT in water. Additional functionality can also be added through reactions with hydroxy groups. Luo *et al.* used hydroxymethyl-functionalized EDOT (EDOT-OH) to create pendant carboxylic acid (EDOT-COOH), azide (EDOT-N_3) and *N*-hydroxysuccinimide groups (EDOT-NHS) on the EDOT monomers.[54] The films produced by microemulsion electrochemical polymerization of these monomers are ultra-smooth and have low cytotoxicity. In addition, the carboxylic acid can then be further functionalized with peptides or proteins through carbodiimide chemistry. Carboxylic acid functionalization has also been added to EDOT directly off of the diethoxy ring, producing the simplest possible EDOT-COOH.[55,56] Carboxylic acid-functionalized pyrroles have also been synthesized both as a pendant off of the pyrrole nitrogen and as an end-cap off of the α-position on the pyrrole ring.[59,60] RGD peptide-functionalized PPy made from these monomers have been used to increase cellular adhesion in human umbilical vascular endothelial cells compared to regular PPy. Derivatives of PPy based on poly(3,4-alkylenedioxypyrrole)s such as poly(3,4-etheylenedioxypyrrole) (PEDOP) also show potential for bioelectrode coatings. These polymers have better chemical and electrical stability than PPy and also very low oxidation potentials.[58] Many other EDOT derivatives have also been synthesized for nonbiological applications and have been reviewed in detail by the Reynolds group.[61,62]

The chemical functionality and material properties of conjugated polymer films can also be tailored through the process of electrochemical copolymerization. Monomers with similar oxidation potentials can be simultaneously polymerized to make random copolymer films. Block copolymer films can be formed by sequential polymerization of monomers. With this method, however, it is unclear whether the second polymer is covalently bonded to the first polymer or if they form two unbonded layers. Commonly, functionalized monomers are copolymerized with unfunctionalized monomers to create films with optimized functionality and stability. Biotin-functionalized pyrrole has been copolymerized with pyrrole in order to create stable, conducting films that can react with the protein avidin.[63] Biotin-functionalized enzyme or other protein can then bind to another avidin reactive site, thus producing biomolecule immobilized films.[64] Copolymerization is also advantageous in the formation of films with S-EDOT. Since this monomer is charged, the electrochemical polymerization of pure S-EDOT forms water-soluble oligomers.[65] Incorporation of unfunctionalized EDOT increases the hydrophobicity of the polymer and allows precipitation of the copolymer onto an electrode surface. Other copolymers have been formed including PEDOT/PPy,[66] PEDOT/PEDOT-OH,[67] PEDOT/polyindole,[68] and PPy/polyindole.[69]

1.130.2.4. Melanin

PPy and PEDOT can be biofunctionalized in order to reduce inflammation upon implantation and control cellular behavior, but using a natural conducting polymer may result in a more desirable biological response. The conducting polymer melanin is found in pigmented tissue such as hair, skin and eyes. Interestingly, it is also found in the inner ear and substania nigra of the brain.[70] Although the function of melanin in these areas is not known, it is speculated that it could be involved in ion binding and transport.[71] Eumelanin, a specific type of melanin, has been electrochemically polymerized, often using the monomer L-dopa and counterion sodium tetraborate to produce dark brown films with broadband absorption.[72] However, these films have not been used as biomaterials, possibly due to the toxicity of the tetraborate counterion and, therefore, lack of biocompatibility. Melanin

electrode films have been made using other precursors but most have not been investigated for their ability to interface with biological tissue. However, it has been shown that chemically polymerized eumelanin is not cytotoxic to PC-12 cells nor primary Schwann cells.[73] Recently, 5,6-dimethoxyindole-2-carboxylic acid, a methoxy derivative of a melanin repeat unit, was electrochemically polymerized to produce green films that are also electrochromic, unlike typical eumelanin.[74] The ability to tailor the chemical structure and properties of melanin may result in well-designed melanin films that can be used to interface electrodes with biological tissue; however, this has not yet been obtained.

1.130.3. Conjugated Polymers on Devices

1.130.3.1. Conjugated Polymers for Living Tissue Interfaces

Currently, one of the most successful biomedical applications of conducting polymers is the coating of neural implants to form efficient bioactive interfaces between living tissues and electronic devices. In a living body, this neural electrode works as an electrochemical transducer of electronic to ionic signal and, more specifically, to neuronal signals. The neuronal signal, or action potential, is regulated by ion flux across the cell membrane through ion channel proteins. These ion channels are gated by electromotive potential (voltage-gated), chemical transmitters (ligand-gated) and other activation mechanisms such as pressure (mechanically gated). Each ion channel responds only to its specific gate stimuli.[75] Furthermore, ionic transport through the ion channels is only $\sim 10^8$ ions per second, which is considerably slower than electronic charge carrier mobility ($1\,A \sim 10^{18}$ electrons per second). Thus, if an electrode is designed to interact with cells by effectively providing a gating stimulus, then milder stimuli can be employed to overcome any bottleneck effect of the signal transduction at the interface, which will minimize tissue damage.

Conjugated polymers can provide several gating signals to cells, including charge conduction, storage/release of neurotransmitters and mechanical swelling or contraction. For practical reasons, the conventional neural electrode studies utilized electrochemical potential mechanisms.[76,77] At the interface of electrochemical cells, charge exchange occurs between ions and electrons by capacitive (nonfaradaic), pseudocapacitive (reversible faradaic), and irreversible faradaic charge transfers. Merrill *et al.* reviewed the details of these charge injection mechanisms and safe stimulation protocols of neural electrodes.[77] Among these, the desirable charge transfer mechanism is reversible faradaic charge injection/reception at the interface because both electrodes and living tissues are less damaged by harmful irreversible reactions and corrosion. In polymer electrodes, this pseudocapacitive charge can be significantly increased by ion exchange in the polymer chains, micro-/nanopores affecting ionic boundary layers,[78] and ion pools controlled by a Donnan potential equilibrium (**Figure 4**).[79] One note here is that charge exchange sites can exist not just at the surface but also throughout the whole volume of conducting polymer, unlike metallic and ceramic electrodes. Furthermore, these reversible faradaic transfers are relatively slow to reconcile fast electronic injection to the slow biological ion channel gating at cell surfaces. Thus, conjugated polymers work more efficiently as electrochemical transducers and are superior to conventional electrode materials in living tissue applications. In addition, polymers are easily tailored to mimic the chemical structures, morphologies, and functions of living tissues so that their material properties become more chemically and mechanically similar to living tissues.

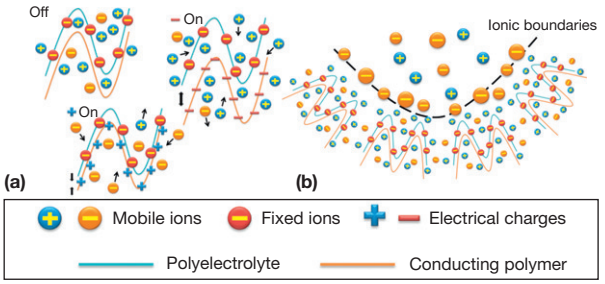

Figure 4 (a) Charge balancing between mobile cations and anions depending on the net potential of the molecular backbone and (b) Donnan equilibrium across an interface where the local concentration is balanced by a net ionic charge.

1.130.3.2. Neural Electrodes for Recording and Stimulating

Early studies of neural stimulation through conjugated polymers were performed by the Langer group. As mentioned previously, Schmidt *et al.* demonstrated that electrical stimulation of PC-12 neural cells on PPy:PSS results in enhanced neurite outgrowth.[31] This work ignited the applications of electrically conducting polymers toward living tissue interfaces with two ramifications: coatings on neural electrodes and nerve regeneration guidance channels. Soon after, Cui *et al.* reported that PPy:PSS could be selectively coated on multichannel microelectrodes, often called the 'Michigan Probe,' which are designed for single cell neural stimulation and recording. Compared to bare Au, this PPy:PSS coating can reduce the impedance of a microelectrode site by more than two orders of magnitude. *In vivo* guinea pig tests demonstrated that PPy:PSS coatings improved acute neural recordings dramatically compared to bare metal electrodes.[80] In order to mimic extracellular matrix, the same group mixed extracellular matrix components such as fibronectin and laminin fragments with the PPy coating.[28] Human neuroblastoma cells showed a greater affinity for these PPy/peptide coatings than Au electrodes *in vitro*. Furthermore, this polymeric electrode coating has shown great potential for *in vivo* and possibly chronic neural communication. Demonstration of longevity upon implantation is one of the ultimate challenges in neural probe research. Both low impedance of implanted electrodes and close proximity of neurons are required for effective neural signal recording. The latter can be potentially accomplished by recruiting a high population of neurons to the surface and by minimizing glial scarring at the interface. Migration of neurons away from electrodes is typical with implanted devices, especially hard materials. The PPy/peptide interface promotes the adhesion of living neural cells, demonstrated by *in vivo* guinea pig implantation and histology experiments. Although inflammatory gliosis still

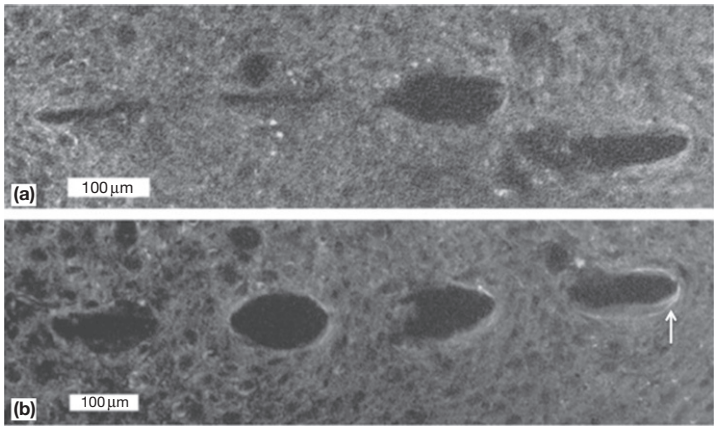

Figure 5 Immunostaining of neurofilaments around (a) uncoated bare Au electrode and (b) PPy/peptide coated electrode probes after 2 weeks of implantation. Higher densities of neurofilaments are shown around the coated than the uncoated probes. A representative neurofilament is highlighted with an arrow. This result explains why the coated probes have more neural signal recordable sites. Reprinted from Cui, X. Y.; Wiler, J.; Dzaman, M.; Altschuler, R. A.; Martin, D. C. *Biomaterials* **2003**, *24*, 777–787, with permission from Elsevier.

proceeds over time, the PPy/peptide certainly improved recording over a 3 weeks period by recruiting neural cells to the electrode interface (Figure 5).[38] In later studies, it was shown that PEDOT on neural probe electrodes is more chemically and electrically stable than PPy (Figure 6),[49] as initially indicated by Yamato *et al.*,[39] while sharing the advantages of PPy such as biocompatibility and the ability to be doped with biomolecules. In a report by Nyberg *et al.*, PEDOT:PSS coated microelectrodes demonstrated more sensitive and stable recordings of cortical cell neural networks compared to ITO electrodes.[81] In addition, Ludwig *et al.* demonstrated the *in vivo* biocompatibility of PEDOT by implanting PEDOT: perchlorate coated 'Michigan Probes' in the motor cortexes of eight rats.[82] PEDOT lowered the impedance of the electrodes and increased the signal-to-noise ratio for 6 weeks after implantation. However, after 6 weeks scar formation around the implant created an increase in impedance for both the PEDOT-coated and control neural probes.

The diverse morphologies of conjugated polymers have been utilized to improve the physical properties of neural electrodes. Given the softness and slow charge transport of cells, efforts have been made to create porous and soft polymers. Yang *et al.*, demonstrated that the porosity could be controlled both in PPy and PEDOT polymers by polystyrene (PS) microsphere templating techniques.[83] It has also been found that PEDOT forms nanofibrillar structures when mixed with poly(acrylic acid) (PAA) and lithium perchlorate.[43] The mechanical properties of PEDOT coatings with different morphologies have been tested, with the lowest modulus of PEDOT reported to be around 10 MPa.[44] The lowest impedances were also obtained with the softest, roughest coatings. This pattern implies that ionic transport in and out of the polymer is facilitated with fuzzier PEDOT morphologies (Figure 7). In a study by Gelmi *et al.*, the stiffness of PPy was adjusted through the use of different counterions.[84] When PPy is electrochemically polymerized with *para*-toluenesulfonic acid (pTS), hyaluronic acid (HA), dextran sulfate (DS), chondroitin sulfate A (CS), and poly(2-methoxyaniline-5-sulfonic acid) (PMAS), the Young's moduli were 1000, 706, 660, 290, and 30 MPa, respectively. This controllability of stiffness may be useful for applications at harder tissue interfaces such as muscle.

1.130.3.3. Nerve Regeneration Guidance Channels and Bionic Interfaces

The full function of injured or severed nerves can be recovered only if properly treated. Clinically, the gold standard of peripheral nerve regeneration is utilization of autologous nerve grafts, which are taken from the injured patient, as guidance conduits. However, autologous nerve grafts are not always available. Thus, foreign or synthetic materials should be adopted for clinical applications. The ideal nerve guidance conduits may require durability, flexibility, biodegradability, supply of bioactive substances such as growth factors and support cells, oriented intraluminal channels, and electrical activity.[85,86] Many studies have been performed, but so far no synthetic material meets all of these conditions. Instead, acellular nerve tissue grafts from human tissue donors are commercialized and expected to fulfill the clinical needs. The past research efforts on creating synthetic guidance channels may not be applicable directly to neural regeneration, but the research findings are still beneficial for chronic bionic interfaces that are now emerging.

The key difference between peripheral nerve guidance channels and central nervous system electrodes is that guidance channels aim to promote axonal outgrowth and alignment so that the channels interface mostly with axons rather than cell bodies. This interaction has been demonstrated by Corey *et al.* in the use of aligned electrospun nanofibers made out of poly-L-lactate, which influence the directionality of neurite growth in dorsal root ganglia (DRG) explants.[87] The Wallace group combined biodegradable fibers with a PPy conducting polymer platform to stimulate aligned axonal growth.[88] Electrical stimulation through the conducting polymer enhanced both axonal growth and migration of Schwann cells from DRG explants (Figure 8). Furthermore, the axonal growth and migration of Schwann cells were aligned along the uniaxial poly(lactic acid)

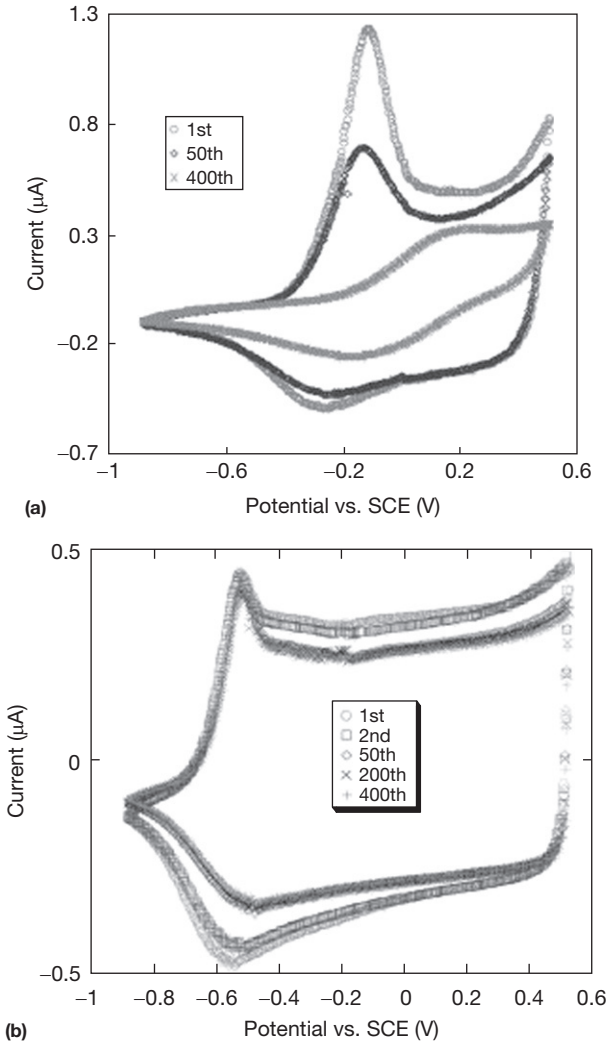

Figure 6 Electrochemical stability by cyclic voltammetry of (a) PPy:PSS and (b) PEDOT:PSS with scan rate 0.1 V s^{-1}. While PPy:PSS loses its charge storage capacity with repeated cycles, PEDOT:PSS maintains a relatively large storage capacity. Reprinted from Cui, X. Y.; Martin, D. C. *Sensors Actuat. B Chem.* **2003**, *89*, 92–102, with permission from Elsevier.

(PLA) and poly(lactic-*co*-glycolide) (PLGA) fibers. In another similar study, Lee *et al.* demonstrated that PC-12 cells could be aligned on PPy coated PLGA nanofibers.[89] With electrical stimulation and fiber alignment, the cells had 40–90% more neurites than control samples and the neurites were also 40–50% longer.

Certainly, electrical stimulation of neural cells on conducting polymers facilitates neurite outgrowth, which has been confirmed by many other reports. One addition to this principle is that conducting polymers with bioactive molecules such as growth factors enhance the length of neurites synergistically with electrical stimulation. Richardson *et al.* and Thompson *et al.* reported that both electrical stimulation through PPy:pTS and delivery of neurotrophin-3 (NT-3) growth factor affect the length and the number of neurites on cells in cochlear explants.[90,91]

1.130.3.4. Neural Communication Through Ionic Stimulation

One of the most unique applications for conjugated polymers is a static ion pump with selective ion flux controls. Conventional neural electrode concepts involve charge transduction between electrons and ions at cellular interfaces. However, ion pumps made using PEDOT:PSS can directly inject ions to communicate with cells, even without creating fluid flow or pressure build-up. Isaksson *et al.* created microfabricated PEDOT:PSS patches that can selectively drive cellular signaling ions, such as Ca^{2+} and K^{+}, to microchannels containing individual neural cells.[92] It was shown that stimulation with ions could affect the behavior of cells in the microchannel without influencing cells 500 μm away. This ion pump was further developed to deliver selective neurotransmitters *in vivo* to guinea pig cochlea through a syringe-like pump design.[93] This direct ion-injecting paradigm has advantages in establishing communication between living tissues and devices including the safety of avoiding electrical shock, the versatility in delivering bioactive ions, and direct controllability by electrophoretic modulation. Thus, it is expected that new neural electrode designs following this ion pump concept will be actively researched in the future. A similar concept utilizes the fact that conjugated polymers can accept various quantities of electrons or ions, which can be described as different electrochemical states. The varying electrochemical redox states of PEDOT have been used to influence cellular behavior.[94] Epithelial cells were tested on PEDOT:pTS surfaces *in vitro*. Interestingly, the cells proliferated selectively on reduced PEDOT surfaces, not on the oxidized material. The cause, as the authors suggested, may be the conformational changes of fibronectin on oxidized PEDOT:pTS, and the resulting inability for cellular adhesion. This electrochemical modulation technique may be used as an on/off type tool for manipulating living tissues.

1.130.4. Implantable Modification of Conjugated Polymers

1.130.4.1. Conjugated Polymer/Hydrogel Composites

Conducting polymers can be modified with hydrogels, which improve small molecule transport, the degree of hydration, and the mechanical flexibility of the composite. As a result, these conjugated polymers composites become even more similar to the extracellular matrix. Conducting hydrogels are used in various applications such as biosensors and drug delivery, which were discussed in recent reviews.[95,96] Our discussion here will be limited to neural electrode applications of conjugated polymer hydrogels. The most important features of hydrogels are their mechanical softness and flexibility. Thus, conducting polymer hydrogels can provide a mechanical buffer layer between the rigid electrodes and living tissues. The brain, whose elastic and shear moduli are the orders of 1[97] and 10 kPa,[98] respectively, is one of the softest tissues in the body. Furthermore, regeneration of nervous systems,[99] rate of neurite extension,[100] and neuronal differentiation of stem cells[101] all exhibit a preference for soft, elastic culture matrices.

Secondly, hydrogels contain structures that function well as electrochemical transducers. While conducting polymers

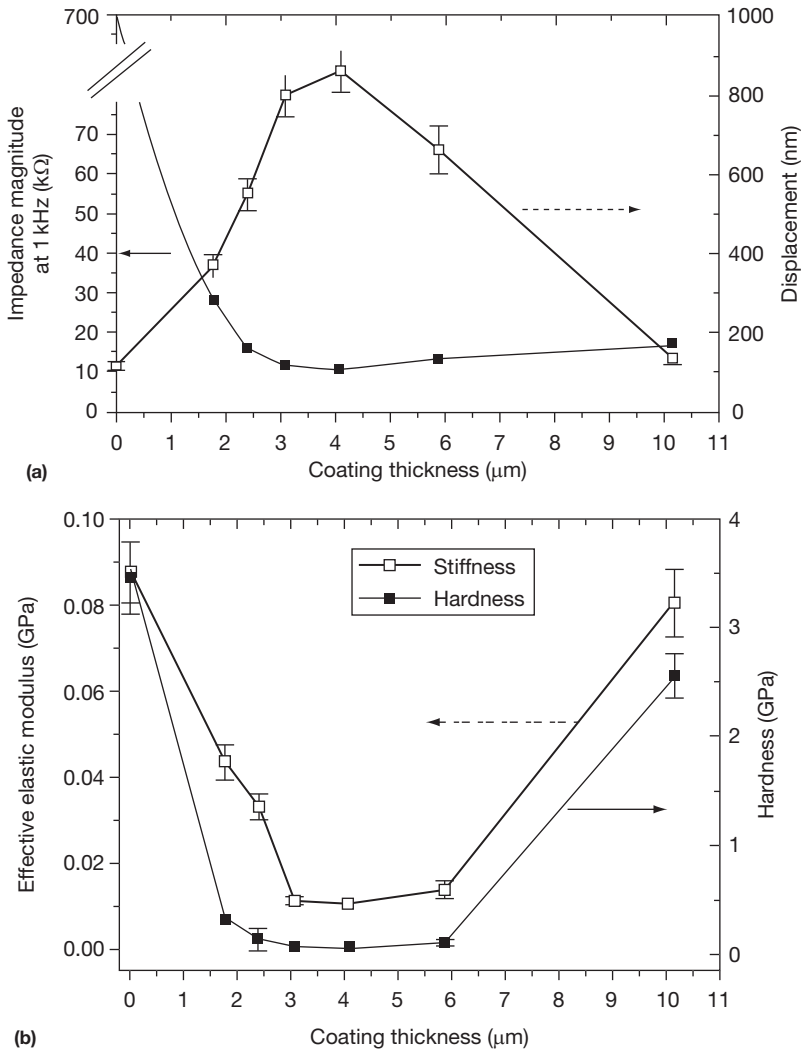

Figure 7 (a) Impedances and displacement of nanoindentation and (b) modulus and hardness as a function of PEDOT thickness. Reprinted from Yang, J. Y.; Martin, D. C. *J. Mater. Res.* **2006**, *21*, 1124–1132, with permission from Material Research Society.

provide delocalized electromigration pathways through the conjugated backbone, electrical field-mediated ion movement can occur from the polymeric chains to fluid media and vice versa. In a conducting polymer gel, the capacity of this ion flux is even further expanded by the elevated porosity and hydration. Thus, the merits of employing conducting gel bioelectrodes cover not only mechanical and biological properties, such as low interfacial tension and the promotion of cell adhesion, but also improvement of electrochemical efficiency and electrode safety by reducing possible tissue damage through irreversible faradaic reactions.

Charge transfer efficiency studies were performed in the early works on conjugated polymer hydrogels, following the technical demonstration of electrochemical polymerization through hydrogel networks.[102] Kim *et al.* introduced biocompatible conducting composite hydrogels with natural alginate and PPy on neural microelectrodes.[103] After alginate gels containing pyrrole monomer were formed by $CaCl_2$ cross-linking, PPy/PSS was vertically grown from the microelectrode along the gel by galvanostatic deposition. This vertical polymerization through a gel is a general process of conducting polymer growth and has been shown in other materials like PEDOT (**Figure 9**).[104] Also, the polymerization pattern corroborates the theory that electrical charges are locally injected by ion flux out of alginate chains and long distance electro-migrations are only guided by conducting polymer chains inside the hydrogel (**Figure 4**). Thus, these expanded ion migration pools in the PPy/PSS/alginate conducting hydrogels are reflected by the exceptionally high charge storage capacity, 560 mC cm^{-2}[103] which can be compared to 186 mC cm^{-2} for a PPy/PSS only coating.[80]

Neural electrodes with conducting polymer/hydrogel composites have been tested to establish stable recording performances with hopes of chronic recording in the future. Kim *et al.*, found that alginate hydrogel with PEDOT grown through it can relay stable neural recordings to microelectrodes in a guinea pig animal model.[105] PEDOT-hydrogel coatings perform better than hydrogel coatings alone. Since PEDOT is

grown through the hydrogel, a better electrical connection is maintained with the surrounding neurons. Currently, long-term electrochemical stability of a conducting hydrogel coating has not yet been obtained. Meanwhile, several other techniques such as conducting elastomers and conducting polymer nanotubes have been employed to reduce the mechanical modulus while preserving electrochemical durability. Keohan *et al.* used PPy conductive elastomer to soften the

interfaces of cuff electrodes.[106] PPy-siloxane copolymers showed electrochemical stability over more than 10 days of stimulation *in vitro*. Another way to buffer the mechanical stiffness of metallic electrodes is to form conducting polymer nanotubes. In a recent report by Abidian *et al.* it was demonstrated that PEDOT nanotube coatings on a neural microelectrode could enhance *in vivo* signal-to-noise ratio significantly. Furthermore, these enhancements were translated to the chronic performance stability of PEDOT nanotube-coated neural electrodes, which lasted up to 49 days.[107]

Although some long-term *in vivo* studies have been reported, the ultimate challenge in neural electrodes is creating an interface that is stable and robust for years. Generally, the communication breakup of neural electrodes may be caused, not by the failure or degradation of materials, but by inflammation such as implantation trauma, Wallerian degeneration, and glial scar formation (gliosis). The insulating scars, which are gradually thickened, isolate electrodes from tissues, similar to body piercing effects, thereby disrupting communication signals. Therefore, a chronic interface may be possible by quenching the inflammation response toward implanted electrodes. A new approach has been demonstrated involving anti-inflammatory drugs that can quench gliosis and thus extend the life of the neural electrodes. Demonstrating that hydrogels are excellent biomolecule carriers, Kim *et al.* showed that PLGA nanoparticles with dexamethasone, which is an anti-inflammatory and immune-suppressive steroid, could be mixed into an alginate hydrogel coating on neural electrodes.[108] *In vivo* Guinea pig studies revealed that the impedances of the coated electrodes were stable for more than three weeks while noncoated metal electrodes lost their functionality in 16 days. Similarly, Zhong *et al.* showed that the anti-inflammatory neuropeptide α-melanocyte stimulating hormone (α-MSH) can be used in coating neural electrodes.[109]

1.130.5. Conjugated Polymer-Based Drug Delivery

The delivery of drugs to targeted locations in the body in a controlled way is a significant technical challenge. Traditional oral- or injection-based delivery relies on maintaining a high systemic drug concentration; this consequently requires multiple doses, and a large fraction of the delivered drug is often cleared from the body before performing its therapeutic function. Particularly in the case of highly toxic drugs, local, targeted delivery is critical as high systemic concentrations could lead to undesirable side effects. In other instances, sensitive compounds must be protected from enzymatic or hydrolytic degradation before reaching the target site.

Many strategies have been recently developed to overcome such limitations. Drugs have been conjugated to synthetic polymers such as poly(ethylene glycol) (PEG) to provide enhanced water solubility and circulation times, while helping prevent uptake by the spleen, liver, and kidneys.[110] Conjugation with linear polymers is typically through one or both chain ends, which limits loading capacity. As an alternative, several groups have begun using dendrimers,[111] which present many surface functional groups in a compact macromolecular architecture. Liposome and micelle-based carriers can also provide a protected environment for the drug to circulate and allow for very high loading.[112] Targeting of specific delivery sites has been attempted through the use of recognition elements such as peptides,[113] or in the case of cancer treatment through the enhanced permeation and retention (EPR) effect.[114] When systemic circulation is especially undesirable, drugs have been encapsulated within hydrogels[115] or biodegradable polymers,[116] allowing for much slower release and localized delivery through implantation of the conjugate at the site of interest.

In contrast to such passive strategies, conducting polymers have provided a means for targeted, triggered delivery through electrical or electrochemical actuation. PPy and PEDOT in particular have proven to be highly biocompatible, both *in vitro* and *in vivo*. Thin films can be electrochemically deposited on conducting substrates or cast from solutions of chemically synthesized polymers, and many unique geometries have been demonstrated such as porous sponges,[117] nanotubes,[107,118–120] and coated acellularized scaffolds.[121]

The use of conducting polymers for drug delivery is based on actuation through reversible oxidation and reduction of the polymer backbone. In the fully oxidized state, the polymer is positively charged and has anions associated for charge neutrality. The actuation mechanism depends in part on the nature of the counterion, whether large and bulky or small and mobile. As the polymer is biased and reduced, the overall cationic charge density decreases, and in the case of small anions this change is accompanied by the expulsion of counterions and a decrease in the polymer volume. In the case of large, immobile counterions such as PSS, anion expulsion is not possible and so cations in the surrounding solution diffuse into the film and increase its volume. This effect has been utilized in macroscopic soft actuators[122] as well as microscopic drug delivery vectors.

Triggered drug delivery using conducting polymers can be achieved in several ways, but the most common strategy is to directly incorporate the drug of interest as the counterion during polymer synthesis. Because electrochemical polymerization results in cationic polymer chains, anionic drugs are the primary targets. When a particular anionic species cannot be directly incorporated during deposition, ion exchange via electrochemical cycling in the presence of the desired compound is used to 'load' the film. Cationic drugs are less common but can be incorporated when the primary counterion is bulky, such as PSS. Glutamate,[123] dopamine,[123] adenosine 5′-triphosphate (ATP),[124,125] salicylate,[126] naproxen,[126] and neurotrophin-3[127,128] have all been incorporated into conducting polymer layers as counterions and subsequently released electrochemically.

Much more challenging, however, is the delivery of neutral drugs. Because conducting polymer actuation is based on charging and discharging of the polymer backbone and the associated release of counterions, no driving force exists for the movement of neutral species. Early attempts involved doping the conducting polymer film with an ionic cyclodextrin followed by loading with a neutral guest, but its release still relied on a redox reaction of the guest molecule.[129] In neural applications, inflammation and scar tissue formation are highly undesirable and so the delivery of anti-inflammatory drugs, such as dexamethasone, is an important target. Several strategies have been developed to overcome this limitation; the

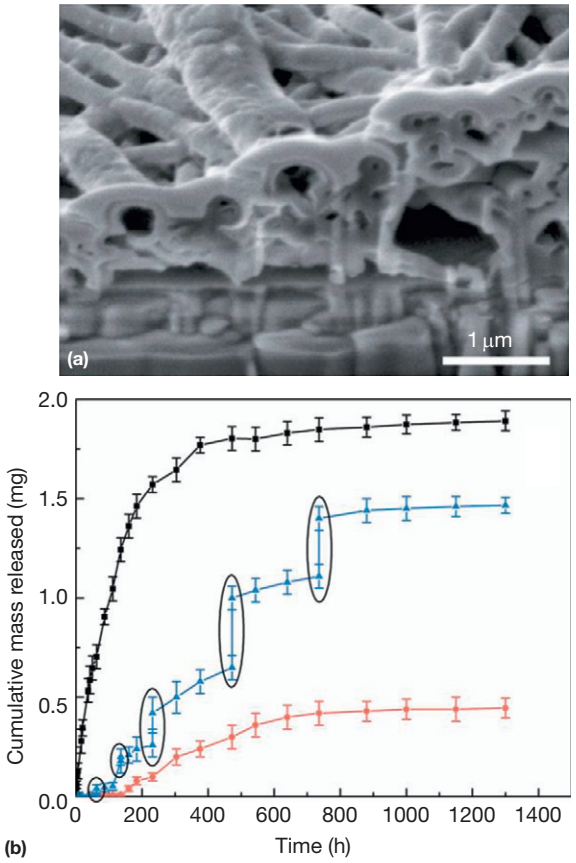

Figure 10 Electrically stimulated release of dexamethasone from PEDOT nanotubes (top) and SEM micrograph showing the size and morphology of the nanotubes. Reprinted from Abidian, M. R.; Kim, D. H.; Martin, D. C. *Adv. Mater* **2006**, *18*, 405–409, with permission from Wiley.

pro-drug dexamethasone disodium phosphate can be converted *in vivo* into an active drug and has been incorporated into PPy as a counterion during deposition.[117,130,131] More recently, triggered release of neutral dexamethasone has been achieved through its incorporation in PEDOT nanotubes.[119] Fibers of a degradable polymer containing the drug were electrospun, then coated with PEDOT via electrochemical deposition (Figure 10). Degradation of the fibers resulted in hollow nanotubes containing the drug, which could be compressed and released using an applied bias. On actuation via an externally applied voltage bias, dexamethasone was shown to be released into the solution, either through cracks and pores in the tube walls or out the ends of the tubes.

Beyond delivering a single drug, it is desirable to trigger the release of multiple different drugs at defined time points. To demonstrate this, a microchip has been developed with addressable microelectrodes onto which PPy can be deposited electrochemically. The electrically triggered release of two different drugs, ATP and sulfosalicylic acid, was achieved.[132] Chemical triggers can also be utilized for drug release. Reduction of PPy/ATP films by either hydrazine or the bioreductant dithiothreitol resulted in the release of ATP and a decrease in the film conductivity.[53]

1.130.6. Synthesis of Conducting Polymers *In Vivo*

Conducting polymers, in particular PPy and PEDOT, are demonstrably biocompatible and have been utilized in implantable devices as electrically active coatings, sensors, and actuators. It is presumed, however, that even more effective electrical connectivity with living tissue would be achieved through one of several routes, including seeding of the device with neural progenitor cells or electrochemical polymerization directly within the tissue itself (rather than by implantation of a pre-formed device). The former strategy attempts to minimize the formation of the reactive scar around the implant through the secretion of neuroprotective and neurotrophic factors and consequently allow the signaling neurons to remain closer to the electrode. This strategy has shown some success over the short term in neural probes, with an initial reduction in nonneuronal encapsulation, but over long-term implantation a greater concentration of nonneuronal cells compared to nonseeded probes was observed.[133] Similarly, cochlear implants seeded with brain derived neurotrophic factor (BDNF)-secreting fibroblasts yielded a significant improvement in spinal ganglion cell survival for several weeks post-implantation.[134]

In contrast, electrochemical deposition of conducting polymer within living tissue has been proposed as a strategy to effectively extend the electrode past the glial scar by the formation of conductive filaments through the interstitial spaces. This strategy provides several potential benefits. First, the natural immune response could be allowed to proceed unhindered, after which electrochemical polymerization would be performed to extend the electrical connection past the scar layer. Additionally, signal transport between the electronically conductive metal electrode and ionically conductive neurons could be facilitated through intimate contact of each with the conducting polymer.

Initial studies have demonstrated the feasibility of this approach. Both erythrocytes[37] and neural cells[47] have been shown to maintain reasonable viability upon exposure to low concentrations of monomer (0.001–0.01 M) as well as low electrical current (0.5–5 mA mm^{-2}). After culturing cells on electrodes and allowing for attachment to the substrate, PEDOT can be grown around the cells to yield a thin, nodular coating that reflects the cell morphology (Figure 11). Removal of the cells using trypsin results in a cell-templated PEDOT film containing holes and caves, and repopulation with new cells demonstrated their enhanced affinity toward the templated regions. Although cell viability could be maintained for up to a week after PEDOT deposition, apoptosis was induced as long as 24–72 h after deposition. Additionally, disruption of the cytoskeleton was observed through a reduction in F-actin stress fibers, reflecting a lack of focal adhesions and possibly contributing to apoptosis. Interaction between PEDOT and neural cells could potentially be improved by the incorporation of cell adhesive peptides or extracellular matrix components either as dopants or via chemical attachment to the polymer backbone, and both strategies are being actively researched by a number of groups.

With the demonstration that cell viability can be maintained after electrochemical polymerization, experiments were undertaken to show that such polymerizations could be

(c) Diagram representing PEDOT polymerized around living cells. (d) PEDOT (dark substance) polymerized in the presence of a monolayer of SY5Y neural cells cultured on an Au/Pd electrode. (e) Nuclei of SY5Y cells stained with Hoechst 33342 (blue florescence). (f) Merged image showing nuclei of cells around which PEDOT is polymerized. Reprinted from Richardson-Burns, S. M.; Hendricks, J. L.; Foster, B.; Povlich, L. K.; Kim, D. H.; Martin, D. C. *Biomaterials* **2007**, *28*, 1539–1552, with permission from Elsevier.

done directly within living tissue, allowing for intimate contact between implanted electrodes and electrically active cells such as neurons, cardiac cells, or skeletal muscle cells. Electrochemical polymerization of EDOT was demonstrated in rat brain slice cultures by embedding the slice in gelatin, exposing the entire slice to dilute monomer solution, and applying current to a gold wire working electrode implanted in the tissue (Figure 12).[48] PEDOT was grown as micro and nano filaments through the extracellular space, and with an even modest total polymerization charge (90 mC) the PEDOT cloud extended nearly 1 mm away from the electrode. The presence of the PEDOT cloud drastically improved the electrical properties of the electrode, reducing the impedance by 1–2 orders of magnitude primarily through an increase in the effective electrode surface area due to the filamentous structure. Exposing a large volume of tissue to EDOT monomer is unfeasible and undesirable, so new strategies are being developed to locally deliver both the monomer solution and

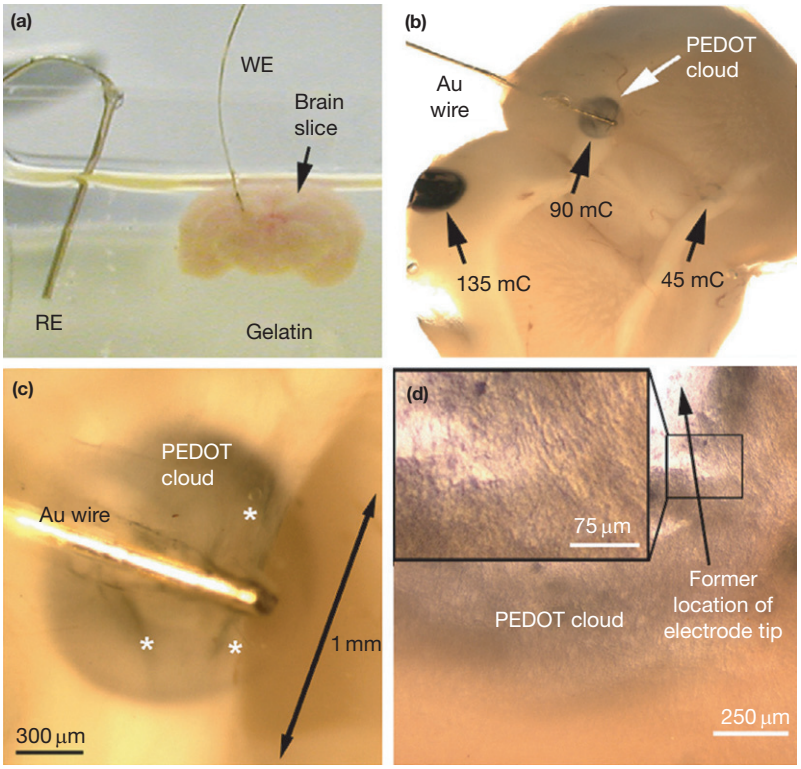

Figure 12 A network of conducting PEDOT filaments can be polymerized directly within brain tissue from an implanted electrode. (a) An image of the set-up used to polymerize PEDOT directly within a mouse brain slice. The tissue slice is physically stabilized within gelatin then a microwire electrode is inserted into the tissue and a platinum wire reference/counter electrode is inserted into the gelatin. (b) A mouse brain slice (2 mm thick) within which three distinct PEDOT networks were polymerized from a Au microwire using increasing polymer deposition charges of 45, 90, and 135 mC. (c) A higher magnification image reveals that the PEDOT cloud integrates directly within the tissue and appears to intensify near and follow white matter fiber tracts (see white stars). (d) High magnification optical micrograph reveals the microscale structure of the PEDOT filaments within the network and suggests that tissue and extracellular matrix structures were used as a scaffold for polymerization. These data are representative of similar findings in roughly 20 brain slices in which PEDOT was polymerized using similar deposition conditions. Reprinted from Richardson-Burns, S. M.; Hendricks, J. L.; Martin, D. C. *J. Neural Eng.* **2007**, *4*, L6–L13, with permission from IOPP.

polymerization current and extend this technology to the direct polymerization of EDOT *in vivo*.

Given that the counterion incorporated during electrochemical polymerization can have a significant effect on the electrical, structural, and mechanical properties of conducting polymers, an important question is what anions would be incorporated during *in vivo* polymerization within the complex ionic environment of living tissue. Recent studies have shown that in mixtures of ions (such as PBS), Cl^- is preferentially incorporated over $H_2PO_4^-$, HPO_4^{-2}, and $LiClO^{4-}$.[135] When PSS is present, however, its polyanionic character leads to a high preference for incorporation since association of a chain with one $PEDOT^+$ site allows for association and quenching of many more neighboring sites. It is therefore possible that during *in vivo* electrochemical polymerization, extracellular matrix components or proteins could serve as counterions.

1.130.7. Summary and Future Outlook

Conjugated polymers such as PPy and PEDOT have shown tremendous potential as materials for interfacing electrically conducting devices with biological tissue. Besides being semi-conducting, these polymers are organic, relatively soft, ionically conductive, have low cytotoxity and have the ability to be morphologically and chemically tailored. These properties and the low electrical impedance of conjugated polymer films make them suitable for neural microelectrode coatings and nerve regeneration fibers. PEDOT and its derivatives have proven to be the most promising of these polymers for their chemical and electrically stability. In addition, composites of conjugated polymers with hydrogels are softer, even more tissue-like materials. The actuation ability of conjugated polymers also enables the release of ions for ionic stimulation of cells, or drugs to manipulate cellular behavior. The current state of development for biologically interfacing conjugated polymers requires further investigation into *in vivo* interactions. For chronic cortical neural probes, it is necessary to maintain a long-term electrical connection between electrodes and neurons. Currently, this is impeded by the formation of insulating glial scars around implanted probes. Therefore, methods such as anti-inflammatory drug delivery, *in vivo* polymerization or other techniques that reduce or work around the scarring should be optimized and tested in animal models to demonstrate their effectiveness. Conjugated polymer constructs have also shown promise as nerve guidance fibers, but

these also need to demonstrate regenerative capabilities *in vivo*. As biofunctionalized conjugated polymers, drug-loaded constructs or techniques such as *in vivo* polymerization are shown to work successfully, conjugated polymers may prove to be an essential component for stable, permanent connections between electronic devices and biological tissue.

Acknowledgments

Research in the Martin group has been supported in part by the National Institutes of Health, the US Army Multidisciplinary University Research Initiative, the National Science Foundation, Biotectix LLC, the Michigan University Commercialization Initiative, the University of Michigan College of Engineering Translational Research (GAP) funding, and the University of Delaware. DCM is a cofounder and Chief Scientific Officer for Biotectix LLC (www.biotectix.com) an Allied Minds (www.alliedminds.com), University of Michigan spin-off company that is investigating the use of conducting polymers on a variety of biomedical devices.

1.131.1. Introduction

Regardless of the payload (drug, solvent, fertilizer, pesticide, etc.), a delivery system should possess two major tools to function. It should accommodate the payload and release it later on at a controlled rate. Novel delivery systems possess an extra tool to deliver the load to a desirable site, and are intended for targeting delivery. Hydrogels have long been known for their ability to house drugs and to prevent drug release by a simple diffusion process. Due to their long polymeric chains, they provide a physical barrier to drug transport, as a result of which a drug needs to take a longer path to

diffuse out of the delivery system. The barrier properties of the polymer chains become more significant when the chains are hydrated in an aqueous medium. Although these features are attractive in controlled drug delivery, some applications require a faster transport kinetic. The presence of pores within a hydrogel structure, through which the drug can be released at a faster rate, adds another dimension to the transport process.

Pores inside a hydrogel structure are generally closed, although populated. Porous hydrogels in general have a closed pore structure, with no well-tailored size or distribution. Superporous hydrogels (SPHs), on the other hand, are hydrogels with an interconnected structure with a relatively narrow pore size and distribution. The predecessor of SPHs, that is, superabsorbent polymers, are for instance found in ultrathin or ultra-absorbent baby diapers and feminine incontinence products due to their outstanding urine or blood absorption capability. These are made of a very hydrophilic but cross-linked structure (mostly based on acrylic acid and its sodium salt) with the ability to absorb 500–1000 $g\,g^{-1}$ of distilled water and 40–70 $g\,g^{-1}$ of saline (an aqueous solution containing 0.9 wt% sodium chloride). These structures are very sensitive to pH, nonsolvents, and ionic strength of the swelling medium. Since this product is supplied in granule and particle form, its swelling rate can be adjusted by the particle size, which significantly affects the particle surface area and hence its absorption ability. In other words, the larger particles absorb aqueous fluids at a slower rate than their smaller counterparts. Superporous hydrogels with the same swelling capacity, on the other hand, absorb aqueous fluids at almost the same rate, irrespective of their size in a dry state. Increased surface area in superporous hydrogels is provided by pores inside their structure. With an increase in their pore content and decrease in pore size, more hydrogel surface would be exposed to the swelling environment, which makes the swelling kinetic faster.

1.131.2. Hydrogels in Drug Delivery

There are more than 100 prescription drugs in the US market, in which one excipient is commonly used, that is, hydroxypropyl methylcellulose (HPMC). Although this polymer is water soluble, it provides gelling properties when exposed to an aqueous environment. HPMC with different degrees of substitutions is used in tablet form to control the release of the drug over a longer period of time. Apparently, there are two features that enable the HPMC to function as a controlled delivery system. First, it is very hydrophilic due to its hydroxypropyl contents. Second, the HPMC chains are in a very compressed form in a tablet, which prevents them from a fast dissolution in the aqueous environment. These two features provide gelling properties such as those found in a chemically cross-linked hydrogel. Although there is no chemical cross-linker in the HPMC structure, the applied pressure during tablet preparation supplies enough entanglement and barrier for the retarded dissolution of the polymer.

1.131.3. Superporous Hydrogels

A superporous hydrogel is a composite polymer made of a solid hydrogel and air. The SPH is a unique class of porous

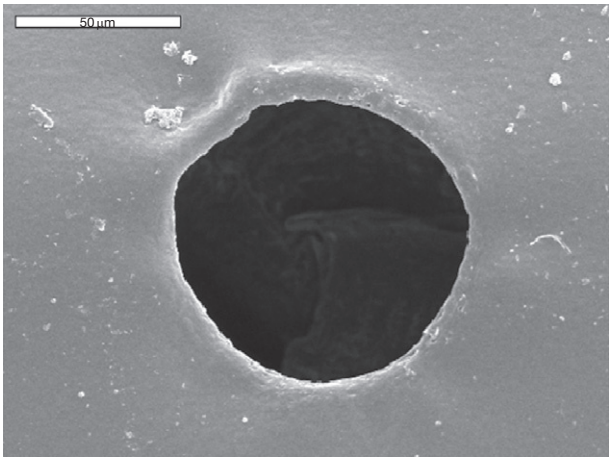

Figure 1 A typical superporous hydrogel with an average pore size of 50 µm.

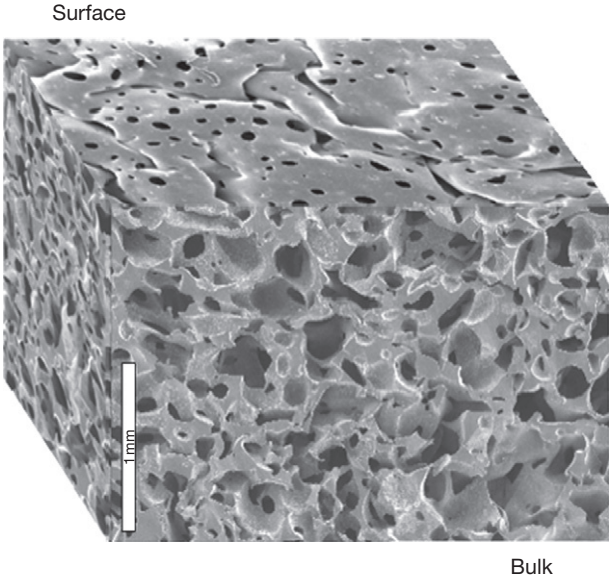

Figure 2 A three-dimensional porous structure of a typical superporous hydrogel.

hydrogels with an average pore size of 50–100 µm (Figure 1) and an interconnected pore structure (Figure 2).[1] As its pores are open, the fluid can travel in a three-dimensional path, as a result of which the swelling rate of a typical SPH becomes independent of the SPH size in its dry state.[2] While in nonporous hydrogels the solid part is responsible for the swelling and mechanical property, the air portion of the SPH structure plays a vital role in determining the final SPH properties. Generally speaking, properties such as density, swelling capacity, and mechanical strength are improved by solid content, while the swelling rate increases as the SPH air content increases. The pore content, size, morphology, and isotropicity are all pore features of the SPH, which could potentially affect SPH stability and function to a lesser or greater extent.

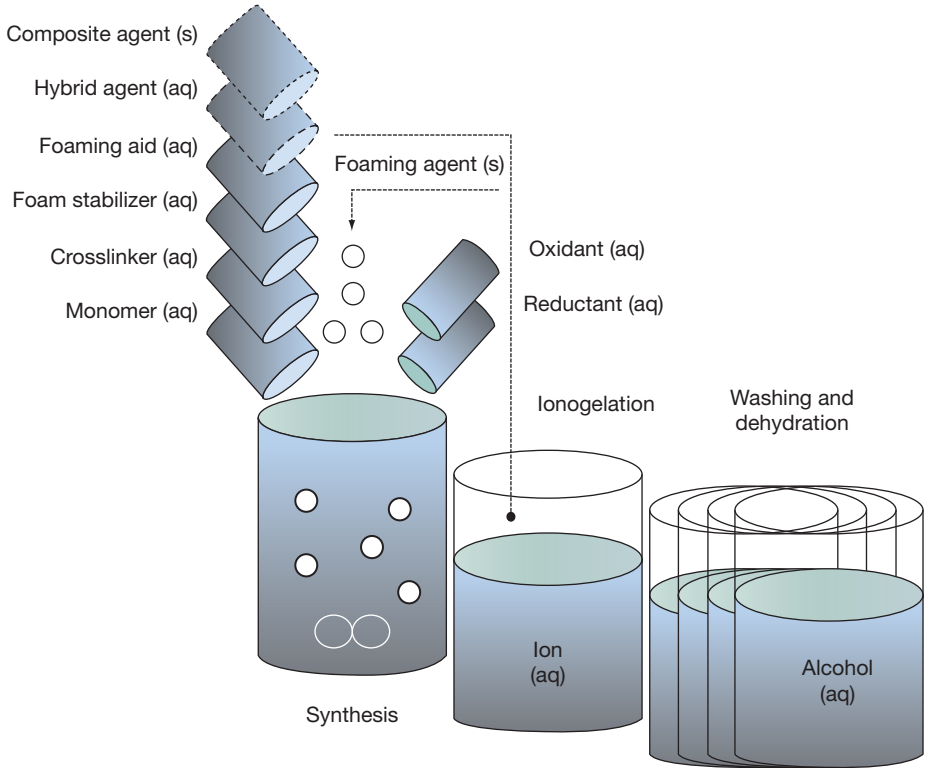

Figure 3 Synthesis, treatment, and purification of a typical superporous hydrogel.

1.131.4. SPH Synthesis

In the preparation of SPHs, a bicarbonate foaming agent is used, which is water soluble and becomes active in an acidic aqueous medium. So a solution polymerization is a preferred method of SPH synthesis. Aqueous solutions of monomer, cross-linker, foam stabilizer, and foaming aid are added in turn to the reacting mixture under very mild mixing. Following a complete homogenization, the reductant and oxidant are added consecutively and are mixed quickly with the reacting mixture. In a very short period of time, the solid foaming agent (e.g., bicarbonate) is effectively dispersed and mixed throughout the reacting solution. The bicarbonate reacts with the foaming aid (e.g., an organic acid) to generate carbon dioxide gases; this reaction in turn increases the pH of the reacting solution, which favors the decomposition of the initiator. Due to the retarding effect of the oxygen, there is an induction, or lag period, which is followed by a fast exothermic polymerization reaction.[3] The foaming and gelling reactions occur almost simultaneously and proceed to their maximum extent at the polymerization temperature, which is determined by the type of monomer, its concentration in the solution, and initiator concentration. A successful SPH is synthesized if the chemical gelation and physical foaming happen in a synchronized way.[4,5] The formation of the SPH foam requires the CO_2 gases to be entrapped within the hydrogel matrix, and this would be possible if the reacting hydrogel mass reaches a certain viscosity, μ_f. The foaming viscosity is determined by the rate at which the gelling reaction happens. At viscosities well below and beyond the μ_f, the efficiency of the foaming process would be decreased significantly and no SPH would actually be formed.

Figure 4 Steps in producing a superporous hydrogel foam.

With no increase in the foam height and no increase in the reaction temperature, both gelling and foaming reactions are slowed down and the SPH foam is then relaxed for further treatment, purification, and drying. The overall procedure of SPH synthesis is shown in Figures 3 and 4 (see Chapter 1.121, Polymer Fundamentals: Polymer Synthesis).

1.131.5. SPH Properties

1.131.5.1. Swelling Capacity

Swelling capacity in hydrogels and SPH polymers in particular is defined by the structural hunger for an aqueous fluid. Apparently, the more hydrophilic the structure of the hydrogel, the stronger the intermolecular interactions that can be built by the hydrogel with its surrounding aqueous medium. A stronger polymer–water interaction would be established if the hydrogel structure contains ionizable groups such as carboxyl or its salt derivatives such as potassium or sodium carboxylate. These hydrophilic and ionic functional groups are responsible for the polymer–water interaction, electrostatic forces, and osmotic forces, which are the driving forces for the swelling process to occur. By far the most important consideration in hydrogel

swelling is the status of water with respect to the hydrogel core. Like the electronic layers surrounding the nucleus of an atom, several layers of water are built up around the hydrophilic and ionic groups. An electron is separated with more ease in the presence of electron-loving atoms if it is located in the outermost electronic layers. Likewise, water molecules within the hydrogel located at the outermost layers, far from the hydrophilic or ionic groups, can be separated with ease. As a result, the status of water in hydrogels is generally defined as free and bound water, which reflects the extent of polymer and water interaction within a hydrogel.

Swelling capacity in hydrogels is generally measured under free and loaded conditions. A hydrogel is simply placed in water or an aqueous solution with a little or no pressure applied on the hydrogel. The hydrogel begins the process of water absorption via its functional groups and continues to absorb water until all the functional groups receive the same amount of water. The amount of water absorbed can simply be calculated by measuring the hydrogel weight before and after the swelling.

1.131.5.2. Swelling Rate

The rate at which water or an aqueous medium is absorbed into the hydrogel structure depends on the hydrogel's chemical and physical structure. As far as the chemistry is concerned, the hydrogels containing more hydrophilic and ionic groups offer a faster swelling process. At the same chemical composition, hydrogels small in size or thin (film), and having a porous structure, can swell faster in an aqueous medium than nonporous, large in size, and thick (sheet) hydrogels. A nonporous hydrogel structure absorbs water at its surface layer by layer. In other words, the water is absorbed into the structure of such hydrogels following a two-dimensional path. Then, the first partially swollen layer acts as a water reservoir for the lower layers. With a porous structure, on the other hand, the whole hydrogel mass could have the same access to the water, and hence water can penetrate into the hydrogel structure following a three-dimensional path. To measure the swelling rate or the swelling kinetic, the amount of water absorbed into the hydrogel structure is measured versus time. While the amount of water absorbed at times zero and infinite reflect the weight of the hydrogel in its dry and fully swollen states, respectively, the hydrogel behavior within this time period reflects the mechanism of the swelling kinetic. For instance, the swelling kinetic would be zero order if the absorption is linear. On the other hand, the absorption occurs as a first-order kinetic if the behavior is exponential. Generally, the absorption mechanism changes with the cross-link content of the hydrogel. A zero-order kinetic is favored at higher cross-link content.

1.131.5.3. Mechanical Strength

A hydrogel in its swollen state is a composite material composed of solid, liquid, and air. Apparently, the extent of intermolecular forces within a solid is more extensive than in the other two. Therefore, a hydrogel with more solid properties (less water and air content) is considered stronger in its swollen state. To measure the mechanical properties, a hydrogel is stressed under static or dynamic loads until it fails.[6,7] The testing force should be selected on the basis of actual service conditions. For example, if the SPH is required to resist the compressive forces, a compression test should be designed accordingly. Similarly, if the SPH is expected to resist a dynamic compression (compression–decompression cycles) force, an appropriate dynamic test should be designed to evaluate the SPH for such an application.[7] For gastric retention studies, the SPH for instance is required to not only resist the combined forces of compression, tension, and bending altogether, but also serve in a very harsh acidic condition. A gastric simulator, which examines the mechanical strength of the SPH by mimicking the real gastric conditions, has been reported.[8–10] The SPHs for such application should quickly swell up in the acidic medium of the stomach juice to a size larger than the pyloric sphincter. The SPH is assumed to resist the mechanical pressures inside the stomach while it is saturated with the stomach fluid. Evaluating and screening hydrogels that resist the real stomach pressures have always been challenging. A texture analyzer and compressive or tensile mechanical tester are normally used to evaluate the mechanical properties of hydrogels. Although such equipment can predict the comparative properties of hydrogels, they fail to predict real mechanical properties. The simulator generates mixed forces of compression, tension, bending, and twisting, based on a water-hammer effect. The sample under test will receive almost the same amount of forces throughout its body. Finally, the stress concentrated on the weakest part of the SPH body would result in the formation of craze, crack, and finally disintegration of the whole platform. The simulator can practically measure the amount of work needed to break the hydrogel apart under real service conditions.

The swelling capacity, swelling rate, and hydrogel strength are all ultimately dependent on the bound water and free water within the hydrogel. Due to the lack of accuracy in measuring the amount of water in each status, all measurements would face a larger standard deviation. Therefore, any measuring procedure or instrument needs to be validated to obtain more accurate and reliable data.

1.131.6. SPH Generations

Hydrogels with fast swelling and superabsorbent properties, different from conventional superabsorbent polymers, were first reported by Chen *et al.*[11] Fundamental structural and property differences between the superabsorbent hydrogels and superporous hydrogels have been reviewed, with an emphasis on the evolution of SPHs and different generations of SPHs.[12] Superporous hydrogels were evolved about a decade ago, and their introduction was triggered by a need strongly felt in the pharmaceutical area.[13] There are dozens of drugs with a limited absorption across the gastrointestinal tract, which are extensively absorbed at certain areas of the GI tract such as the upper intestine. These are called drugs with a narrow absorption window. To increase their absorption and hence their bioavailability, these drugs need to be retained in the stomach (gastric) area for an extended period of time. There are currently a few technologies available to increase the retention of such drugs in the gastric medium; among them the floatable, mucoadhesive, and swellable delivery systems have been studied extensively. With the swellable delivery system, the drug would be

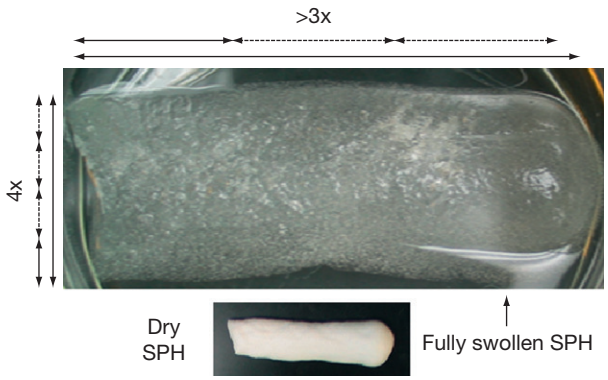

Figure 5 Unique swelling feature of a superporous hydrogel polymer.

accommodated in the swellable hydrogel structure and take a very rough path to release itself from the platform by diffusion. In this way, the drug can stay longer in the area of interest and release itself in a more controlled manner. The early superporous hydrogels, like their superabsorbent predecessor, possessed a very high absorption capacity and a very fast swelling rate. These features were attractive enough for their development in this area of application. Figure 5 shows a typical SPH, in which its dimensions are increased to about four times the original length in about a minute after complete swelling in water.

1.131.6.1. The First SPH Generation

A variety of monomers and polymers, as well as approaches, have been exploited to make SPHs with different structures and properties.[11,14] Among monomers, those with very hydrophilic (e.g., carboxyl or amide in acrylic acid and acrylamide respectively) or ionic (e.g., carboxylate in sodium or potassium acrylate) functions could offer superior swelling properties. These hydrogels are generally prepared in solution by incorporating monomers, initiators, and cross-linkers, as well as foaming agents, into the reaction. The final product is a superporous hydrogel with an interconnected pore structure, which could absorb great amounts of water in a few minutes. However, these hydrogels do not possess any mechanical strength due to the vast number of water layers around their hydrophilic cores. In other words, such hydrogels contain a high proportion of free or semibound water in their swollen state, which make them weak under mechanical pressures. As there is no provision to increase their mechanical strength, these hydrogels are called conventional superporous hydrogels. Figure 6 shows a typical synthetic procedure and structure of the first SPH generation.

1.131.6.2. The Second SPH Generation

The need for better mechanical property triggered the development of the second generation of SPHs or the SPH composites.[15–17] These SPHs are prepared by adding a swellable filler to the original formulation of the conventional SPHs. The swellable filler is selected among pharmaceutically acceptable cross-linked and hydrophilic polymers, including cross-linked sodium carboxymethylcellulose (CMC), cross-linked poly(vinyl pyrrolidone), and cross-linked sodium starch glycolate. These are

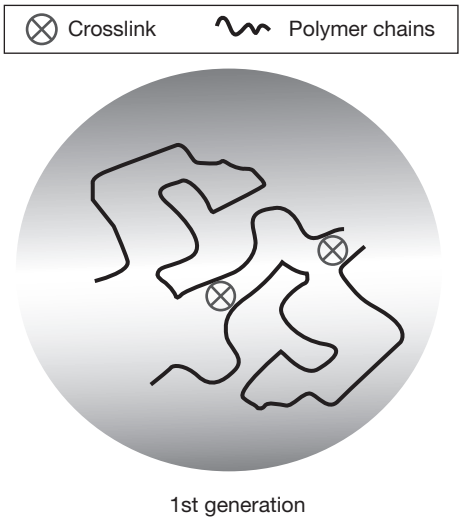

Figure 6 A conventional superporous hydrogel.

commonly used as a superdisintegrant in the preparation of tablets and other solid doses. The use of these in hydrogel formulation could positively affect the SPH strength, presumably due to the strength nods or the physical cross-links built into the hydrogel structure (see **Chapter 4.423, Polymeric Drug Conjugates by Controlled Radical Polymerization**).

1.131.6.3. The Third SPH Generation

Although the SPHs of the second generation could provide a hydrogel with a better strength, much higher strength was felt to be needed, for the gastric retention application in particular. This triggered the development of the third SPH generation, also called superporous hydrogel hybrids (SPHHs), with superior mechanical properties. The primary, secondary, and tertiary approaches have so far been disclosed. The SPH is prepared in a conventional way, but an active material is added during SPH synthesis, which is then treated in the ion solutions. While the primary approach is particularly useful in making SPHs with rubbery properties, SPHs with good mechanical strength can be obtained by adopting the secondary approach.[3] Although the mechanical properties of SPHs can be significantly enhanced after an ion treatment, the ion composition was found to be a useful tool for better controlling the swelling and mechanical properties. Depending on the activity of the ion (sodium, calcium, aluminum, and iron in particular), any ion composition can be used to modify and modulate SPH properties.[4] Figure 7 displays the fundamental structural differences between the second, the third, and the modified SPH generations.

SPH hybrids are prepared according to conventional SPH formulations but a water soluble and ionogelling polymer (synthetic or natural) is added during hydrogel preparation. After preparation, the SPH is treated in an ion solution to become strong and elastic.[3,18] A dried SPH hybrid possesses a folded surface morphology as shown in Figure 8. Utilizing an ionogelling monomer in the basic monomer solution has also been practiced to obtain improved SPH structures. For example, a hydroxyethyl methacrylate (HEMA)-based SPH with modulated swelling and mechanical property has been prepared by

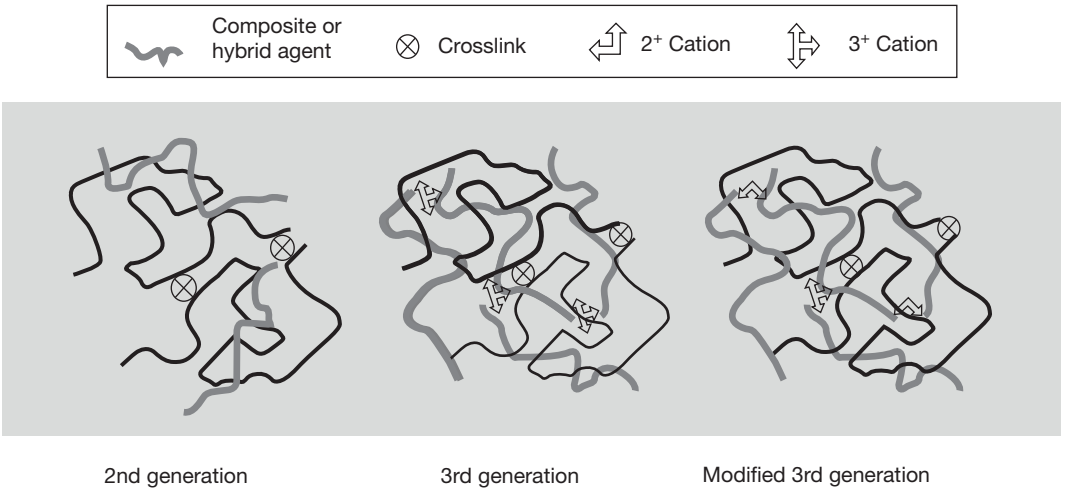

Figure 7 Different superporous hydrogel generations.

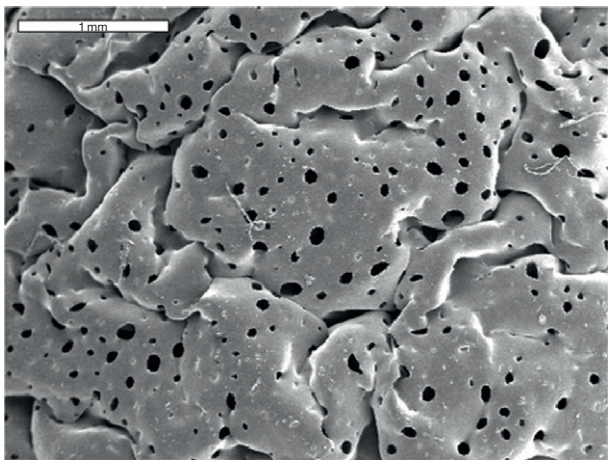

Figure 8 The surface morphology of a typical superporous hydrogel hybrid.

adding acrylic acid into the HEMA formulation containing a cross-linker. After formation, the SPH foam is treated in calcium or aluminum ions to improve the SPH strength and swelling. It then displays stable swelling and mechanical properties in a very harsh service environment such as gastric medium.[5]

1.131.6.4. Research on SPHs

By far the most common monomers used in the preparation of SPHs are acrylic acid and acrylamide. The swelling response of SPHs based on acrylamide and acrylic acid has been studied with the change in the pH of the swelling medium and pressure.[19,20] Solid-state NMR, swelling, density, and scanning electron microscopy were utilized to characterize the SPH composites of acrylamide and acrylic acid polymers cross-linked with *N*,*N*′-methylenebisacrylamide. Apparent density and SEM measurements showed that the SPH composites are more porous than conventional SPHs, which results in hydrogels with superior swelling but weaker mechanical properties.[21] Due to their ionic structures, the swelling property of the poly(acrylamide-*co*-acrylic acid) copolymeric SPHs are dependent on the pH and ionic strength of the solution. These SPH structures display a fast 'on–off' shrinking–swelling cycle in the pH range of 1.2 and 7.5, respectively.[19] Floatable SPHs loaded with vitamin B12 were prepared via copolymerization of acrylamide and acrylic acid in the presence of a porogen and a catalyst.[22] The increased surface area of SPHs has been utilized for grafting purposes. Acrylic acid could be grafted at a high grafting efficiency on polyacrylamide gels using potassium diperiodatocuprate. This feature also helps with the purification process by facilitating the mass transfer process as well as the adsorption of ligands.[23] The PEG-grafted superporous hydrogels based on acrylic acid and acrylamide are prepared in the presence of PEG acrylate and a foaming agent. This modification has caused about sixfold increase in the swelling rate.[24] An amphiphilic coating based on poly(ethylene glycol–tetramethyleneoxide) has been used to improve the swelling kinetics of SPHs.[25] The effect of acidification has been examined on the swelling and mechanical properties of poly(acrylamide-*co*-acrylic acid) SPHs. SPH swells much less in acidic water than in distilled water. Acidification reduces the swelling ratio but improves the mechanical properties.[26] The interpenetrating network of cross-linked poly(acrylamide-*co*-acrylic acid) with polyethyleneimine has also been examined.[27] The effect of synthetic factors on the swelling of superabsorbent hydrogels based on neutralized acrylic acid and methylenebisacrylamide has been studied. The swelling was interpreted by a Voigt-based viscoelastic model, and the hydrogel kinetic and thermodynamic parameters were found accordingly.[28] A partially neutralized acrylic based superabsorbent hydrogel has been studied using different water-soluble and oil-soluble cross-linkers and a combined porogen system of bicarbonate/acetone system. Highly porous gels were obtained under conditions where the gelation period was short. Highly cross-linked hydrogels showed almost no swelling dependence on salt.[29] SEM morphological studies and swelling studies show the synergistic effect of the combined porogen system compared to the use of individual gas blowing systems.[30] Porous polyacrylamide has been synthesized using calcium carbonate microparticles, followed by an acid treatment. The hydrogel

swelling is adversely affected by the calcium microparticles and the chemical cross-linker.[31] In another study, a Taguchi experimental design was used to evaluate the effect of the synthetic variables on the gel strength of the acrylamide-based hydrogels and superporous hydrogels.[32] Poly(vinyl alcohol) has been used to improve the strength of the SPHs based on potassium salt of sulfopropyl acrylate, acrylic acid, and PEG diacrylate. The SPH is intended for gastric retention application.[33] An SPH hybrid of acrylamide and sodium alginate has been prepared via a two-step polymerization and treatment. The process involves polymerization and cross-linking of acrylamide in the presence of alginate, followed by treating the prepared SPH in an ion solution. The SPH prepared via this approach possesses superior mechanical and elastic properties.[18] The mechanical property of the conventional SPH polymers has been improved via network-in-network formation by including polyacrylonitrile in the reaction.[34] In another study, the gel strength of the superabsorbent hydrogel was increased via addition of kaolin during the hydrogel synthesis. FT-IR study confirmed the existence of acrylic grafts on the kaolin surface. Despite an increase in gel strength, the swelling property of the hydrogel was reduced to a great extent. The thermal property of the prepared hydrogels has been characterized using thermal analysis including DSC and TGA.[35] Interpenetrated SPH network of poly(acrylamide-*co*-acrylic acid) with chitosan and glycol chitosan was prepared. In distilled water, both systems behave similarly but swelling increases in acidic medium with increase in chitosan concentration. Since glycol chitosan is more hydrophilic than chitosan, a significant increase in swelling rate was observed[36] (see **Chapter 2.213, Chitosan**).

N-isopropyl acrylamide (NIPAM) and acrylamide have been used to prepare thermosensitive SPHs with pore size of about 100 μm. An on–off swelling–shrinking cycle is obtained if a certain composition of the thermosensitive superabsorbent SPH is heated up from a low (e.g., 10 °C) to a high (e.g., 65 °C) temperature.[14] A higher temperature favors the hydrophobic interactions and the polymer loses its water affinity due to a weaker hydrophilic interaction. A temperature-sensitive poly (NIPAM) hydrogel was prepared in an aqueous sodium chloride solution. This technique resulted in a hydrogel with significantly higher swelling and swelling response due to the effect of salt, which was claimed to be responsible for phase separation and heterogeneity of the structure. These porous hydrogels are characterized by a larger pore and smaller pore at low and high temperature respectively, which result in complete and no release of the bovine serum albumin, respectively.[37] Superporous hydrogel of CMC–NIPAM hydrogel was attained via simultaneous irradiation cross-linking and addition of a foaming agent.[38] Sucrose-based hydrogels and their SPH counterparts were prepared by reacting sucrose with glycidyl acrylate, followed by its polymerization. The superporous sucrogels showed faster swelling and degradation in both acidic and basic media.[39]

A combined gas-foaming and freeze-drying technique has been used to prepare interpenetrated SPHs based on glycol chitosan and poly(vinyl alcohol). It was shown that the number of freezing–thawing cycles has a more significant effect on the hydrogel strength than the freezing time. A differential scanning calorimetry was used to evaluate the thermal behavior associated with the hydrogen bond-induced crystalline structure of the hydrogel.[40] Highly porous poly(2-hydroxyethyl methacrylate) slabs were prepared by a simultaneous polymerization and cross-linking of the HEMA monomer and ethylene dimethacrylate. Porosity was achieved using porogens such as cyclohexanol, dodecan-1-ol, and saccharose. Low density values for these hydrogels indicate a closed cell rather than an interconnected structure. Mercury porosimetry was used to evaluate the superporosity and microporosity status of the gels.[41] Hydrofluoric acid (HF) treatment was also used to extract nanosized silica particles from a hydrogel matrix to make a porous hydrogel.[42]

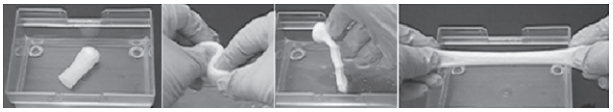

Figure 9 Mechanical property of a typical superporous hydrogel hybrid under various forces.

Superporous hydrogels interpenetrated with sodium alginate have displayed pH- and salt-responsive swelling properties. Moreover, the alginate-modified SPH shows no significant cell or mucosal damage based on thiazolyl blue, lactate dehydrogenase assays, as well as rat's intestine morphology.[43] A fully interpenetrated superporous hydrogel with superior mechanical and elastic properties is obtained when a synthetic monomer is polymerized and cross-linked in the presence of a hydrocolloid with ionogelling ability. A fully interpenetrated network is obtained when the hydrogel is treated in an ion solution containing calcium, iron, or aluminum.[18] **Figure 9** shows a typical acrylamide–alginate-based SPH hybrid in its fully swollen state, which resists compression, bending and tensile forces for a long period of time before it breaks apart. Pectin has been used as a base for an intelligent superabsorbent polymer with pH and thermosensitive swelling properties, which can potentially be used for controlled delivery of nonsteroidal anti-flammatory drugs. Results have shown that the drug could be delivered to the intestine without being lost in the stomach.[44]

1.131.7. SPH Scale Up

Scale up is the process of preparing the SPH on a large scale. A larger scale means an increase in the starting materials, an increase in the container size, and dealing with a very exothermic reaction on a large scale. If the synthesis of an SPH is successful in a container with a certain geometry, it does not necessarily mean a successful synthesis on a larger scale. During the SPH polymerization, heat is released, which is entrapped in the reacting mix due to the insulation property of the pores inside the forming SPH structure. The heat buildup can increase the rate at which normal polymerization happens, the rate of gas formation, and also the chance of popcorn polymerization by which cross-link density of the SPH increases to a great extent. To release the heat from the reacting mixture, an adequate surface should be provided, which is determined by the aspect ratio of the container (diameter/height ratio).

Dispersion of the foaming agent into the SPH formulation during the synthesis is a typical active suspension process. There are generally three types of suspension processes: dispersion of a nonreactive filler into a nonreactive medium (e.g., paint formulation), dispersion of a nonreactive filler into a reacting medium (e.g., kaolin in hydrogel synthesis), and finally, dispersion of a reactive filler into a reactive medium (e.g., bicarbonate in SPH synthesis). Once dispersed, the bicarbonate particles can increase the pH by consuming the acid component of the formulation, which in turn increases the rate at which the redox couple would react. This in turn increases the magnitude of the polymerization reaction and its exothermicity. In other words, the extent of the gelling reaction would critically depend on the amount of the bicarbonate in the system. If not well-dispersed, a so-called 'local hot spot' is produced around which a polymerization to a very high extent is expected. This causes an undesirable heterogeneity in the SPH structure. By far the most challenging aspect of the manufacture of SPHs on a large scale is the dispersion of bicarbonate into an ongoing reaction. An SPH with a uniform pore size and distribution is achieved if the bicarbonate is evenly dispersed into the gelling mass. In general, the bicarbonate dispersion within the reacting mass should be completed in a few seconds. If not, the gelling and foaming reactions would become closely dependent on each other and would affect progress to a great extent. The bicarbonate can effectively be dispersed if a high-pressure gun powder is used.[45] Moreover, the mixing agitator should have a very specific function, to be able to sweep the bottom part of the reaction very effectively to avoid the formation of a nonporous hydrogel at the bottom of the container. Heat buildup, and hence a faster hydrogel formation, may be observed in areas where mixing is not effective. Another important operational factor is the size of the bicarbonate particles. As these particles are reactive, their reactivity would be dependent on their size. As bicarbonate size decreases, its surface area increases. This in turn increases the rate at which pH increases, the rate at which CO_2 gases are formed, and the rate of both chemical gelling and physical foaming reactions. The corresponding rates of these two critical reactions can be controlled by selecting appropriate bicarbonate or mixing bicarbonates of different sizes.

1.131.8. SPH Stability

In determining the stability of a given drug, adequate documentation is provided to the FDA or similar organizations to prove the identity, purity, and potency of the drug. For a superporous hydrogel product, the same procedure should be followed.

1.131.8.1. SPH Identity

There are certain instances in which the identity of an SPH product may change. Moisture, oxygen, ultraviolet light, and heat are potentially the most important factors. The moisture originates from two sources, the moisture retained in the product, and environmental moisture. The product moisture can be minimized by freeze drying, while the environmental moisture is minimized by storing the SPH product under a dry condition using silica gel. Although the SPH itself is also hygroscopic, a silica gel is more effective and faster in moisture absorption. As far as the chemical structure is concerned, an SPH containing, for example, ester (–COO), amide (–NHCO), and anhydride (–COOC) groups would be more susceptible to hydrolysis.

If the SPH contains groups such as ethers (ROR′), and aldehyde (–RCHO), it needs to be protected from oxidative reactions. The most common way to protect the SPH from oxygen invasion is to use different primary, secondary, and tertiary antioxidants. Primary antioxidants such as butylated hydroxyl anisol (BHA), butylated hydroxyl toluene (BHT), tocopherol (vitamin E), and propyl gallate can provide electrons to free radicals and act as free radical scavengers. Compounds such as ascorbic acid and sodium bisulfite are secondary antioxidants and can consume oxygen through autooxidation. The last group of antioxidants, that is, tertiary antioxidants, can react with the ions responsible for initiating the oxidation reactions. The ion scavengers include citric acid, tartaric acid, and ethylenediamine tetraacetic acid.

Functional groups including carbonyl (–CO–) and the C=C bond make a superporous hydrogel sensitive to ultraviolet light. Theoretically, these groups may absorb light at or greater than 280 nm. Photolysis can be prevented by storing the SPHs in an opaque or a dark-colored container. Heat can also change the SPH identity by expediting the hydrolytic, oxidative, and photolytic reactions.

1.131.8.2. SPH Purity

The SPH impurities can be classified as primary, secondary, and tertiary. Primary impurities are residual monomer, initiator, and cross-linker left from the polymerization and cross-linking reaction. Due to incomplete conversion of the monomer to polymer, and incomplete inclusion of the cross-linker into the polymer structure, unreacted monomers and cross-linkers need to be removed after SPH synthesis. Many researchers attempt to find ways to reduce residual monomers, but reducing the residual initiators is also a very important consideration. Following monomer removal, the SPH is generally washed with water and alcohol solutions for complete purification. These two are considered secondary impurities. More water will be removed by adding more alcohol and alcohol itself is removed by low pressure drying. One of the very major challenges regarding SPHs for pharmaceutical applications is that they must be reasonably pure. Different methods have been proposed to make a pure SPH. These include the use of low and high glass transition monomers during the SPH synthesis and the use of physically induced expansion and contraction in a solvent–nonsolvent system, as well as the use of mechanical processes such as filtration, rubbing, and centrifugation.[45] The last type of impurities originate from two sources, that is, during SPH storage and SPH service. Since water exists in the SPH even at a very low concentration, this may result in a long-term hydrolysis. Oxidative reactions may also proceed in a given SPH as moisture can act as a plasticizer and facilitate the inclusion of oxygen into the SPH structure. Generally speaking, these reactions are associated with a change in the SPH appearance and color, from snow-white to off-white or pale yellow. During service, the SPH may face a harsh environment such as

very low acidic conditions, and so on, so its structure may be changed or degraded, which is associated with the generation of impurities. Appropriate analytical tests and methods should be developed for a complete characterization of all types of impurities within the SPH product.

1.131.8.3. SPH Potency

The SPH potency can be defined as its swelling power, which depends on the exact amounts of the SPH and its chemical structure. For instance, the SPH potency for a typical gastric retention application may be defined as the amount of HCl solution that one gram of the SPH can absorb over a certain period of time, that is, $g\,g^{-1}\,s^{-1}$ or $ml\,g^{-1}\,s^{-1}$. The cross-link density and the pore structure of the SPH can affect this factor significantly. Although complete care needs to be taken to purify the SPH product, increased cross-link density (physical or chemical) may arise from other sources including polymer crystallization, polymorph formation, entanglement, and complexation. Polymer chains can adopt different conformations during long-term storage, which might affect their swelling ability. Since the SPH is required to be compressed for proper encapsulation, this partial pressure would increase the intermolecular forces between the chains, by which the swelling rate would be affected. The most common sources of increased cross-link density are the SPH interaction with the oppositely charged species such as calcium, aluminum, iron, sulfate, and phosphate ions. The SPH as a final product when it is encapsulated in an orally administrable capsule may face another instability due to the SPH–capsule interaction either directly or indirectly. For instance, this may happen due to a charge difference between the SPH structure and the structure of the capsule or due to the interaction between the ions within the SPH structure and the capsule material, which results in polymer–polymer interchain complexation and ion–polymer complexation, respectively.

Although the SPH potency should not theoretically be correlated to the amount of pore, the pore can affect both the SPH swelling capacity and its rate. Since the SPH product is soft in general, and the pores are embedded into a soft SPH matrix, their shape and size can be changed upon application of minor pressures. Pores not only provide capillary action to the water diffusion process, but they also increase the contact surface area with the aqueous medium. Any change in the shape and size of the pores would imbalance the swelling–pore correlation. As SPHs for oral delivery are required to be encapsulated, the original size of the SPH needs to be reduced in order to fit the capsule size. This compression effect apparently affects the SPH pore structure, which might affect the ultimate swelling property of the SPH. A swelling–compression correlation has been found, whose magnitude depends on the orientation of the SPH during compression. In other words, the original noncompressed SPH swelling is preserved if the SPH is compressed along the gas movement line which is from the bottom to the top. Compression force applied in the opposite direction severely affects the swelling kinetic of an SPH.[20] The SEM and swelling studies displayed that the swelling kinetics of the SPH is not affected by the surface morphology and surface porosity measured via mercury porositometry. Studies show that SPH swelling is predominantly determined by the internal SPH structure.[1]

From the biopharmaceutics perspective, the SPH may lose its potency due to interaction with foods or beverages. Fatty foods, oils, and materials of such nature may reduce the SPH potency by making the swelling environment more lypophilic. On the other hand, more basic or more acidic juices as well as salts may also affect the SPH potency to a lesser or greater extent. If the SPH is ionic in nature, its potency would dramatically be reduced by increasing the ionic strength of the swelling medium. The effect of different beverages on the swelling behavior of multiple SPH formulations has been studied for gastric retention applications.[46]

1.131.9. SPH Safety

The SPH may be considered safe if it does not affect the human body either chemically or physically. To be considered chemically safe, the SPH should contain less than tolerated amounts of residual materials. This requires developing a very effective purification process and very accurate analytical methods. The SPH is considered physically safe if its administration does not pose any threat to the human body. One of the most serious concerns in administrating a swellable material is esophagus obstruction. Due to its rapid water absorption, a naked SPH may absorb water in the esophagus area, become expanded and hence obstruct the area. This can be avoided by using proper encapsulation materials and methods. Multiple SPH doses may be administered to ensure that esophagus obstruction does not occur under severe and aggressive conditions.

Another aspect of an SPH dosage form is its chemical interaction with the stomach acids. For instance, an ester-based superporous hydrogel is susceptible to ester hydrolysis under severe acidic conditions in the stomach, in particular under long-fasting gastric conditions. An adequate number of studies should be conducted to ensure that there are no, or only safe, by products of such a reaction. In the preparation of SPHs and their dosage form for human clinical studies, care must be taken to use materials with nonanimal origin, which require a TSE (transmissible spongiform encephalopathy) certificate for every starting material.

1.131.10. SPH Platform Design for Drug Delivery

To deliver a drug via a swellable platform, the drug needs to be incorporated into the SPH platform. The drug is first formulated into a drug delivery system (DDS) and the DDS is then incorporated into the SPH platform. Although many designs are possible, two designs have been practiced for gastric retention and peroral intestinal delivery of different drugs. Depending on the position of the DDS with respect to the SPH platform, these may be called internal DDS and external DDS designs as shown in Figure 10. In the former, the DDS is placed in the center of the SPH platform and is held in place using an SPH plug. The SPH plug is also held in place by gluing it onto the SPH body from the top. The whole platform is then encapsulated inside an orally administrable capsule.

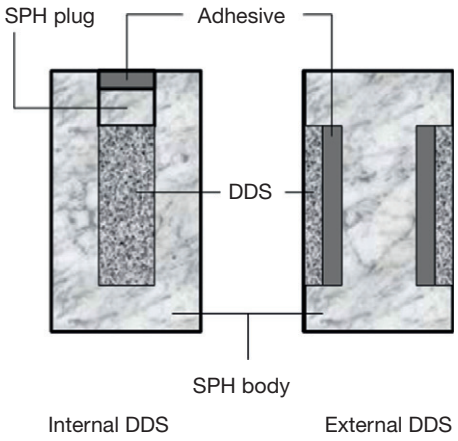

Figure 10 Different platform designs for the superporous-hydrogel-based drug delivery.

Upon administration and the exposure of the capsule to the stomach acid (for gastric retention), the capsule is dissolved and the SPH platform would be exposed to the gastric contents. This results in an immediate expansion of the SPH to its full extent, which is followed by drug release by diffusion.[47–50] In the external DDS approach, the SPH is attached externally to the SPH body using biocompatible glue, and the platform is then encapsulated in an oral capsule. For peroral intestinal delivery, the capsule itself is enterically coated to prevent the capsule and the SPH from premature dissolution or swelling in the gastric medium. Upon entering the intestine area, the higher pH favors capsule dissolution, which is followed by SPH expansion. The SPH would expand to a size large enough to dock itself into the intestinal wall. The drug is then released directly through the intestinal cells.[51–53]

1.131.11. SPH in Drug Delivery and Other Areas

SPHs were originally intended for prolonging retention of drugs with a narrow window of absorption. In designing a superporous hydrogel for such applications, one needs to consider the drug–SPH interaction, which is caused by interaction of their functional groups. Drugs such as acetohydroxamic acid (AHA),[54] repaglinide,[56] metoclopramide,[57,58] and amoxicillin[59,60] contain amide groups. Amine groups can be found in drugs such as acyclovir,[61] amoxicillin, cefuroxime axetil,[62] furosemide,[63] gabapentin,[64] levodopa,[65–67] metformin HCl,[68] metoclopramide, ranitidine HCl,[69] and famotidine.[70] The carboxyl groups are part of amoxicillin, ciprofloxacin,[71] furosemide, gabapentin, ibuprofen,[57] levodopa, and repaglinide-can structures. All these drugs have been examined for gastric retention applications via different methods. From a compatibility perspective, SPHs containing ion may not be a good choice to prolong the gastric retention of levodopa or gabapentine, which contain carboxyl groups. SPHs containing carboxyl groups may interact via hydrogen bonding with the drugs containing carboxyl and amine groups. SPHs, due to their moisture content, may expedite the hydrolysis of amide-containing drugs during storage. SPH compatibility with other excipients used to make the DDS also requires careful evaluation.

1.131.11.1. Gastric Retention

A holy grail in oral drug delivery is to develop a dosage form with the ability to control drug release for a relatively long period of time. Besides floating and mucoadhesion concepts, a swelling concept has also been exploited to extend the residence time of the drugs with a narrow absorption window.[47,49,72–75] Following the discovery of *Helicobacter pylori*, a need for an efficient dosage form with the ability to remain in the gastric medium was also felt. A gastroretentive platform needs to be designed based on a good knowledge of physiological factors and biopharmaceutical aspects of the gastric medium.[76] The SPH design for gastric retention applications has been the subject of several articles.[15,77,78]

Gastric retention requires the swellable platform to stay in the gastric medium for a reasonable period of time, that is, a few hours after dose administration. The mechanism by which a platform would stay in the gastric medium is by swelling, and this requires the SPH to swell to a size larger than the pylorus diameter. Assuming an average pylorus diameter of 1.5–2 cm, at least two out of three dimensions of the hydrogel should be larger than 2 cm. On the other hand, the platform needs to be administered orally using a conventional capsule for human administration. Generally, a 00 gelatin or HPMC capsule with an outer diameter of 8.53 mm, height of 23.30 mm, and volume of 0.95 ml is used. A simple calculation shows that a swellable hydrogel for such an application should expand in the gastric medium to at least 2.3 times its original dimension, or to at least 12 times its original volume. The required rate at which a swellable hydrogel should expand is dependent on many factors, which affect gastric emptying. For example, if the stomach contains only water, it takes about 25 min to have half of the consumed water depleted from the stomach. This is a good assumption to design a platform with a desirable swellability. The hydrogel would face a premature depletion from the stomach if it cannot swell to its maximum size in less than 25 min. In order to stay integrated in the gastric medium for a desirable period of time, the SPH should resist gastric contraction and expansion forces, which are maximized during the housekeeping period of the phase III stomach motility. By far, this is the most challenging part in designing SPHs for such applications. The maximum volume that the SPH can acquire in its dry state is about 0.95 ml for encapsulation into, for example, a 00 gelatin capsule. Depending on the drug loading capacity, a certain volume of the SPH is occupied by the drug or the DDS. In other words, the effective capsule volume occupied by the SPH would be around 0.6 ml. With the SPH having a density of 1 g ml^{-1}, the maximum feasible weight of the SPH inside the capsule would be around 0.6 g. The calculation shows that the SPH in its fully swollen state would contain about 95 wt% of water. Ironically, a hydrogel which contains 5% of solid and 95% of water should resist the very aggressive stomach forces, which requires significant intermolecular forces within the swollen SPH structure to preserve the SPH integrity in such conditions. Moreover, the SPH needs to possess all these required properties under a very low pH condition of the stomach. The SPH screened for such application also requires to be very safe chemically and physically, and this needs to be proved first in animals. As far as its efficacy is concerned, the proof of gastric retention can be first conducted

in animal models, but for many reasons the results would not necessarily prove the concept in humans. Since no animal has proved to be a reliable model for such studies, the proof of gastric retention would at best be confirmed by conducting a small-scale study in humans.

One of the most important considerations in using swellable platforms for gastric retention is the SPH–DDS interaction. Two studies have been conducted in which the drug model was formulated into a wax and a solid based delivery system. In both studies, the dissolution was performed in a USPII paddle type apparatus using 900 ml of 0.01 N HCl (pH 2.0) at $37 \pm 0.2\,^{\circ}C$ and 100 rpm. An HP8453 UV/VIS was used to measure the absorbance of the drug model at 280 nm. Different formulations were prepared by including a model drug into a low (Gelucire) and high (Compritol) molecular weight wax.[50,79] The amount of drug loaded into the wax system was about 20 wt%. An HPMC capsule was used to encapsulate both the wax and the wax-loaded SPH. The study showed that the same amount of drug is released from the wax system and the SPH–wax system when a low melting wax was used as the delivery system. On the other hand, a prolonged release was observed over a much longer period of time for the higher melting wax system. Apparently, as shown in Figure 11, the low melting wax is removed from the SPH system at the dissolution temperature of 37 °C, while the majority of the high melting wax still remains over the same retention time (i.e., 48 h) in the dissolution medium. With the latter, the SPH pores are presumably blocked by the wax, which results in a much slower drug release.

In another study, a delivery system with a drug loading of 75 wt% was designed using the combination of a fast dissolving polymer (polyvinyl pyrrolidone) and a slow dissolving polymer (hydroxypropyl methylcellulose) at different ratios.[80] While the pure drug model was released from the SPH in less than 30 min, the delivery system containing higher HPMC contents showed an extended release over a much longer period of time resembling a zero-order kinetic at the highest HPMC/PVP ratio as shown in Figure 12. These observations may be accounted for in terms of the solubility behavior of the two polymers. As the PVP is very water soluble, it can be dissolved in water even when only a small amount of water is available. On the other hand, a complete dissolution of HPMC requires much more water to be freely available to the polymer. When a tablet containing HPMC is enclosed within the SPH platform, the HPMC, due to the lack of water availability, produces a very thick gelatinous mass inside the SPH. This causes the drug to experience a much longer path for its complete release from the platform.

The proof of the gastric retention principle for various SPH hybrids has been studied in swine. The study showed that an acrylate–chitosan hybrid could provide a minimum of 24 h retention in the swine stomach under different fed and fasted conditions.[81,82] The safety and toxicity of different hydrogel formulations have been studied for gastric retention applications.[83] SPH retention in man has been studied using scintigraphy. SPHs radiolabeled with ^{99}Tc were encapsulated in an enteric-coated gelatin capsule and administered orally.[84] In a study on SPHs based on chitosan and glycol chitosan for gastric retention application, it was found that the swelling property of the glycol chitosan is superior to that of chitosan alone.[85] Superporous hydrogel of (acrylic acid-*co*-acrylamide)/*O*-carboxymethyl chitosan has been evaluated for oral insulin delivery. Followed by insulin loading and release, the circular dichroism (CD) spectra indicated a stable insulin conformation as well as its bioactivity according to hypoglycemic effect in mice. The hydrogel could bind to Ca^{2+} and entrap enzymes, which resulted in inactivation of trypsin and α-chymotrypsin. Results of this study showed a significant hypoglycemic effect for insulin loaded into the SPH and better bioavailability compared to subcutaneous insulin injection.[86] Another study with the same polymer indicated a physical interaction between the polymer and insulin.[87] The polymer was also examined for its cytotoxicity and genotoxicity. The study showed that the SPH caused minimal damage to cell viability, lysosomal activity, and metabolic activity. A study on mice showed that the SPH which contains minute amounts of monomer and cross-linker, is truly biocompatible and can be considered a safe carrier for protein delivery.[88] Glycol chitosan SPHs were prepared and loaded with dispersed and conjugated amoxicillin to treat the

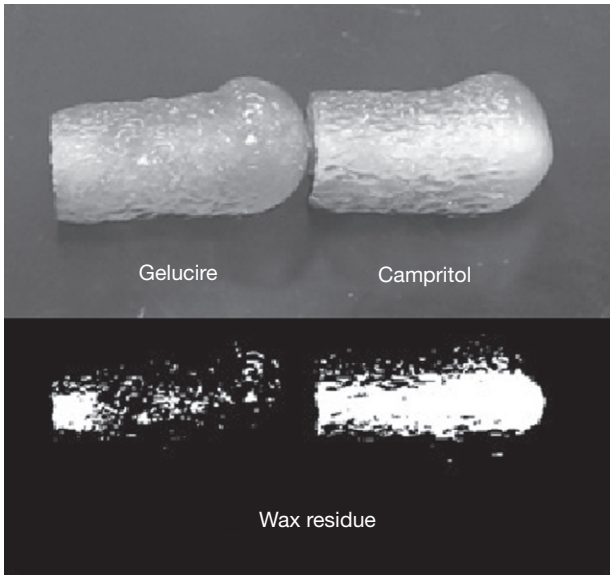

Figure 11 Superporous hydrogel with wax-based delivery systems.

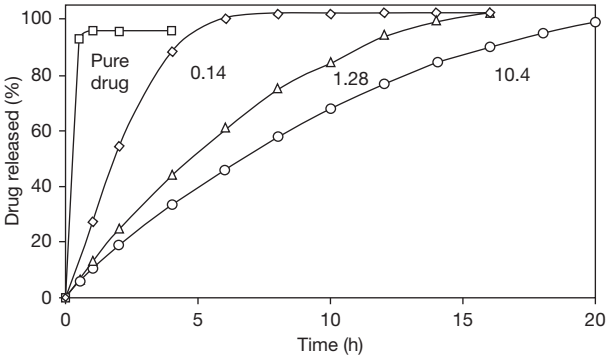

Figure 12 Drug release from superporous hydrogel with solid-based delivery systems.

H. pylori. A prolonged drug delivery effect was observed for the conjugated system whose release mechanism was due to hydrolysis as opposed to diffusion for the dispersed drug.[89]

1.131.11.2. Peroral Intestinal Delivery

Conventional and composite generations of SPHs have been widely studied for peroral peptide and protein administration.[90] The CSPHs and SPHCs were evaluated for enhancing the drug transport (different molecular weights) across the porcine intestine (*in vitro* study).[51] Among the factors studied were the possible damage to intestinal cells, the ability of SPH for mechanical fixation, the SPH effect on paracellular drug permeability, and cytotoxicity in Caco-2 monolayers.[91] The release behavior of peptides such as buserelin, octreotide, and insulin,[92] the intestinal *in vitro* absorption of desmopressin,[93] and the mechanism of paracellular tight junction opening in the Caco-2 cells[94] have also been studied. Due to improved mechanical properties, *in vitro* mucoadhesion forces and loading capability, hydrogels based on acrylic acid-*co*-acrylamide and *O*-carboxymethyl chitosan have been proposed as a potential mucoadhesive system for peroral delivery of proteins and peptides.[95]

1.131.11.3. SPHs as Diet Aid

A highly swelling SPH with gastric retention ability can be designed to occupy a large portion of the stomach volume to induce fullness in humans. To achieve a sense of fullness, a minimum of 400 ml of the stomach volume should presumably be occupied by the SPH. If a pure SPH with no drug or DDS is used for this application, around 0.6 g of the SPH can be housed in a 00 capsule as mentioned before. To be effective in such application, a single 0.6 g dose of SPH should have a potency of at least 650 ml g^{-1}. Using conventional materials and techniques, this potency can hardly be achieved under very low acidic conditions of the stomach. Therefore, the application requires the use of multiple doses of SPH to achieve adequate volume, which brings more safety risks as related to the impurities and physical esophagus obstruction. Moreover, water itself due to the high concentration (minimum of 650 ml) should also be studied as a control to see if it can induce any fullness effect at such concentration. Potentially, an SPH platform as a diet aid may be formulated with other excipients to achieve its maximum potency. These may include excipients to adjust stomach pH or relax stomach motility.

1.131.11.4. SPHs as Superdisintegrant

Superdisintegrants are pharmaceutically acceptable polymers based on cellulose, poly(vinyl pyrrolidone), and starch derivatives, which have a tailor-made swelling property. These are supplied in particle form and mixed into a solid dosage formulation to offer a desirable disintegration. The SPHs are also cross-linked hydrophilic polymers, whose swelling capacity and rate can be tailored for such applications. Nonetheless, there are issues that need to be addressed before the use of SPH particles can be justified. For gastric retention, intestinal retention, and diet application, the SPH is produced and used as a single platform, generally in a cylindrical shape as shown in

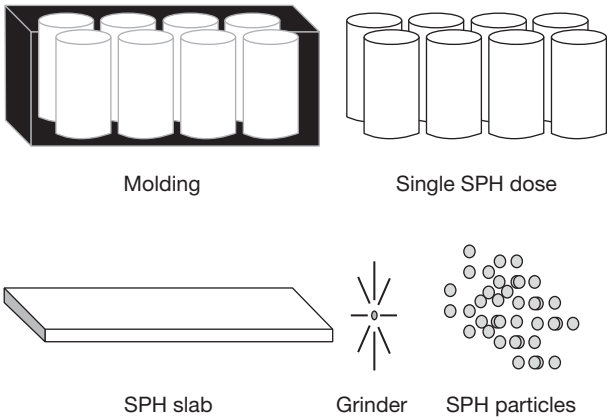

Figure 13 Manufacturing superporous hydrogels for various applications.

Figure 13. The SPH particulates on the other hand can be produced in powder form by grinding the SPH slabs using appropriate equipment or can be produced directly in particle form by an inverse dispersion technique. With the grinding technique, which is cost effective and commercially more attractive, the most challenging issue would be to keep the production environment as dry as possible. The SPH dust can sit and make a gel coat on almost any piece of equipment during processing. A major difference between the SPH superdisintegrant and conventional superdisintegrants is that the former can provide a much larger surface due to its size and its pore content. In one study, the SPH particles, in particular those based on poly(acrylic acid) were used as a wicking agent in the formulation of fast-disintegrating tablets.[96]

1.131.11.5. Other Applications

Sodium CMC and hydroxyethyl cellulose cross-linked with divinyl sulphone have been used to remove body fluids during surgery and to collect body fluids in the treatment of edema. The polymer biocompatibility is also promising in diuretic therapy.[97,98] Sodium CMC and hydroxyethyl cellulose as well as poly(ethylene glycols) of different molecular weights have been used in developing orally administrable hydrogels for water absorption.[98] High capacity super water absorbents were injected intracerebrally for studying hypothalamic areas in controlling the female production cycle.[99] The SPH microspheres were used in the clinical evaluation of transcatheter arterial embolization for hypervascular metastatic bone tumor.[100] In another biomedical application, freeze-dried water absorbents were used to design plugs and haemostatic and other medical devices.[101] These were also used in compact and light-weight bags[102] and in surgical drapes[103] to manage body fluids. As the core for wound dressing, the polyacrylate water absorbents could retain microorganisms and reduce the number of viable germs.[104] Hydrogels based on sodium acrylate, *N*-vinyl pyrrolidone, and silver were also studied for their antibacterial activity[105] (see **Chapter 1.122, Structural Biomedical Polymers (Nondegradable)**).

In cell scaffolding, PEG diacrylate has been studied for cell infiltration and vascularization.[106] To be used as a support for

cell cultivation, an SPH based on HEMA and ethylene dimethacrylate has been prepared. The porosity of the structure was achieved via a salt-leaching technique using sodium chloride and ammonium persulfate. Different techniques including SEM, mercury porositometry, and dynamic desorption of nitrogen were used to characterize the hydrogels.[107] A hydrogel with good mechanical properties to function with a healthy cartilage, yet porous to allow tissue integration, is very much needed for articular cartilage repair. Such a potential material has been prepared using poly(vinyl alcohol) and poly(vinyl pyrrolidone) through a double emulsion process followed by a freezing–thawing process.[108] Superporous hydrogels have the potential to be used as scaffold for cell transplantation. A highly interconnected poly(ethylene glycol) diacrylate with macropores in the range of 100–600 μm has shown a rapid cell uptake and cell seeding.[109] The SPH formulation containing hydroxyapatite as filler can potentially be used as scaffold in bone tissue engineering due to improved mechanical strength.[110] Different techniques including FTIR, SEM/EDX, and cytocompatibility using L929 fibroblasts were utilized to characterize the prepared SPHs. A photo-cross-linking reaction and a foaming process have been utilized in developing a PEG-based superporous hydrogel with high pore interconnectivity. This feature is essential for applications such as tissue engineering where tissue invasion and nutrient transport are basic requirements.[111] Kroupova *et al.* have shown that SPHs have the potential to initiate the differentiation of embryonic stein (ES) cells[112] (see **Chapter 1.132, Dynamic Hydrogels**).

1.131.12. Conclusions

Due to their hydrophilic, cross-linked, and porous structure, SPH polymers display a swelling behavior different from that of conventional water swelling hydrogels. This feature has been utilized in developing swellable platforms for drug delivery applications. SPHs have been studied for prolonging the retention of drugs with a narrow window of absorption, and for peroral intestinal absorption of peptide and protein drugs. The feasibility of SPHs in pharmaceutical applications relies on many factors, including its scale up, safety, and stability. This chapter discusses the basic concepts in developing a synthetic swellable platform for certain pharmaceutical and biomedical applications.

Glossary

Donnan equilibrium An unequal distribution of diffusible ions between two solutions that are in contact due to a physical restraint preventing one or more ionic species from passing freely between the two solutions.

Interpenetrating polymer networks (IPN) A structure containing two or more interlocking polymer networks that are not covalently bonded to one another.

Lower critical solution temperature (LCST) The temperature below which the polymer is miscible with a solvent phase in all proportions.

Upper critical solution temperature (UCST) The temperature above which the polymer is miscible with a solvent phase in all proportions.

Abbreviations

AAPBA	3–Acrylamidophenylborionic acid
AFP	Alpha fetoprotein
BCAm	Benzo-18-crown-6-acrylamide
BMA	Butyl methacrylate
bR	Bacteriorhodopsin
BZ	Belousov–Zhabotinsky
DAMA	*N*-(*N*′,*N*′-dicarboxymethylaminopropyl) methacrylamide
DMAA	*N*,*N*′ -dimethylacrylamide
ELP	Elastin-like peptide
GEMA	2-Glucosyloxyethyl methacrylate
HPMA	*N*-(2-hydroxypropyl)-methacrylamide
IEP	Isoelectric point

IPN	Interpenetrating polymer networks	**SP**	Spirobenzopyran
LCST	Lower critical solution temperature	**UCST**	Upper critical solution temperature
MIP	Molecularly imprinted polymer	**VBC**	Viscosity B coefficient
NiPAAm	*N*-isopropylacrylamide	**VEGF**	Vascular epithelial growth factor
RGD	Arginine-glycine-aspartic acid	**VPTT**	Volume phase transition temperature

1.132.1. Introduction

Also referred to as smart, intelligent, environmentally sensitive, or responsive, dynamic hydrogels are hydrophilic polymer networks that undergo a structural modification in response to specific environmental stimuli. The stimulus acts by altering the balance of molecular forces within the hydrogel–solvent system, which causes the hydrogel structure to rearrange to achieve the lowest possible free energy state. The structural change is accompanied by alterations in the chemical and mechanical properties of the hydrogel. It is the ability to change these properties in a controllable manner that has made dynamic hydrogels an enabling technology in biomedical applications ranging from drug delivery to chemical analysis.

The materials used to create dynamic hydrogels, along with their corresponding activating stimuli, are as diverse as the potential applications. Neutral and ionic polymers, enzymes, and nanoparticles have all been incorporated into dynamic hydrogels in order to create structures that are sensitive to stimuli such as temperature, pH, ligands, and light. Hydrogels formed with multiple materials via copolymerization, formation of interpenetrating polymer networks (IPNs), and particle entrapment can be made to respond to several distinct stimuli. Regardless of the material and stimulus used, the structure of the network at any given time is a thermodynamic balance between (a) covalent forces holding the polymer backbone together; (b) noncovalent intramolecular and intermolecular interactions between polymer chains and the solvent; and (c) entropy acting to minimize the free energy of the system. Herein, we describe the historical development of dynamic synthetic hydrogels, discuss the forces and stimuli used to achieve dynamic structural changes, and review applications of dynamic hydrogels.

The scope of this chapter is limited primarily to chemically cross-linked hydrogels that are made via synthetic processes. Several aspects make synthetic hydrogels an attractive alternative to materials derived from natural sources, such as Matrigel. For example, the use of high purity monomers makes the chemistry in synthetic hydrogels relatively well defined in comparison to materials such as Matrigel, which has been found to contain over 300 different proteins.[1] In addition, batch-to-batch variability in properties of naturally derived hydrogels limits their utility as a class of robust, dynamic hydrogels. Because the focus of the chapter is on biomaterials, dynamic hydrogel behavior in aqueous solutions will be emphasized.

1.132.1.1. Motivation: Utility of Dynamic Hydrogels

Hydrogels have been used extensively in applications requiring stable, biocompatible materials, dating back to the introduction of the first soft contact lenses by Wichterle and Lim.[2] While static and slowly degradable hydrogel structures are effective in uses such as contact lenses and burn dressings,[3] the ability to change the physical and chemical properties of hydrogels on demand leads to a wider array of potential biomedical applications. Specifically, dynamic hydrogels can be used to address applications related to artificial muscles, memory and switching elements, sensors, detectors, and separations tools that would otherwise not be possible with static hydrogels. For example, a hydrogel that can be made to expand and contract based on an electrical or chemical signal would be able to mimic natural muscles for prosthetic devices.

In addition to enabling new utilities, dynamic hydrogels can also provide more flexibility in areas where fixed hydrogels were previously employed. One area of particular interest is controlled release drug delivery. The first hydrogels used in drug delivery typically depended upon diffusion and erosion mechanisms to achieve sustained release. While these approaches can be tailored to achieve a variety of dosing regimens, they are not necessarily the most efficient means of accomplishing the desired release profile. In particular, these approaches make it difficult to alter the release profile once the treatment has been administered. Such a predetermined release profile works well in applications where a constant concentration in the blood stream is required; however, these approaches are ill-equipped to address dosing applications where the appropriate release rate changes in time based on the physiological conditions.

One of the great appeals of dynamic hydrogels is their ability to sense conditions in their local environment and respond in a controllable manner. For example, a dynamic hydrogel might be designed to undergo a structural change based on the concentration of glucose in solution, and the structural change could then be used to release insulin, which would be of interest in managing type I diabetes. The power of such a system is that the hydrogel acts on a continuous and autonomous basis to both monitor a parameter of interest (glucose level) and act in a predetermined manner based on that reading (e.g., increase insulin release if the sugar level is too high), creating a simple control loop. In contrast, traditional treatment requires patients to make the conscious effort to periodically measure blood glucose levels and administer the necessary insulin dose.

1.132.1.2. Historical Context: Development of Dynamic Hydrogels

In 1948, Kuhn and Katchalsky reported that solutions containing poly(methacrylic acid) showed a marked increase in viscosity when titrated with a basic solution.[4] The change in physical properties of poly(methacrylic acid) during titration

was attributed to the elongation of the polymer chain due to ionic interactions between the charged carboxylic acid groups. Soon thereafter, the two groups developed polyionic hydrogels to test their hypothesis that molecular scale conformational changes could be translated into macroscopic motion.[5,6] Their effort was successful in demonstrating that a hydrogel fiber could elongate and contract when exposed to various pH conditions. In a later work, they demonstrated that the hydrogel could be put through several expansion–contraction cycles and showed that the contractions could perform work on a load, indicating that the materials might be used as artificial muscles.[7] It was noted that the hydrogel underwent continuous swelling upon titration with a base until the solution pH approached the pK_a of the acid groups in the hydrogel. Partial collapse of the hydrogel began to occur when titration continued beyond the pK_a, which they attributed to charge shielding from the neutralization salts in solution. The observed behavior made it clear that the physical state of the hydrogel depended upon molecular forces that could be manipulated with different stimuli.

The concept of using dynamic hydrogels to transform chemical potential into mechanical work was further refined to create an engine driven by hydrogels that alternated between swollen and collapse states based on the solution conditions.[8,9] The extensive theoretical and experimental work that followed found that in addition to pH, hydrogel conformational changes could be induced by changes in parameters such as solvent composition,[10–13] temperature,[14] and solution ionic strength.[15,16] The kinetics of these transitions and the corresponding water transport in hydrogels have also received considerable attention,[17–21] with interesting transient effects having been observed in some instances.[22,23]

1.132.2. Functional Modes/General Dynamic Mechanisms

Dynamic hydrogel networks are held together via chemical bonds or physical interactions. These cross-links tend to reduce the dynamic behavior of the hydrogel by physically restricting the range of motion of the polymer chains within the network.[24] Nevertheless, cross-linked hydrogels can swell to several times their original volume when exposed to the appropriate environmental conditions. The polymer chains that make up hydrogels interact with both themselves and their environment to form structures that achieve the lowest possible free energy state of the system. Consequently, the degree of swelling in the network is determined in large part by the cumulative effect of hydrophobic interactions and other relatively weak molecular forces, much like the tertiary structure of proteins. As is the case with some proteins, a slight perturbation in the balance of these molecular interactions can result in large conformational changes within the molecular structure. The following sections review the forces that are frequently involved in dynamic changes in hydrogel structures.

1.132.2.1. Hydrogen Bonding and Hydrophobic Interactions

Hydrogen bonding, the force that is largely responsible for the unique properties of water, plays a crucial role in determining the structure of hydrogels. Hydrogen bonding can occur between polymer chains and water molecules as well as between two chains within the polymer network. The most common hydrogen bonding sites within hydrogels are amine, amide, alcohol, and carboxylic acid groups. The dipole–dipole interaction in hydrogen bonds is relatively weak (10–30 kJ mol^{-1}) in comparison to covalent bonds (~350 kJ mol^{-1} for a typical carbon–carbon bond); the energy required to break a hydrogen bond is on the order of the kinetic energy of a water molecule at room temperature. Increasing the temperature above room temperature further weakens the extent of these interactions. Nevertheless, the cumulative force of many of these interactions acting in concert can be significant.

In comparison, hydrophobic interactions are even weaker than hydrogen bonds (<10 kJ mol^{-1}), so much so that it has only been recently that the strength of these interactions could be measured.[25] Previously, it was a matter of debate whether the interactions between nonpolar groups in aqueous solution was due solely to entropic exclusion of water. In contrast to hydrogen bonds, hydrophobic interactions are generally enhanced by increasing temperatures. In hydrogels with both hydrophobic and hydrophilic groups, hydrogen bonding acts to solvate the hydrophilic regions of the polymer while hydrophobic interactions and entropy favor polymer–polymer interactions. Given that these molecular interactions are dependent upon temperature and pressure, the balance between hydrogen bonding and hydrophobic interactions can be shifted by changes in thermodynamic parameters.

1.132.2.2. Electrostatic Interactions and Donnan Equilibrium

The structure of hydrogels containing ionizable groups is largely dependent upon the degree of ionization of the polymer chains. In an uncharged state, ionic hydrogels behave in a manner similar to hydrogels containing polar groups and the chains in the hydrogel can participate in hydrogen bonding. Hydrogen bonding is gradually disrupted as functional groups become ionized and coulombic forces act to separate the like-charged groups on the polymer chains, resulting in hydrogel swelling. The repulsive force can be overcome to a certain extent by shielding effects from soluble counter ions, as observed previously.[7]

In addition to electrostatic interactions, the immobilized charge of the ionizable groups on the polymer chains has the effect of increasing the internal osmotic pressure of the hydrogel due to a Donnan equilibrium partitioning of counter ions between the hydrogel and the bulk solution. The increased internal osmotic pressure contributes to the swelling of the hydrogel.

1.132.2.3. Competitive Binding

Individual polymer chains within a hydrogel can also associate with one another through noncovalent interactions.[26] For example, a hydrogel containing a protein and its ligand covalently attached to the polymer backbone in their active states will form dynamic cross-links due to the protein–ligand binding interactions.[75] The interactions are in a dynamic equilibrium, making the associations reversible in nature. Introduction of soluble

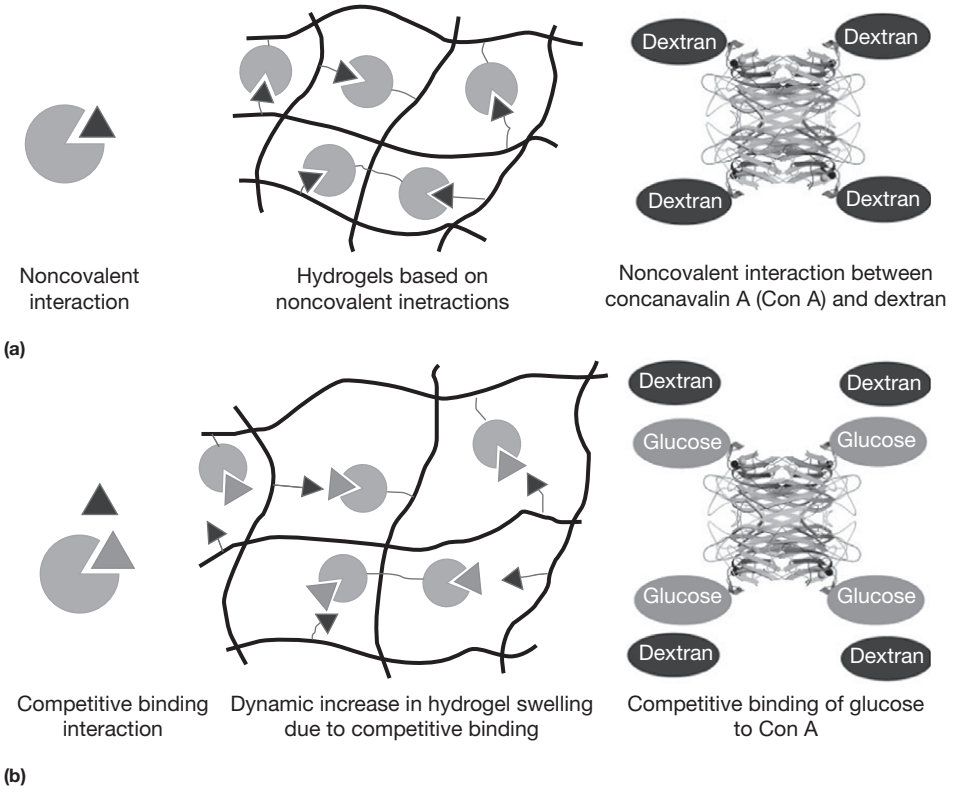

Figure 1 Swelling of a dynamic hydrogel via competitive ligand binding. The hydrogel structure swells as the interactions with immobilized ligands are displaced by soluble ligand, reducing the effective cross-linking density in the hydrogel. Reproduced from Mohammed, J. S.; Murphy, W. L. *Adv. Mater.* **2009**, *21*, 2361–2374, with permission from Copyright Wiley-VCH Verlag GmbH & Co., KGaA.

ligand into the solution will compete for binding sites and a new equilibrium will be established based on the binding constants and concentrations of the ligand in solution and those bound to the hydrogel. Thus, the degree of swelling in the hydrogel will increase as soluble ligand displaces the hydrogel immobilized ligand. The hydrogel swelling can be gradually reversed by exchanging the solution with solution that does not contain soluble ligand. The concept of using competitive binding to create dynamic hydrogels is shown schematically in Figure 1.

1.132.2.4. Covalent Bonding and Bond Cleavage

Many hydrogels are covalently bonded networks of water-soluble polymers. The covalent bonds in the network act to maintain a network structure that would otherwise be dispersed due to entropy and forces such as osmotic pressure. Covalent bonds are significantly stronger than other intermolecular forces and are therefore generally stable, even if they are not thermodynamically favorable. However, these bonds can be dissociated in catalyzed reactions, causing the hydrogel structure to swell or even dissolve. For example, poly(lactic acid) has been used extensively as a component of hydrogel networks because it is degraded by acid-catalyzed hydrolysis. Similarly, certain cells excrete proteases to remodel the local extracellular matrix. Hydrogels that have cross-links containing protease-specific peptide sequences can be created to develop materials that respond to a particular protease, the presence of which may be associated with tissue development or a disease state.

1.132.3. Specific Stimuli and Response Mechanisms

Given the variety of mechanisms by which structural changes can be brought about and the wide range of applications for which they are being developed, it is reasonable to expect that there would be a diverse set of stimuli used to trigger dynamic responses in hydrogels. In many cases, the most appropriate triggering mechanism is dictated by the application in which the hydrogel is to be used. For example, a hydrogel that is impervious under low pH conditions and permeable under neutral or basic pH conditions might be the most appropriate means of oral administration of a drug that is both acid labile and readily absorbed in the more neutral pH of the intestine. The following section reviews some of the more common stimuli that have been used to trigger dynamic responses from hydrogels. There are many instances where the activating mechanism involves a cascade effect where the stimulus acts indirectly to achieve a dynamic hydrogel response. For example, the absorbance of light might be used to increase the temperature within a hydrogel and the change in temperature could then be used to cause a structural change in the hydrogel. In such an instance, the mechanism is listed by the initial stimulus (i.e., light).

1.132.3.1. Physical Stimulus

One attractive feature of using physical stimuli (e.g., temperature, pressure, electromagnetic forces) to initiate a dynamic

response from hydrogels is that they can be applied to closed systems, which may be advantageous for several reasons. In a case where the hydrogel needs to be rapidly switched back and forth between states, it would be easier to cycle the temperature of the sample than it would be to remove chemicals from the hydrogel structure. Physical stimuli can also reduce response times in thick hydrogels by eliminating mass transfer limitations that are present when chemicals are used as stimuli.

1.132.3.1.1. Temperature

Temperature-sensitive structures are prevalent throughout materials science and the field of dynamic hydrogels is no exception. Hydrogels can be made to either collapse or swell upon heating, depending on the monomers used to form the hydrogel. Lower critical solution temperature (LCST) hydrogels, occasionally referred to as volume phase transition temperature (VPTT) hydrogels, exhibit a decrease in volume when heated above their critical temperature. LCST hydrogels contain both hydrophobic and hydrophilic regions, which can be accomplished either with a pure monomer or a copolymer blend. Hydrogels made of *N*-isopropylacrylamide (NiPAAm) demonstrate LCST behavior and have been studied extensively, in large part because the hydrogels undergo a phase transition near *in vivo* temperatures.[27] The reader is referred to a review by Schild for further reading on the history and early uses of NiPAAm hydrogels.[28] In addition to NiPAAm, many other *N*,*N*′-alkyl substituted acrylamide monomers have various swelling behaviors upon heating, ranging from continuous swelling to discontinuous collapse.[29] The diverse swelling behavior observed in the series of analogs was due to both the hydrophobicity and size of the pendant groups. LCST hydrogels based on temperature-sensitive amino acid sequences have also been demonstrated using elastin-like peptides (ELP).[30,31] ELP offer the advantage of precise molecular weights and can be incorporated into fusion proteins to create dual functional materials.[32] Even with the wide selection of materials that display LCST behavior, NiPAAm continues to be the most widely used monomer for creating temperature-dependent hydrogels.

NiPAAm monomers contain a hydrophilic amide group and a hydrophobic isopropyl pendant group. At lower temperatures, the free energy of the system is dominated by enthalpic gains from hydrogen bonding between the water molecules and the hydrophilic regions of the hydrogel network. As the polymer is heated, the free energy balance shifts toward favoring hydrophobic interactions and entropic gains, leading to the aggregation of the hydrophobic regions of the polymer and collapse of the hydrogel network.[33] The transition of the hydrogel from a swollen to a collapsed state has been shown to be an endothermic process, demonstrating the importance of the entropic contribution to the phase transition.[33] The increase in polymer–polymer interactions and reduction in water content of hydrogels above the LCST have been verified using gravimetric, NMR, and small angle neutron scattering methods,[18,34,35] and a number of theoretical models have been developed to describe the phase transition.[36]

Nonuniform collapse has been observed in larger hydrogel structures when heated above the LCST.[37] Rapid heat transfer and fewer chain entanglements at the surface cause a dense skin to form at the surface of the hydrogel while the inner structure remains in a uncollapsed state that contains entrapped water. The interior of the hydrogel eventually collapses, but the transition can take an extended period of time and the change can be pulsating in nature.[38] Further, it was observed that the rate of transition of a thermoresponsive hydrogel was a function of the temperature, with the rate of change being essentially zero at the critical temperature and increasing as the temperature is increased beyond the critical temperature.[39] The slow transition time demonstrated by these hydrogels near their LCST could be a drawback in certain applications where are rapid response is required. Using a comb polymer architecture, Yoshida and coworkers demonstrated that response times for NiPAAm hydrogels could be decreased to as little as 20 min versus more than a month for a NiPAAm network without grafted groups.[40] The comb regions of the polymer network, which had a greater degree of freedom because their movement was restricted on only one end by the network, rapidly formed nucleation sites for the network portion of the polymer to aggregate around.

The volume transition at the LCST is sharp for homogenuous hydrogels made with a single monomer and becomes more gradual as the hydrogel structure becomes less homogeneous. For example, the average molecular weight of the polymer chains in a homopolymer network has been shown to impact the LCST.[41] Different oligomers can be grafted into a single hydrogel to produce multiple phase transitions in a single material.[41] Multiple phase transitions have also been demonstrated in core–shell nanoparticles, where the LCST of the core was lower than that of the outer shell.[42] It was shown that the particles could exist in three states: (a) collapsed core–collapsed shell; (b) collapsed core–expanded shell; and (c) expanded core and shell. The collapsed core–expanded shell state contained a transition region between the two domains that had an intermediate density between the two regions. The transition temperature of NiPAAm was found to be unchanged when it was incorporated into an IPN with poly(tetramethylene ether glycol) (PTMEG); however, the swollen volume was decreased proportionally with the amount of PTMEG used in the formulation.[37] A hydrogel made with NiPAAm and poly(acrylamide), which was heterogeneously distributed throughout the structure, was shown to exhibit temperature-sensitive shape memory.[43] In addition to bending, it was shown that the hydrogel could be used to grasp particles and fold the hydrogel into predetermined geometries.

In addition to making the phase transition more gradual, copolymerization also shifts the LCST of the hydrogel. Incorporation of hydrophobic monomers into the polymer network via copolymerization tends to decrease the transition temperature.[44] Conversely, copolymerization with hydrophilic monomers leads to an increase in the LCST and can even eliminate the discontinuous phase transition entirely.[45] The number of ionizable groups in the network and the pH of the solution have been found to play a key role in the temperature dependence of the phase transition.[46] A network made up of poly(*N*,*N*-diethylacrylamide) in water showed a continuous volume change upon heating, whereas a similar network containing 3 mol% sodium methacrylate showed a discontinuous phase transition at 51 °C.[47] Studies with hydrogels containing cationic functional groups showed a similar dependence on the concentration of the ionic groups.[48,49]

Kokufuta observed that the addition of surfactants to the solution containing a NiPAAm hydrogel increased the phase transition temperature and the degree of swelling when the transition occurred.[50] The effect varied by concentration and type of surfactant, with sodium dodecyl sulfate (SDS) having the greatest impact. The long alkyl chains of the surfactant molecules were thought to have associated with the isopropyl groups of NiPAAm through hydrophobic interactions, which would essentially fix the ionic charge of the surfactant to the hydrogel.

In contrast to LCST hydrogels, upper critical solution temperature (UCST) materials expand as the material is heated past the critical temperature and their behavior can be characterized using a thermal mixing model.[12,13,27] These hydrogels are typically composed of hydrophilic monomers, such as acrylamide and acrylic acid. Ilmain demonstrated a UCST IPN hydrogel that demonstrated a volume change that was dominated by hydrogen bonding interactions.[51] The hydrogel contained acrylamide and acrylic acid networks that formed hydrogen bonding pairs, akin to the pairing that occurs in DNA. Heating of the network led to the disruption of the hydrogen bonds and allowed the hydrogel to swell. Bae and coworkers demonstrated a similar IPN made with *N*-acryloylpyrrolidine and poly(oxyethylene) that exhibited a greater degree of maximal swelling when the network consisted of a 50–50% mixture of the two polymers than when either monomer was in excess.[52] The authors attributed the increased swelling of the 50–50% blend to enthalpically unfavorable mixing between the two monomers, which would lead to a repulsive force.

Katono found that incorporating butyl methacrylate (BMA) into an IPN of BMA/acrylamide and acrylic acid decreased the degree of swelling when the network was heated.[53] Addition of BMA also changed the swelling from a discontinuous to a continuous transition as a function of temperature. Hydrogels that did not contain BMA did not have reproducible swelling volumes when the temperature was cycled above and below the UCST. The swelling ratio became more reproducible as the BMA content was increased to 30% of the BMA–acrylamide copolymer portion of the IPN. These effects were thought to have been the result of the increased hydrophobic nature of the hydrogel. The hydrophobic effect is enhanced when the temperature is increased, which led to the suppression in swollen volume. The lower swelling volume in turn kept the hydrogen bonding pairs of the two polymer networks in close proximity, where they could more easily recombine when the temperature was reduced.

Demonstrating an alternative approach, Wang and coworkers demonstrated the use of a coiled-coil protein motif as a way to create a temperature-sensitive hydrogel.[54] The histidine-tagged protein was coordinated to an *N*-(2-hydroxypropyl)-methacrylamide (HPMA) backbone that contained the metal chelating monomer *N*-(*N*′,*N*′-dicarboxymethylaminopropyl) methacrylamide (DAMA). The protein chains were attached to the main polymer backbone through transition metal complexes between the polyhistidine tail of the polymer and the DAMA groups. The coils unraveled above the melting temperature of the protein and collapsed upon cooling below the melting.

1.132.3.1.2. Electrical, magnetic, and electromagnetic fields

1.132.3.1.2.1. Electric field

The ease with which electrical fields can be controlled with modern electronics has enabled extensive studies of hydrogels that are sensitive to electric fields. One of the first demonstrations of coupling electronic input to dynamic hydrogel action was demonstrated using a poly(vinyl alcohol)–poly(acrylic acid) copolymer fiber impregnated with platinum particles.[55] When the fiber was held at a negative potential, the polymer acted as the cathode in the electrolysis of water and the local proton concentration was depleted as hydrogen gas was formed. As a result, the acidic groups in the polymer dissociated and the fiber subsequently swelled due to the buildup of charge within the network. When the hydrogel was held at a positive potential, the electrolysis reaction was reversed and the hydrogel contracted as the acidic groups in the polymer were protonated.

Further extending this concept, Fragala and coworkers isolated a weak acid hydrogel between two electrodes by placing it between anion and cation ion exchange membranes.[56] The selective nature of the ion exchange membranes allowed protons to preferentially diffuse into or out of the central chamber, depending on the direction of the current. Passive diffusion across the membrane was minimal, so the pH in the central chamber could be held for an extended period of time after the applied voltage was removed. The design had the additional benefit that the overall chemical composition of the system was not changed, so the fiber could be repeatedly actuated without adding additional chemicals. Grodzinsky and coworkers were able to demonstrate that both static[57] and oscillating[58] tensile forces could be generated in a collagen membrane by altering the intramembrane ionic strength with an electric field applied transversely to the length of the cylindrical membrane.

Tanaka and coworkers developed a partially hydrolyzed acrylamide hydrogel that collapsed when exposed to electric field strengths of less than $2\,V\,cm^{-1}$.[59] In a 50% acetone–water mixture, the rod-shaped hydrogels first showed tapering toward the anode, and this effect became more pronounced as the field strength was increased. Eventually, uniform collapse across the length of the hydrogel was observed. In pure water, the samples demonstrated uniform collapse along the length of the hydrogel, regardless of the field strength. The collapse was attributed to stresses built up in the hydrogel due to the electric field acting on the charged groups of the polymer and the ions in solution. In a later study, the authors found that the change was actually due to a pH gradient that had formed within the hydrogel.[60] A study using poly (2-acrylamido-2-methyl-1-1-propanesulfonic acid) found that organic solvents, such as acetone and ethanol, reduced the rate and the magnitude of the hydrogel collapse for a given applied electrical field.[61] It was also shown that water permeation through the hydrogel could be increased by applying an electric field while the edges of the hydrogel were immobilized to prevent collapse of the bulk structure.

Shiga found that an acrylic acid-*co*-acrylamide hydrogel underwent similar behavior in a DC electric field.[62] The study found that hydrogels with a low concentration of carboxylic acid groups shrank in a DC electric field, but hydrogels with a high concentration of the acid groups swelled. Further, it was noted that the ends of long, thin hydrogels could be bent

toward the cathode. A net weight gain was associated with the deflection, indicating that asymmetric swelling was occurring on the anode side of the hydrogel due to osmotic pressure.

Bending toward the anode was observed in a composite hydrogel rod that had a core made out of a poly(vinyl alcohol)–poly(sodium acrylate) copolymer and an outer shell made out of poly(vinyl alcohol).[63] Cross sections of the hydrogel immediately after having been exposed to an electric field indicated that the region near the anode had a lower pH and the region near the cathode had an increased pH. Swelling on the cathode side of the hydrogel was due to osmotic pressure caused by the higher pH in the region. Polyampholytic hydrogels containing both anionic and cationic functional groups behaved similar to an anionic hydrogel when the pH was above the isoelectric point (IEP) and acted as a cationic hydrogel when the pH was below the IEP when exposed to an electric field.[64] Addition of a cationic surfactant to a solution containing an anionic hydrogel was shown to change the direction of bending in an electric field toward the anode.[65] The surfactant neutralized surface charges on the anode side of the poly (2-acrylamido-2-methyl propane) sulfonic acid hydrogel, which reduced the osmotic pressure at the hydrogel–solution interface. Association between the hydrocarbon tails of the surfactants further stabilized the bent conformation of the hydrogel.

An interpenetrating network of chitosan and poly(aniline) showed bending and oscillatory motions in an electric field.[66] At neutral pH, periodic swelling and contraction on the anode side of the hydrogel were observed. The hydrogel had a partial positive charge at the neutral pH, which caused the hydrogel to initially deflect toward the anode due to charge shielding resulting from the migrating counter ions. Hydrolysis near the anode led to protonation of the aniline groups, which made them susceptible to oxidation. The protonation had the added effect of causing the hydrogel to bend back toward the cathode. The subsequent oxidation caused shrinkage on the anode side, causing the hydrogel to bend toward the anode.

In studies using isopropylacrylamide beads, Hirotsu found that ionic hydrogels contracted when an electric field was applied, but neutral hydrogels did not.[67] The effect was observed for DC fields but not AC fields in the 10–100 Hz frequency range. Further, it was noted that the electrodes had to be submerged in the fluid containing the hydrogel for the field to have an effect. The collapse occurred on the positive electrode side first, and beads nearest the anode had the quickest response time, the lag time being nearly proportional to the square of the distance from the electrode, indicating that the kinetics were controlled by diffusion. Under large applied fields, it was noted that the hydrogel volume oscillated wildly for several hours. The oscillatory motion of hydrogels in an AC field was later modeled as a mechanical vibration in a cantilever beam made with poly(vinyl alcohol)–poly(sodium acrylate) hydrogel.[68] The resonance frequency was found to be proportional to the hydrogel thickness for hydrogels less than 1 mm thick, with the resonance frequency being on the order of 1–2 Hz. It was also noted that the number of nodes in the oscillating hydrogel increased as the frequency of the field increased.

Suleimenov and coworkers found that the initial rate of shrinkage of a hydrogel in an electric field was initially increased in the presence of an orthogonal magnetic field, eventually achieving the same rate as without a magnetic field.[69] The effect was attributed to segregation of charge carriers within the hydrogel due to the Hall effect. The postulated increase in charge density at the surface of the hydrogel would then be more strongly attracted to the oppositely charged electrodes used to establish the electric field.

1.132.3.1.2.2. Magnetic field

Incorporation of superparamagnetic materials can lead to hydrogels that are sensitive to magnetic fields.[70] Termed ferrohydrogels, these materials can be elongated, compacted, or bent when exposed to a nonuniform magnetic field.[71] The response times for magnetic field-actuated hydrogels are generally not rate limited by polymer chain diffusion or relaxation times, so they can be cycled between states faster than hydrogels that are actuated by many other forms of stimulus. The degree of deformation of ferrohydrogels is proportional to both the field strength and the volume of ferromagnetic material incorporated into the hydrogel, allowing for a continuum of deformation states. The brittleness of the hydrogel construct usually increases as the superparamagnetic loading increases. Fuhrer and coworkers overcame this limitation by creating a hydrogel with magnetic pendant groups.[72] The backbone consisted of poly(2-hydroxyethyl methacrylate) to which composite cobalt–carbon nanoparticles were attached using vinyl modification of the carbon portion of the particle with a vinyl biphenyl linker. Covalent attachment of the nanoparticles also prevented them from being leached into solution over time.

Hydrogels containing superparamagnetic materials can retain sensitivity to other stimuli, such as temperature and pH.[73] Takahashi demonstrated that temperature-sensitive NiPAAm-*co*-acrylamide hydrogels containing iron(III) oxide particles could be made to collapse by applying an alternating magnetic field, which heated the hydrogel due to magnetic hysteresis.[74] It was noted that the hydrogel experience uniform shrinking because heating was more evenly dispersed throughout the hydrogel than is the case when the trigger is introduced by conductive heat transfer.

1.132.3.1.2.3. Electromagnetic field

Light has been used to induce a phase transition in hydrogels via several different mechanisms. Many early efforts incorporated dyes into the network structure of temperature-sensitive hydrogels. Absorption of light by dye molecules leads to heating of the local hydrogel structure, which in turn causes the temperature-sensitive hydrogels to collapse.[75] Suzuki demonstrated such a system using a NiPAAm hydrogel that contained copper chlorophyllin cross-linked into the hydrogel structure.[76] A portion of the hydrogel was then selectively illuminated with a focused laser beam that heated the exposed region due to absorbance by the chromophore, resulting in shrinkage of the hydrogel only in the immediate area of illumination. Rapid heat transfer to the bulk solution surrounding the hydrogel played a critical role in ensuring that only the illuminated region collapsed. Gold nanoparticles have also been imbedded into NiPAAm hydrogels to achieve IR light-triggered collapse.[77,78]

A similar approach has been used to create pH-sensitive hydrogels that respond to light. Saaem developed photoresponsive hydrogels by coupling bacteriorhodopsin (bR), a

photoactuated proton pump, to poly(acrylic acid).[79] The bR molecules were oriented on the polymer backbone such that protons were pumped toward the polymer chain, decreasing the local pH. When exposed to green light, the low pH in proximity to the polymer chain caused the acrylic acid groups to become protonated and allowed the hydrogel to collapse.

Light sensitivity can also be conferred upon hydrogels by incorporating compounds that dissociate or change conformation upon exposure to light. Irie demonstrated just such an approach by cross-linking the photodissociating compound leucocyanide into a poly(acrylamide) hydrogel.[80] The leucocyanide groups dissociated when exposed to ultraviolet (UV) light and created a higher osmotic pressure within the hydrogel, which in turn caused the hydrogel to swell. The degree of swelling was found to be proportional to the concentration of the immobilized leucocyanide at low concentrations due to the increased osmotic pressure; however, higher concentrations were found to be less effective due to hydrophobic interactions between the leucocyanide groups. Following up on this work, the group later created hydrogels using NiPAAm instead of acrylamide, conferring both temperature and light sensitivity on the hydrogel.[81] Irie observed that hydrogels containing leucocyanide groups could also be made to selectively respond to electric fields.[82] The leucocyanide groups were ionized by UV light, making the hydrogels susceptible to electric fields; the electric field response was lost after the UV illumination was removed.

Szilagyi and coworkers incorporated an acrylated chromophore, spirobenzopyran (SP), into a NiPAAm hydrogel network and showed that photoisomerization could be used to induce a structural change.[83] Upon illumination with blue light, the protonated open ring structure of the chromophore transitioned to a deprotonated, closed ring. This transition led to a significant increase in the hydrophobicity of the pendant group and resulted in the collapse of the hydrogel. To verify that the collapse was due to a change in hydrophobicity and not heating, the material was shown to preferentially capture negatively charged polystyrene beads when in the dark state versus the illuminated state where the chromophore was in the hydrophobic state.

Juodkazis and coworkers demonstrated that optical pressure could be used to cause the collapse of hydrogels.[84] A NiPAAm hydrogel was shown to reversibly collapse when illuminated with an infrared laser, as shown in Figure 2. The radiation force from the laser promoted the interaction between hydrophobic regions of the hydrogel, causing the hydrogel within the laser spot to collapse. Evaluation of the local temperature profile using a thermosensitive dye indicated that heating was not a significant factor in the collapse of the hydrogel.

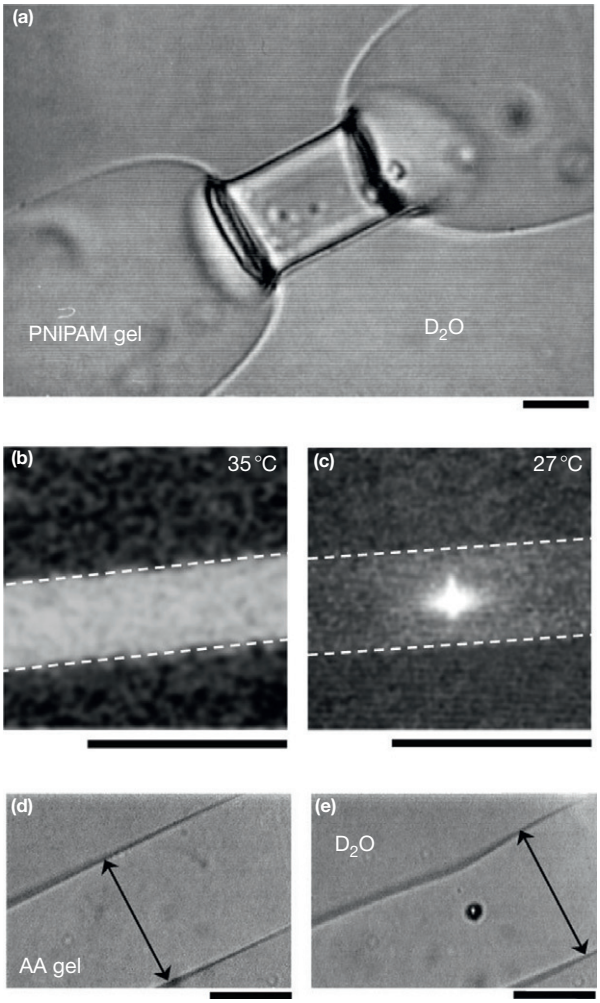

Figure 2 (a) Collapse of a portion of an *N*-isopropylacrylamide (NiPAAm) hydrogel rod using a focused laser to apply radiation force. The radiation force promoted chain–chain interactions within the hydrogel, leading to the collapse of the network. Deuterated water was used to minimize absorbance-based heating in the system. (b) Photoluminescence of 8-anilino-1-naphthalene-sulfonic acid sodium salt (ANS-Na), which is enhanced in hydrophobic environments, in a NiPAAm gel heated above the lower critical solution temperature (LCST) temperature. (c) ANS-Na luminescence in a NiPAAm gel below the LCST is enhanced in the region exposed to the radiation force of a laser spot. (d and e) Compaction of an acrylamide gel with radiation forces. The scale bars are equal to 20 μm. 1.132.3.1.3. Pressure

The application of isotropic pressure has been shown to cause NiPAAm hydrogels to swell from their collapsed state when the samples were held under isothermal conditions.[85,86] The increase in pressure reduced the free volume of the system, which led to a reduction in the entropy of the system. The reduction in the free volume of the system also causes the internal energy of the system to increase through enhanced polymer–polymer and water–water interactions. The swelling of the hydrogel in response to the increase in pressure results in additional polymer–water interactions, which helps to reduce the free energy of the system.

The net effect of the pressure dependence is an observed shift in the LCST of the hydrogel to higher temperatures.[87] The phenomenon of pressure dependence appeared to have a critical value range above which the effect was no longer observed in NiPAAm hydrogels. The pressure-induced swelling was discontinuous in nature at 35 °C and gradually became continuous as the temperature was increased to 38 °C. NiPAAm hydrogels containing ionized functional groups showed pressure-induced swelling behavior between 37 and 42 °C.

Upon further increasing the pressure, the ionized hydrogels began to return to the collapsed state due to the pressure dependence of the hydrophilic interactions between the water molecules and the polymer chains.

1.132.3.2. Chemical Stimulus

While there are many advantages to using physical stimuli to trigger dynamic hydrogel response, the use of chemical responsive hydrogels would enable more intricate interaction with biological systems. For example, a hydrogel might be developed to release medication in response to a specific antigen. The ability for hydrogels to respond to specific molecules would also allow them to be used in applications that require feedback control mechanisms. The following sections discuss methods that are commonly used to create chemically responsive hydrogel structures.

1.132.3.2.1. pH

As was observed by Katchalsky and Kuhn, hydrogels containing acidic moieties swell when the pH of the solution is increased and the acid groups become deprotonated.[5,6] Conversely, hydrogels containing cationic groups tend to swell under low pH conditions. The swelling in both cases is due to an increase in electrostatic repulsion and internal osmotic pressure, which result from the increase in fixed charges in the polymer network. The effect becomes particularly noticeable near the pK_a of the functional groups in the hydrogel.

Firestone observed that the rate of swelling in a pH-sensitive hydrogel containing amine groups increased as the degree of ionization of the functional groups increased.[88] Conversely, the rate of deswelling in the hydrogel became slower as the pH was increased, possibly due to reduced proton mobility in the hydrogels resulting from interactions with the deprotonated amine groups at more basic pH conditions. In studying the pH dependence of *n*-alkyl methacrylate esters copolymerized with (dimethylamino)ethyl methacrylate, Siegel found that increasing the length of the alkyl chain on the methacrylate esters reduced the degree of swelling upon phase transition and shifted the phase transition to a lower pH for methyl, ethyl, and propyl groups.[89] Additionally, the discontinuous phase transition became more gradual with increased side chain length. These effects were attributed to the reduction in the concentration of charged groups within the hydrogel, which reduced the osmotic pressure, and the increased hydrophobic nature of the polymer, which made water uptake less favorable. However, the trend did not hold for butyl and hexyl groups, which they attributed in part to the increased stiffness of the polymer chain.

Luo and coworkers developed a poly(silamine) hydrogel that showed swelling in low pH conditions due to the protonation of the amine groups.[90] Unlike many hydrogels, the poly (silamine) hydrogels became more rigid in the swollen state. The increased rigidity of the swollen hydrogel was thought to be a result of a coordination of the protonated amine group, the counter ion, and the silicon atoms in the backbone. The coordination of the four atoms would then restrict the rotational freedom of the hydrogel chains.

A systematic study of acrylic acid hydrogel derivatives with varying amounts of *n*-alkyl acrylates ($n = 8$, 12, 18) determined that the transition pH became more basic as the length of the alkyl chain became longer and as the hydrophobic monomer content was increased in the hydrogel.[91] Further, the rate and degree of swelling did not seem to be impacted by chain length in the hydrogel samples that were tested. A potentiometric titration of the hydrogels found that the addition of alkyl groups had shifted the apparent pK_a of the acid groups in the hydrogels.

Nishi developed an IPN hydrogel membrane made with poly(oxyethylene) and poly(acrylic acid) and demonstrated that the flux and molecular weight selectivity of molecules passing through the membrane could be altered by varying the pH of the solution.[92] The hydrogel membrane swelled and the flux dropped off significantly at higher pH values due to the deprotonation of the acrylic acid groups. In the uncharged state, chains of poly(oxyethylene) and poly(acrylic acid) are known to associate.[93] Since the membrane was fixed in place by the test housing, the association of the two polymer networks was thought to enlarge the pores within the membrane to compensate for the inability of the membrane to contract to relieve the contractile stress. In the charged state, the hydrogel chains would no longer associate and the pores could relax back to their naturally smaller size.

The swelling volume of amphoteric hydrogels made with the copolymers trimethyl(*N*-acryloyl-3-aminopropyl)ammonium chloride–sodium acrylate–acrylamide–*N*,*N*′-methylenebisacrylamide has been shown to vary depending on the ratio of cationic groups to anionic groups, with the least amount of swelling for an equimolar composition and increased swelling for increasingly disproportionate ratios.[94] The reduced swelling with equimolar composition was likely due to hydrogen bonding within the gel while the increased swelling for disproportionate concentrations was due to an increase in the concentration of osmotic pressure-inducing ions in the hydrogel.

1.132.3.2.2. Ionic strength

Tanaka noted that the collapse of a partially hydrolyzed acrylamide hydrogel could be induced by increasing the salinity of the solution surrounding the hydrogel.[95,96] The report noted that the transition occurred at a much lower salt concentration when divalent magnesium cations replaced monovalent sodium. The swelling in weakly charged ionic hydrogels in the presence of monovalent ions was found to be in good agreement with Donnan equilibrium theory; however, the theory did not fully explain the behavior of the hydrogels in the presence of divalent ions.[97] A discontinuous phase transition was noted in an acrylic acid acrylamide copolymer hydrogel when the concentration of copper ions reached a certain threshold, which was found to be inversely related to the concentration of acidic groups in the polymer.[98] The authors did not observe the discontinuous phase transition for nickel ions. The varying behavior for the two divalent cations was attributed to the formation of coordination complexes between the copper ions and acid groups in the hydrogel, which acted as weak cross-links within the hydrogel.

Ampholytic hydrogels made with the copolymers acrylamido methyl propylsulfonic acid, methacryl-amido propyl trimethyl ammonium chloride, and dimethyl acrylamide that had equal amounts of cationic and anionic groups were shown

to swell in cesium salt solutions with concentrations above 10 mM.[99] The effect became more pronounced as the number of charged species in the hydrogel backbone increased. Polymers with a 1.4% excess of basic groups showed a rather complex response to varying solution concentrations of salt. The swelling ratio was steady below 10 μM and then increased slightly up to a salt concentration of 100 μM. The swelling then decreased as the concentration was increased from 100 μM to 10 mM and then steadily increased for salt concentrations up to 1 M. The multiple inflection points were attributed to changes in the relative importance of dissociation, polyampholytic, and polyelectrolyte effects. Ampholytic hydrogel response to salinity has also been studied as a function of the net charge of the hydrogel.[64] The hydrogels were found to swell to a greater degree in a 0.1 M KCl solution than when they were in distilled water when the pH was near the IEP of the hydrogel. Conversely, the presence of salt suppressed the level of swelling as the solution pH deviated from the IEP.

The salt concentration in solution can also impact the degree of swelling in nonionic hydrogels. Sodium chloride was also found to induce a phase transition in NiPAAm.[100] Sodium salts of phosphate and sulfate showed a gradual reduction in the degree of swelling in the hydrogel; however, they did not result in a phase transition. Inomata found that the phase transition temperature of NiPAAm could be reduced by adding KCl to the solution surrounding the hydrogel.[101] A 0.1 mM solution of KCl reduced the transition temperature from 33.8 to 20.6 °C. Other anions showed a less pronounced effect and the cation did not appear to play a role in the phenomenon. The reduction in transition temperature and the viscosity B coefficient (VBC), which depends in part on the interaction between the solvent and the polymer chains, showed a linear correlation for the monovalent anions tested. The authors attributed the observed relationship to the tendency of ions with a more positive VBC to promote hydrophobic interactions, which would cause the collapsed NiPAAm state to be favorable at a lower temperature. The work also investigated the impact of adding tetra alkylammonium bromides with various alkyl chain lengths to the solution and observed that the transition temperature was lowered in some instances while in others it was increased.

1.132.3.2.3. Ligand binding and ion-specific interactions

Crown ethers can be incorporated into hydrogel networks to confer cation-specific shifts in the LCST of hydrogel networks.[102] One particular hydrogel consisted of a copolymer of NiPAAm and benzo-18-crown-6-acrylamide (BCAm). The LCST of the polymer increased due to higher osmotic pressure when barium ions were captured by the crown ether structures and no change was observed when potassium ions replaced the barium ions in solution. The LCST was decreased when cesium ions were introduced into the solution, most likely due to a coordination effect in which the cesium ions became sandwiched between two crown ether structures. A similar study using a benzo-15-crown-acrylamide unit found that the LCST was preferentially reduced by potassium ions.[103]

Molecularly imprinted polymers (MIPs), also referred to as molecular recognition polymers, are an emerging method for developing molecular-specific responses from hydrogels.[104–106] The technique incorporates the specific guest molecule into the polymer blend before polymerization. Polymerization with the molecule in the hydrogel is thought to create a binding pocket in the hydrogel that will be able to preferentially interact with the molecule of interest. The templating molecule can then be rinsed out, leaving the binding pocket available for interactions when the appropriate molecule is present in solution.

Watanabe demonstrated molecular recognition hydrogels formed with NiPAAm and acrylic acid that demonstrated selective swelling from the collapsed state when specific molecular recognition molecules were introduced into solution.[107] Hydrogels were prepared in the presence of norephedrine or adrenaline. The NiPAAm monomers caused the hydrogels to be in a collapsed state at 50 °C. The hydrogel prepared with norephedrine showed concentration-dependent swelling in the presence of norephedrine, but did not swell when exposed to adrenaline. The opposite response was observed in the hydrogel prepared in the presence of adrenaline. Miyata and coworkers used molecular imprinting to create a hydrogel that would contract when exposed to the glycoprotein α fetoprotein (AFP), a tumor-specific marker.[108] To prepare the responsive hydrogel, lectin specific to the glycoprotein (Con A) and a polyclonal antibody (anti-AFP) were conjugated with *N*-succinimidylacrylate. The monomers were reacted with acrylamide and *N*,*N*′-methylenebisacrylamide in the presence of AFP. The hydrogel was then soaked in buffer to remove the AFP. A control hydrogel was prepared without AFP present. The AFP-templated hydrogel contracted when AFP was introduced into the solution, whereas the control hydrogel swelled slightly. Both hydrogels swelled to a small extent when exposed to ovalbumin, indicating that the templating process conferred a degree of specificity for AFP binding upon the hydrogel.

1.132.3.3. Biochemical Stimulus

Several mechanisms for achieving dynamic hydrogel response based on biochemical recognition have also been developed. These approaches take advantage of the high binding affinity and selective nature of biomolecular interactions. The ability to recognize and respond to specific molecules would enable dynamic hydrogels to be used in feedback loops and other complex behavior that occurs in biological systems. The following sections review some of the means by which biological molecular recognition has been translated into dynamic hydrogel behavior.

1.132.3.3.1. Competitive ligand binding

Miyata created a hydrogel with 2-glucosyloxyethyl methacrylate (GEMA) which was able to differentiate between mannose, glucose, and galactose.[109] Entrapped in the hydrogel was the lectin concanavalin A, a protein which binds to carbohydrates. The lectin had four binding sites that allowed it to associate with the glucose pendant groups of the GEMA polymer, creating physical cross-links in the hydrogel. These cross-links could then be competitively dissociated with free glucose and mannose, allowing the hydrogel to swell. The degree of swelling in the hydrogel was related both to the concentration of the free sugar in solution and the affinity of the lectin for the particular sugar. The hydrogel showed the greatest response for mannose, followed by glucose, and showed little response for galactose. The system was later improved by chemically cross-linking the

lectin into the hydrogel structure so that the swelling process could be reversible.[110] Kokufata covalently cross-linked concanavalin A into a NiPAAm hydrogel and showed that a phase transition could be induced when the cross-linked lectin associated with specific sugars.[111] The hydrogel swelled in the presence of the charged species dextran sulfate and collapsed back to its previous volume when an uncharged carbohydrate was introduced into the solution.

Miyata and coworkers demonstrated an antigen-sensitive hydrogel by covalently cross-linking antigen into the hydrogel and forming cross-links with free antibody.[112] The cross-links were disrupted when free antigen was introduced into the system and began to displace the interactions between the immobilized antigen and the antibody molecules, which allowed the hydrogel to swell. The interaction was shown to be antigen specific, but the process was not reversible. Later, they demonstrated a reversible system by immobilizing both the antibody and antigen in the hydrogel.[113]

1.132.3.3.2. Enzyme catalysis

Hydrogel swelling can also be initiated by enzyme-catalyzed reactions. An enzyme can be incorporated into the hydrogel structure and then catalyze a reaction, with the byproduct leading to a conformational change by one of the mechanisms listed above. For example, glucose oxidase has been incorporated into pH-responsive hydrogels to convert glucose into gluconic acid; the gluconic acid reduces the pH within the hydrogel, which in turn causes the pH-sensitive hydrogel to swell.[114] Similarly, rabbit liver esterase and urease have been immobilized to create hydrogels that were responsive to the presence of ethyl butyrate and urea, respectively.[115,116] The phase transitions were rapid and did not require the buildup of product in the bulk solution.

Alternatively, hydrogel cross-links have been designed so that they can be degraded by specific proteases. Unlike many of the systems discussed previously, this means of activation is not typically reversible. Hydrogels formed from albumin-cross-linked poly(vinylpyrrolidine) were shown to degrade in the presence of pepsin.[117] A phosphoester–poly(ethylene glycol) (PEG) hydrogel that was prepared as a matrix for bone tissue engineering was shown to undergo faster degradation in the presence of alkaline phosphatase.[118] A PEG hydrogel was synthesized with peptide cross-links that were susceptible to cleavage by matrix metalloprotease, and it was shown that metalloproteases released during cell culture enabled the artificial matrix to be remodeled.[119]

The need for two stimuli to achieve hydrogel activation may be of interest in some applications to provide an additional level of control. Yamamoto demonstrated an IPN hydrogel made with gelatin and dextran that required the presence of both dextranase and α-chymotrypsin to degrade the hydrogel.[120] Steric hindrance effects were believed to limit the enzymatic activity unless both of the enzymes were acting in concert. A degradable hydrogel requiring both the presence of the enzyme papain and a temperature below 35 °C has also been developed.[121] The hydrogel was readily degraded below the LCST, but the degradation could be stopped by increasing the temperature above the LCST, which was thought to limit the papain activity through steric hindrance.

1.132.3.3.3. Conformational shifts

Proteins that undergo dynamic conformational changes in response to specific ligands have also been incorporated into hydrogels to create dynamic structures. Several different approaches have been taken to translate conformational shifts in the structure of calmodulin into macroscopic changes in hydrogels. In one approach, the calmodullin molecule was tethered to the backbone of the hydrogel, along with a small molecule ligand.[122] The hydrogel showed reversible collapse upon the introduction of calcium ions, which caused a conformational change in the protein. The hydrogel also showed the properties of a competitive binding mechanism when free ligand was introduced into the system. In an alternative approach, double cysteine-substituted calmodulin was incorporated into a PEG tetraacrylate hydrogel backbone using Michael addition chemistry.[123] Introduction of the free ligand into solution caused calmodulin to transform from an open dumbbell conformation to a collapsed conformation. The collapse of the calmodulin molecules essentially shortened the average chain length in the hydrogel network (see Figure 3) and resulted in an approximate 15% reduction in the total volume of the hydrogel. A later work using PEG diacrylate instead of tetraacrylate demonstrated that the network volume could be reduced to 35% of the original volume.[124]

Yuan and coworkers demonstrated a hydrogel containing adenylate kinase that was able to undergo contraction when exposed to its substrate, ATP.[125] The polymer consisted of HPMA backbone with maleimide pendant groups. A mutated adenylate kinase, which had the native cysteine group substituted out and two cysteine groups added, was then attached to the maleimide groups via thiol–maleimide coupling reaction. The hydrogel reswelled when washed with ATP-free buffer for 30 min.

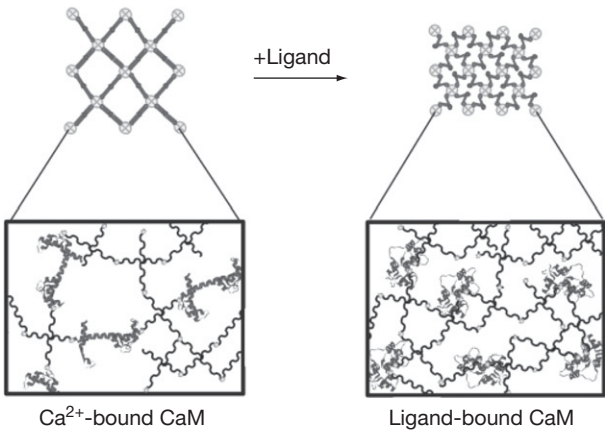

Figure 3 Collapse of a dynamic hydrogel brought about by the conformational change of a cross-linked protein. The ends of the protein molecule are cross-linked into the hydrogel structure. The two ends of the protein are brought closer together after the ligand binds to the protein, resulting in a reduction in the effective distance between polymer chains in the hydrogel. 1.132.4. Biomedical Applications

The diverse chemistries and trigger methods used to create dynamic hydrogels enable their properties to be tailored for specific applications. Further, the utility of dynamic hydrogels is not limited to applications such as artificial muscles that require macroscopic changes in size. For instance, the pore size of hydrogel networks can be altered by dynamic changes in hydrogel structure, which can have a profound effect on mass transfer within hydrogels.[126] For example, the tunable pore size was shown to be an effective means of optimizing the separation in a size exclusion chromatography column. In another example, Dong and Hoffman showed that enzymatic activity could be reversibly regulated by immobilizing an enzyme in a dynamic hydrogel.[127] The immobilized enzyme showed an increase in kinetics with increasing temperature due to Arrhenius effect up to the LCST temperature of the hydrogel, but showed a sharp reduction thereafter. The system was cycled several times to demonstrate that the reduced kinetics were due to the phase transition of the hydrogel and not due to enzyme deactivation. Similarly, the rate of enzymatic conversion has also been controlled using pressure sensitive hydrogels.[128]

Combining the high water capacity of hydrogels along with tunable pore size has led to their use as selective absorbent to take up low molecular weight solutes, leaving a solution enriched in higher molecular weight molecules.[129–131] Upon reversing the swelling of the hydrogels in fresh water, a portion of the solute molecules were rapidly expelled from the hydrogel along with water as the hydrogels collapsed. Solute continued to be released from the hydrogel via diffusion, which was considerably slower than the initial release. The selectivity of the process was reduced somewhat by the random nature of the polymerization process, which resulted in nonhomogeneous pore size throughout the hydrogel. We conclude the chapter by reviewing some of the other applications where the micro- and macroscopic properties of dynamic hydrogels have been used to create unique solutions to biomedical engineering problems.

1.132.4.1. Controlled Release of Soluble Factors

Self-regulation is vital to many biological systems. For example, blood sugar levels in humans must be maintained in a narrow range to prevent severe physiological damage. The body has a feedback system that (a) senses the concentration of glucose and (b) reacts by releasing the appropriate hormones (i.e., glucagon or insulin), which correct perturbations. The ability to both measure a parameter and selectively take action based upon its value is essential for creating self-regulating systems. In the case of type 1 diabetes, the body loses its ability to self-regulate because it is unable to release insulin. Currently, treatment for the condition requires electric monitoring of blood sugar levels followed by an insulin injection, if needed. Conversely, antibiotic treatments for infections are most effective when there is a constant concentration of the antibiotic in the circulatory system. Although these two instances represent two very different dosing profiles, dynamic hydrogels can potentially be tailored to meet the needs of both applications. The following sections discuss how dynamic hydrogels can be used to achieve various controlled release profiles.

1.132.4.1.1. Step function release

Bae and coworkers demonstrated a thermally responsive hydrogel that was able to switch between a constant release rate and a zero release rate.[44] The copolymer hydrogel utilized NiPAAm for its temperature sensitivity and BMA to improve the mechanical properties of the hydrogel. The hydrogel showed sustained release below the LCST, and the release stopped abruptly when the hydrogel was heated above the LCST. An IPN of NiPAAm and polytetramethylene ether glycol was shown to have a similar on–off release profile as a function of temperature.[132] The phase transition temperature for the hydrogel loaded with the drug indomethacin was lower than that for the hydrogel without the drug. The presence of the hydrophobic drug was thought to reduce the transition temperature by participating in hydrophobic interactions with the polymer chains. The authors also noted that they could reduce the amount of time it took to transition from the on release state to the off state by increasing the transition temperature.

Temperature-responsive hydrogels capable of releasing insulin have also been developed.[133] The IPN network of NiPAAm and poly(tetramethylene ether glycol) was permeable to both glucose and insulin below the LCST. Increasing the temperature above the LCST immediately stopped diffusion of both species out of the hydrogel due to a dense outer skin on the surface of the hydrogel. Diffusion of glucose through the hydrogel was quickly reestablished when the hydrogel was cooled back below the LCST, but there was a lag time of several hours before insulin diffusion rates were restored.

Kiser and coworkers demonstrated a novel hydrogel–lipid construct that mimicked the structure of secretory granules, the inert lipid-coated particles used to direct intra and extracellular transport of proteases and other molecules.[134] The particles consisted of a pH-sensitive methacrylic acid hydrogel core coated with a lipid bilayer. The lipid coating served as a barrier that isolated the hydrogel from the surrounding solution. The hydrogel then showed rapid swelling when the lipid bilayer was electroporated, achieving maximum swelling in 4 s (see **Figure 4**). The particles showed a burst release of the drug doxorubicin, with most of the drug being released within 13 min.

The use of pH-sensitive hydrogels has enabled the targeting of drug release to specific regions of the digestive system to maximize uptake efficiencies. Certain therapeutics, such as proteins, are easily hydrolyzed in the harsh conditions of the stomach. To protect them, they can be placed in an acidic hydrogel, which remains in the collapsed form when exposed to the acidic conditions of the stomach. The hydrogel then swells as it passes into the higher pH conditions of the intestine, enabling the drug molecules to diffuse out of the hydrogel. For example, a study of oral insulin treatment found that delivery via a pH-sensitive hydrogel was a more effective means of reducing serum glucose levels in rats than an oral dose of insulin solution.[135]

1.132.4.1.2. Rate modification

Aoki and coworkers created a thermally responsive IPN that showed an increase in the rate of release of ketoprofen when the hydrogel was heated from 20 to 40 °C.[136] The release rate from two different hydrogels was evaluated in the study. Both hydrogels contained an IPN of acrylic acid and

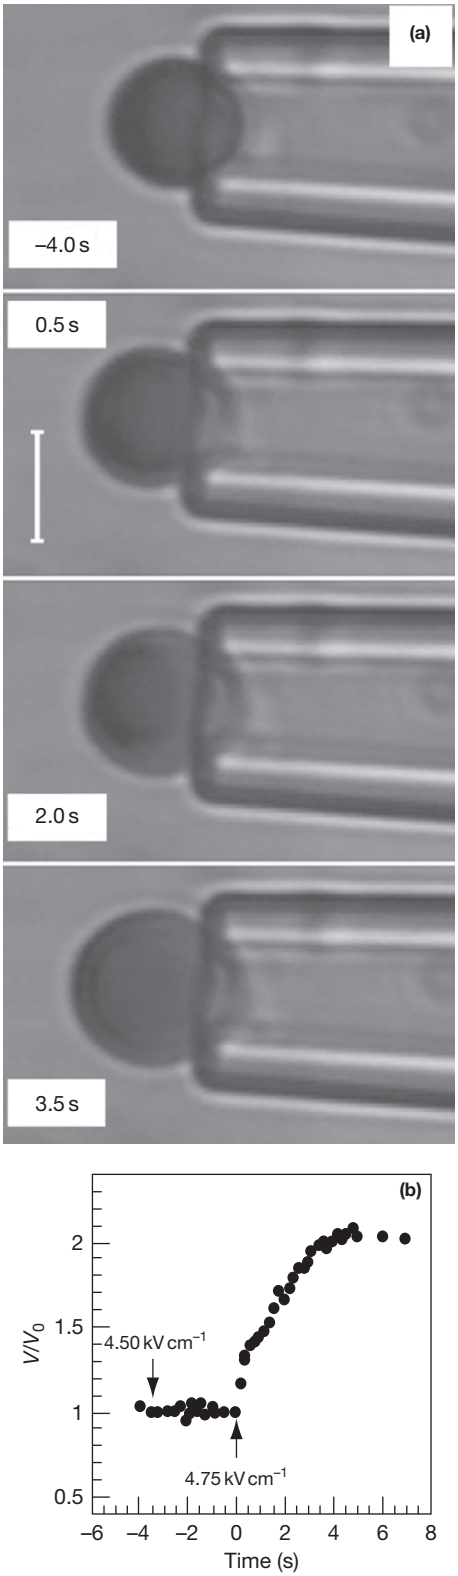

Figure 4 Rapid swelling of a pH-sensitive hydrogel after electroporation of the lipid bilayer surrounding the particle. The images show the hydrogel before being exposed to the critical electric field strength, 0.5, 2.0, and 3.5 s after exposure. The scale bar is equal to 4 μm. Reprinted from Kiser, P. F.; Wilson, G.; Needham, D. *Nature* **1998**, *394*, 459–462, with permission from Macmillan Publishers Ltd., Copyright 1998.

butylmethacrylate. In addition to these two components, one of the hydrogels also contained *N*,*N*′-dimethylacrylamide (DMAA). The release rate from the hydrogel containing DMAA doubled upon heating and was consistent through several heating cycles. The hydrogel without DMAA showed over a threefold increase in release rate on the first heating cycle, but showed steady decay in subsequent heating cycles. The difference in performance between the two hydrogels was attributed to the intermolecular bonding within the two hydrogels. The hydrogel without DMAA had a large degree of intramolecular hydrogen bonding between acrylic acid residues; these interactions were disrupted at 40 °C, which caused the hydrogel to undergo a large degree of swelling. In contrast, the hydrogel containing DMAA contained more stable intermolecular hydrogen bonding which was not disrupted at 40 °C, which limited the swelling in the hydrogel and consequently resulted in a lower rate of diffusion out of the hydrogel.

Controlled release has also been achieved using UCST hydrogels made with acrylic acid and acrylamide-*co*-butylmethacrylate.[53] The hydrogel showed a 20-fold increase in release rate of ketoprofen when it was heated from 10 to 30 °C. A twofold increase in diffusion would be expected due to Arrhenius kinetics, indicating that the primary cause for the increased release rate was due to the conformational change in the hydrogel structure rather than a temperature-dependent increase in ketoprofen transport.

A dextran hydrogel was developed for targeted drug release in the colon.[137] The hydrogel showed diffusion-limited release of hydrocortisone under normal conditions and showed much faster erosion-limited conditions in the presence of dextranase, an enzyme secreted by intestinal bacteria. Similarly, Kopecek developed hydrogels containing azoaromatic bonds that could be cleaved by the intestinal enzyme azoreductase.[138]

Siegel showed that the rate of caffeine release from a pH-sensitive hydrogel was related to the rate of water absorption by the hydrogel during the swelling process.[139] The methyl methacrylate/*N*,*N*-dimethylaminoethyl methacrylate hydrogel showed minimal release at neutral pH and zero order release for pH 5 and 3 solutions, with the pH 3 solution showing a faster release rate. Ishihara used a pH-sensitive hydrogel to develop a compound membrane system that showed glucose-sensitive release of insulin.[114] The system consisted of a hydrogel membrane containing immobilized glucose oxidase and a second membrane containing polyamine groups. The glucose oxidase converted glucose into gluconic acid, which dropped the local pH and protonated the amino groups on the second membrane. Protonation of the amino groups caused the membrane to take up additional water, which in turn increased the permeability of the membrane to insulin. Membranes containing both the amine functionality and glucose oxidase were developed shortly thereafter and were shown to swell and have higher insulin permeability in the presence of glucose.[140,141] Glucose oxidase was later incorporated into a pH-sensitive capsule to demonstrate controlled release of insulin.[142]

In an alternative approach, Hassan and coworkers incorporated glucose oxidase into a hydrogel containing methacrylic acid that collapsed in the presence of glucose.[143] The hydrogel was designed to oxidize glucose and lower the

pH, which would protonate the methacrylic acid and allow the hydrogel structure to collapse. The collapse of the hydrogel would then squeeze insulin out of the polymer network. The hydrogel also incorporated a catalase to eliminate the byproduct hydrogen peroxide that would otherwise inhibit the conversion of glucose to gluconic acid. Collapse-mediated release was also shown to be an effective means of modulating the release rate of vascular epithelial growth factor (VEGF) from a dynamic hydrogel.[144] The dynamic hydrogel contained calmodulin molecules cross-linked into the polymer backbone. The release rate of VEGF significantly increased when the calmodulin ligand trifluoperazine was introduced into solution, causing the hydrogel network to collapse.

While the previous examples illustrated glucose-sensitive hydrogels that required biochemical recognition, chemical methods have also been explored. Kataoka utilized the fact that glucose molecules stabilized the ionic form of 3-acrylamidophenylborionic acid (AAPBA).[145] The stabilization of the anionic form of the acid groups led to an equilibrium shift in the dissociation of the acid groups. The increase in fixed charge on the NiPAAm network led to increased swelling of the hydrogel, which was proportional to the solution concentration of glucose. Insulin release from the hydrogel was found to be proportional to the solution concentration of glucose.

Siegel proposed using hydrogel swelling to act as a mechanical actuator for insulin dosing.[146] The design consisted of a glucose-sensitive hydrogel and a chamber containing insulin separated by a movable partition. Swelling of the hydrogel would then act as a piston to compress the partition separating it from the insulin, which would in turn force insulin out of the device and into the surrounding tissue.

1.132.4.1.3. Switchable surface

Hydrogel surface properties are often altered when the hydrogel network undergoes a dynamic restructuring. Switchable NiPAAm hydrogels have been used to selectively attach and detach cells from surfaces.[147] At higher temperatures, the material presents a hydrophobic surface that is comparable to traditional cell culture plastic and cells can be grown to confluence. The cells can then be harvested by reducing the temperature below the LCST of the hydrogel, which results in an increase in surface hydrophilicity and lift-off of the attached cells. This approach is advantageous because it does not disrupt the cell–cell interactions as is the case with traditional trypsin treatments.[148] Ulijn and coworkers demonstrated an alternative approach to selective cell capture using Fmoc-F chemistry to prevent cells from adhering to a surface functionalized with the integrin binding peptide arginine–glycine–aspartic acid (RGD). Upon treatment with chymotrypsin, the surface was activated and allowed osteoblasts to adhere to the surface.[149] NiPAAm switchable films have shown to be similarly effective in controlling the adhesion of proteins onto surfaces.[150] The film presented a hydrophilic surface below the LCST, which prevented myoglobin adsorption. The film could then be turned hydrophobic by heating the hydrogel above the LCST, which led to protein adsorption on the surface. The protein was then released from the surface after the film temperature fell below the LCST.

The ability to switch the surface properties of NiPAAm between hydrophobic and hydrophilic has also been used to enable directional movement on surfaces. Kim and coworkers showed that the frictional force of NiPAAm on glass and pig intestine changed when the hydrogel switched from the collapsed state to the swollen state and vice versa.[151] They found that the frictional force required to move a NiPAAm test piece increased by 80% when the polymer was in the hydrophobic state. They then showed that this difference in frictional force was sufficient enough to allow one end of an inchworm-like device to be anchored to a pig intestine surface while the other end, in the hydrophobic state, was allowed to freely slide along the surface. They proposed that alternating the properties of the two ends would then allow directional motion to take place.

1.132.4.2. Sensing and Detection

The ability to respond to a specific stimulus with a dramatic structural change makes dynamic hydrogels an attractive class of materials for creating sensors. A wide variety of mechanisms have been used to translate dynamic hydrogel response into molecular sensors. A CO_2 sensor was created by measuring the swelling of a pH-sensitive hydrogel that was held in a confined space.[152] The CO_2 in the gas sample reached a vapor–liquid equilibrium with the solution in the hydrogel. The dissolved CO_2 formed carboxylic acid, which altered the pH of solution and caused the hydrogel to swell. Hydrogel swelling within a confined space was also used to develop an ionic strength sensor.[153]

Sharma and coworkers developed a creatine sensor by integrating polystyrene latex particles into a polyacrylamide hydrogel.[154] Creatinine deiminase was incorporated into the hydrogel to hydrolyze any creatine in solution to form a hydroxyl ion, and 2-nitrophenol was incorporated as a proton donor. Hydroxyl atoms produced in the presence of creatine led to deprotonation of the 2-nitrophenol groups in the hydrogel, and the fixed charges on the polymer backbone caused the hydrogel to swell. The concentration of creatine in solution could then be measured by measuring the shift in the light diffraction pattern of the styrene latex particles in the hydrogel.

Dong and coworkers demonstrated dynamic hydrogel lenses made out of NiPAAm and acrylic acid that were able to change their focal lengths based on temperature and pH stimuli.[155] A similar tunable focal length lens system was developed using a hydrogel made with immobilized calmodulin and phenothiazine, a calmodulin ligand.[156] Introduction of another calmodulin ligand, chloropromazine, disrupted the calmodulin–phenothiazine interactions that acted as cross-links and allowed the hydrogel to swell. The swelling, which was proportional to the amount of chloropromazine in solution, changed the focal length of the lens. Similar lens systems were demonstrated for protein and antigen detection.[157,158] A hydrogel with cross-links formed by complementary oligonucleotide pendant groups was coupled to an interferometer to create a label-free oligonucleotide sensor.[159] Competitive binding between the immobilized strands and free oligonucleotide in the sample solution led to hydrogel swelling, which was measured by the interferometer.

1.132.4.3. Mechanical Actuation: Artificial Muscles, Robotics, and Microfluidics

1.132.4.3.1. Artificial muscles and robotics

Many aspects of dynamic hydrogels closely mimic natural muscle functions. For example, both systems can be made to bend, relax, contract, and exert force based on chemical signals. A variety of hydrogel analogs have been developed to mimic muscles actions that occur in nature. In a series of works, Yoshida and coworkers demonstrated hydrogels systems that oscillated between swollen and shrunken states, akin to a beating heart. The first demonstration used a NiPAAm–acrylic acid copolymer suspended in a stirred tank reactor that was continuously replenished with chemicals to run a hydrogen peroxide–hydrogen sulfite–hexacyanoferrate (II) reaction that produced an oscillating pH.[160] The idea was further advanced when a ruthenium catalyst was cross-linked in a NiPAAm hydrogel to drive an oscillating Belousov–Zhabotinsky (BZ) reaction.[161] Changes in the redox state of the catalyst caused a shift in the transition temperature of the hydrogel, which in turn caused swelling/shrinking when the hydrogel was near the critical temperature. This demonstration was a great advancement over the previous system because the stimulus for the oscillation was generated internally. Yoshida and Uesusuki demonstrated an oscillating system that was activated by ATP.[162] The anionic poly(NiPAAm-*co*-2-(methacryloyl-oxy) ethyl phosphate) hydrogel contained immobilized creatine kinase, which generated an oscillating calcium concentration as it reacted with the ATP. The divalent Ca^{2+} ions served as physical cross-links between the phosphate groups in the anionic hydrogel. When calcium levels were low, the hydrogel swelled, and the hydrogel contracted when the calcium concentration was higher.

Kurauchi and coworkers demonstrated a grasping hand made out of electric field-sensitive poly(vinyl alcohol)-*co*-poly (acrylic acid).[163] The hand was able to pick up an egg in solution. The work also demonstrated that the electric field-responsive polymer could be used to create an artificial fish that could swim in solution using a flapping tail. Similarly, a thin polyanion hydrogel was attached to a polystyrene body to create a hydrogel that moved with an eel-like motion in an alternating electric field in the presence of a cationic surfactant.[164] The hydrogel bent in the cycling electric field due to preferential surfactant accumulation on the side of the hydrogel nearest the anode, thereby displacing water. Electric-field-sensitive PEG hydrogels have also been shown to achieve locomotion through other methods, one of which mimicked the swimming motion of an octopus.[165] Glucose sensing and delivery of beads from the body of these swimming structures were also demonstrated. Hydrogel locomotion has also been achieved by inducing collapse and expansion of select regions of a poly(NiPAAm) hydrogel confined in a tube, generating earthworm-like motion that resulted in the net displacement of the hydrogel.[166]

1.132.4.3.2. Microfluidics

Dynamic hydrogels have been incorporated into microfluidic devices for a number of applications, including sensing and autonomous control. The small dimensions and high surface area-to-volume ratios characteristic of microfluidic devices offer rapid mass transfer and, therefore, faster hydrogel response times than are seen in many applications. Beebe and coworkers were the first to take advantage of responsive hydrogels in microfluidic applications when they demonstrated hydrogel valves that could be opened and closed based on solution pH and showed that the valves could be used to route liquid through the device based on pH (see **Figure 5**).[167] Autonomous pH control was later demonstrated using a similar system.[168] At a near neutral pH, the pH-sensitive valve was in a swollen form and isolated the channel from a stream of high pH solution. The hydrogel became protonated and shrank when the solution pH dropped, allowing high pH solution to mix in with the main stream. As the pH increased, the hydrogel began to reswell and close off the valve. Changes in hydrogel chemistry and channel geometries could be used to adjust the set point of the pH control loop. A similar valving concept actuated by electrical signal was developed by creating a hydrogel containing poly(aniline), a redox-sensitive polymer.[169] Activation using redox chemistry helped the valves to actuate quickly, and the use of the hydrogel structure allowed the valves to achieve a greater degree of swelling than could be achieved with the redox polymer alone.

Hydrogel swelling within the confined space of a microchannel has also been used to drive fluid flow.[170,171] The basic design involves isolating a responsive hydrogel from a fluid reservoir by placing a flexible membrane between the two volumes. Swelling of the hydrogel causes a displacement of the membrane into the fluid reservoir, providing an increase of pressure that in turn drives fluid flow through a channel that is attached to the fluid reservoir.

Several microfluidic chemical sensors have been developed that rely on the degradation of a dynamic hydrogels to identify the presence of specific species. For example, a microfluidic chymotrypsin sensor was formed by fabricating hydrogel posts

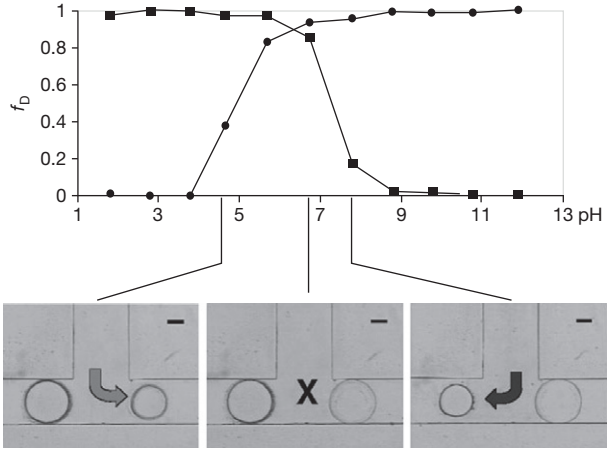

Figure 5 A microfluidic device for directing fluid based on pH. The valve on the right (circles) swells in basic conditions and contracts in acidic conditions, while the valve on the left (squares) swells in acidic conditions and contracts in basic conditions. The scale bar is equal to 300 μm. Reprinted from Beebe, D. J.; Moore, J. S.; Bauer, J. M.; *et al. Nature* **2000**, *404*, 588–590, with permission from Macmillan Publishers Ltd., Copyright 2000.

that contained a chymotrypsin recognition peptide sequence in the hydrogel backbone.[172] The post dissolved in the presence of chymotrypsin, but a control post made with a scrambled peptide sequence remained intact. Frisk used a similar approach to develop a peptide–hydrogel construct that dissolved upon exposure to Botulinum neurotoxin A.[173]

1.132.5. Future Directions

Dynamic hydrogels are being developed for a wide range of applications and a diverse set of synthetic materials can be used to tailor hydrogel performance to fit the need of a particular application. New materials and molecular triggers will continue to be a point of interest in dynamic hydrogel development. Creating hydrogels that can respond to specific diseases or infections will be a particular point of emphasis. For example, compound hydrogel systems with surface labeling that can attach to specific cell types will be useful for targeting imaging and therapeutic agents. Indeed, NiPAAm particles with folate groups attached to the surface were shown to be taken up preferentially by KB cells.[174]

One emerging area is the creation of hydrogels that can play an active role in tissue development. Hydrogels that can selectively display or release growth factors, sequester soluble signals, and change mechanical properties on demand would be of great value in tissue development. The ability to control the cellular microenvironment using hydrogels would also be an invaluable tool for elucidating fundamental signaling events in tissue development.

Many of these applications will require monodisperse micro- and nanoparticles with small feature sizes.[175] Smaller particles are more easily injected into the body, more mobile, and faster responding than larger hydrogels due to their smaller size. Nanoscale hydrogels could potentially be used to perform intracellular delivery via endocytosis. Methods such as precipitation polymerization[176,177] and nanoimprint lithography[178] will continue to be developed to allow ever smaller hydrogels to be formed with a variety of geometries.

Abbreviations

C-dots	Core– shell fluorescent silica nanoparticles comprised of dye-rich core with a pure silica shell
CoCr	Cobalt–chromium alloys
DNA	Deoxyribonucleic acid
FAD	Flavin adenine dinucleotide (FAD), its reduced form is $FADH_2$
GaOOH(s)	Gallium hydroxides
GFP	Green fluorescent protein is a protein composed of 238 amino acid residues (26.9 kDa) that exhibits bright green fluorescence when exposed to blue light. The blue fluorescent protein is color mutant of GFP protein family
GOx	Glucose oxidase enzyme
HF	Hydrofluoric acid
His165	His is an abbreviation of histidine amino acid, also known as 2-Amino-3-(1H-imidazol-4-yl) propanoic acid; 165 refer to its position in the polypeptide chain, forming silica proteins filament (silicateins)
MSN	Mesoporous silica nanoparticles
NAD[H]	Nacotinamide adenine dinucleotide, abbreviated NAD^+, is a coenzyme found in all living cells. [H] suffix refers to hydrogenase [P] refer to phospahte
NIR	Near infrared
OPTA	*O*–phthalic hemithioacetal
Q	Quaternary sites
R5-	A synthetic peptide derived from Sil 1 proteins and composed of 19 amino acid sequence [H2NSSKKSGSYSGSKGSKRRIL–COOH]
RGD	A peptide sequence composed of arginine-glycine-aspartate
[Ru (phen)$_3$] Cl$_2$	Tris-(1,10-Phenanthroline) ruthenium (II) chloride
SAMs	Self-assembled Monolayer
Ser26	Ser is an abbreviation of serine amino acid, also known as 2-amino-3-hydroxypropionic acid; 26 refer to its position in the polypeptide chain, forming silica proteins filament (silicateins)
S_N^2-type	Nucleophilic substitution-type 2
TEM	Transmission electron microscopy
TEOS	Tetraethyl orthosilicate; also named tetraethoxysilane

2.201.1. Introduction

The mechanisms underlying biomineralization, which produce mineral-based components that form the shells, skeletons, and teeth of diverse organisms, are inspiring examples of Nature's ability to genetically control the growth of intricate macroscopic forms.[1] The decryption of these genetically encoded mechanisms is poised to revolutionize nanotechnology, especially nanomedical technology, as it affords us unprecedented ability to engineer therapeutic and bio-analytical systems that are on the same size-scale as biological molecules (at the nanoscale) and biological cells (at the microscale). To realize this potential, the scientific community must be able to exploit Nature's genetically encoded mechanisms governing materials synthesis and functionality at the nano- and microscales and develop novel functional materials based on these concepts. In particular, the developing understanding of biomineralization, and the subsequent translation of its mechanisms to new synthetic approaches for mineral synthesis, has significant implications for drug delivery, bone repair, biosensing, and many other medical technologies.

Biomineralization methods differ dramatically from anthropogenic solution-based methods for growing minerals in several important ways. They are produced in highly dynamic nonequilibrium systems that precisely organize the placement of metal or metalloid atoms or ions into (oftentimes crystalline) inorganic structures and, additionally, they are produced in very mild conditions (ambient pressure, temperature, and near neutral pH). The mild and dynamic conditions of biomineralization facilitate a variety of biomolecule–mineral interactions that lead to extraordinary and distinctive architectures.[2,3] While many of the mechanistic details of biomineralization remain to be elucidated, some general principles are understood.[4–7] Biological molecules participate as regulatory elements during mineralization, influencing kinetic and thermodynamic variables that govern mineral nucleation and growth; this influence may be exerted through surface recognition, templating, or dimensional constraint; through regulation of local pH levels and the concentrations of metal ions or other chemical species; or through more complex interactions.[8]

The major classes of minerals upon which most biological hard materials are based include calcium and magnesium carbonates,[4,9,10] calcium phosphate,[4,11] iron oxide,[4,12] and silica.[13–15] Owing to studies conducted over the past 10 years on marine sponge and diatom mineral structures, biosilica is arguably the most well-understood biomineral material in terms of the known biochemical and molecular mechanisms that contribute to the mineral's nucleation and directed growth. As a result of this understanding, a variety of new synthetic approaches toward silica materials have been developed that, through the use of appropriately selected catalysts and precipitation-accelerating agents, can produce structures at much milder and more biologically relevant conditions than the conventional industrial approaches for silica synthesis.

Silica is widely considered to have excellent biocompatibility and provides an advantageous balance between stability and degradability.[16,17] Silica biocompatibility can be tuned by controlling the structural and compositional material features (such as particle size, porosity, dopant chemistry, and surface coatings), and differences in these features can dramatically affect material toxicity.[18] Owing to the potential therapeutic and analytical utility of silica-based materials for a wide range of nanomedical applications,[19,20] there is an increased demand for well-defined biocompatible silica-based composites from cheap starting materials produced under mild conditions. Nature has developed a wide variety of mechanisms for successfully integrating silica structures within biological systems; it should thus provide valuable lessons for designing more biocompatible and functional silica structures. This chapter focuses on bio-inspired routes to silica synthesis and the potential applications of the synthesized materials in medical technologies. The chapter is developed in three main sections. In Section 2.201.2, we describe the natural biomineral components and associated mineral-synthesizing molecules that have served as models for bio-inspired silica syntheses, and the novel anthropogenic routes to silica synthesis that have been derived from these models. In Section 2.201.3, we review studies that establish the utility of silica in four unique biomedical applications – imaging, sensing, drug delivery, and tissue and implant engineering – and we discuss initial studies utilizing bio-inspired silica syntheses for these applications. In Section 2.201.4, we address the issue of toxicity and discuss a number of future prospects for productively merging bio-inspired silica syntheses with medicine.

2.201.2. Biosilicification

2.201.2.1. Introduction

The major current strategies for synthesizing silica for biomedical applications include variations of the Stöber process[21] and microemulsion techniques.[22] Both of these solution-based strategies rely on the controlled hydrolysis and subsequent condensation of silicon alkoxide precursors in ethanol–water mixtures with high concentrations of ammonium hydroxide as the hydrolytic catalyst.[17] These strategies are attractive because they are industrially scalable and yield highly uniform, chemically stable silica nanoparticles that can be functionalized in a variety of ways for use in specific applications,[17] as highlighted in Section 2.201.3. While these widely used synthetic approaches have demonstrated the promise of silica-based materials for biomedical applications, they also have disadvantages that must be addressed through further research. These procedures typically employ extreme pH or hydrothermal processing steps that are incompatible with DNA and protein stability, imposing procedural limitations that require silica synthesis to precede biological integration; further, resultant morphologies are limited to spherical configurations from 10 nm to 2 μm; and the silica chemistry – such as the extent of hydration or condensation – while influential on the resultant oxide properties, is poorly controlled.[17]

There is a need for fundamentally new, biologically compatible synthetic approaches to design silica-based materials with defined compositions, morphologies, and ultrastructures, and with consequently tailored stability and dissolution, mechanical, immunological, and fluorescent properties. Such approaches should further allow complex silica structures to be synthesized under environmentally benign conditions with high reproducibility. These latter features are, in fact, already exhibited in natural biomineralizing systems. Thus natural

biosilicification serves as an attractive model on which new synthetic approaches could be based. Indeed, the extent to which biology has evolved silica-based materials with tailored properties, spanning multiple phyla and length-scales,[23–25] demonstrates an intimate and robust relationship at the metabolic level between the synthesis and structure of silica-based materials and their physiological performance.

The natural evidence demonstrating feasibility that facile synthesis of silica occurs in biological systems with a level of complexity unmatched by current technologies is persuasive: biosilica is produced at a rate of gigatons per year. Silica synthesis is found in algae, protozoa, sponges, and higher plants; in diatoms alone – unicellular algae with a biosilica outer wall – there are more than 100 000 distinct species, each exhibiting unique silica architectures with intricate nano- and microscale designs.[26] Evolutionarily selected functions for natural biosilica continue to be discovered. For example, biosilica skeletons of marine sponges have recently been shown to exhibit sophisticated hierarchical architecture from the nanoscale to the macroscale that endow the support structure with robust mechanical properties (**Figure 1**).[27–30]

In other sponges, silica skeletal elements have been suggested to act as light waveguides, perhaps to harvest light under deep sea conditions to attract sponge larvae or symbiotic shrimp, or promote survival of symbiotic algae.[31,32]

Sponges and diatoms are relatively simple organisms, but their ancient evolutionary history has endowed them with a complex ensemble of molecular and biochemical specializations – including the ability to produce silica from the silicic acid dissolved in fresh or salt water. The cellular processes that contribute to the growth of these organisms and govern biosilicification have not yet been fully deciphered and remain the subject of current investigations.[33,34] A wide range of cellular functions contribute to biosilica formation, including (but not limited to) cell differentiation, protein signaling, gene regulation, and microtubule permutations.[33,35] For each skeletal component, a host of genetically encoded, mineral-associated biomolecules and cellular regulatory programs contribute to its genesis, growth, maintenance, and directed dissolution; and govern environmental silicon sequestration and internal transport, storage, and site-specific incorporation in mineral nucleation or growth.[36,37] The complexity of these dynamic interactions complicates efforts to elucidate the process of mineral synthesis in its entirety. However, studies of sponge and diatom biosilica, as well as related bio-inspired materials investigations, have demonstrated that by reducing the initially extensive mineral complex down to a few functional components, it is possible to extract, from simplified model systems, the salient features that can be used to create new materials synthesis strategies.

A variety of biomolecules have been identified as key regulators in the process of natural silicification; these include silicon transport proteins in both diatoms[38–40] and sponges,[41] protein networks that direct silica growth[39,42] and specialized mineralization compartments.[43–46] Each identified regulatory element represents a potential model for new bio-inspired strategies for synthesis under mild conditions, provided the mechanistic details of its *in vivo* activity can be elucidated. To date the most informative models for natural silica synthesis have been biopolymers found occluded within the encasing silica of sponges and diatoms: silicateins from sponges, and silaffins and polyamines from diatoms, both initially isolated by hydrofluoric acid (HF) dissolution of the oxide material. The first evidence of biocatalytic silica formation was advanced through the discovery of silicatein, when DNA sequence analysis revealed that the structure of this protein is related to a well-known family of enzymatic hydrolases.[13,14] Subsequent identification of silaffins and polyamines showed these diatom-derived molecules accelerate silica precipitation from silicic acid.[47] Thus, a variety of in-depth biochemical studies were focused on the silicateins, silaffins, and polyamines, to illuminate their mechanisms of silica formation. These studies included site-directed genetic mutational analysis;[48] mass spectrometry analysis for identification of posttranslational modifications[47]; and characterization of a number of *in vitro* mineralization reactions and the corresponding mineral products from near-neutral aqueous conditions with soluble mineral precursors using either natively extracted proteins,[13,49–53] recombinantly expressed proteins,[48] or a variety of bio-inspired *in vitro* biomolecular analogues.[49,51,54] As the details of these studies are reviewed extensively elsewhere,[23–25,55] here, we briefly review the most salient lessons learned from silicateins, silaffins, and polyamines, and show how these lessons inspired novel approaches for silica synthesis with relevance to biomedical applications.

2.201.2.2. Natural Biomolecules Directing Silicification in Sponges and Diatoms

2.201.2.2.1. Sponge-derived biomolecules: silicateins

Silicateins are biomineralizing enzymes that self-assemble into polymeric filaments that present catalytically active and templating surfaces to initiate biosilica polycondensation from molecular precursors in a variety of marine sponges. First identified in the marine sponge *Tethya aurantia*, the silicatein filaments were found axially occluded within needle-like biosilica skeletal elements (known as spicules) microns in diameter and up to millimeters in length.[14] Three distinct

silicatein monomers were found to compose the polymeric filament; these monomers were found to be highly homologous to a well-known family of hydrolytic enzymes. Homology modeling led to an energy-minimized folded silicatein structure[56] and, combined with *in vitro* mineralization studies,[13,48,49,51,52,54,57,58] a proposed mechanism for silicatein activity. Purified native filaments were found to catalyze silica polycondensation at near-nuetral pH using TEOS (tetraethyl orthosilicate) as a precursor molecule, while heat denatured filaments lacked this activity.[13] The silica synthesized was found to deposit on the filament surface. In the proposed mechanism, the TEOS precursor molecule is hydrolyzed through enzymatic catalysis involving key amino acid residues, Ser26 and His165, at the putative enzyme active site. The released, reactive silanol species then undergoes subsequent polycondensation with other precursor molecules. As condensation proceeds, unique chemical and atomic topological features of the protein surface guide the deposition of the forming mineral onto the macroscopic protein template.

The mechanisms of both catalysis and templating have been substantiated in a number of ways, including site-directed mutagenesis of recombinant silicatein. When the key active site residues were knocked out, the ability of recombinant silicatein to catalyze silica polycondensation was dramatically reduced.[48] In addition to these requisite chemical interactions involving active site residues, the size and configuration of the active site pocket also appears to be important for catalysis. In a mutagenic study on cathepsin L, an enzyme that was initially found to have no silica condensing activity, investigators were able to introduce silicification activity by introducing silicatein-like character into the residues flanking the active site.[59] However, even with these modifications, reengineered cathepsin L enzymes were reactive only with prehydrolyzed silicic acid and not TEOS. These results suggest that both the chemical environment of the active site and other features governing the interactions with metal- or metalloid-bearing precursors are important for catalytic mineralization. Moving beyond the active site pocket and considering the solution-exposed surface of the folded protein, silicatein has been shown to be serine-rich, leading to the proposal that an array of hydroxyl moieties on the protein surface act as oxide condensation sites to guide mineral deposition.[14] This proposal was supported through the development of silicatein-mimetic surfaces constructed on gold using self-assembled monolayers (SAMs) of alkane-thiols terminated with either hydroxyl or imidizole groups (the functionalities identified by site-directed mutagenesis as essential for catalysis in the native enzyme) exposed to the solution. Using a planar substrate with alternating stripes of hydroxyl-terminated and imidazole-terminated alkane thiols, when the surface was reacted with a gallium nitrate precursor, GaOOH(s) synthesis was catalyzed initially at the interface between the two chemical groups, and subsequent deposition occurred preferentially on the hydroxyl-terminated strips (**Figure 2**).[58]

This result confirmed the role of hydroxyl moieties as oxide (or oxo-hydroxide) deposition sites when arranged adjacent to a catalytic site. In a previous study, cellulose fibers rich in hydroxyl groups (but lacking the critical amine functionality) were shown to be incapable of initiating silica deposition when reacted with TEOS.[13] An intimate temporal and spatial link between the dual functionalities of catalysis and templating thus seems important for the biogenic formation of higher-order silica structures. Another level of control exhibited by silicatein in such biogenic mineralization is afforded through the protein's self-assembly into filaments, a process shown to be driven by the interaction of hydrophobic patches on the protein surface and not present in related hydrolases.[56] The assembly process was further shown to proceed through fractal intermediates.[56,60]

In summary, silicatein initiates silica synthesis through catalytic hydrolysis of molecular precursors in the vicinity of condensation sites to promote local deposition, and these deposition events are collectively guided into structures of higher-order length-scales in part through geometric ordering of the polymerized protein template. The membrane surrounding the silicatein filament is presumed to provide additional structure-directing information. As illustrated by the SAM-based silicatein-mimetic surface described above, *in vitro* silicatein analogues have been used to substantiate the proposed model of silicatein activity. Other silicatein-analogue systems have been based on block copolypeptides,[54] other block copolymers,[61] catalytic small molecules,[51] and SAMs arranged on gold nanoparticles.[49] These experimental systems not only represent simplified *in vitro* models for studying silicatein activity, they also serve as valuable translational steps for engineering bio-inspired methods for silica synthesis under mild conditions. Such bio-inspired routes are attractive because they should afford the mechanistic control that underlies growth of sponge skeleton biosilica yet provide design strategies tractable enough to be merged with current industrial and laboratory synthetic approaches. In **Section 2.201.2.3**, we highlight the silicatein-mimetic systems based on block copolypeptides and small molecules.

2.201.2.2.2. Diatom-derived molecules: silaffins and long-chain polyamines

Diatomaceous earth is a widely available natural resource and has several industrial uses (such as a filtration material, an abrasive, a mechanical insecticide, an absorbent for liquids, and an activator for blood clotting). The detailed nanoscale architectures of the diatom cell frustules (i.e., silica cell-walls) that constitute this natural material are exquisite.[62–64] Considering the mild conditions under which they are synthesized, these frustules outstrip in complexity the material products of even the most skilled human engineers. The opportunity to design new industrial applications for such nano-architectured composite materials is highly appealing. The physical mechanisms affording this opportunity are becoming elucidated through identification of the biomolecules physically associated with diatom biosilica; several classes have been identified to date, including two subfamilies of 'silaffins' (named for biomolecules with 'silica affinity'), 'silacidins' (acidic silica-associated biomolecules), and long-chain polyamines.[47,50,65–69]

The activity of these biomolecules are investigated through *in vitro* mineralization studies which have mainly focused on the use of silicic acid as a mineral precursor under acidic conditions (pH ~5, intended to replicate the suspected *in vivo* environment).[24,47] The precipitation of silica from silicic acid is accelerated under these conditions by some of the identified molecules (the 'natSil 1' family of silaffins and long-chain polyamines) but not others (the 'natSil 2' family of silaffins and silacidins).

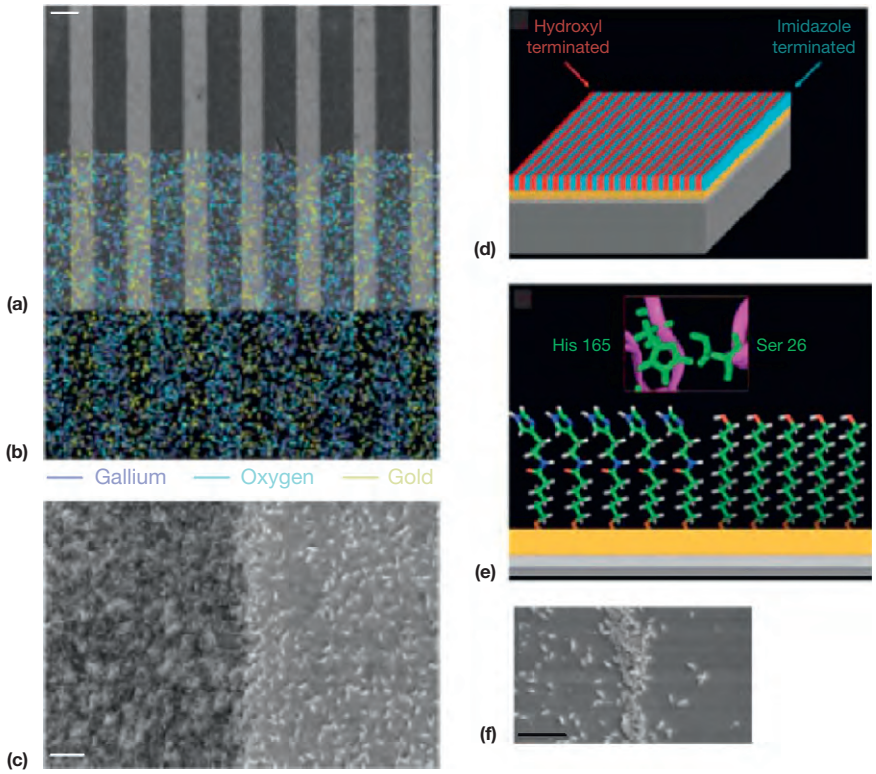

Figure 2 Products formed via catalytic templating from a biomimetic surface. The surface consists of a gold surface patterned with alternating stripes of self-assembled monolayers (SAMs) using hydroxyl- and imidazole-terminated alkane thiols that mimic the catalytic functionalities identified by genetic engineering of the silica-synthesizing enzyme, silicatein. (a) Scanning electron micrograph (SEM) depicting the product formed from the low-temperature hydrolysis and polycondensation of gallium nitrate (scale bar = 10 μm). (b) Energy dispersive X-ray spectroscopy elemental mapping demonstrating that gallium-rich products condensed on the hydroxyl stripes. (c) Higher magnification SEM image showing higher inorganic particle density on the hydroxyl bands, confirming the role of the hydroxyl groups in templating the mineral product. (d) Schematic depiction of the bifunctional SAM geometry. To produce the bifunctionalized SAM surface, a poly(dimethylsiloxane) stamp inked with an alkane thiole (either hydroxyl- or imidazole-terminated) is brought into contact with a gold surface, facilitating transfer by bonding of the thiol to the gold. After the initial printing of the first alkane thiol, the wafer is then immersed in the second alkane thiol solution to form stripes of the second monolayer. (e) Presentation of the essential functionalities required for hydrolysis, similar to those found in silicatein: an imidizole and hydroxyl hydrogen bonding pair. (f) Sample removed after a short reaction time with gallium nitrate demonstrates significantly more condensed product (gallium oxohydroxide) at the hydroxyl-imidiazole interface, with substantially less product away from the interface, supporting the mechanism of catalysis as proposed for the silicatein enzyme. Scale bar = 1 μm. Reprinted with permission from Kisailus, D.; Truong, Q.; Amemiya, Y.; Weaver, J. C.; Morse, D. E. *Proc. Natl. Acad. Sci. USA* **2006**, *103*, 5652–5657. Copyright (2006) National Academy of Sciences, USA.

Certain reaction conditions, including combinations of the different biomolecules or adjustments in the ionic strength of the solution, strengthen or attenuate the efficiency of silicification in a concentration-dependent manner. The first of the identified molecules, natSil 1[47] is rich in glycine, serine, and lysine and decorated with posttranslational modifications that endow the molecule with strongly zwitterionic character, mainly via serine phosphorylation and novel polyalkylamine modification of lysine residues. These posttranslationally modified natSil 1 molecules accelerate silica precipitation from silicic acid whereas analogous nonmodified polypeptides lack this activity under the same conditions.[47] This points to the importance of (bio-) polymer-directed electrostatic interactions in the precipitation of silica from silicic acid. Polyamine units provide multiple positive charges that are thought to act by stabilizing negatively charged prenucleation silica clusters. This proposed biological activity follows a previous investigation where synthetic polyamines were shown to accelerate silicic acid polymerization at neutral pH leading to hybrid organic–inorganic gel network formation.[70] While polyamines are found as posttranslational modifications of natSil 1, other free long-chain polyamines have also been identified in the diatom system, and shown to play an important independent role in accelerating silica precipitation as well.[67] The demonstration that zwitterionic salts facilitate this activity[71] further supports the importance of electrostatic interactions in this process. The additional finding of the natSil 2 class of silaffins[50] and silacidins,[69] which are polyanionic molecules that interact with natSil-1A and long-chain polyamines to form a silica-precipitating organic matrix, further highlighted the role of electrostatically driven interactions in biosilicification. NatSil 2 and silacidins are posttranslationally modified with phosphates, sulfates, or polysaccharides, and do not induce silica precipitation independently; rather, they act to modulate silicification by natSil 1 and long-chain polyamines in a concentration-dependent manner, yielding either enhanced silica yield[69] or unique silica microstructures at different mixture ratios,[50] presumably through controlling the self-assembled structure of the biomolecular matrix.

To begin translating these concepts to bio-inspired strategies, it is beneficial to explore the use of simplified functional elements from this complex system. These have initially been found through the use of the natSil-1-mimetic polypeptide R5[72] and polylysine.[70] Bio-inspired use of the R5 polypeptide is described in more detail in the following section.

2.201.2.3. Bio-inspired Silica Synthesis

Here we briefly describe three precedent-forming biomimetic systems that were further developed for medical applications (detailed in Section 2.201.3). Just as biological systems utilize a wide variety of molecular species in growth and development, from small molecules to extended macromolecular scaffolds, the three systems described here also utilize molecular agents for silicification of disparate sizes and structures: block co-polypeptides,[54] short polypeptides,[47] and small molecules.[51] This molecular diversity indicates that a variety of engineering strategies are available for creating new bio-inspired methods for silica synthesis.

Cha *et al.*[54] studied reactions of homopolypeptides and block co-polypeptides with TEOS, demonstrating that the catalytic, structure-directing and templating features of silicatein could be mimicked in a synthetic system. Scanning different homopolymer compositions for the TEOS reaction confirmed that amino-acid nucleophilicity promoted silica polycondensation: more nucleophilic constituent amino acids tended to produce more mineral silica product. This feature of biocatalytic silicification was suggested by earlier studies of silicatein. Of all the synthetic polypeptides studied, cysteine-lysine block co-polypeptides (closely corresponding to the amino acids identified by genetic engineering as essential constituents of the native enzyme's catalytic active site) produced the most silica, and provided several features of biomimetic control, for both silica yield and structure. Hydrogen bonding between the lysine amine and cysteine sulfhydryl served to increase the nucleophilicity of the TEOS-attacking nucleophile (the sulfhydryl group), just as was proposed to occur at the active site of silicatein (with the hydroxyl of serine serving as the nucleophile).[13,48] The polyamine domains of the copolymer structure also may act to promote clustering between negatively charged hydrolyzed silanol species by reducing electrostatic repulsion and stabilizing prenucleation clusters; this mechanism also has been proposed for polyamine-promoted synthesis of silica from silicic acid in diatoms.[47] It was further found that disulfide-mediated concatenation of the catalytic and structure-directing silicatein-mimetic peptides led to the catalytic synthesis and templating of long fibrilar bundles of silica, whereas blocking this concatenation led to the production of transparent, glassy silica spheres.[54] This co-polypeptide system thus provided structure-directing control of catalytically synthesized silica structures at neutral pH through both chemical and structural engineering of the biomimetic catalytic template. Interestingly, in cysteine-glutamate copolymers, the negatively charged glutamate residues abolished the silica-condensing activity of cysteine, a phenomenon ostensibly similar to the mitigation of natSil 1 silica-condensing activity by negatively charged natSil 2 molecules from diatoms.[50] While only a limited number of biomedical related studies have utilized block co-polypeptide systems directly (see Section 2.201.4.4), this system represents the first bio-inspired silica synthesis study. The results may still provide useful design lessons for the future development of silica structures for applications such as restorative bone, tooth, or other tissue engineering.

Much bio-inspired silica synthesis work stemming from diatom studies has focused on the use of the R5 peptide – a commercially available 19-mer polypeptide that represents a basic repeat-domain of natSil 1.[47] The demonstration of its utility in bio-inspired silica synthesis coincided with the development of related polypeptide-based selection strategies for synthesis of nonoxide material systems,[73–75] substantiating the utility of short polypeptides for biomimetic mineral engineering efforts. The R5 polypeptide is an unmodified version of a sequence that is naturally posttranslationally modified (by serine phosphorylation and lysine polyamination). This peptide has been shown to exhibit silica-condensing activity when reacted with monosilicic acid in phosphate buffer at pH 5.[47] One such use of this peptide involved the production of a holographically patterned polymeric-silica composite structure for photonic applications.[72] Silica- and silicon-based photonic materials synthesized with pulsed HF-etching have found a variety of novel uses in biomedical applications,[76–78] suggesting that there may be future potential for integrating bio-inspired synthetic silica approaches for the development of photonic materials for new therapeutic strategies.

In a later study, R5-accelerated silicification was used to encapsulate enzymes in a solid silica matrix under mild conditions that conserved enzyme function.[79] This approach is characterized by several advantages over alternative strategies for enzyme encapsulation,[80] especially over approaches using traditional silica synthesis strategies, which involve harsh conditions detrimental to the stability and activity of enzymes. Furthermore, this route for enzyme encapsulation in many cases leads to higher enzyme turnover and more stable enzymes that can operate over extended times and temperatures relative to the same enzymes free in solution.[80] Excellent reviews are available detailing developments of enzyme encapsulation via bio-inspired silicification.[24,80] We describe this technology further in Section 2.201.3.3.

The use of small molecules for bio-inspired silica synthesis may provide the most direct link between activity of natural polymers and current industrial systems. Inspired by the genetic engineering that identified the catalytic moieties of the silicatein active site as a nucleophilic group and a hydrogen-bonding amine,[48] the initial block co-polypeptide silicatein-mimetic investigations[54] and the studies of the biomimetic SAMs consistent with these results,[57,58] Roth *et al.*[51] demonstrated that small bifunctional molecules containing both such groups also act as mimics of the enzyme's catalytic site, producing silica from TEOS at neutral pH and low temperature. The most successful of these small bifunctional catalysts, cysteamine, presents a nucleophilic sulfhydryl group and an amine group linked and sterically constrained by a short carbon chain that spaces the two functional groups at a distance apparently optimal for hydrogen bonding. Shorter and longer terminally bifunctional analogs were progressively less active. This sterically determined positioning apparently facilitates catalysis of the alkoxide hydrolysis by a mechanism similar to that proposed for silicatein (and proven for certain homologous hydrolases), in which the nucleophilicity of the active group (oxygen or sulfur) is enhanced by hydrogen bonding to its partner amine.[13] This enhancement is

thought to facilitate nucleophilic attack at precursor silicon centers, facilitating hydrolysis of the alkoxide and subsequent polycondensation. Comparison of the activity of cysteamine to that of other small homologs showed that the immediate chemical environment of the functional moieties had a large impact on the ability to catalyze silica formation from silicon alkoxide precursors; small molecules with more highly substituted amines or weaker nucleophilic groups were less effective than cysteamine. The simple structures and ready availabilities of these small molecules promote their facile integration into applications for bio-inspired silica synthesis. For example, as described in **Section 2.201.3.2**, in the same study demonstrating its catalytic activity, Roth *et al.* demonstrated that cysteamine could be reacted with TMOS (tetramethyl orthosilicate) at neutral pH and low temperature to encapsulate proteins, enzymes, and live cells in silica with micropatterned features – avoiding the exposure to strongly acid or alkaline catalysts typically used for such encapsulations.[51]

We review a selected number of studies demonstrating mild, bio-inspired variations of the Stöber and microemulsion processes in **Section 2.201.4**. Cysteamine itself, while perhaps a strong candidate as a catalyst that can further develop such work, has not yet been used in this capacity. However, the copolymer, polypeptide, and small molecule catalytic systems that have been described in this section represent the kinds of biomimetic studies that will continue to further reveal underlying mechanisms of natural silicification while opening new routes for biocompatible synthetic silica production.

2.201.3. Bio-inspired Silica Synthesis for Biomedical Applications

2.201.3.1. Introduction

Silica-based nanomaterials exhibit high chemical and thermal stability, are easily solubilized in aqueous media, are nontoxic, and are readily synthesized with mesoporous structures or as capsules. Silica nanoparticles are optically transparent, making them highly attractive for encapsulating dyes and contrast agents.[17,81] The presence of a high surface density of silanol groups on silica nanoparticles facilitates their surface functionalization with a number of biologically active molecules, such as peptides, proteins, DNA, linking agents such as biotin and avidin, antigens, and antibodies.[82] These attributes make silica potentially useful for a wide number of medical applications such as drug encapsulation and delivery, biocompatible coatings (such as for implants), sensing, bioassays, and scaffolds for tissue engineering. However, while current silica synthesis procedures allow versatile control of silica nanoparticles, production of silica structures at higher-order length-scales or of more complex morphologies is limited. Thus, recent research to develop silica for medical uses has mainly utilized engineered silica nanoparticles. In this section we review key application areas where the use of silica nanomaterials for medicine has been demonstrated, and we describe relevant nascent efforts to harness bio-inspired silica synthesis methods for these applications. Rather than being exhaustive, we limit our review to four types of biomedical applications: (1) medical imaging, (2) biosensing, (3) drug delivery, and (4) tissue and implant engineering.

2.201.3.2. Silica Nanoparticles for Medical Imaging

In 2009 the U.S. medical-imaging market was worth more than 2 billion dollars,[83] but new report by BCC Research, forecast exponential growth by 2012 reaching $11.4 billion http://www.bccresearch.com/. In such a demanding market, new contrast agents must meet strict performance requirements. An ideal contrast agent must be highly efficient such that its signal resolution is maximized while dosage is minimized; it must be specific, nontoxic, sufficiently stable *in vivo* to avoid too rapid metabolic breakdown, yet its clearance from the body must be rapid after useful labeling has been achieved.

Organic dyes have been the most widely used materials for optical imaging. However, these contrast agents suffer from rapid photobleaching; also, their emission spectra often overlap with autofluorescence from tissues in which fluorophores such as nicotinamide (NAD[H]), flavins, collagen, and elastin are present. Furthermore, numerous photochemical reactions occur in the cellular environment that can lead to photodegradation of the dye. The encapsulation of dyes in an inert and transparent matrix such as silica is the most practical methodology presently in use to maximize both their *in vitro* and *in vivo* stability.[84–86] The fabrication of fluorescent silica nanoparticles with multifunctional features, strong resistance to photobleaching, high quantum yield, high absorbency, emission in the near infrared (NIR) 700–900 nm window, and adequate dispersibility in biological environments are highly useful for medical imaging technologies.[83] The ability of silica to encapsulate optically active molecules and dyes minimizes oxygen access, increases chemical stability, and allows surface modification of the shell to enhance hydrophilic character and cellular uptake. One further advantage of dye encapsulation in silica is the possibility of tuning the luminescence intensity of dye-doped silica nanoparticles as a function of the number of dye molecules doped in the silica matrix. Higher numbers of dye molecules usually lead to a stronger emission signal except at the concentration limit where self-quenching occurs. Luminescence intensity can also be improved by changing the quantum yield or the nanoparticle size.[87]

Wiesner and coworkers[88] have injected dye-doped 30-nm-diameter silica nanoparticles via the mouse tail-vein and monitored the fluorescence signal from the injected nanoparticles over the course of several weeks. No toxicity or abnormalities were evident over the course of the experiments and the particles were excreted via the reticuloendothelial system over the experimental time period. Furthermore, the particles were applied to *in vivo* vascular imaging via multiphoton microscopy (**Figure 3(b)**) and as probes for sentinel lymph node mapping as a demonstration of their applicability to clinically relevant procedures.

As mentioned in the previous section, the most common methods for encapsulating dyes use either the Stöber method[21] or reverse micelle techniques.[82] The Stöber method is often used to synthesize pure silica nanoparticles, and variations of this method have been used to encapsulate dyes within silica nanoparticles.[89] The traditional Stöber method involves the hydrolysis of a silicon alkoxide precursor (such as TEOS) in a mixture of ethanol and aqueous ammonium hydroxide. Silanol and silicic acid species are generated during hydrolysis, and condensation can proceed through

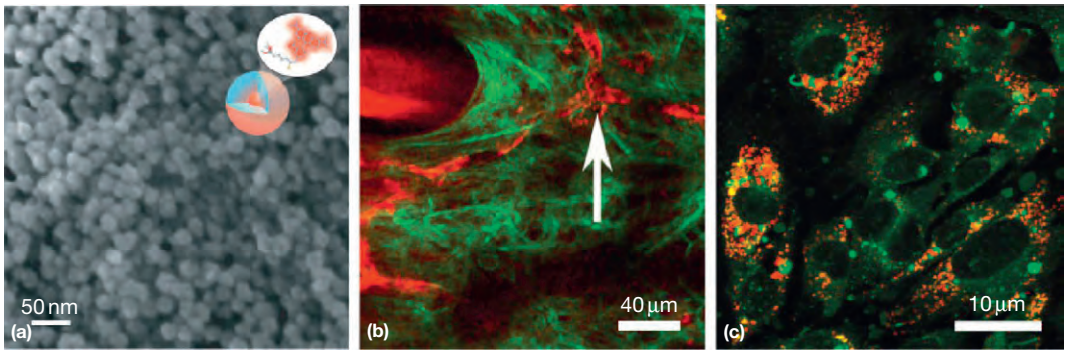

Figure 3 (a) A scanning electron microscopy image of 30-nm-diameter core–shell fluorescent silica nanoparticles comprised of a tetramethylrhodamine dye-rich core with a pure silica shell ('C-dots'), shown schematically in the upper right inset. (b) Intravenous injection of C-dots in mouse shows appreciable fluorescence. *In vivo* multiphoton microscopy of C-dots (red) overlaid on the second harmonic image from collagen autofluorescence (green). Arrow highlights C-dot fluorescence from capillaries. (The red structure in the upper-left is an autofluorescent hair follical.) either S_N2-type attack of silanol species with prehydrolyzed precursors, or through precipitation of silica from silicic acid when its concentration exceeds its solubility in the ethanol-based solution. The particles obtained using this approach have a diameter between <10 nm and ~1 μm, and are generally nonuniform in size.[82]

Reverse micelle methods represent an alternative yet related approach allowing the synthesis of more monodisperse populations of particles. Reverse micelles, also known as water-in-oil (W/O) microemulsion systems, create thermodynamically stable aggregates of amphiphilic surfactants whose polar head-groups surround nanometer-sized water cores; the hydrophobic tails of the surfactant extend into an apolar continuous phase. The nanodroplets of water in the bulk oil phase act as nanoreactors in which particles form from the hydrolysis and subsequent polycondensation of silane precursors. The diameter of the prepared particles is controlled by the size of the water cores and the water-to-surfactant molar ratio, since the reaction is restricted to the water core. The microemulsion method is usually slower than the Stöber approach (2 days vs. few hours).[82] A basic pH is typically required for the Stöber method; this can interfere with the chemistry of some organic dyes, affecting their luminescence. The Stöber method and its variants have been used successfully to prepare fluorescent silica particles that contain the inorganic dye $[Ru(phen)_3]Cl_2$ yielding mono-dispersed silica nanoparticles; their derivatization with trialkoxysilane and their application as signal amplifiers in bioassays performed on glass slides was reported.[89]

The encapsulation of organic dyes is in some cases complicated due to the high hydrophilicity of the silica matrix and the relatively high hydrophobicity of the dye molecules to be encapsulated. Even after successful loading, dyes tend to leak out of the matrix; this effect can be ameliorated by chemical modification of the dye through covalent linkages to partner molecules or adjustments in the pH of encapsulation.[90] However, at neutral pH generally required for bioanalytical applications, acid-stabilized dyes can readily leak from the silica matrix. Another limitation of synthetic methods commonly used to prepare luminescent silica particles has been the use of large amounts of surfactants in microemulsions, requiring extensive washing for removal from the solid products, and the difficulty in scaling-up this synthesis method to suite industrial needs.[89]

As an alternative method, bio-inspired silica synthesis for dye-encapsulation offers the advantages of being scalable and operable at neutral pH. Roth *et al.*[51] showed the silicatein-mimetic small molecule cysteamine was particularly successful in encapsulating firefly luciferase, green and blue fluorescent proteins (GFPs, BFPs), and *E. coli* cells expressing GFP in silica matrices. The benign conditions used for catalytic synthesis of these silica composites conserved the activities of the encapsulated enzyme, fluorescent proteins, and live cells as shown by fluorescence measurements (**Figure 4**).

In conjunction with microcontact printing, this biomimetically catalyzed encapsulation method was used to produce patterned functional arrays of silica nanoparticulate composite materials.[51] Such an approach may find future application in development of chip implants that change their spectral properties as they degrade or as they release a loaded drug, or that could be imaged using visible light if implanted in transparent media such as the vitreous body of the eye.[91] Alternatively, if NIR, tissue-penetrating spectral features were encapsulated into such a chip, the fixture conceivably could be probed through the skin or through several millimeters of visibly opaque tissue. In an analogous fashion, Li *et al.*[92] demonstrated a drug delivery matrix that could be read through the skin by positioning the main spectral feature of the poly-lactide imprint within the low absorbance, NIR window of human tissue.

2.201.3.3. Silica-Based Nanomaterials for Biosensors

The market for biosensors is reaching $7 billion and the trend is showing constant increase.[93] Large shares of this market are devoted to home-use health monitoring devices (e.g., glucose biosensors and pregnancy test strips), while a number of other applications are growing rapidly; these include food quality assurance, environmental monitoring, industrial process control, and the detection and identification of infectious agents.

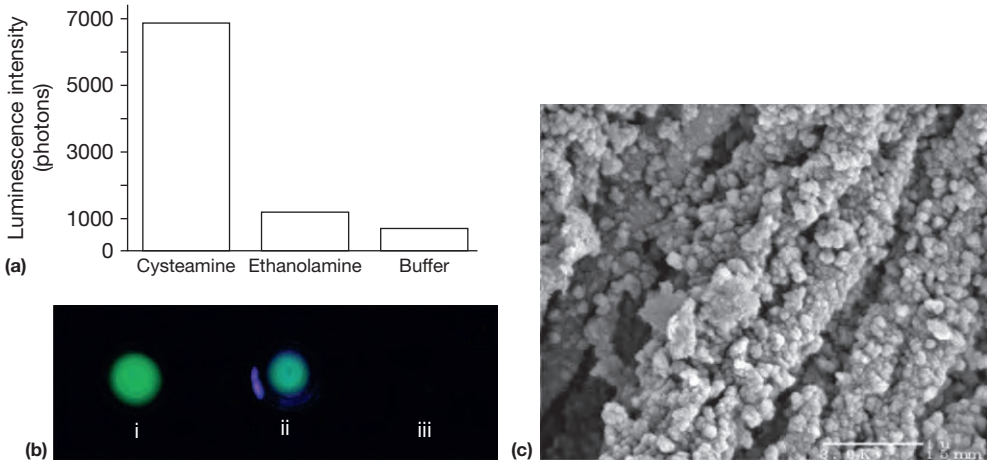

Figure 4 (a) Luminescence intensity produced by silica encapsulated luciferase (enzyme) after addition of luciferin reagent. Silica matrices formed by hydrolysis and polycondensation from silicon alkoxide catalyzed by cysteamine, ethanolamine, or buffer alone. (b) Fluorescent images of green fluorescent protein (GFP) entrapped within silica matrixes formed with (i) cysteamine, (ii) ethanolamine, and (iii) buffer only. (c) Scanning electron micrograph of silica obtained from polycondensation of tetraethyl orthosilicate catalyzed by 10 mM cysteamine. Scale bar = 1 μm. Reproduced by permission from Roth, K. M.; Zhou, Y.; Yang, W.; Morse, D. E. *J. Am. Chem. Soc.* **2005**, *127*, 325–330. Copyright (2005) American Chemical Society, USA.

Like contrast agents, ideal biosensors should be highly sensitive, specific, rapid, and inexpensive. Biosensors usually consist of two components: a highly specific recognition element and a transducer that converts the molecular recognition event into a quantifiable signal.[94] A variety of processes have been investigated to achieve signal transduction including electrochemical processes,[95–98] field-effect transistor processes,[99] and optical processes (absorption, fluorescence, interference).[100–102]

Porous silica-based materials have been employed for building a variety of biosensors using drugs, enzymes, antibodies, and DNA aptamers as recognition elements.[103–105] In such biosensors it is ideal to have well-formed regular pores to ensure quick diffusion of the analytes to the sensing sites. In addition, it is ideal to have a means of control over the rate of diffusion. Radu *et al.*[106] developed an optical biosensor based on mesoporous silica nanoparticles (MSNs). Utilizing a poly(lactic acid) layer as a semipermeable membrane, they spectrophotometrically characterized molecular recognition events between several structurally simple neurotransmitters (dopamine, tyrosine, and glutamic acid) and a pore surface-anchored *o*-phthalic hemithioacetal (OPTA) group that functions as a fluorescence-responsive recognition element that can react with the neurotransmitters through primary amine groups to form the corresponding fluorescent isoindole products. The poly(lactic acid) layer coated on MSNs introduced a unique 'sieving' effect that regulated the rates of diffusion of the amino acid-based neurotransmitters into the sensor mesopores of the silica material.[106]

Glucose biosensors are traditionally comprised of an oxygen electrode, an inner oxygen semipermeable membrane, a thin layer of glucose oxidase (GOx), and an outer dialysis membrane.[107] The outer membrane keeps the enzyme in close proximity to the electrode surface and controls the diffusion of glucose as well as oxygen; the inner membrane allows oxygen to pass while blocking some electroactive interferents from reaching the electrode.[93] GOx catalyzes the oxidation of glucose to gluconolactone while a redox cofactor (e.g., flavin adenine dinucleotide, FAD) is reduced to FADH2. A GOx- and horseradish peroxidase-loaded mesoporous silica material has been used as a selective sensor for glucose detection.[108,109] Myoglobin and hemoglobin were also immobilized in mesoporous silica-modified electrodes for use as sensors for H_2O_2 and NO_2.[110,111] Ren *et al.*[112] described an amperometric glucose biosensor fabricated by the immobilization of GOx in a platinum and silica sol.

As discussed above, bio-inspired silicification reactions recently have been shown to provide a useful tool for the construction of inorganic matrix structures capable of achieving high levels enzyme entrapment without the adverse effects on catalytic activity of the entrapped protein that previously were seen with conventional procedures.[113] Specifically, R5-mediated silica synthesis has been used to encapsulate butyryl cholinesterase,[79] catalase and horseradish peroxidase[114] without any loss of the enzymatic activity. Immobilization of nitrobenzene nitroreductase in silica produced by polyethyleneimine-accelerated silica synthesis[115] and butyryl cholinesterase in silica produced by lysozyme-mediated synthesis[116] has also been reported. (Lysozyme is a member of the hydrolase superfamily of enzymes, and thus related to silicatein.) Recently, a biosensor for organophosphates was created by encapsulating organophosphate hydrolase in a silica matrix directly on a waveguide surface, using surface-bound lysozyme as the biomolecular catalyst for silicification.[117] Due to the neutral pH at which the enzyme-silica layer was synthesized and the enhanced enzyme stability imparted by the encapsulating silica matrix, the resulting biosensor remained active for 60 days. As a wide variety of enzymes have been shown to be amenable to similar stabilizing silica encapsulation,[80] this bio-inspired strategy for developing biosensors may have wide applicability. Further, the catalytic or synthesis accelerating agents for bio-inspired silicification are diverse and amenable to directed modifications (see **Section 2.201.2.3**); such versatility may provide novel routes for integrating silica–enzyme analyte-recognition layers with the signal transduction

components of new biosensors, just as a (transducing-) surface-immobilized biocatalytic element was utilized in the work of Ramanathan *et al.*[117]

2.201.3.4. Silica Nanoparticles for Drug Encapsulation and Delivery

In 2007, the drug delivery market in the United States alone reached $82 billion.[118] With an annual growth rate of 10% the worldwide drug delivery market is expected to garner $700–$800 billion by 2015.[119] Nanomaterial-based drug delivery will play essential roles in site-directed or targeted drug release, to improve therapeutic efficacy and minimize toxicity,[120] and in novel delivery technologies for protein and peptide therapeutics. Any future drug delivery system must provide[121]: (1) *in vitro* and *in vivo* stability, (2) optimized physiological availability, specificity, and efficacy, (3) optimized biological half life, (4) patient convenience facilitating compliance, (5) low dosing frequency, (6) minimal toxicity, (7) minimal unwanted systemic exposure, and (8) optimized product life cycle management.

Advanced drug delivery systems such as micelles, liposomes, and polymeric nanoparticles have been designed over the past four decades that enable more effective drug administration.[118] The major limitation of these systems is their weak thermal and chemical stability and rapid elimination by the immune system.[118] In contrast, silica nanomaterials are potentially convenient drug delivery systems that are nontoxic (depending on size and conditions; see **Section 2.201.4.1**), highly soluble, relatively stable, and capable of encapsulating and transporting the desired guest molecules without significant loss before reaching the targeted location. Various schemes also have been engineered for their release of cargo in a controlled manner.[20,78] These characteristics, in addition to their biocompatibility, make them highly desirable as drug vectors, especially for toxic drugs that require low release before reaching the targeted cells or tissues. Furthermore, silica displays an advantageous balance between stability and degradability that makes it a useful drug delivery vector.

As an example of the utility of silica for drug delivery, MSNs surface functionalized with amino groups were used for *in vivo* gene delivery to the brain of a mouse.[29,122] Furthermore, *in vitro* cell targeting drug delivery studies using silica nanoparticles as carrier systems have been reported recently where the nanoparticles were conjugated to site-specific recognition element such as folic acid (targeting folate receptors)[123] and RGD (arginine-glycine-aspartate) peptides (which target integrin cell adhesion molecules displayed from cellular membranes).[124] Monoclonal antibody-functionalized MSNs for selective targeting of breast cancer cells have also been reported.[125] Novel organic–inorganic nanospheres formed by a hybrid organosilica shell and an internal liposomal core containing bioactive molecules such as doxorubicin have been successfully synthesized.[126] The external shell includes labile silsesquioxane linkers containing ester functional groups and provides stability to the system at the typical pH value of the blood stream (pH 7.5), but the ester groups are broken within the glioma cells, thereby liberating the drug.[126]

The above examples demonstrate that surface functionalized mesoporous silica materials provide an improved capacity for site-specific targeting of drug cargo. Release can be controlled either by physical (e.g., the size and morphology of the pores) or chemical means (such as disulfide-reduction, photochemical, or redox reactions).[20] External stimuli such as magnetic fields have also been used to release the drug cargo from mesoporous silica previously embedded with superparamagnetic nanoparticles. Macromolecules such as low generation polyamidoamine (PAMAM) dendrimers have also been used to cap the pores of mesoporous silica, providing a double drug delivery system (where both PAMAM and silica can carry and release distinct drug cargos).[20] One of the most commonly used approaches to release drug cargo is based on differential pH. Sailor and coworker[78] recently used chitosan hydrogel-capped porous SiO_2 as a pH responsive nano-valve for triggered release of insulin. In another recent example, investigators loaded small cargo molecules into hollow silica nanoparticles with mesoporous walls and sealed the pore openings with chemical nanovalves constructed on the nanoparticle surfaces.[127] Nanovalve design was based on cyclodextrin capping agents that were complexed to surface-anchored anilinoalkane stalks that disassembled in a pH-triggered manner.

The hollow, MSNs in the study of Du *et al.*[127] were synthesized using an alkaneamine template that is proposed to self-assemble around cotemplates of spherical micelles formed from poly(vinylpyrrolidone). This strategy suggests a general synergistic and sometimes subtle relationship between conventional silica syntheses and bio-inspired approaches. The alkaneamine template molecule closely mimics the alkylamine backbone of long-chain polyamines found in diatoms[53]; its use thus obviates the need for acid or base accelerators of silica precipitation. In fact, mesoporous silica has been produced in a wide variety of structures and morphologies, using many unique organic-molecule templating strategies,[54,128,129] many of which are biomimetic strategies.[130–132] It is not surprising that similarity emerges between synthetic and biological methods of silicification as new synthetic approaches begin to permit construction of more complex silica structures. The parallel progress in conventional and bio-inspired silica synthesis strategies will presumably continue to reveal further complementary principles as increasingly complex silica structures become achievable. To specifically design these structures for biomedical applications, there is strong incentive to remain aware of progressive research elucidating natural silicification so that the most biologically compatible synthetic strategies can be developed. For example, mesoporous silica structures have recently been identified in marine sponges.[133] Subsequent mechanistic investigations on the formation of this natural mesoporous silica might inform and inspire the development of novel, biocompatible synthetic approaches for constructing mesoporous silica for drug delivery applications. We further discuss the complementary relationship between conventional and bio-inspired silica syntheses in **Section 2.201.4.2**.

2.201.3.5. Silica-Based Nanomaterials for Implants and Tissue Engineering

Current demand for tissue engineering therapy is staggering both in scope and cost. By one estimate Americans spend ~$400 billion a year on treating some type of tissue loss or end-stage organ failure.[134] Each year 20 000 organ transplants, 500 000 joint replacements, and millions of dental and oral

craniofacial procedures, ranging from tooth restorations to major reconstruction of facial soft and mineralized tissues take place in the United States alone.[134]

Incorporation of biomimetic concepts with the methods of nanotechnology will enable the development of materials that mimic structural components of biological tissues in synthetic materials needed for various implant applications. In comparison to smooth surfaces, those with nanoscale features have been shown to promote better adsorption of proteins that are necessary to mediate cell adhesion and subsequent tissue regrowth.[135] But more than the surface topology alone, surface chemistry has been shown to be equally important.[136] Combining both of these advantageous features, surfaces and coatings that incorporate features resembling those made by biomineralization show great potential for implant and tissue repair – in part because these biomimetic substrates and surfaces can be quickly integrated and remodeled by cells *in vivo*.[135] Silica has been used successfully as an osteogenic scaffold material in tissue engineering of bone and cartilage; efficacious forms include bioactive glasses and composite materials.[137–142] Of equal importance to the biocompatibility of silica for these applications is the fact that it is progressively dissolved and replaced by the body's own biominerals, providing temporary stability while serving as a sacrificial osteogenic template.[141,143–145] Building on the promising results thus far, there is an increasing demand to improve these materials for their use in bone replacement and tissue engineering.

A high-performing implant material should be lightweight, reliable, durable, mechanically robust, and biologically responsive. Biological tissues possess hierarchically organized structures that facilitate optimum fluid transfer and healing, and exhibit remarkable biomechanical properties that are difficult to replicate. Bio-inspired approaches are thus of interest for producing materials to mimic, match, and be effectively integrated with natural systems without inducing the rejection or toxicity currently encountered with many implants. Living tissues usually display several types of responses to traditional implants[146]: (1) if the material is toxic, the surrounding tissue dies; (2) if the material is nontoxic and dissolves, the surrounding tissue replaces it; (3) if the material is nontoxic and biologically inactive, a fibrous tissue capsule of variable thickness forms; and (4) if the material is nontoxic and biologically 'active,' interfacial bonds may form.

The use of biomimetically formed silica can provide suitable coatings on metal implants to increase their biocompatibility and to provide reactive surfaces for the conjugation of specific molecules (oligopeptides, etc.) that act as potent recognition signals governing the deposition and attachment of extracellular matrix glycoproteins and the attachment of specific cell types.[147,148] Similar approaches may be advantageous for bone and dental tissue replacements as such strategies that allow the formation of bioactive coatings under mild *in vivo* conditions.[149–151] Thus, Schröder *et al.*[152] reported that mineralization (formation of calcium phosphate) by human osteosarcoma (bone tumor) cells is markedly increased when grown on culture plates precoated with silicatein and type 1 collagen and subsequently modified with biosilica via reaction with the silica precursor, TEOS (**Figure 5**).

Silicatein or its biomimetics also may provide a promising approach for producing silica coatings on titanium, titanium alloys, and CoCr implants used in surgery.[152] These results indicate that surfaces modified by silicatein-catalyzed silica formation are bioactive and enhance osteoblast function. Such surfaces may be of interest for tissue engineering or coatings of medical implants to promote new bone formation, as suggested in **Figure 5**.[152,193] In dentistry, silica-based bioactive coatings may open new possibilities for novel restorative materials, sealing of dentin tubules, controlling material–tooth interphases, and promoting mineralization along implant surfaces.[151,153]

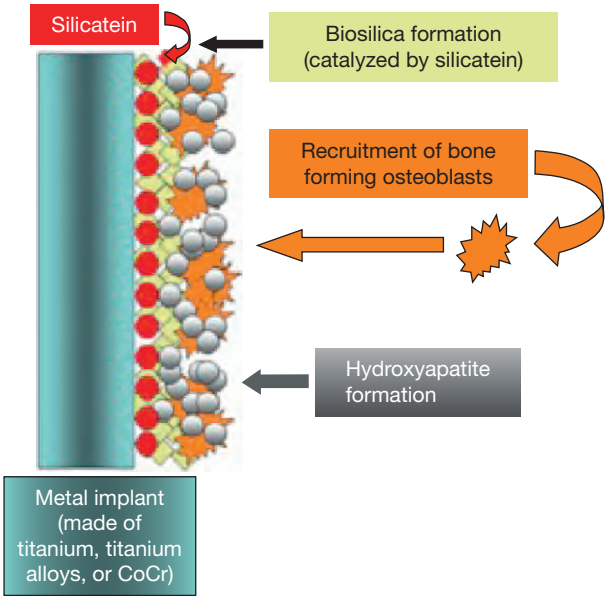

Figure 5 Scheme showing recruitment of bone-forming cells (osteoblasts) and formation of hydroxyapatite on a metal surface activated by the silicatein-catalyzed formation of a silica coating. Reproduced from Schröder, H. C.; Schlossmache, U.; Boreiko, A.; *et al.* In *Progress in Molecular and Subcellular Biology*; Müller, W. E. G., Grachev, M. A., Eds.; Springer: Berlin, 2009; Vol. 47, pp 251–273, DOI: 10.1007/978-3-540-88552-8, with kind permission of Springer Science+Business Media.

While silicatein-catalyzed silica formation has been used to demonstrate the utility of biocatalytic silica synthesis for implant coatings, the diversity of bio-inspired and biomimetic strategies available for silica synthesis can be expected to lead to additional and more readily controlled routes for producing silica-based bioactive implant coatings. Furthermore, many natural biosilica structures display impressive examples of hierarchical structure with unique mechanical advantages.[27] In the following section we review a number of studies that have begun to mimic natural design features that allow such higher-order mineral structures to be fabricated, and that have implications for the future development of more sophisticated biocompatible mineral implant materials.

2.201.4. Perspectives and Challenges

One of the ultimate goals of using bio-inspired synthesis for nanomaterials is to open new biomedical pathways while

improving existing ones. As the ability to control formation of silica structures under mild conditions continues to develop, considering the ease of integration of silica into composite structures, and its amenability to surface functionalization and its biocompatibility, we anticipate that more areas of medicine will be impacted by bio-inspired silica synthesis-based nanotechnology. However, paths to innovation will require concerted interdisciplinary research efforts. Here we describe challenges and opportunities in the following four areas: (1) biocompatibility, (2) new synthesis strategies, (3) genetic engineering, and (4) hierarchical design.

2.201.4.1. Silica Biocompatibility

Although silica is widely considered to have excellent biocompatibility, and has been 'generally recognized as safe' by the US Food and Drug Administration,[17] recent studies revealed evidence of toxicity in some nonoptimally designed cases.[18,154–156,192] Toxicity effects in these studies were found to depend on a number of parameters, including the size, morphology, porosity, surface chemistry, and dosage of the silica particles, and (in mice or rats) the location and manner of their physiological introduction. Studies showing desirable biocompatibility and nontoxicity of functional silica nanoparticles[157–160] indicate that it is possible to optimize these parameters for silica materials and thus avoid the calamitous lessons of asbestosis and silicosis. Bio-inspired silica synthesis routes can be used advantageously to reduce human cytotoxicity and improve biocompatibility both through implementation of benign synthetic conditions and through the resulting enhanced control over composite silica structure.

2.201.4.2. Novel Bio-inspired Silica Synthesis

Efforts to introduce bio-inspired modifications to the Stöber and microemulsion synthesis methods have already begun. For example, several studies have produced uniform silica nanoparticles (<12 nm) employing basic amino acids (lysine and arginine) in place of ammonia as the catalyst.[161,162] These syntheses did not require an alcohol solvent and were performed in the relatively mild pH range of 9–10 (vs. the conventional pH range for Stöber silica synthesis, 11–12). Using a cyclic amine as a bio-inspired catalyst, Masse *et al.*[163] produced unique core-shell silica nanoparticle structures with a granular core (templated onto the molecular catalyst) and a surrounding smooth silica outer layer, though this work was done at pH 12. Employing a microemulsion approach, Jin *et al.*[87] showed that silica nanoparticle sizes could be adjusted in the size range of 20–100 nm by varying the alkane chain length of the alcohol solvent phase. Such efforts may be interpreted as providing a controllable *in vitro* analogue to biomembrane permutations in compartmentalized biomineralization. In a related study, Bauer *et al.*[164] used a branched polyamine as a silicification accelerator from silicic acid in reverse micelles to obtain microscale silica particles at a range of pHs from neutral to basic. By changing the surfactant concentrations, they were able to produce hollow silica spheres up to several microns in size.

In addition to such studies developing milder conditions or better structural control, related chemical and physical investigations are further elucidating the basic mechanism of silica formation. For example, in their study showing the synthesis and stabilization of silica in organic nonalcoholic media using primary amines as catalysts, El Hawi *et al.*[165] used NMR to elucidate the molecular configuration of the coordination sphere of silica nuclei at early times during condensation. Their results showed that the relative physical proximity between the solvent, catalyst, and silicon Q sites are solvent-dependent and help determine the resulting nanoparticle sizes. Exploring another silica growth parameter with implications for both biomineralization and new bio-inspired synthetic strategies, Nozawa *et al.*[166] adjusted the conventional Stöber process by progressively adding TEOS to the solution during the reaction, in a manner that may be analogous to the controlled entry of silica precursors into biological silica mineralization vesicles. This progressive introduction of precursor led to the formation of monodisperse silica spheres up to 2 μm, significantly extending the size-limit of particles that can be synthesized with the Stöber method. As these and new bio-inspired silica synthesis strategies are further developed, and as the field of nanomedicine grows, there is a strong likelihood that one or more facile, biocompatible, and industrially scalable processes will emerge as a drivers for the development of next-generation biomedical devices, just as lessons from silicatein have led to the bio-inspired development of a new low-temperature synthesis method for a variety of nanostructured inorganics with applications ranging from batteries to infrared devices.[23,167–169]

2.201.4.3. Genetically Engineering Silica Biomaterials

Future genetic work with biomolecular catalysts of silicification is also likely to open the door to exciting new technologies for nanomedicine. The discovery that the interface between the inorganic world of silicon and the biopolymers that control siloxane polycondensation includes dynamic catalysts related to well-known and readily cloned enzymes offers prospects for biotechnological control that were previously unimagined. The importance of enzymes for the production of pharmaceutical, biotechnological, and industrial products,[170] their unique chemical versatility, and their relevance for understanding disease and developing novel therapeutics have driven the creation of a variety of enzyme engineering methodologies.[171–178] The possibility for reengineering silicatein or related enzymes for biomedical applications is highly appealing. Novel enzyme engineering methodologies might be advanced to screen libraries of genetically encoded, combinatorially altered silica-synthesizing enzymes for variants with specialized activities, such as the ability to synthesize silica-drug composites with defined sizes, dissolution rates and surface features, for example. While realization of such enzyme-enabled genetic tuning of biosilica properties will require significant advances in several fields, work showing that short polypeptides can be evolutionarily selected *in vitro* for mineral binding[179] and synthesis[10,74,75] (including silica synthesis[180]) suggests that such developments may be imminent. The opportunity to genetically evolve different mineral systems in this way could enable application in each of the four areas reviewed in Section 2.201.3 (imaging, biosensing, drug delivery, and tissue and implant engineering). Of these, one of the most dramatic new applications would be in the area of tissue and implant

engineering. *In vivo* mineralization catalyzed by appropriately engineered enzymes could stimulate bone or tooth growth in a site-specific, directed manner.

2.201.4.4. Hierarchical Design of Silica-Based Next Generation Implants

Shape-engineered nanomaterials are highly desirable for numerous biomedical applications.[181] New synthetic strategies are now being developed that move in this direction. Studies using either a ternary surfactant[182] or a self-assembling polypeptide[183] as the molecular templating element showed that silica helices[182] or centimeter-long, double-walled silica nanotubes could be synthesized by this approach.[183] Pouget *et al.* proposed a synthesis mechanism whereby polypeptide template self-assembly and mineralization proceed in a synergistic manner, driven by electrostatic interactions between the polypeptide monomers and the silica monomers. In related work employing a variety of biomimetic strategies, complex hierarchical silica-polymer composite mesostructures were produced using a shape-directing block copolymers system to assemble silica nanoparticles, followed by selected disassembly of the nanoparticles induced through swelling of one of the polymer phases.[184] These examples illustrate work that begins to mimic the multi-length-scale structural complexity observed in natural biosilica components, and thus may provide a starting point for designing more complex tissue scaffolds and silica implant materials (**Figure 6**).

While lessons learned from natural biominerals are likely to lead to advances in bone and dental tissue engineering, biomimetic strategies for engineering silica- and silicon-based materials may also contribute to engineering soft tissues. The medical device industry is moving from permanently implanted prostheses (based largely on metals and commonly used engineering plastics) to the development of a wide range of safe and effective biocompatible and biodegradable tissue scaffolds.[185] Thus, silicone polymers, elastomers, oligomers, and gels have been utilized in various biomedical applications including implants over the past several decades.[186] The finding that the silicateins can be harnessed to produce synthetic silsesquioxane (silicone) polymer networks *in vitro*[13,48] suggests there may be promise for adapting biomolecular mechanisms to develop new, environmentally benign routes for the synthesis of high-performance biocompatible polymeric implants materials. The demonstration that silicatein can also be used to catalyze polymerization of completely organic materials such as polylactides[187,188] further supports the prospect that new routes for synthesizing soft tissue biomaterials, such as function-specific, tailored, and biodegradable lactide-silicone and related complex polymer scaffolds, may be accessible through enzymatic strategies.

2.201.5. Conclusion

Technologies based on inorganic nanomaterials will increasingly become integrated with human health through devices implanted or circulating in the body to boost health and performance, to treat disease and to repair tissues and organs. By some estimates this merging will be seen to accelerate over the next two decades.[189] This vision, and the related revolution in nanomedicine, will require biocompatible, cheap, and scalable materials such as the silica-based nanomaterials discussed here. Silicon biotechnology has begun to reveal the proteins, genes, and molecular mechanisms controlling the biological

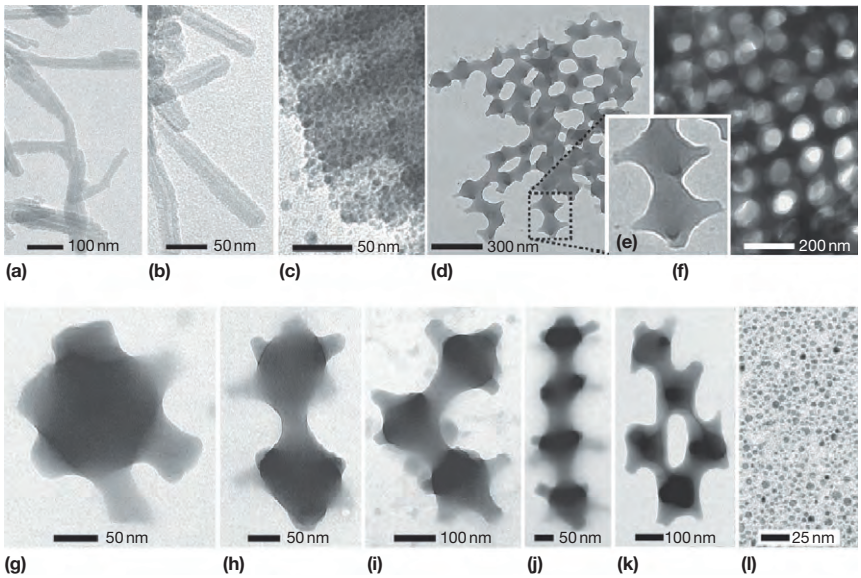

Figure 6 TEM images of a complex hybrid mesoporous silica mimicking features of natural biosilica structures, synthesized by assembly of silica nanoparticles on a shape-directing block co-polypeptide template with subsequent selected disassembly of silica nanoparticles. (a, b) Nanotubes formed during disassembly in toluene. (c) A partially disassembled mesostructure formed during disassembly in pentane in which the nanoparticles within the silica-rich walls are visible. (d–l) A structure consisting of silica-rich channels connected by sixfold nodes (d–f) and the subsequent disassembly into structural building units (g–l). C.; Disalvo, J. F.; Wiesner, U. *Nat. Mater.* **2007**, *6*, 156–161. Copyright (2007) Nature Publishing Group, USA.

nanofabrication of silicon-based materials.[190,191] The ability to translate these insights to new bio-inspired approaches for synthesizing silica-based composites holds large promise for advancing capabilities in medical diagnostics and therapeutics. Silica nanostructures created via current industrial strategies have already constructively impacted medical imaging, biosensing, drug delivery, and implant engineering. Further developments in each of these areas may be significantly accelerated by genetically engineered routes for silica synthesis. Collectively these advances will allow us to emulate nature by successfully integrating important biomolecular and pharmaceutical agents with functional silica structures in living systems.

Glossary

Adeno-associated virus A nonenveloped, single-stranded DNA virus that is nonpathogenic in humans and can be engineered to deliver transgenes up to 4.9 kilobases.

Adenovirus A nonenveloped, double-stranded DNA virus that naturally infects the upper respiratory tract and can be engineered to deliver transgenes up to 36 kilobases.

Artificial virus A nonviral vector that has been functionalized to mimic the gene delivery properties displayed by viruses for efficient gene delivery to cells.

Directed evolution The process of performing iterative rounds of genetic diversification (e.g., mutation) and selection in order to improve the fitness of selected mutants toward specified selection criteria.

Gene therapy The introduction of genetic material into cells as a means to manipulate gene expression profiles to achieve a favorable clinical outcome.

Gene vector A delivery system, viral or nonviral, used to introduce exogenous nucleic acids into cells.

Library selection The process of applying selective pressures to a genetically diverse library in order to identify mutants with a desired characteristic.

Lipoplex A lipid/nucleic acid complex used to deliver DNA into cells.

Monogenetic disease An inherited disease caused by mutation of a single gene, resulting in either a loss of gene function or a pathogenic gain of function, such as the production of a toxic mutant protein.

Nonviral vector A system or construct that relies on synthetic or natural materials, such as lipids, polymers, peptides, and small molecules, to accomplish nucleic acid delivery to cells.

Nucleic acid delivery The process of introducing exogenous nucleic acids into cells in such a way that the nucleic acids become available or bioactive to the appropriate intracellular compartments and machinery.

Plasmid For gene delivery to mammalian cells, a circular DNA construct encoding a mammalian expression cassette as well as elements for propagation in bacteria.
Polyplex A polymer/nucleic acid complex used to deliver DNA into cells.
Reporter gene An exogenous gene used to obtain information about the quality and/or quantity of gene expression afforded by a gene delivery system.
Retroviruses A family of enveloped viruses that integrate into the host genome and can be engineered to deliver transgenes up to ~10 kilobases.
Transduction The process of introducing nucleic acids into cells using viral vectors.
Transfection The process of introducing nucleic acids into cells using nonviral vectors.
Transgene A gene that is transferred from an exogenous source to a recipient cell.

Abbreviations

AAV	Adeno-associated virus
Ad	Adenovirus
DOPE	Dioleoylphosphatidylethanolamine
DOTAP	1,2-Dioleoyl-3-trimethylammonium propane
FISH	Fluorescence *in situ* hybridization
GFP	Green fluorescent protein
GMP	Good Manufacturing Practice
ICC	Immunocytochemistry
miRNA	MicroRNA
MLV	Murine leukemia virus
NLS	Nuclear localization signal
PEG	Poly(ethylene glycol)
PEI	Poly(ethylenimine)
PLL	Poly-L-lysine
RT-qPCR	Reverse transcription-quantitative polymerase chain reaction
SCID-X1	X-linked severe combined immunodeficiency
siRNA	Short interfering RNA
VAPs	Viral attachment proteins

2.202.1. Introduction

Gene therapy offers a promising future treatment approach for myriad diseases and disorders, many of which are intractable using the current tools of clinical medicine. Section 2.202.1 introduces the concept of gene therapy as a means of treating disease at the genetic level and discusses the prospects and challenges of the gene therapy field. It also provides an introduction to traditional gene delivery methods and techniques for evaluating the performance of gene delivery vectors. Ultimately, several challenges that currently hinder the clinical translation of gene delivery vectors must be overcome. Consequently, Sections 2.202.2 and 2.202.3 describe strategies to engineer improved gene delivery vectors. Specifically, Section 2.202.2 discusses approaches to modify viruses in order to improve and/or tune their properties for gene delivery applications, while Section 2.202.3 describes the approach of designing biologically inspired 'artificial viruses' by functionalizing nonviral gene delivery vectors. The final section summarizes the current status of gene therapy as a field and suggest future directions for engineering improved gene delivery systems for gene therapy applications.

2.202.1.1. Defining Gene Therapy

The concept of a 'magic bullet' that selectively eliminates disease while avoiding healthy tissues, postulated by Paul Ehrlich in the early 1900s, has inspired a century-long quest to design targeted medicines. Although originally conceived as small molecule chemotherapeutics or antibodies that target disease-causing cells associated with cancer or bacterial infections,[1] the magic bullet concept has since become the paradigm of targeted medicine for the treatment of myriad human diseases. With recent scientific and technological advances, this bullet is materializing in forms far beyond what may have been conceivable a century ago. The integration of various fields – including biomaterials, tissue engineering, and molecular therapies – has opened doors toward revolutionary disease treatments. An exceptionally promising avenue in modern targeted medicine is gene therapy. In a broad sense, gene therapy encompasses strategies to replace, repair, or modify the expression levels of specific genes.[2–4] The traditional concept of gene therapy involves introducing a therapeutic gene into a patient's cells to correct a disease caused by a genetic mutation and/or by the lack of a necessary gene product. In the case of a monogenetic disease, this approach can be curative because it directly addresses the genetic cause of the disease. Even in cases where the genetic cause of a disease is unknown, genes encoding therapeutic proteins can be delivered as an alternative to protein therapy. More recently, insight into the mechanisms of RNA interference via short interfering RNA (siRNA) and microRNA (miRNA) has opened the possibility of manipulating gene expression profiles at the level of transcription, thereby expanding the types of diseases that can be treated by gene therapy.[5,6] Yet another approach involves *in situ* gene repair, where synthetic DNA molecules that target the disease-causing mutation are introduced to the cell in such a way as to trigger the cell's endogenous DNA repair mechanisms.[7] The genetic manipulation strategies that encompass the current field of gene therapy are illustrated in Figure 1.

2.202.1.2. Prospects and Challenges of Gene Therapy

A progressively increasing understanding of the genetic basis of disease has facilitated the identification of therapeutic targets, leading to the development of strategies and genetic cargos to

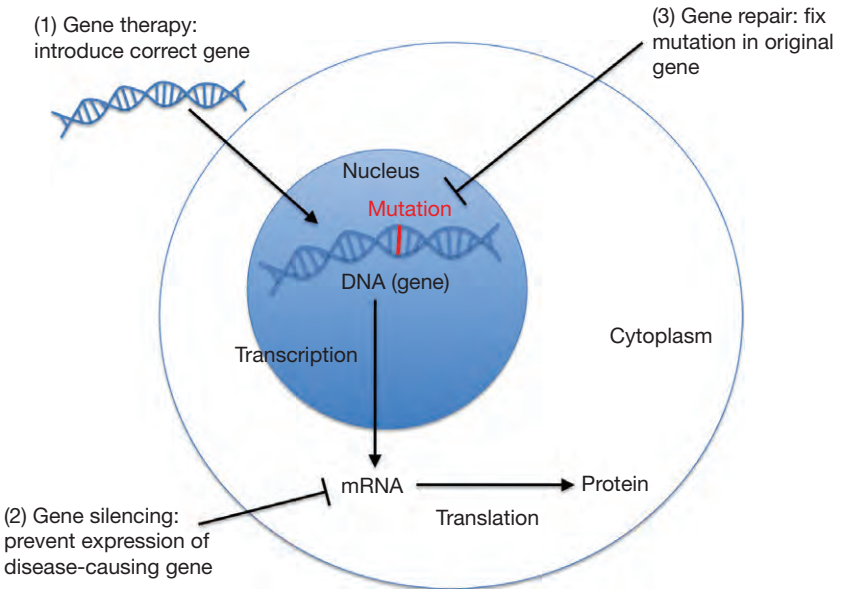

Figure 1 Gene therapy: strategies for correcting disease at the genetic level. Gene therapy encompasses strategies to replace, repair, or modify the expression levels of specific genes. (1) The traditional concept of gene therapy involves introducing a corrective gene to the cell nucleus so that it can express the nonmutated form of a protein. The therapeutic gene can also encode a therapeutic protein that treats a disease for which the genetic basis is not yet understood (not pictured). (2) Gene silencing strategies involve silencing the expression of disease-causing genes by targeting mRNA transcripts for destruction. (3) *In situ* gene repair can be employed to fix disease-causing genetic mutations using the cell's endogenous DNA repair mechanisms.

treat monogenetic diseases such as hemophilia and cystic fibrosis, as well as genetically complex disorders such as cancer, neurological disease, and viral infectious disease.[8] Even when the genetic basis of a disease is unclear, genes whose protein products are known to have a therapeutic effect can be delivered (e.g., neurotrophins to protect diseased neurons in neurogenerative disease and suicide genes or cytokines to promote tumor regression in cancer). Given its potential to address myriad diseases at the molecular level, gene therapy represents a therapeutic modality capable of achieving the specificity and efficacy required of an ideal magic bullet.

There are, however, many clear challenges in the development of such genetic medicines. Foremost is the design of delivery vectors that safely and efficiently deliver their genetic cargo to targeted cells. Although various physical and chemical methods of gene delivery have been explored (see Al-Dosari and Gao[9] for a recent review), viruses are natural candidates as gene delivery vectors because of their innate ability to deliver genetic material to host cells. Indeed, preliminary success has been achieved in clinical trials using viral vectors such as adenovirus (Ad), adeno-associated virus (AAV), and retrovirus (primarily murine leukemia virus (MLV)). These vectors are naturally occurring viruses that have been genetically modified to package therapeutic genes. Notably, a clinical trial evaluating MLV-based retroviral delivery of a cytokine receptor subunit to the hematopoietic stem cells of patients with X-linked severe combined immunodeficiency (SCID-X1) resulted in full correction of the disease phenotype.[10] Additional early phase clinical trials have yielded encouraging results in the treatment of hemophilia B,[11] cancer,[12] cystic fibrosis,[13] and X-linked adrenoleukodystrophy.[14] Recently, very promising results have been achieved in phase I clinical trials employing adeno-associated viral vectors carrying therapeutic genes designed to treat Parkinson's disease[15] and the blinding disease, Leber's congenital amaurosis.[16–20]

Despite encouraging results from these gene therapy trials, a number of setbacks in the field have slowed progress toward clinical approval of gene therapies. In 1999, a severe adverse event involved a fatal immune reaction to an adenoviral vector carrying a gene intended to treat a metabolic deficiency,[21] underscoring the need to better understand the interactions between viruses and the immune system. In addition, 3 years after the apparently successful SCID-X1 gene therapy trial, 3 of the 15 treated patients developed T cell leukemia as a result of retroviral insertion near an oncogene promoter[22,23] (though it should be noted that 12 patients were fully cured of an otherwise fatal disorder). Importantly, these failures were not caused by the therapeutic transgene itself, but were instead due to unfavorable interactions between the vector and its host. Thus, in order to realize the remarkable potential of gene therapy to treat human disease, intelligent vector design is critical.

2.202.1.3. Design Requirements for Therapeutic Gene Vectors

The design requirements for ideal gene transfer vectors can be understood in the context of the gene delivery pathway. Effective gene vectors are macromolecular assemblies that must integrate a set of complex biological 'activities' that enable them to overcome a series of barriers encountered along the delivery pathway, including (i) navigation through the extracellular space and arrival at targeted cells, (ii) passage through cellular membranes, (iii) intracellular trafficking toward the nucleus, and (iv) unpackaging and nuclear delivery

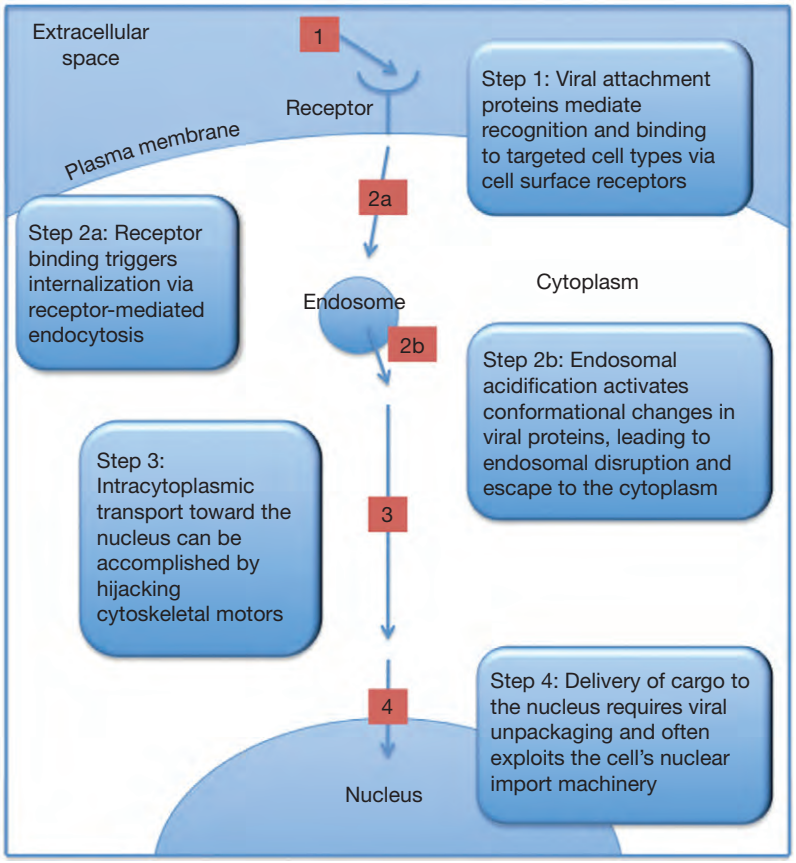

Figure 2 The multistep gene delivery pathway. The ability of viruses to efficiently infect cells relies on their deployment of various molecular mechanisms to overcome a series of intracellular barriers, from cellular binding to nuclear entry. Mechanisms commonly employed by viruses in their cellular entry programs include (1) recognition and binding to specific cellular receptors by viral attachment proteins, (2) entry via endocytosis and acid-triggered endosomal escape from early endosomes (pH ~6.0), (3) intracellular transport on cytoskeletal motor proteins, and (4) unpackaging and nuclear entry via the cell's nuclear import machinery.

of the genetic cargo. As natural gene vectors, viruses employ various mechanisms to overcome these intracellular barriers, as illustrated in Figure 2. However, additional criteria must be met as well. Specifically, a vehicle should ideally deliver therapeutic genetic material with high specificity and efficacy while avoiding toxicity or immunogenicity. Additionally, for viral vectors that integrate their transgene into the host chromosome, the position of insertion must be controlled such that insertion does not lead to oncogenesis. Further, gene delivery systems must be economically produced, must comply with Good Manufacturing Practice (GMP) guidelines,[24–26] and should ideally be amenable to controllable expression levels of the therapeutic transgene.

The challenge of designing this ideal vector has stimulated numerous and diverse research efforts. Both natural viruses and synthetic materials have been studied as platforms for gene delivery vectors, and progress has been made through both rational design and library selection approaches. Efforts to address the complexity of the gene delivery problem are necessarily multidisciplinary, synthesizing insights and tools from virology, cell biology, immunology, medicine, engineering, and chemistry. The development of delivery systems that satisfy the design requirements for gene therapy applications is currently pursued through two major research efforts: (i) viral engineering, which seeks to reengineer natural viruses for use as therapeutic delivery vectors and (ii) the development of 'artificial viruses,' which is concerned with designing synthetic materials endowed with gene delivery capabilities (Figure 3). These strategies will be described in detail in Sections 2.202.2 and 2.202.3, respectively.

2.202.1.4. Techniques for Evaluating Gene Delivery Vectors

The ultimate measure of successful gene transfer is the correction of a disease phenotype by the delivery of a therapeutic gene. However, the development of vectors for gene delivery applications necessitates techniques capable of qualitatively and quantitatively characterizing gene expression in model systems, such as cells, tissues, and organisms. This section will introduce methods for evaluating the performance of gene delivery vectors. Vectors that perform well in these assays would then advance to preclinical studies using a therapeutic gene in a relevant disease model.

2.202.1.4.1. Reporter genes

Reporter genes are exogenous genes used to detect and measure gene expression achieved by a gene delivery system. Early studies employed reporter genes such as chloramphenicol

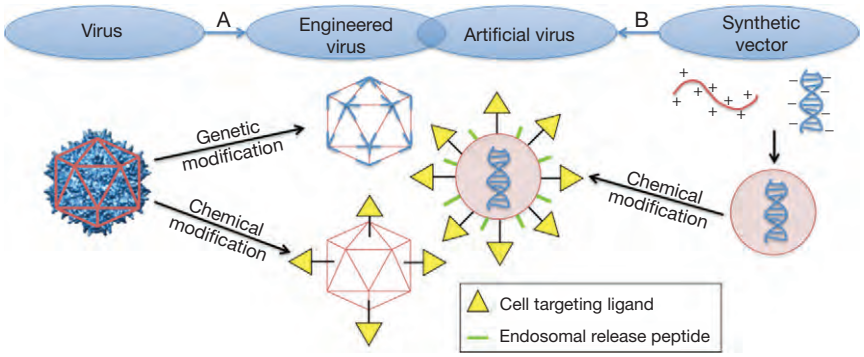

Figure 3 Design strategies for gene delivery vectors. (a) Viral engineering involves chemically and/or genetically modifying the viral capsid. Modifications can be introduced to the viral capsid through rational design or library screening and directed evolution. (Three-dimensional reconstruction of AAV capsid from VIPER database (http://viperdb.scripps.edu).) (b) Artificial viruses are generated by introducing functional modular elements, such as targeting ligands and endosomal release peptides, to synthetic vectors composed of DNA condensed by cationic lipids or polymers. The design of increasingly sophisticated artificial viruses may lead to the generation of systems that resemble engineered viruses.

acetyltransferase and β-galactosidase, enzymes that convert their corresponding substrate to a compound that is detectable via its radioactivity or optical absorbance, respectively. More recently, reporters that are fluorescent or luminescent have been adopted because of their more sensitive and facile detection and quantification. An important fluorescent reporter is the green fluorescent protein (GFP), which was originally isolated from the jellyfish *Aequorea victoria*,[27] while the most common luminescent reporter is firefly luciferase from *Photinus pyralis*.[28]

In order for transgenes to be expressed in mammalian cells, they must be delivered as part of an expression cassette consisting of three major elements: (i) a promoter/enhancer element that serves as a docking site for transcription factors, (ii) the transgene coding region itself flanked by start and stop codons, and (iii) a polyadenylation signal, which plays an important role in mRNA processing in the cell. The promoter is typically a constitutively active, strong promoter, although tissue-specific or inducible promoters can be used to tune a gene delivery system for controlled expression in a particular cell or tissue type or for tunable expression levels. This expression cassette can be packaged as part of a recombinant viral genome or can be inserted into a plasmid and delivered using nonviral gene delivery agents such as polymers or lipids.

Several considerations should be made in selecting a reporter gene. GFP is a robust marker for both qualitative and quantitative determination of gene expression in live cell populations, and it is suitable for histology (see **Section 2.202.1.4.2** for assays).[29] Luciferase might be selected if highly sensitive detection is required because of its extremely low background, but it typically requires cell or tissue lysis for detection in the luminescence reaction.[30] Another consideration is the reporter gene size. Certain viruses have a limited genome capacity, such as AAV with a ~4.9 kilobase genome, which excludes the use of expression cassettes much larger than this size. (Most other viruses studied for gene therapy applications have larger genome capacities.) Also, it is important to consider the half-life of the reporter gene in cells. For example, the half-life of GFP is over 24 h, which enables robust detection of gene expression in individual cells but complicates analysis of gene expression dynamics. On the other hand, the relatively short half-life of luciferase enables kinetic analysis of gene expression on short timescales.[31]

2.202.1.4.2. Gene expression assays

Gene expression assays are important tools used to study the ability of a gene vector to deliver its genetic cargo to a population of cells where it will have its therapeutic effect. In an experimental design, the type of reporter gene and gene expression assay employed are dependent on the specific therapeutic goal. Gene expression assays can be performed in both *in vitro* and *in vivo* models, as described in the following sections.

2.202.1.4.2.1. In vitro *assays*

Cell-based (*in vitro*) assays are an important tool to study gene expression mediated by a gene delivery vector of interest. The particular cell culture model selected depends on the therapeutic application. Often, a vector is initially tested in an immortalized cell line, which is readily available from a cell bank and easily cultured. (It should be noted, however, that the cell line selected must express the appropriate receptors in the case of a delivery vector that relies on particular surface receptors for cellular entry and intracellular processing.) Later, the vector can be further tested and optimized using a more relevant cell type (such as primary cells isolated from the tissue or organ of interest) and/or a more sophisticated culture system that mimics the physiological characteristics of the target tissue or organ (e.g., a specialized culture system that enables localized delivery to polarized cells or a coculture system that replicates the cellular organization of an organ).

A variety of assays can be performed to evaluate gene delivery to an *in vitro* system. Commonly, gene expression is detected by the presence of the protein that is produced by successful nuclear delivery and processing of the transgene expression cassette. The appropriate detection method is determined by the nature of the reporter gene. In the case of GFP or other fluorescent proteins, fluorescence can be detected and measured in live or fixed cells by any of a number of

techniques, including fluorescence microscopy, flow cytometry, or fluorescence spectrophotometry. Enzymatic reporter gene products, such as the luciferase and β-galactosidase proteins, produce detectable signals upon exposure to their respective substrates. Luciferase, for example, catalyzes a reaction that emits light in the presence of its cell membrane-permeable substrate, luciferin. A more general technique to detect virtually any expressed gene is immunocytochemistry (ICC), which utilizes antibodies that specifically recognize the protein of interest and can be detected using labeled primary or secondary antibodies. Another antibody-based technique that can be used to detect reporter proteins is the Western blot. Quantification of the signals produced by reporter genes can provide information about the efficiency of transfection or transduction by a particular vector as well as the dynamics and duration of gene expression. Accurate quantification of gene expression must take into account the number of cells transfected as well as the half-life of the reporter protein.

An alternative *in vitro* assay for gene delivery is the detection of mRNA produced by the transcription of the delivered transgene. Established techniques such as the Northern blot, fluorescence *in situ* hybridization (FISH), and reverse transcription-quantitative polymerase chain reaction (RT-qPCR) enable the detection of mRNA transcripts. Not only are such assays highly specific and sensitive, but they also enable detection of expression earlier than a protein reporter can be detected. Additionally, the short half-lives of mRNA transcripts facilitate detailed analysis of gene expression dynamics.

If *in vitro* assays reveal that gene delivery is inefficient, limitations of the delivery system can be diagnosed by studying its intracellular trafficking in cells. Techniques have been developed to fluorescently label gene delivery vectors and/or their enclosed nucleic acid cargo and track their intracellular path.[32–35] Information pertaining to the internalization and intracellular trafficking of the gene delivery vector can inform rational design efforts to improve the delivery efficiency. Finally, it is important to determine whether the gene delivery vector or its expression product is toxic to cells. Cytotoxicity assays, such as those that assess cell membrane integrity or measure the reducing potential of the cell, and even more complex assays like microarray analysis are relatively straightforward to perform and may accompany gene expression assays in the full characterization of a gene delivery vector.

2.202.1.4.2.2. In vivo *assays*

Although *in vitro* assays are an important system to begin evaluating new gene delivery vectors, it is impossible to recapitulate the complexity of a whole organism in an *in vitro* system. Consequently, in cases where a gene delivery vector is intended for *in vivo* administration, it is important to perform studies that evaluate the tolerable dosage for a given administration route, the biodistribution profile of the vector and transgene product, and the dynamics of expression in a relevant model organism. One option for studying gene delivery *in vivo* is to isolate selected organs or tissues at a specified timepoint after administration and assay for reporter gene expression by one of the techniques described above for *in vitro* assays. Such techniques are useful to sensitively detect gene expression in a tissue of interest and to characterize the biodistribution of the gene product among major tissues and organs. However, the destructive nature of these assays limits the acquisition of data pertaining to the expression dynamics of the reporter gene.

More recently, noninvasive imaging techniques have been developed that enable the acquisition of dynamic, whole-body biodistribution information while minimizing the number of animals required. *In vivo* bioluminescence imaging, which utilizes a light-emitting reporter (typically firefly luciferase), is a common technique for imaging gene expression in small laboratory animals, including mice and rats.[36] At a selected timepoint after gene vector administration, the animals are injected with the luciferase substrate, luciferin, and imaged using a charge-coupled device (CCD) camera to examine profile of gene expression. Using this technique, data can be obtained regarding the magnitude and location of gene expression. The same animals can then be reimaged at later timepoints to follow the expression dynamics of the luciferase reporter gene. A limitation of *in vivo* bioluminescence imaging is that the imaging depth is small (in the range of a few centimeters), restricting studies to small animals or superficial tissues in larger animals. To overcome this limitation, Gambhir *et al.* introduced a technique that utilizes positron emission tomography (PET) in combination with a reporter gene that sequesters a positron-labeled compound in the cell as a detectable marker of gene expression.[37,38] As this modality affords a large imaging depth, it could be readily translated to larger animals and humans.

2.202.2. Viral Engineering

Viruses possess the ability to efficiently deliver genes to cells. As such, they have been utilized as gene delivery vectors in numerous preclinical and clinical studies with increasing levels of success. Nevertheless, complications have arisen due to adverse reactions to viral gene vectors, some of which evolved in nature as human pathogens. It would be beneficial to modify viruses to minimize their immunostimulatory or pathogenic properties while retaining their efficient gene delivery abilities. Such efforts have become increasingly possible with an improved understanding of molecular virology. Two major approaches that have been employed to modify viral properties are rational design and library selection, which can be coupled with directed evolution. Because viruses are multiprotein assemblies with a high density of molecular contacts between interfacing proteins, unique challenges including inherent limitations in modularity arise in attempts to predictably engineer their properties. The design strategies employed in viral engineering, as well as unique challenges posed by attempts to engineer a biological system with a low degree of modularity, are discussed in the following sections.

2.202.2.1. Viruses as Gene Delivery Vectors

Given their natural gene delivery capabilities, it is obvious why viruses were selected as prototypical therapeutic gene delivery vectors. In addition, advances in virology and viral structural biology have progressively elucidated basic mechanisms responsible for this efficient viral gene delivery. Although viruses exist in diverse forms, they share common features (**Figure 4**).

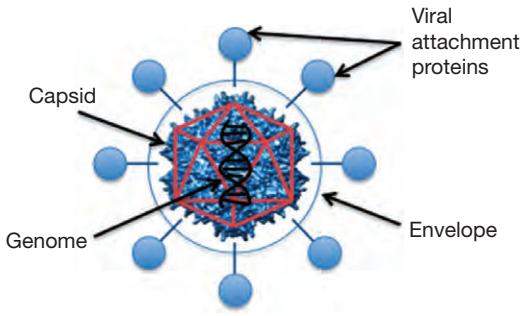

Figure 4 Schematic of a generalized virus. The viral capsid is a multiprotein assembly that surrounds the viral genome and, in some cases, viral accessory proteins. Viral attachment proteins are displayed from the viral surface, either the viral capsid or envelope.

The viral genome consists of either DNA or RNA that encodes the viral capsid, a protein shell that surrounds the genome, as well as accessory proteins necessary to support the viral infection cycle. Some viral capsids, including those of simple retroviruses and lentiviruses, are further enveloped by a lipid bilayer. Viral attachment proteins (VAPs) displayed on the viral surface interact with cellular receptors to mediate binding and entry as the first step in viral infection. Subsequently, viruses deploy specific functionalities encoded in their proteome in overcoming intracellular barriers. In many cases, viral proteins contain functional domains that mediate escape from the degradative endolysosomal pathway,[39] that interact with the intracellular transport machinery for assisted transport through the cytosol,[40] and that exploit the cell's endogenous nuclear import machinery to accomplish nuclear entry.[41] Interestingly, while simple retroviruses such as MLV rely on nuclear envelope breakdown during cell division to accomplish nuclear delivery of their genomes, other viruses such as lentivirus, AAV, and Ad are capable of introducing their genetic material into the intact nuclei of nondividing cells.

Although viruses have evolved mechanisms to accomplish efficient gene delivery to host cells as part of their natural infection process, viral evolution does not necessarily favor specific, important properties that would be beneficial for human therapeutic applications. Some viruses, including certain retroviruses, are natural pathogens and, even when attenuated to reduce replication and pathogenicity, pose inherent safety risks ranging from inflammatory responses to insertional oncogenesis, which was encountered in the SCID-X1 clinical trials.[22,23] Even viruses considered nonpathogenic, such as AAV, elicit adaptive immune responses that do not necessarily pose a risk to patients but whose memory (i.e., the generation of antibodies that neutralize the infectivity of the viral vector or memory T cells that can respond to eliminate the transduced cells) poses major challenges for vector administration and readministration. Consequently, valid concerns with the immunogenicity and toxicity of viral vectors used for gene therapy have been raised.[4,8] There have therefore been efforts to attenuate viral vector interactions with the immune system. Another limitation posed by the use of viruses as delivery vectors is that the natural tropism of the virus may not match the desired biodistribution profile of a therapeutic gene vector. For example, AAV transduces a broad range of tissues to enhance its ability to replicate,[42] whereas HIV infects only a small set of cells as part of its life cycle.[43] Therefore, the development of vehicles that target specific cells of therapeutic value is challenging. The following sections will discuss strategies to overcome the limitations of using viral vectors for gene therapy.

2.202.2.2. Rational Approaches to Vector Design

Increasing insights into fundamental virology have fostered the possibility to manipulate viral properties on the basis of a rational understanding of structure–function relationships. Rational design strategies have predominantly focused on modifying the molecular recognition characteristics of the viral shell to introduce several key properties, including tissue- or cell-specific targeting and evasion of unwanted host immune responses. Various approaches for modifying the viral shell are illustrated in **Figure 5**.

2.202.2.2.1. Retargeting

Given our basic understanding of the role that VAPs play in viral recognition and binding to cell surface receptors, the retargeting of viruses toward clinically relevant cells or tissues has been the primary focus of efforts to reengineer viruses for gene delivery applications. As different viral strains and families exhibit distinct tissue transduction patterns, a common means to redirect viruses is by vector pseudotyping, which involves the modular swapping of VAPs between viral strains. Pseudotyping has been routinely applied to modify the tropism of retroviral vectors[44,45] and has become common for nonenveloped vectors including Ad[46] and AAV.[47,48] It is also possible to generate mosaic particles that combine VAPs from multiple sources into the same virion particle, highlighting a certain extent of modularity in the assembly properties of these proteins.[49] Efforts to identify additional natural virus variants may offer a more extensive collection of viral proteins from which to build novel vectors.[48,50,51]

Although some success has been achieved using pseudotyping to retarget viral vectors, this approach is largely restricted to the natural transduction repertoires of existing viruses. Therefore, in cases where the desired tissue transduction profile cannot be achieved using targeting modules derived from natural viruses, chemical and genetic modifications of viral capsids are complementary approaches. For example, cell-specific targeting ligands, receptors, or antibodies can be attached to the viral 'chassis' via chemical conjugation[52,53] or using biomolecular adaptors such as bispecific antibodies[54,55] or avidin/biotin.[56,57] Alternatively, exogenous targeting ligands, such as peptides or antibody fragments, can be genetically incorporated into capsid proteins. For example, insertion of peptides bearing the integrin-binding RGD motif or the polycation oligolysine into Ad capsid proteins has achieved successful vector retargeting, although other peptide motifs tested were unable to redirect Ad tropism.[58]

2.202.2.2.2. Immune evasion

By employing similar approaches to those used for vector retargeting, progress has been made in modifying vectors to avoid the host immune response. A problem commonly encountered when using human viruses for therapeutic applications is preexisting immunity, as many of us have been

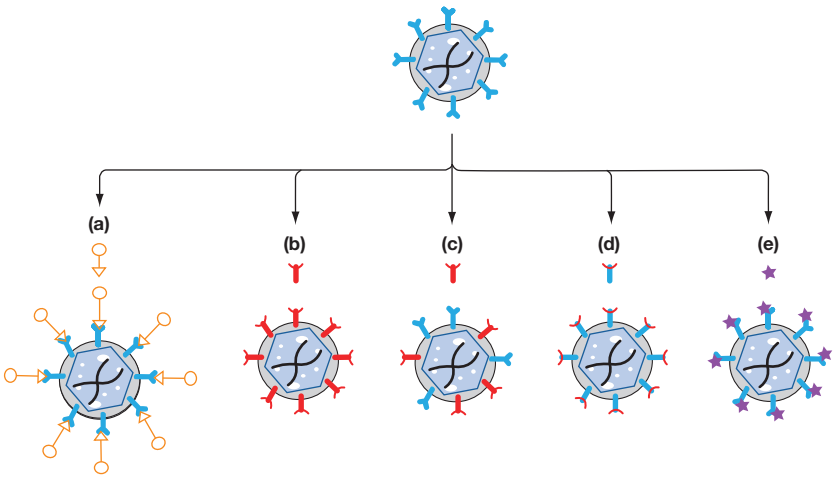

Figure 5 Rational design strategies for engineered viruses. Various modifications can be made to the viral surface, including (a) ligand display by attachment via a bispecific adaptor, (b) pseudotyping with viral attachment proteins (VAPs) from another viral strain, (c and d) creating mosaic or chimeric viral particles that incorporate VAPs from multiple sources, and (e) introducing genetically engineered VAPs bearing mutations and/or peptide insertions. Reproduced from Schaffer, D. V.; *et al. Annu. Rev. Biomed. Eng.* **2008**, *10*, 169–194, with permission from Annual Reviews, Inc.

exposed to and thereby 'naturally vaccinated' against a number of viruses. Consequently, upon systemic delivery of viral vectors based on human viruses or animal viruses with sufficient amino acid sequence similarity to related human viruses, their surface proteins may be recognized by neutralizing antibodies that bind and block viral infection. To avoid this outcome, that is, to protect the virus from the immune system, pseudotyped or chimeric vectors can be employed to take advantage of VAPs from natural variants that are not recognized by host immunity. This strategy has been successfully demonstrated for Ad[59] and AAV.[60,61] Another approach is to chemically modify the viral surface with polymers to sterically shield it from immune recognition. Poly(ethylene glycol) (PEG) is a hydrophilic polymer commonly employed for this purpose, and successful immune evasion has been achieved by PEGylation of both lentiviral[62] and adenoviral vectors,[63] although it has been only moderately successful for AAV.[64] As PEGylation has been shown to ablate native viral tropism in some instances, strategies are being pursued to conjugate targeting ligands to the distal ends of PEG chains to simultaneously achieve immune evasion and vector retargeting.[52,65,66] A more detailed discussion and additional examples of rational vector design are provided in recent reviews.[67,68]

2.202.2.3. Library Approaches to Vector Design

Despite selected examples where it has been possible to successfully manipulate the properties of natural viruses via rational design, efforts to modify viruses often result in a loss of innate function rather than a gain in novel function. There are numerous reasons underlying this problem, many of which are related to the inherent biological complexity of viruses. First, there is a low degree of modularity in a self-assembled viral capsid with many intersubunit contacts, such that swapping pieces of viral proteins responsible for distinct activities to achieve novel functions is challenging (refer to **Figure 2** for a summary of viral activities). In addition, viral capsids most often do not follow a one domain, one function design, as certain viral properties are distributed across nonadjacent protein domains in the viral capsid.[69,70] It is therefore extremely challenging first to identify which regions underlie specific functions, and second to reengineer those distributed functions. In some cases, attempts to introduce novel properties by swapping domains among viral serotypes have instead resulted in unintended inactivation of viral infectivity,[71] suggesting that rational domain swapping may be on the basis of a model of the viral capsid that underestimates its structural and functional complexity. As a related problem, insertion of an exogenous sequence, such as a targeting peptide, into the viral capsid can often disrupt one or more capsid functions and thereby reduce infectivity.

An additional challenge at the genome level is that viral evolution has favored an economical use of their genomes such that a high density of biological functions are often encoded in overlapping open reading frames in the viral genome. Given the high degree of functional overlap in both viral nucleic acids and proteins, it can be difficult to deconvolve and modularize viral sequence–function relationships to aid in design. Finally, even if structure–function relationships can be elucidated in certain cases, it can be difficult to predict and control the emergent properties of complex biological systems. Library selection and directed evolution offer an opportunity to overcome these challenges, as discussed in the following sections.

2.202.2.3.1. Library selection

Library selection approaches offer an invaluable tool for viral engineering as they obviate the need for detailed knowledge of structure–function relationships. This approach, which involves a single round generation of large libraries of genetic mutants and selection of variants based on novel phenotypes (**Figure 6**), is particularly well suited for viruses because of the fact that the viral genotype and phenotype are physically linked. Consequently, libraries can be selected or screened, and the genomes of variants with the desired properties can be isolated and characterized.

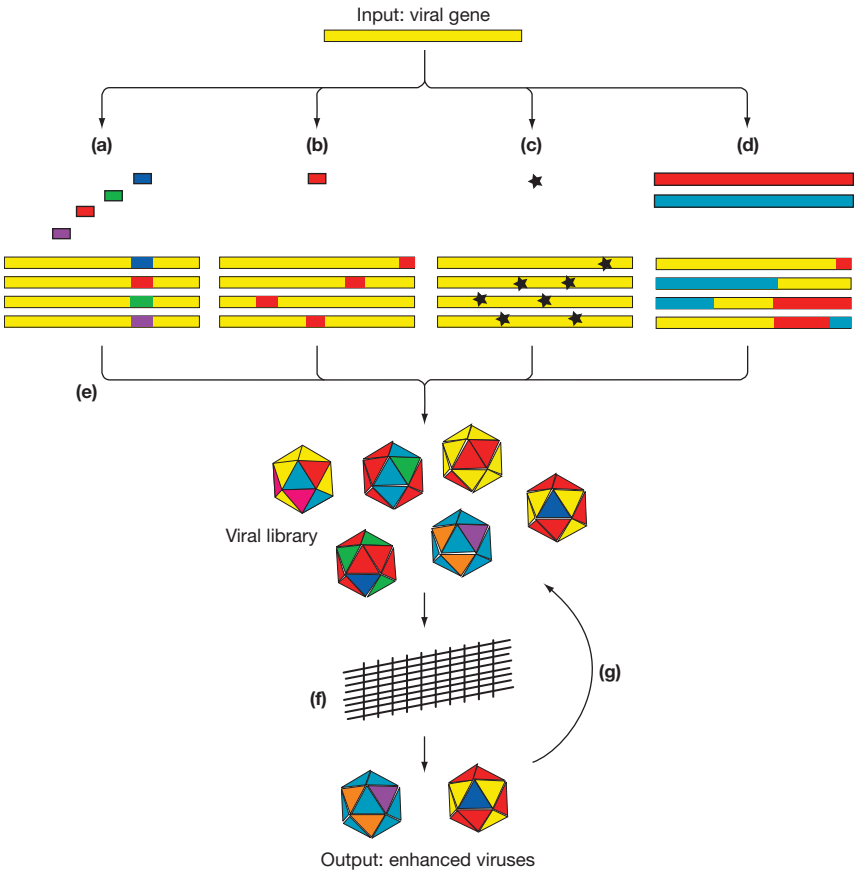

Figure 6 The viral library selection process. Libraries of viral mutants can be generated by (a) insertion of random peptides at a single, defined location, (b) the insertion of a peptide at multiple, random locations, (c) random point mutagenesis accomplished through error-prone PCR, and (d) DNA shuffling. A highly diverse library is then packaged (e) and subjected to selective pressures (f). Successful mutants are collected and can be subjected to additional rounds of selection (g). Reprinted from Schaffer, D. V.; *et al. Annu. Rev. Biomed. Eng.* **2008**, *10*, 169–194, with permission from Annual Reviews, Inc.

Several classes of viral libraries have been constructed using various strategies to generate genetic diversity, including random peptide display, random insertional mutagenesis, and random point mutagenesis (reviewed in Schaffer *et al.*[68]). Additionally, recombination-based strategies can be applied to pools of related viral genes or repeat regions to generate highly diverse chimeric libraries.[72–74] Library selection has been applied to several viral vectors that are candidates for therapeutic gene delivery and, in many cases, has led to the identification of variants with superior gene delivery efficiency and specificity. As one example, an AAV library was generated by random peptide insertion at a permissive site in the viral capsid and subjected to a selection protocol to identify variants capable of infecting a nonpermissive cell line.[75] Following multiple rounds of selection for AAV capsids capable of binding to receptors on a cell line that could not be infected with wild-type AAV, a consensus peptide sequence that endowed AAV with the ability to infect a selected cell line was identified. Library selection has also been employed to modify the transduction characteristics of retroviruses. While gamma retroviruses such as MLV have shown promise as human gene therapy vectors, they suffer from an inability to undergo nuclear entry and are therefore unable to infect nondividing cells, such as neurons. To overcome this limitation, Yu *et al.* generated a library of MLV variants with randomly inserted nuclear localization sequence peptides and, from this library, identified MLV variants capable of infecting neurons.[76]

In addition to generating a wide array of engineered viruses with novel properties that could be beneficial for gene delivery applications, library selection strategies can also contribute toward increasing elucidation of structure–function relationships underlying the mechanisms of viral infection. Notably, the selection of random viral chimeras incorporating fragments of capsid proteins from various serotypes can yield insights into the locations of modular functional domains that would not have been predicted *a priori*.[73] As illustrated in Figure 7, functional domains are often distributed across the viral capsid in exposed surface loops, and viral properties could be altered considerably by loop swapping, where surface loops from one serotype were modularly transplanted onto the chassis of another serotype. This random chimera approach can therefore take steps toward learning how to 'modularize' viruses, yielding basic information that can be applied toward future rational design.

In addition to identifying functional capsid domains in viral chimeras, libraries can be studied to map viral functional

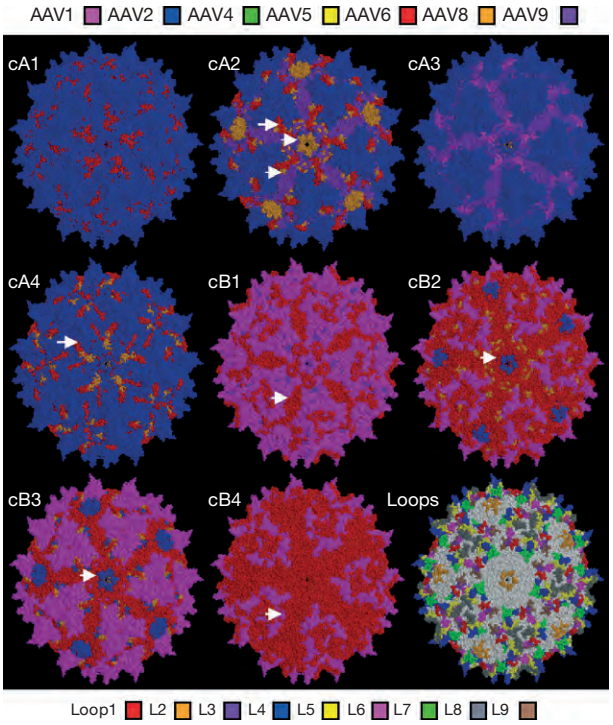

Figure 7 Capsid structure representations of AAV chimeras. AAV chimeras were generated by *in vitro* recombination of seven serotypes. Eight variants were selected for further study, four with substantial sequence similarity to AAV2 (cA1-4) and four with similarity to AAV1/6 (cB1-4). The resulting chimeras displayed strikingly different properties from the parent serotypes with respect to cell tropism and resistance to antibody neutralization. Molecular models of the capsids of the selected AAV chimeras reveal that contributions from multiple serotypes, often distributed across the capsid in surface loops, account for functional diversity among variants. Reprinted from Koerber, J. T., *et al. Mol. Ther.* **2008**, *16*, 1703–1709, with permission from Nature Publishing Group.

domains using a forward genetics approach employing random mutant pools of a single serotype. This approach has recently been employed to map the capsid regions of AAV5 and AAV6 responsible for their distinct cell-binding profiles (Koerber *et al.*, submitted). Such efforts enhance our basic knowledge of virology and can aid future design efforts.

2.202.2.3.2. Directed evolution

Viruses are highly adaptable biological entities, as readily apparent in their ability to undergo repeated rounds of mutagenesis and selection as part of the natural evolution process. Directed evolution, which mimics natural evolution by employing iterative rounds of mutation and selection, in contrast to the single round of genetic diversification and selection discussed in library selection, represents a powerful technique for rapidly and progressively improving viral vectors for gene delivery applications. By allowing for the accumulation of multiple beneficial mutations through iterative rounds of mutagenesis and selection, this process offers the potential to introduce synergistic mutations that confer entirely novel properties on the viral capsid. This accumulation of multiple beneficial mutations can be achieved by selecting promising mutants from the original library and subsequently performing additional mutagenesis and selection to further hone the properties of the selected mutants. As an example, Maheshri *et al.*[70] employed PCR-based mutagenesis and directed evolution of the AAV capsid to introduce novel properties such as resistance to neutralizing antibodies and altered heparin affinity. Recently, our group has demonstrated the utility of directed evolution approaches to target therapeutically attractive cell types – such as human airway epithelia,[77] glial cells in the central nervous system,[78] Muller cells in the retina,[79] and stem cells (Jang *et al.*, submitted) – as well as to target specific organs through *in vivo* panning (Kwon *et al.*, unpublished work). In these examples, additional rounds of mutagenesis and selection afforded further enhancement of the selected properties, thus supporting the value of this iterative approach for generating vectors capable of overcoming a variety of gene delivery challenges.

2.202.3. Design of Artificial Viruses

Rather than attempting to manipulate the highly complex viral architecture from the top down, a number of parallel efforts have focused on a 'bottom-up' approach that involves synthesizing an artificial virus from individual chemical or biological elements. The design of artificial viruses based on synthetic gene vectors may give rise to modular gene delivery systems that are easily manipulated and tuned. This section will describe efforts toward this goal.

2.202.3.1. Materials for Gene Delivery

Synthetic gene vectors are based on materials, such as cationic lipids or polymers, capable of condensing nucleic acids into nanoparticulate complexes that can be taken up by cells.[80–83] Common materials used for nonviral gene delivery, as well as a schematic of polyplex formation, are illustrated in **Figure 8**. Synthetic vectors address many of the limitations posed by the use of viral vectors, offering minimal or reduced toxicity and immunogenicity, greater flexibility in the genetic payload, the potential for straightforward and economical scale-up and production, and the possibility of modular design. However, with a few notable exceptions, current synthetic vectors are plagued by inefficiency compared to their viral counterparts. For example, whereas viral vectors have evolved cunning strategies to efficiently enter host cells, navigate through the intracellular milieu, and deliver their genetic cargo to the nucleus,[84] synthetic vectors passively rely on natural intracellular transport processes and mass action to achieve nuclear delivery.[85,86] Therefore, even in cases where synthetic vectors mediate gene expression levels equivalent to viral vectors, they require uptake of several orders of magnitude more gene copies to compensate for their intracellular trafficking inefficiencies.[87,88]

2.202.3.2. Functionalization of Synthetic Gene Delivery Vectors

As we elucidate the mechanisms underlying viral infection, it is becoming increasingly possible to apply this information and explore biomimetic strategies to enhance the efficiencies of synthetic delivery systems.[89] Toward this end, one could envision using virus-derived or virus-mimetic modules to functionalize

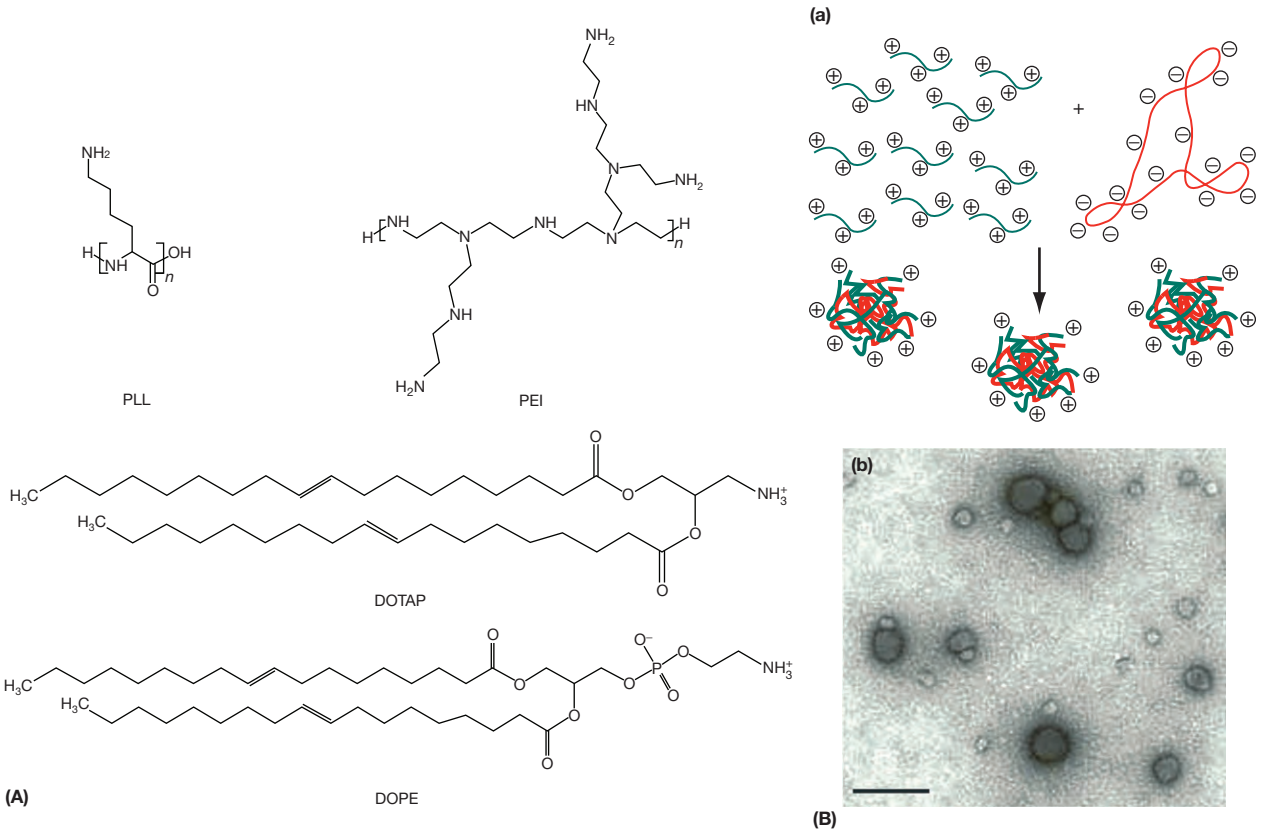

Figure 8 Materials for nonviral gene delivery. (A) The chemical structures of common polymers and lipids used as synthetic gene vectors are illustrated. Common cationic polymers include poly-L-lysine (PLL) and poly(ethylenimine) (PEI). A cationic lipid commonly used for gene delivery is 1,2-dioleoyl-3-trimethylammonium propane (DOTAP), while dioleoylphosphatidylethanolamine (DOPE) is a neutral 'helper' lipid often found in cationic lipid formulations. Reprinted from Bergen, J. M.; *et al. Pharm. Res*. **2008**, *25*, 983–998, with permission from Springer. (B) Polyplexes are formed in aqueous solutions by the electrostatic interactions between positively charged polymers and negatively charged DNA (a), resulting in the formation of nanoparticles (scale bar = 200 nm; image is a transmission electron micrograph). Figure 9 Conceptual model of a multifunctional 'artificial virus.' A multifunctional artificial virus may be assembled as three layers. (a) The core consists of plasmid DNA encoding the therapeutic gene. The plasmid has been modified with functional elements like dynein-binding peptides and nuclear localization signals (NLS) that promote intracellular trafficking toward the nucleus and entry of the gene into the nucleus through nuclear pores, respectively. (b) The functionalized plasmid DNA is condensed with a cationic material, such as a cationic polymer, which is then decorated with membrane-destabilizing peptides, which will function to release the particle from the cell's endosome. (c) The outer layer consists of a shell of polymers or peptides that prevents the particles from aggregating and binding to off-target cells. Binding to targeted cells is mediated through the targeting ligands displayed on the outside of the shell. Reproduced from Mastrobattista, E.; *et al. Nat. Rev. Drug Discov.* **2006**, *5*, 115–121, with permission from Nature Publishing Group.

synthetic vectors with elements to enhance their intracellular delivery efficiencies. This could give rise to 'artificial viruses' built from the minimal essential elements necessary for efficient transfection of targeted cells. A conceptual model of an 'artificial virus' is illustrated in Figure 9. Fueled by insights into molecular virology and studies of viral trafficking, considerable progress has been made toward improving the efficiency of synthetic gene delivery vectors by adding modular, functional parts. Ultimately,

integrating multiple functional modules into multicomponent assemblies has the potential to generate artificial viruses capable of efficient and specific gene delivery. Lessons learned from attempts to mimic essential viral properties are also likely to generate further insights into molecular virology.

2.202.3.2.1. Ligands for cell binding and internalization

Just as viruses display attachment proteins on their capsid or envelope to mediate cellular recognition and binding,[90] artificial viruses must be designed to incorporate modules that direct cellular binding and internalization. An obvious strategy is to attach recombinant VAPs to the surface of synthetic vectors as targeting components. This approach was attempted by Medina-Kauwe *et al.*[91] by incorporating adenoviral penton base proteins into a synthetic vector, although the resulting targeted vector mediated significantly lower transfection efficiencies than the parent virus. These results were partially explained by the internalization of the recombinant penton base proteins via routes that differed from those of Ad itself, highlighting the need to account for context-dependent functionalities of VAPs and providing another example of challenges with viral protein modularity.[92] Aside from VAPs, various biological molecules – including antibodies, growth factors, transferrin, carbohydrates, small molecules, and peptides – have been explored as potential targeting ligands for synthetic vectors.[93,94] In order to maximize the efficacy of targeting strategies, design parameters such as the surface properties of the complex, the length of the spacer between the ligand and complex, and ligand valency should be considered,[95] as these parameters can profoundly influence the ability of the targeting ligand to perform as a modular component of the system.

2.202.3.2.2. Endosomal escape ligands

Both viruses and synthetic vectors must overcome formidable cellular membranes to gain entry into the host cell. While certain enveloped viruses undergo fusion with the plasma membrane concomitant to receptor binding, most nonenveloped viruses and synthetic vectors, as well as some types of enveloped viruses, undergo cellular internalization via endocytosis and must subsequently escape endocytic vesicles to avoid degradation in the endo-lysosomal pathway. Viruses have evolved mechanisms to evade this degradative pathway, some of which rely on acid-induced conformational changes in viral capsid or envelope proteins that lead to exposure of fusogenic domains that mediate endosomal disruption or membrane fusion.[39,96] For example, it has been demonstrated that endosomal acidification triggers disassembly of the Ad capsid, releasing protein VI to lyse the endosomal membrane.[97] Enveloped viruses that undergo endocytosis, such as influenza virus, enter the cytoplasm following fusion events mediated by acid-triggered conformational changes in viral envelope proteins.[98,99]

The ability of viruses to efficiently escape endosomes contributes significantly to their superior gene delivery efficiencies compared to synthetic vectors. In several cases, it has been possible to improve the delivery efficiencies of synthetic vectors by incorporating virus-derived fusogenic peptides. For example, attachment of a peptide derived from the N-terminus of the influenza virus hemagglutinin subunit HA-2 to both polymer- and lipid-based synthetic vectors has resulted in enhanced gene transfer.[100,101] More recently, a peptide derived from the endodomain of HIV gp41, which is involved in membrane fusion between the virus and the cell membrane, was shown to enhance gene delivery by a polymeric synthetic vector.[102] Additional fusogenic peptides identified from natural sources or designed with properties that mimic fusogenic domains have also been shown to be effective enhancers of synthetic gene delivery (see Wagner,[103] Bergen and Pun,[104] and Martin and Rice[105] for reviews).

Finally, certain synthetic polymers and lipids used to deliver genes have themselves been shown or even designed to incorporate endosomolytic properties.[106–110] Of particular interest is a class of 'smart' polymers designed to disrupt biological membranes in a pH-dependent manner.[111] These polymers incorporate pH-responsive functionalities such that they undergo a hydrophilic-to-hydrophobic conversion in the acidifying endosome. At endosomal pH (~6.0), the hydrophobic polymer is believed to partition into the endosomal membrane, mediating disruption. By attaching cell targeting motifs and therapeutic nucleic acids to the polymer backbone, these pH-responsive, 'smart' polymers are capable of enhancing nucleic acid delivery to the cell cytosol. Additional polymeric gene delivery systems designed for enhanced endosomal escape are discussed elsewhere.[81] Despite significant progress designing nonviral nucleic acid carriers that overcome the endosomal barrier, increases in transfection afforded by these strategies are unable to rival the gene transfer efficiencies of viruses, suggesting that additional functionalities are necessary to achieve highly efficient gene delivery.

2.202.3.2.3. Ligands for cytosolic trafficking

A potentially major, but often overlooked, barrier to intracellular trafficking is the limited cytoplasmic mobility of nanoparticulate gene carriers. Recent studies have established that the translational diffusion of macromolecules and nanoparticles in the cytoplasm is severely restricted, primarily due to molecular crowding.[112–114] To facilitate efficient intracellular transport of macromolecules, cells have developed a highly complex active transport infrastructure that conveys cargo along cytoskeletal filaments. For retrograde transport toward the nucleus, dynein is the primary minus end-directed motor.[115,116] Several viruses – including Ad, influenza virus, herpes simplex virus, HIV, and human papillomavirus – have been shown to recruit the dynein motor for assisted transport toward the host cell nucleus.[40,117–121] The ability to harness a motor complex for assisted transport toward the nucleus is a desirable attribute for synthetic gene carriers.[122–125] It has been demonstrated that synthetic gene delivery systems can undergo motor-mediated transport along microtubules following entry into cells.[32,126–129] However, as synthetic systems are believed to rely on either transport within vesicles or the ability of specific plasmid sequences to access dynein-associated protein complexes in the cell, a need remains to identify strategies to improve intracellular transport efficiencies of vectors following their release from endosomes. Despite attempts to identify virus-mimetic ligands capable of mediating attachment of synthetic vectors to the dynein motor complex,[123] successful dynein recruitment by synthetic vectors following endosomal escape remains a challenge.

2.202.3.2.4. Nuclear entry ligands

The nuclear envelope presents a final barrier that must be overcome to achieve successful nuclear gene delivery. While synthetic vectors and simple retroviruses typically rely on nuclear envelope breakdown during cell division for delivery of exogenous DNA,[130] many viruses have been shown to exploit the cell's nuclear import machinery to achieve efficient nuclear delivery to interphase cells. Nuclear import of the viral genome can be accomplished through the recognition of a viral nuclear localization signal (NLS) by the cell's nuclear import machinery.[99] The attachment of synthetic peptides bearing an NLS motif to synthetic vectors has been explored as a biomimetic strategy to enhance their gene delivery efficiencies (see Cartier and Reszka[131] for a review). However, NLS-bearing synthetic vectors have often failed to achieve nuclear delivery of their cargo,[132,133] presumably because of a size limitation for nuclear import dictated by the diameter of the nuclear pore complex.[134,135] Consequently, size is a critical parameter that should be considered when designing artificial viruses.

2.202.4. Conclusions and Future Work

Gene therapy offers remarkable potential as a future therapeutic modality. The previous sections have described the current challenges facing the field as well as efforts to engineer improved gene delivery vectors to overcome these challenges. Beyond current efforts at designing engineered viruses, there are various additional research endeavors that could contribute greatly toward therapeutic translation, including the engineering of the genetic cargo to be delivered. This section will describe future directions for this field.

2.202.4.1. Future Directions

Viral engineering is a multidisciplinary field that draws from a variety of disciplines, including virology, cell biology, immunology, medicine, engineering, and chemistry. Additional advances may be achieved by merging gene delivery with other cutting-edge fields such as synthetic biology and tissue engineering, as described in the following sections.

2.202.4.1.1. Engineering control systems for gene expression

Designing vectors that accomplish efficient gene delivery to targeted cells is a major step toward achieving therapeutic gene delivery. However, as with any drug-based therapy, the levels of the expressed protein must be maintained within an optimal dosage range, that is, the therapeutic window. Inefficient delivery systems may result in the production of subtherapeutic levels of transgene product. However, both viral and synthetic gene delivery systems typically employ strong, constitutive viral or endogenous promoters capable of driving the expression of large amounts of the therapeutic transgene, which can exceed therapeutic dosages for some cargos and thus pose toxicity problems if delivery is efficient. Success to date has largely relied on the treatment of disease conditions that can benefit from relatively low amounts of secreted transgene product or that can tolerate uncontrolled expression levels. However, the unregulated expression of certain transgenes can severely limit their therapeutic efficacy. For example, expression of neurotrophic factors in the brain has been shown to alleviate the clinical symptoms of certain neurodegenerative diseases;[136,137] however, overexpression of these factors can negate the clinical benefits and can even lead to deleterious side effects such as sensory neurite ingrowth[138] and aberrant fiber sprouting.[139] In another cautionary example, it was demonstrated that overexpression of certain short hairpin RNA constructs led to liver toxicity and morbidity in mice via competitive inhibition of endogenous miRNA processing.[140] To avoid potential adverse effects caused by the unregulated expression of therapeutic genes, the ideal gene delivery system would be subject to expression control to maintain therapeutic levels of the transgene product.

The majority of systems currently studied to control expression levels in gene delivery applications function at the transcriptional level by employing inducible promoters controlled by small molecules such as tetracycline, rapamycin, progesterone, or ecdysone.[141–145] However, although improved variants of these systems are being developed, the original systems can sometimes exhibit relatively high basal expression levels because of leaky promoters and relatively low levels of expression upon induction, limiting the possible dosage range.[142,146] With the development of increasingly sophisticated gene regulatory elements that function in mammalian cells, there is opportunity to integrate these elements with therapeutic gene delivery systems. The growing field of synthetic biology already offers a number of expression control options that function at the transcriptional and/or posttranscriptional levels. An elegant example of an efficient, tunable transcriptional switch that functions in mammalian cells was recently presented by Deans *et al.*[147] (**Figure 10**). Their switch, which included modules that responded to repressor proteins as well as RNAi-mediated knockdown of the transcript, was tunable on the basis of the amount of inducer and achieved >99% repression in the absence of inducer.

At the posttranscriptional level, synthetic biology offers RNA-based regulatory elements capable of controlling gene expression. Bayer *et al.* designed ligand-controlled riboregulators containing an antisense domain to target mRNA transcripts as well as an aptamer domain that was susceptible to allosteric control by an exogenous ligand[148] (**Figure 11**). Switching was reversible and tunable on the basis of the concentration of the ligand. Integrating improved gene delivery vectors with gene expression control elements has the potential to generate superior and safe delivery and expression systems for gene therapy applications. Further sophistication may be achieved by designing systems that respond to physiological cues rather than external stimuli.[149] Just as beta cells in the pancreas rely on natural biofeedback mechanisms to regulate blood insulin levels, fully integrated control systems could be engineered to sense levels of a therapeutic gene product in the body and implement control algorithms to maintain expression levels within the therapeutic window. While challenging, the application of sophisticated control systems toward therapeutic gene expression will benefit from continued efforts by synthetic biologists to design novel gene regulatory networks.

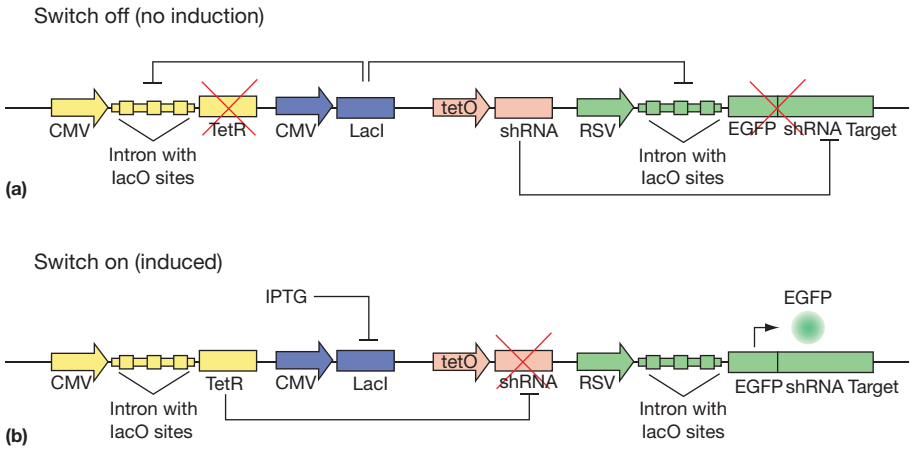

Figure 10 Gene expression control using a synthetic gene network. (a) In the uninduced state, constitutive expression of LacI directly inhibits the expression of the EGFP reporter gene by binding to *lac* operator sites upstream of the EGFP gene. Leaky expression of the EGFP reporter is prevented by the expression of short hairpin RNA (shRNA) designed to destroy any mRNA transcript that may be produced. Consequently, GFP expression is maintained at undetectable levels. (b) Upon induction with isopropyl-β-thiogalactopyranoside (IPTG), LacI activity is suppressed, releasing its inhibition of EGFP expression and simultaneously preventing the expression of the shRNA that blocks the EGFP mRNA transcript. In this state, GFP expression is robust. Reprinted from Deans, T. L.; *et al*. *Cell* **2007**, *130*, 363–372. Copyright (2007), with permission from Elsevier.

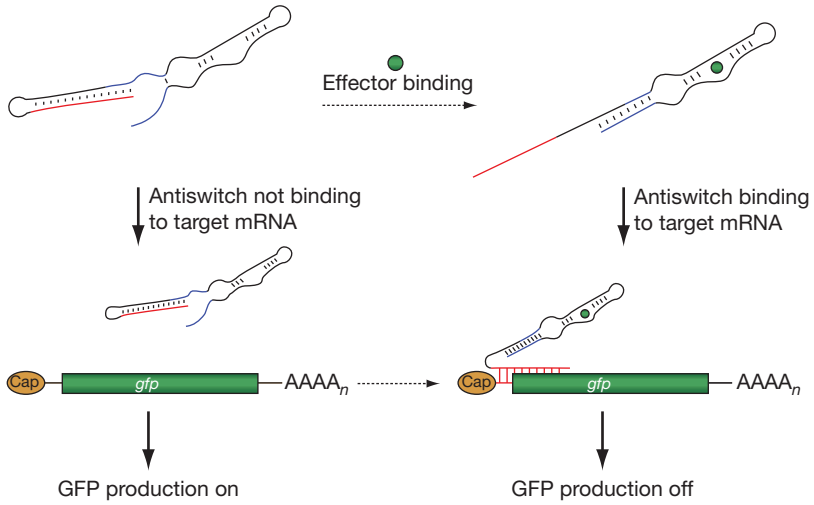

Figure 11 Posttranscriptional control via the antiswitch regulator. In the absence of an exogenous ligand, the antiswitch does not bind to its target mRNA and translation occurs. Once introduced, the ligand binds to the antiswitch, inducing a conformational change in the regulator and exposing the antisense domain, which silences gene expression. Removal of the ligand reverses this inhibition. Reprinted from Bayer, T. S.; Smolke, C. D. *Nat. Biotechnol*. **2005**, *23*, 337–343, with permission from Nature Publishing Group.

2.202.4.1.2. Integration of gene delivery systems with biomaterials

The convergence of gene therapy with tissue engineering has opened up exciting opportunities for regenerative medicine (see Bleiziffer *et al.*[150] and De Laporte and Shea[151] for recent reviews). Already, there has been significant work toward integrating gene delivery systems into biomaterial scaffolds with the idea that cells infiltrating the scaffold and taking up genes available on the scaffold's surface will express factors that promote tissue healing and/or regeneration. Both viral and nonviral gene delivery vectors have been incorporated into scaffolds made from both natural and synthetic materials. Applications utilizing gene delivery from biomaterial scaffolds have already focused on regenerating tissues such as skin, bone, cartilage, nerve, liver, pancreas, and blood vessels.[150] The numerous examples of successful gene integration into biomaterial scaffolds highlight the potential for this technology.

Despite its therapeutic potential, much of the preliminary work demonstrating that genes can be integrated into biomaterial scaffolds relies on nonspecific interactions between the gene delivery system and the scaffold, with limited control on the spatial patterning of genes in the matrix or the temporal release profile of the adsorbed genes. Advances in vector engineering may lead to improved strategies to more precisely integrate gene delivery systems into biomaterial scaffolds. For example, gene delivery vectors could be engineered to

display ligands on their surface that bind to a patterned receptor on the surface of the scaffold. (The feasibility of this concept has already been demonstrated in an *in vitro* system,[152] although additional development is required to translate this technology to a three-dimensional scaffold.) Using multiple ligand–receptor pairs, various genes could be patterned onto a scaffold to direct tissue organization. Additionally, specific ligand/receptor pairs with known binding affinity or specific linkage chemistries could be selected to tune the temporal release profile of genes. Finally, the delivered gene expression cassettes could also be engineered for controlled expression, further tuning the expression of the therapeutic gene.

2.202.4.1.3. Alternative gene delivery systems

Although most current gene delivery systems are on the basis of mammalian viruses or synthetic materials designed to mimic the gene delivery properties of viruses, there remains the possibility of utilizing alternative biological systems as gene delivery vectors. One potential alternative delivery vehicle is the bacteriophage. Although natural bacteriophages are prokaryotic viruses, several groups have demonstrated the feasibility of engineering phage to deliver genes to mammalian cells.[153,154] In these studies, filamentous phage genetically engineered to display targeting ligands on their surface were demonstrated to mediate gene delivery to mammalian cells in culture. While gene transfer efficiencies were low, and considerable improvements are needed, gains may conceivably be achieved by building further modifications onto the phage-based 'scaffold' in modular fashion. However, as with mammalian viruses, manipulation of phage is challenged by the lack of modularity in its compact capsid and genome. One approach to address this may be to employ a 'simplified' phage. It was demonstrated by Chan *et al.*[155] that, by removing elements of overlap in the natural phage genome, the redesigned phage could be more easily studied and manipulated because of its increased modularity. One could envision the extension of this system into 'plug-and-play' phage, with new modules being introduced to specify novel properties, such as those required for efficient gene delivery.

Engineered cells are another system that could potentially fulfill the requirements of a gene delivery vehicle. Extensive work by synthetic biologists to engineer bacterial cells that perform novel functions may also lead to the use of engineered bacteria as 'machines' that perform functions such as (i) homing to the target tissue in the body, (ii) sensing levels of endogenous proteins, and (iii) secreting the necessary transgene products.[156–158] These functions might also be performed by engineered eukaryotic cells, from yeast to stem cells, in what could be considered an extension of *ex vivo* gene therapy. Increasingly sophisticated engineered genetic circuits will support the development of cellular machines that can function as highly effective gene and drug delivery systems.

2.202.4.2. Safety Considerations

Although efforts to engineer improved gene delivery vectors hold tremendous potential for the future of gene therapy, it is extremely important to implement measures to prevent unintended consequences of these technologies. Engineering entities that are capable of infecting humans carries risks that must be mitigated through the implementation of safety measures, including the use of nonpathogenic viruses, the utilization of replication-incompetent viral systems, and the development of systems that prevent recombination to create replication-competent virus. In addition, it is well recognized that new capabilities in DNA synthesis raise the potential for misuse of viral engineering technologies. A potentially alarming example of the safety risks posed by increasingly accessible technology to manipulate or build biological systems was the synthesis of an infectious poliovirus on the basis of a published sequence of its genome.[159] However, with thoughtful vector design, rigorous testing to confirm vector safety and efficacy, and appropriate oversight, it will be possible to engineer improved gene delivery systems that can be translated safely from the bench to the bedside.

2.202.4.3. Summary

The field of gene therapy holds remarkable potential to treat previously intractable diseases. A number of recent clinical successes drive further progress in the field, and additional success is likely to result from the development of improved gene delivery systems. This chapter has described two major approaches for engineering next-generation 'magic bullet' gene delivery systems: (i) reengineering natural viruses using rational design and/or library selection approaches and (ii) designing 'artificial viruses' based on synthetic gene delivery systems. Improved gene delivery systems generated using these approaches are likely to fuel continued progress in the field.

Glossary

Codon Three-nucleotide code in mRNA that basepairs with the anticodon of the corresponding tRNA to specify the identity of amino acid to be incorporated during translation. Since there are 64 possible codons and only 20 amino acids, multiple codons may encode for the same amino acid.

Column chromatography A molecular separation technique that employs physical methods to separate or analyze a mixture of compounds. Separation is achieved by exploiting different properties of the mixture's constituents, which facilitate differential retention times of individual compounds in the column.

Endotoxins Lipopolysaccharides found in the cell wall of Gram-negative bacteria that can elicit innate immune responses when introduced into the body.

Noncanonical amino acids Amino acids with side groups distinct from the 20 naturally existing amino acids found in most biosynthesized polypeptide chains. Noncanonical amino acids are engineered to carry novel functionalities such as photo-cross-linking or fluorescence.

Plasmid Circular piece of DNA that contains an origin of replication that enables self-replication to occur independently of genomic DNA.

Posttranslational modification Covalent modification and functionalization (e.g., phosphorylation and glycosylation) that are added to a polypeptide chain after its translation in a eukaryotic expression system.

Protein conformation A unique 3D configuration adopted by a polypeptide chain, usually essential for its function.

Protein domain Part of a protein that folds and functions properly by itself, independent of the rest of the protein. Multiple protein domains can be assembled together to form a multifunctional polypeptide chain.

Protein fusion tag Short peptide sequence that is usually appended 'in-frame' through the encoding DNA template at the N- or C-terminus of a protein. The short peptide sequence allows for the purification of any arbitrary protein by using resins that bind specifically to the peptide tag.

Recombinant expression The introduction of nonnative genes into a cellular host and their subsequent overexpression, usually for the purpose of protein production.

Transcription The process in which RNA polymerase uses a strand of DNA as a template to make complementary RNA molecules. The resulting RNA molecules are called messenger RNAs (mRNAs), which are subsequently used to guide protein translation.

Translation The process in which ribosomes read, one codon at a time, the information encoded in mRNA, and incorporate the corresponding amino acids into a peptide chain to synthesize a protein.

Abbreviations

AFM	Atomic force microscopy
CHO	Chinese hamster ovary
ECM	Extracellular matrix
ELP	Elastin-like polypeptide
FRET	Fluorescence resonance energy transfer
FTIR	Fourier transform infrared
HPLC	High-performance liquid chromatography
ITC	Isothermal titration calorimetry
LCST	Lower critical solution temperature
LPS	Lipopolysaccharides
MALDI-TOF	Matrix-assisted laser desorption ionization time-of-flight
MMPs	Matrix metalloproteinases
MS	Mass spectrometry
NMR	Nuclear magnetic resonance
PAGE	Polyacrylamide gel electrophoresis
SANS	Small-angle neutron scattering
SEM	Scanning electron microscopy
SPR	Surface plasmon resonance
TEM	Transmission electron microscopy
tPA	Tissue plasminogen activator
uPA	Urokinase plasminogen activator

2.203.1. Introduction

Both synthetic and biologically derived polymers have been broadly explored in the fabrication of biomaterials for tissue engineering applications. In an effort to recapitulate natural biological functions, the design criteria of biomaterials have witnessed a paradigm shift. The ideal biomaterial is no longer bioinert, but is one that seamlessly integrates both the structural and interactive elements of the native extracellular environment. By necessity, these criteria demand exquisite control over the material's blueprint. Owing to the statistical nature of synthetic polymerization reactions,[1] synthetic biomaterials generally suffer from a distribution of sequence and composition, which not only interferes with material tunability and reproducibility, but may also negatively affect postimplantation biodistribution and toxicity.[2] The advent of recombinant technology has ushered in a new class of biomaterials, consisting of protein polymers, which are made of repeating amino acid sequences. By virtue of high-fidelity translation, recombinant protein polymers exhibit monodispersity and precise biochemical compositions. Furthermore, genetic engineering techniques have imparted a high degree of modularity and combinatorial freedom during sequence design of the encoding DNA, thus giving birth to a myriad of novel protein-based biomaterials. Unlike many petroleum-based synthetic polymers, protein biomaterials are cytocompatible and biodegradable, upon cleavage of the peptide bonds, into resorbable degradation products. Coupled with large-scale production in microbial systems, engineered proteins thus provide a sustainable source of cytocompatible and bioresorbable materials for cell and tissue engineering.

Historically, many protein-based biomaterials such as Matrigel and collagen are being harvested from the natural extracellular matrix (ECM). However, since these materials are animal derived and subject to extensive *in vivo* posttranslational processing, they pose certain challenges, such as scarcity, immunogenicity, and batch-to-batch irreproducibility. Attempts to overcome these limitations, aided by the repertoire of genetic manipulation tools made available by recombinant technology, have precipitated the development of custom-engineered protein biomaterials. Reports on protein-engineered biomaterials first emerged in the late 1980s; they were built primarily upon motifs from naturally occurring structural proteins such as silk,[3] elastin,[4] and collagen[5] to create protein polymers with exact structural specifications. These early protein-engineered biomaterials were further investigated as potential cellular scaffolds, and the recent emphasis on dynamic cell–material interactions has led to the incorporation of those extracellular domains that are capable of triggering specific cellular responses or reacting to cell-mediated processes. Among the first nonstructural domains to decorate protein biomaterials were the arginine–glycine–aspartic acid (single letter code: RGD) tripeptide and cell-surface integrin-binding sequence which were incorporated to promote cellular adhesion and spreading.[6] Building upon these early successes and by utilizing the diversity of protein domain databases, a wide array of peptide modules, chosen on the basis of structural and biological functionalities, have been stitched together to create highly functional and dynamic biomaterials (Table 1).

Molecular engineering tools, which have been traditionally used in the development of globular proteins for many years, are increasingly becoming an integral aspect of biomaterials research. Underpinning the core of combinatorial design, domain modularity has enabled the assimilation of multiple peptide motifs to create highly functional biomaterials for *in vitro* cell culture, *in vivo* cell implantation, and drug-delivery applications. Advancing from the intersection of protein engineering and materials science, protein-engineered biomaterials require an interdisciplinary set of experimentation and characterization methods. In this chapter, we describe the various strategies employed in the *de novo* design, synthesis, and characterization of modular protein biomaterials, with an emphasis on recombinantly engineered polymers. Other routes leading to the fabrication of protein biomaterials include solid-phase peptide synthesis and the conjugation of peptide blocks by native chemical ligation.[41] For reports on peptide-based and -chemically synthesized protein biomaterials, the reader is referred to several excellent reviews[42,43] and **Chapter 4.411, Peptide- and Protein-Modified Surfaces** and **Chapter 4.415, Surface Engineering Using Peptide Amphiphiles** in this book.

2.203.2. Rational Design and Modular Building Blocks

Control over polymer compositions has been the holy grail of polymer chemistry for many years. While new chemical synthesis schemes, such as living polymerization and atom-transfer radical polymerization, have moved the field closer

to the realization of this goal,[44] synthetic polymers with strict compositional uniformity remain difficult to produce. In contrast, biopolymers such as DNA and proteins have exact composition because their synthesis is guided by molecular templates. In the case of proteins, specification of the primary amino acid sequence results in a unique three-dimensional (3D) dynamic structure that in turn dictates the protein's functions. Eclectic collections of peptide domains are available for incorporation into protein-engineered biomaterials, the most prevalent being those derived from naturally existing wild-type sequences. In addition, artificial domains, generated through computation and high-throughput screening methods, have more recently been utilized in newly developed biomaterials.

Table 1 Representative domains used in the modular design of engineered protein biomaterials

Function	*Representative domains*	*References*
Structural domains		
Elasticity	Elastin-like	3,7–12
	Silk–elastin-like	13
	Resilin	14–16
Fibrous	Spider dragline silk	17–20
	Silkworm silk	21,22
Physical self-assembly	Coiled coils	23–26
	WW domains/polyproline repeats	27
	Calmodulin	28–30
Flexibility	Amino acid sequence with random coil secondary structures	23,31
Bioinstructive domains		
Cell-binding	Cell–ECM: RGD, REDV, IKVAV	32,33
	Cell–cell: Cadherin	34
Growth factors	Vascular endothelial growth factor	35
Growth factor-binding	Heparin-binding domain	36
Bioresponsive domains		
Protease degradation sites	tPA and uPA sites	37
	Fibrin site	38
	Plasmin site	39
Inorganic-binding site	R5 peptide (silica mineralization)	40

The construction of protein-engineered biomaterials is based on the concept of modular domain design, with an underlying assumption that individual peptide building blocks retain their native functionalities when serially fused into a longer protein polymer. With such an assumption, different domains are mixed and matched to generate materials with systematically tunable, mechanical, biochemical, and biodegradation functionalities. As an added advantage over synthetic biomaterials, genetic engineering of protein biomaterials allows the native extracellular elements to be encoded directly into the material's primary amino acid sequence, thereby obviating the downstream peptide grafting steps. In broad terms, domains that constitute the protein-engineered biomaterials can be categorized into structural, bioinstructive, and bioresponsive (**Table 2** and **Figure 1**), all coming together to create highly functional mimics of the ECM.

2.203.2.1. Structural Domains

In contrast to other protein engineering areas, the use of proteins for bio-material applications faces a unique requirement: mechanical integrity. As tissue engineering platforms, biomaterials must accommodate cellular infiltration, in addition to providing structural reinforcement to the regenerating tissue.

Table 2 Commercially available peptide fusion tags for protein purification by affinity column chromatography

Tag	*Length (sequence)*	*Position*	*Binding partner*	*Elution*	*Additional use(s) of tag*
Biotin carboxyl carrier protein (BCCP)	100	N-terminal or C-terminal	Avidin or streptavidin	Biotin or denaturation	Detection, immobilization
FLAG	8 (DYKDDDK)	N-terminal or C-terminal	Monoclonal antibody	Low pH, EDTA, or FLAG peptide	Detection
Glutathione *S*-transferase (GST)	211	N-terminal or C-terminal	Glutathione	Reduced glutathione	Detection, increased expression, increased solubility, and immobilization
Maltose-binding protein	396	N-terminal or C-terminal	Cross-linked amylose	Maltose	Detection, increased expression, increased solubility
Polyhistidine (His-tag)	2–10 (usually 6: HHHHHH)	N-terminal or C-terminal	Divalent metal (e.g., Ni^{2+}, Co^{2+}, Cu^{2+}, Zn^{2+})	Imidazole or low pH	Detection, immobilization
S-tag	15 (KETAAAKFERQHMDS)	N-terminal, C-terminal, or internal	S-fragment of RNAse A	Low pH	Detection
T7	260	N-terminal	Monoclonal antibody	Low pH	Increased expression
Thioredoxin (Trx)	109	N-terminal or C-terminal	Phenylarsinine oxide	Thiol-containing reducing agent (e.g., Dithiothreitol, β-Mercapto ethanol)	Increased solubility

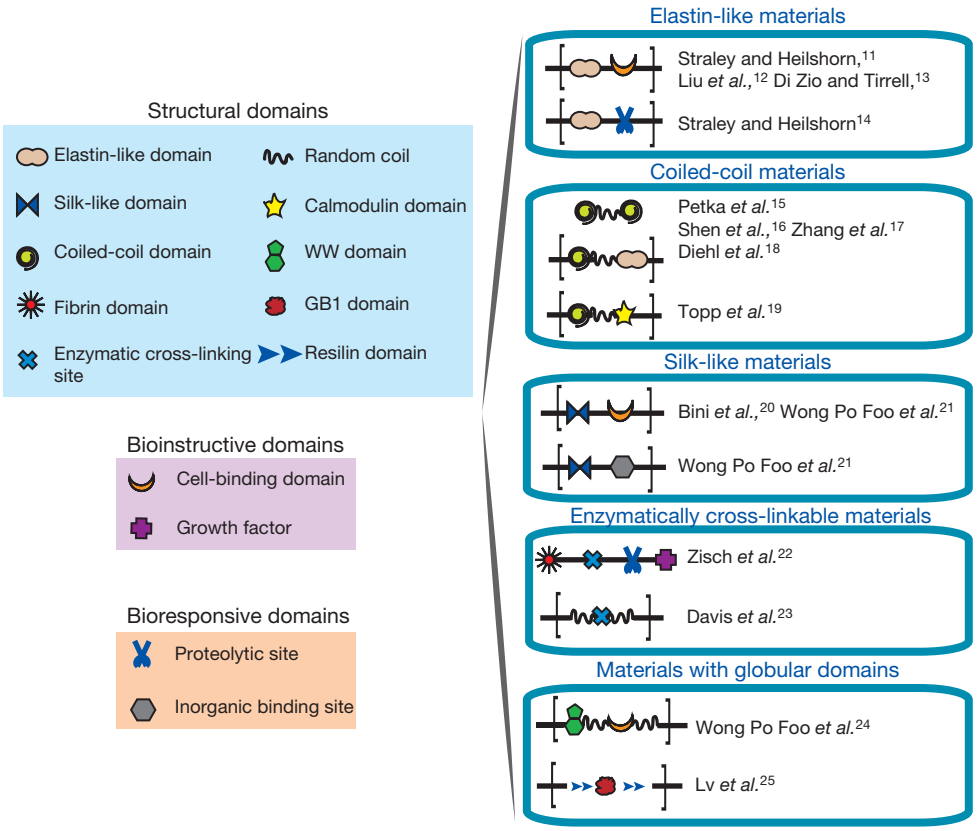

Figure 1 Schematic representation of selected modular protein-engineered biomaterials. Through recombinant technology, peptide domains with diverse structural, bioinstructive, and bioresponsive properties are fused together in the polypeptide chains to create a wide array of functional biomaterials.

Moreover, cell behaviors such as focal adhesion assembly, migration, gene expression, and differentiation are profoundly affected by the elasticity of the matrix,[45] which, in the body, ranges from around 100 Pa (brain) to 100 kPa (bone).[46] Consequently, the development of protein biomaterials for regenerative medicine applications often involves selecting a structural module as the first step in their design.

Logically, the majority of protein biomaterial designs utilize sequences derived from naturally existing structural proteins such as collagen,[47] elastin,[48] silk,[49] and resilin.[15] Materials based upon elastin-like polypeptides of repetitive amino acid sequence $(VPGZG)_n$, where Z is any amino acid except proline, have shown elastomeric properties similar to those of native elastin, prompting soft-tissue applications such as small-diameter vascular grafts[8] and spinal cord repair.[7] In a recent work, a fusion of resilin (an elastomeric protein derived from the wing-hinge of insects) and GB1 protein (a bacterial globular protein capable of rapid and reversible refolding) was designed to create serial molecular springs that mimic the properties of titin, a protein found in muscle.[14]

The mechanical integrity of the bulk material often stems from the physical association or hierarchical self-assembly of their structural modules into supramolecular architectures, as seen in the spontaneous organization of α-helical collagen-like modules into fibrillar architectures[50] or in the assembly of elastin-mimetic triblock copolymers into nanostructured hydrogels.[51] The formation of the desired microstructure is determined at the molecular level through specific interactions between the protein building blocks. Departing from ECM-derived components, material scientists have begun adopting the molecular-binding domains of globular proteins to impart novel properties, such as stimuli-responsiveness and self-assembly, to the structural components of protein biomaterials.

One pioneering example is the leucine zipper hydrogel[23] whose gelation is triggered by the association of coiled-coil domains. The leucine zipper is a naturally found DNA-binding domain of various transcriptional regulatory proteins.[52] A classical leucine zipper motif contains an amphiphilic α-helical structure that comprises six heptad repeats with leucine residues residing in the hydrophobic core of the helix. Driven by electrostatic and hydrophobic interactions, these motifs multimerize into coiled-coil structures that form junction points in the hydrogel network. Owing to the electrostatic nature of the coiled-coil interactions, the hydrogelation process is pH-dependent and pH-reversible. In addition to the interchain association junctions, chain flexibility and favorable chain interactions with the solvent are required for the formation of a swollen hydrogel network. To address these requirements, repeated hydrophilic, polyelectrolyte, random coils of sequence $((AG)_3PEG)_n$ are inserted between two flanking leucine zipper motifs to create triblock copolymers that self-assemble into a swollen, 3D, polymer network at near-neutral pH.

In a different modular design, the $((AG)_3PEG)_n$ spacer sequence has been used to link calmodulin (a Ca^{2+}-sensitive

globular protein) to a leucine zipper domain, to create smart materials whose self-assembly is predictably and reversibly dictated by both pH and Ca^{2+} concentration.[28] Another recent addition to the collection of novel protein-engineered biomaterials is the mixture-induced two-component hydrogel system,[27] where each component is a block copolymer containing multiple repeats of either WW or proline-rich peptide domains that are interspersed with $((AG)_3PEG)_n$ hydrophilic modules. Upon mixing, the WW and proline-rich domains in both the components form physical associations which initiate a sol–gel transition without the need for any external environmental triggers.

The stiffness of self-assembling physical hydrogels is positively correlated with the binding strength and the interval between the association domains. In instances where transient physical cross-linking is incapable of stabilizing a material with desired stiffness, reactive amino acid residues such as cysteine and lysine can be incorporated to mediate covalent cross-linking between the association modules.[53] As seen in synthetic hydrogels, small-molecule cross-linkers, such as bi- and trifunctional isocyanates,[54] *N*-hydroxysuccimidyl esters,[7] and hydroxymethylphosphines[55], have been used to form permanent cross-links in many chemical hydrogels. Other means of chemical cross-linking are catalytic in nature, and are mediated either by photoactivation[15] or by enzymes such as the transglutaminases.[31,56,57]

Cross-linked protein polymers can be viewed as typical amorphous polymeric networks. By stipulating both the intervals between cross-linking sites in the protein primary sequence and the extent of the cross-linking reaction, covalent cross-linking provides a predictive scheme for controlling the mechanical properties of the material such as viscoelasticity, network mesh size, and degree of swelling in water. The mathematical model for polymer elasticity, also known as the rubber elasticity theory, was originally developed by Flory.[1] By approximating each polymer segment as an entropic spring that is deformed in a theta solvent, this model shows the inverse dependence of elastic modulus on the average molecular weight between cross-links (M_c). Accounting for the high water content in hydrogels, the rubber elasticity theory was modified to derive the following relation between shear modulus (G) and M_c:

$$G = \frac{\rho RT}{M_c} Q^{1/3} \qquad [1]$$

where ρ is the polymer density, Q is the volumetric swelling ratio, R is the universal gas constant, and T is absolute temperature.[58] Furthermore, for a highly swollen hydrogel ($Q > 10$), the simplified form of the Flory–Rehner equilibrium swelling theory predicts that Q scales with M_c to the power 3/5.[1]

2.203.2.2. Bioinstructive Domains

Once the structural component has been established, the next step is to customize the scaffold with biofunctional peptide modules. These modules, selected, based on the intended tissue engineering application, can be encoded directly into the primary amino acid sequence as concatenations in the structural domain. One of the first nonstructural peptide motifs to be introduced into protein biomaterials was the (RGD) tripeptide,[6,59] naturally found in various ECM proteins, to promote cell adhesion and spreading by interacting with cell-surface integrins of many cell types.[60] To achieve preferential adhesion of specific cell types, nonintegrin peptide ligands such as the laminin-derived IKVAV sequence have been designed into protein-engineered biomaterials to promote neural cell adhesion and stimulate neurite outgrowth.[32] In another example, the extracellular domain of *N*-cadherin (a key cell–cell adhesion protein in neural development) was fused to the Fc region of the IgG antibody to create an artificial ECM surface that stably adsorbs onto neural stem cells so as to maintain their undifferentiated state and preserve their differentiation potential.[61]

In addition to cell-adhesion domains, other bioinstructive moieties such as growth factors and cell signaling components are being added to the protein-engineered biomaterials toolbox. Such modifications are particularly valuable in regenerative medicine, where protein-engineered ECM scaffolds can be tailored to artificially recapitulate the local *in vivo* niche signals that are thought to direct stem cell self-renewal and differentiation. One example is the incorporation of the active domains of the DSL ligand of the Notch receptor into an elastin-based backbone, for the purpose of modulating glial–neuronal differentiation fates of neural stem cells.[62]

Direct encoding of bioactive sequences into the protein backbone may be problematic in longer peptide sequences (>50 amino acids) whose complex folding may be abolished due to conjugation at the N- and/or C-termini. To eliminate this concern, fully folded soluble factors have been immobilized to the scaffold, either by covalent conjugation or affinity binding. Immobilization of soluble growth factors bestows the benefit of prolonged signal retention not only by dampening burst release, but also by preventing the internalization of the growth-factor–receptor complexes by cells. Covalent conjugation is commonly achieved by cross-linking reactive functional groups on both the growth factor and the biomaterial scaffold. Targets of protein bioconjugation include the terminal amine ($-NH_2$) and carboxyl (–COOH) groups that flank the N- and C-termini of each polypeptide, as well as the amine and sulfhydryl (–SH) groups in the side chains of lysine and cysteine, respectively. However, certain lysine and cysteine residues may play critical roles in maintaining the structural and functional integrity of the growth factor, such that promiscuous modifications at these sites may be deleterious. Problems of nonspecific bioconjugation can be overcome by employing an enzymatic route to cross-linking, as demonstrated by the transglutaminase-mediated conjugation of the vascular endothelial growth factor (VEGF) to a fibrin-based biomaterial. By recombinant DNA technology, a substrate for the transglutaminase factor XIIIa was expressed as an amino-terminal fusion to VEGF, to confer angiogenic activity on the fibrin scaffold.[35]

An alternative approach, which expands the potential of biomaterials as vehicles for controlled drug release, is to immobilize the bioactive signals by noncovalent, affinity-based interactions. One method is to fuse the bioactive factor to an ECM-binding domain. For example, transforming growth factor-beta (TGF-β) has been recombinantly engineered to contain a collagen-binding domain from von Willebrand's factor.[63] Similarly, the fusion of epidermal growth factor (EGF) and a fibronectin-derived collagen-binding domain has

been developed to impart growth factor activity to collagen gels.[64] A less direct approach is to exploit the protein–saccharide interactions that exist in the natural ECM. A particularly important mediator is heparin, a highly anionic, sulfated glycosaminoglycan in the ECM that binds to many proteins such as antithrombin III and various growth factors such as flibroblast growth factor (FGF).[65] Heparin-binding domains, either derived from antithrombin III[36] or from directed evolution by phage display[66], have been covalently incorporated into the biomaterial matrix to immobilize heparin, which in turn binds to the growth factor molecules to sequester them in the matrix.

2.203.2.3. Bioresponsive Domains

Biomaterials for regenerative medicine serve as provisional matrices that are capable of responding to changes in the local microenvironment, as cells migrate and secrete their own ECM. One of the key events in tissue remodeling is the cleaving of the ECM at specific sites by cell-secreted proteases to clear the path for cell migration.[67] Traditionally, biomaterial degradation has been achieved through nonspecific bulk or surface hydrolysis, which fails to recapitulate selective remodeling that is normally observed in the natural context. Cell-mediated degradation was first achieved in synthetic hydrogels by chemically introducing substrates for the matrix metalloproteinases (MMPs), which are enzymes capable of degrading structural ECM constituents such as collagen.[68] For protein-engineered biomaterials, recombinant DNA technology enables the modular integration of protease degradation sites directly into the primary amino acid sequence, which is an added advantage. This not only uncouples the cross-linking sites from the degradation sites, but also allows the scaffold degradation kinetics to be tailored according to specific cellular events. Using modular design, peptide sequences that are sensitive to degradation by neurite growth-cone-specific proteases tPA (tissue plasminogen activator) and uPA (urokinase plasminogen activator) have been encoded into elastin-based protein hydrogels to clear the path for elongating neurites. Minor amino acid sequence mutations in the putative proteolytic sites yield hydrogel variants with 97% sequence homology and identical initial mechanical properties but with degradation kinetics that span two orders of magnitude.[37]

Assisted by modular design principles and a better understanding of cellular behavior, the expanding repository of peptide modules discussed above have led to the development of protein biomaterials that not only present relevant matrix mechanics and bioinstructive chemical signals, but also dynamically respond to the remodeling activities of the local cells. While modular flexibilities constitute one of the most attractive features of protein-engineered biomaterials, the splicing of protein domains may unwittingly introduce secondary structures that in turn alter signal activity or scaffold mechanics. For instance, interspersing identical fibronectin-derived CS5 cell-binding domain sequences within two elastin-like sequences, differing only by 3.4% in amino acid content, significantly altered the cell adhesion properties of the peptide.[69] Furthermore, as a protein domain becomes larger, the fidelity of its tertiary folding may not be preserved when it is fused, in series, to other domains. The responsibility thus lies on the designer to perform theoretical and empirical analyses to verify that the new combination does not affect the preexisting material properties in any unintended manner.

2.203.3. Synthesis and Purification

Downstream of the design steps, recombinant production of the engineered protein polymers is realized through a series of genetic engineering steps, and begins with selecting a host organism whose cellular machinery is capable of producing the target protein. Next, the encoding DNA template is customized in a species-specific manner to optimize protein yield. Following expression, the recombinant protein is isolated from other endogenous host proteins and contaminants through a purification scheme that typically exploits differences in protein size, binding affinity, and other physicochemical properties. A flowchart outlining the production of protein-engineered biomaterial is given in **Figure 2**.

2.203.3.1. Recombinant DNA Technology and Protein Synthesis

The choice of host organism determines the quality and quantity of recombinant protein expression. As the outcome of protein biosynthesis is highly contingent upon cellular machinery, a wide array of recombinant proteins have been expressed in a range of host organisms including mammalian,[70] plant,[71] yeast,[72] and bacterial cells;[73] each selected to optimize the production of the desired protein product. Equipped with specialized organelles for folding and posttranslational modifications (i.e., the endoplasmic reticulum and the Golgi apparatus), eukaryotic cells are generally used for the expression of complex proteins. On the other hand, lower-level prokaryotes, while incapable of elaborate posttranslational processing, have lower technical and economical barriers to large-scale protein expression.

In cases where posttranslational modifications such as glycosylation are essential for protein function, expression in mammalian cells is usually the gold standard. A large sector of commercial recombinant protein production harnesses Chinese hamster ovary (CHO) cell lines as their expression factory.[70] Under optimal fermentation conditions, CHO cells can be cultured in bulk liquid with a doubling time of 15 h. Unfortunately, this rather slow growth rate imposes a prohibitive cost on production scale-ups. As an alternative, scientists have resorted to different strains of yeast such as *Saccharomyces cerevisiae* and *Pichia pastoris* as the expression host. As a eukaryote, yeast possesses dedicated organelles for proper protein folding and modification. Unlike CHO cells, however, yeast has a faster doubling time of 2 h and demands less intensive culture maintenance.

Discounting the need for posttranslational processing, *Escherichia coli* (*E. coli*), a prokaryotic organism, is the most attractive recombinant expression host.[73] The use of *E. coli* for heterologous expression is mainly motivated by its rapid growth rate, ease of culture, well-characterized genetics, and amenability to genetic modification and exogenous gene transformation. Many *E. coli* strains have been mutated to address specific aspects in the cloning and protein synthesis process. In addition, a myriad of plasmid vectors, each harboring

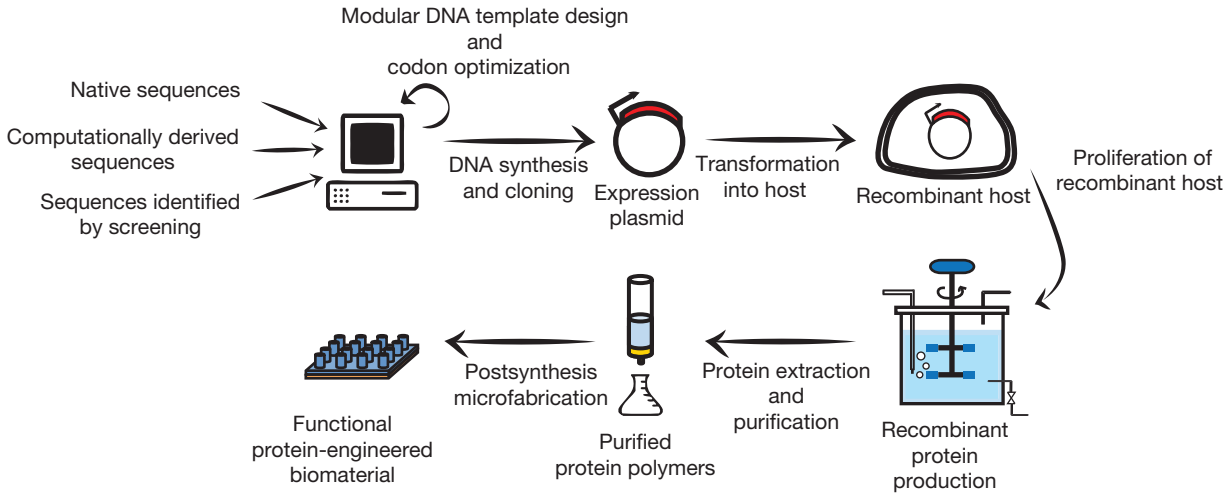

Figure 2 Design and synthesis scheme of recombinantly engineered protein biomaterials. Peptide domains used in the modular design can be derived from wild-type sequences, generated through computation, or identified by high-throughput screens. The modules are then concatenated and back-translated into a DNA template, which is then cloned into a recombinant plasmid and transformed into the host cell of choice, where overexpression of the engineered protein occurs. Following extraction and purification, the target protein is further processed into a biomaterial scaffold with specialized function and morphology.

specialized origins of replication, resistance markers, inducible promoters, and purification tags, are now commercially available for recombinant protein production in *E. coli*. Collectively, these attributes render *E. coli* a very desirable host expression system for the production of simple protein domains that do not require extensive modifications.

The choice of host organism bears a major significance in the subsequent cloning step, especially in the design of the DNA template. Conforming to the central dogma of molecular biology, heterologous proteins are produced via a residue-by-residue transfer of information by transcription (DNA → mRNA), followed by translation (mRNA → protein). During translation, mRNA is read as triplet codons by complementary transfer RNAs, which add amino acids to the growing peptide chain according to the codons they recognize. The genetic code is degenerate, meaning that several synonymous codons can be used to encode a single amino acid. Also, even though the genetic code is generally conserved, the relative abundance of each tRNA pool is species-specific, such that there exists among different host organisms a substantive variability in the frequency of codon usage. For example, though extensively used in humans, the AAG and AGA codons for arginine are scarce in the *E. coli* genome.[74] This phenomenon is referred to as codon bias.[75] The presence of rare codons can trigger translational stalling, leading to mRNA degradation and ultimately a decrease in translational efficiency.[76] By carefully selecting the DNA sequence, codon bias can be harnessed to maximize the yield of recombinant protein expression.

The past decade has witnessed a steep decline in the cost of DNA synthesis, thus allowing bottom-up construction of DNA to be performed routinely. Recombinant protein synthesis strategies derive many benefits from *de novo* DNA design, among which is the possibility of rational codon selection. Even though addressing codon bias can contribute to yield improvement, choosing the same high frequency codon for each amino acid in the protein polymer repeat units may be counterproductive. Highly repetitive DNA sequences are prone to recombination events that lead to undesired genetic mutation.[77] Thus, a degree of codon diversity must be included when designing the template for repetitive amino acid sequences. In addition to codon bias, optimal gene expression involves other factors such as strength of ribosome-binding site and mRNA structure and stability;[78] all of these together render codon optimization a nontrivial process. Algorithms, including publicly available software, are presently being developed and implemented to enhance translational efficiency and protein yield in specific expression systems.[79]

2.203.3.2. Purification of Recombinant Proteins

Purification of a target protein to a level that is necessary for reproducible biomaterial fabrication and cytocompatibility is typically one of the most laborious steps in recombinant protein production. For nonsecreted proteins, extraction begins with cell lysis by repeated freeze–thaw cycles, sonication, high-pressure homogenization, or permeabilization by organic solvents. Subsequently, soluble proteins are fractionated and isolated from the cell lysate by exploiting the differences in size, charge, hydrophobicity, or ligand interactions. In broad strokes, methods of purifying recombinantly engineered protein polymers are facilitated either by column chromatography or batch-phase separation.

2.203.3.2.1. Column chromatography

Column chromatography, in which a protein solution is flowed through a tube packed with a solid matrix, is one of the most routinely used laboratory techniques for the separation of protein mixtures. Depending on their interactions with the matrix, the individual protein species are subjected to different extents of retardation, and can thus be collected in separate fractions as they elute out of the column. The selection of matrix dictates the basis of separation, that is, charge

(ion-exchange chromatography), hydrophobicity (hydrophobic interaction chromatography), size (gel-filtration or size-exclusion chromatography), or the ability to bind to ligand (affinity chromatography).

Ion-exchange chromatography exploits the differential arrangement of charges on the surface of the proteins and is facilitated by a matrix of beads that carry either a positive or negative charge. Examples are diethylaminoethylcellulose (DEAE-cellulose) and caboxymethylcellulose (CM-cellulose), which are positively and negatively charged, respectively. In the column, the movement of proteins that have the opposite-charge with respect to the matrix will be retarded due to electrostatic attraction. As the strength of association is dictated by the ionic strength of the solution and the net charge on the proteins, effective fractionation is achieved by systematically feeding solutions of varying salt concentration and pH into the column. Generally, retention time is reduced either by increasing the counter ion (relative to the matrix) concentration, or by increasing and decreasing the pH in cation and anion exchange columns, respectively.[80,81]

In hydrophobic interaction chromatography, proteins are separated based on the favorability of their interaction with the hydrophobic side chains (phenyl, octyl, or butyl) that protrude from the stationary beads.[82] Exposure of the hydrophobic regions on the protein surface, for immobilization onto the matrix, is achieved by initially applying high-ionic-strength salts (e.g., ammonium sulfate) that promote the dissipation of water from the solvation layer around a protein. More hydrophobic proteins require less salt to promote binding. Therefore, the elution of proteins with increasing hydrophobicity is achieved by applying salt solutions of decreasing ionic strength or concentration.[83]

Size-based protein fractionation by size-exclusion chromatography utilizes an inert but porous matrix.[84,85] Smaller molecules infiltrate the pores more easily, and therefore have longer retention times in the column. Commercially available beads are commonly fabricated from polysaccharides (dextran, agarose, or acrylamide), with cross-linking densities tailored to produce pore sizes that are suitable for the fractionation of molecules of molecular weight ranging from a few to several thousand kilodaltons.

Ordinary column chromatography often suffers from matrix dyshomogeneities, causing uneven solvent flow which in turn limits the resolution of separation. Furthermore, flow rates are intentionally kept low (about one column volume per hour) to achieve sufficient equilibration between the protein solutes and the matrix. A newer chromatography technique, referred to as high-performance liquid chromatography (HPLC), affords much higher resolution by making use of smaller (3–10 μm in diameter) particles that are tightly packed, using a special apparatus, into a stainless steel column.[86] Aided by an elaborate system of pumps and valves, high external pressure is applied to the column to achieve rapid flow rates (about one column volume per minute). By virtue of the small matrix particle size, sufficient solute equilibration in an HPLC column is achievable in spite of the high flow rates. Depending on the nature of the matrix particles, HPLC can be categorized into three separation modes – adsorption chromatography (analogous to hydrophobic interaction chromatography), ion-exchange chromatography, and size-exclusion chromatography.

Common to all of the aforementioned chromatographic methods is an initial capture step which is followed by a gradual retention and elution of the target protein. Given the complex composition of the cell lysate, multiple passages through the column or serial purification through several column types may be necessary to achieve satisfactory purity. These time-intensive procedures typically recover only 50% of the starting material.[87] To sidestep this limitation, systems that take advantage of binding interactions to specific matrix-immobilized ligands have been developed, which give over 90% yield, in a few or even a single column passage. Collectively, these procedures are referred to as affinity chromatography.[88,89]

By recombinant DNA technology, molecular tags exhibiting affinity to their respective ligands can be directly encoded into the plasmid vector, as a fusion to the protein of interest. This way, virtually any recombinant protein can be purified without *a priori* knowledge of its physiochemical properties. Thanks to their size and proteolytic stability, several purification tags impart an additional benefit of increasing the solubility and/or expression of the heterologous protein.[90] Examples of commercially available affinity tags are maltose-binding protein,[91] glutathione *S*-transferase,[92] thioredoxin,[93] cellulose-binding domain, and biotin carboxyl carrier protein,[94] as well as shorter peptide tags such as polyhistidine,[95] S-peptide,[96] and FLAG™ peptide.[29]

For many clinical applications, it is imperative that the affinity tags be removed postpurification because they may prompt unwelcomed effects such as immune response activation. Tag removal is usually achieved by inserting a specific cleavage site between the target protein and the purification tag, and proteolysis is performed either enzymatically (e.g., enterokinase, thrombin)[87] or chemically (e.g., cyanogen bromide cleavage at methionine).[97] A brief summary of affinity chromatography purification tags and tag removal systems is given in **Table 2**.

Affinity chromatography generally allows efficient one-step isolation of a recombinant protein from the cell lysate. Performing orthogonal chromatography modes in succession can further increase purity, although, inevitably, at the expense of increased time and cost.

2.203.3.2.2. Batch phase separation

While invaluable for laboratory-scale purification, column chromatography techniques can rapidly become time- and cost-prohibitive at the final preparative scale-up stage. To facilitate economical and scalable purification, a common strategy is to exploit the differential dependence of the proteins' phase properties on controllable environmental parameters (e.g., temperature or solvent quality). One such example is the reversible lower critical solution temperature (LCST) transition, which is exploited in the purification of recombinant elastin-like polypeptides (ELPs).[48] Below their LCST, ELPs are soluble in water. Unlike most proteins, however, the hydrophobic nature of the ELP peptide sequence favors their desolvation as temperature increases above the LCST, resulting in the aggregation of the protein polymers into an insoluble phase.

This LCST transition of ELPs has made them useful as fusion tags for the purification of recombinant proteins. The exact length and composition of the ELP sequence can be tailored to yield an LCST of about 37 °C, such that the ELP

fusion protein would remain soluble during culture in *E. coli* but precipitate rapidly upon a mild temperature shift. Through alternating cycles of hot (35–45 °C) and cold (4 °C) centrifugation, as well as modulation of extrinsic solvent parameters such as ionic strength, the ELP fusion proteins have been successfully purified from the *E. coli* host contaminants in a scalable, completely nonchromatographic procedure.[9] Modifications to the procedure have allowed ELPs to be used as efficient purification tags for numerous target proteins. Recently, a self-cleaving element derived from the bacterial intein protein has been inserted between the ELP tag and the target protein to facilitate nonenzymatic tag removal.[98] Mild shifts in pH and temperature trigger a rapid C-terminal splicing of the intein element, upon which the tag can be removed by a final thermal precipitation step to yield a pure, unmodified target.

Apart from temperature cycling, ion-based precipitation cycles have also been explored for nonchromatographic protein purification. Such methods rely on the Ca^{2+}-binding affinity of the annexin B1 tag, which allows the annexin B1-intein-target fusion proteins to be selectively precipitated from the solution at 20 mM Ca^{2+}, and the tag subsequently removed by the self-catalytic cleavage of the intein moiety.[99]

2.203.3.2.3. Lipopolysaccharide removal

Other nonproteinaceous host contaminants that are toxic and immunogenic must be eliminated from recombinant protein preparations that are intended for implantable therapeutics. Used as a major workhorse in recombinant technology, *E. coli* provides an easy and economical means of protein production, but may also require an additional purification step due to the presence of lipopolysaccharides (LPS, also known as endotoxins). Common to all Gram-negative bacteria, LPS are an integral part of the outer cell membrane, and occupy up to three-quarters of the bacterial cell surface.[100] Hence, endotoxins are present at high levels in the crude cell lysate and remain a concern even after the removal of contaminating host proteins because even minute quantities in the bloodstream can be lethal.

An LPS molecule is composed of a hydrophilic polysaccharide moiety covalently linked to Lipid A, a hydrophobic moiety that is responsible for the biological toxicity of endotoxins. Individual LPS molecules carry a negative charge at neutral pH and have molecular weights ranging from 10 to 20 kDa, although they tend to self-assemble into 1000 kDa aggregates.[101] Relative to proteins, LPS are highly heat- and pH-stable, and thus cannot be inactivated without also inducing protein denaturation.

By taking advantage of the net negative charge on LPS, endotoxins can be eliminated by anionic-exchange chromatography, although only positively charged target proteins can be simultaneously purified without incurring significant material loss.[102] A more generic method is based on the binding affinity of lipid A to polymyxin B, a peptide antibiotic that can be immobilized on sepharose resin to facilitate endotoxin removal by affinity column chromatography.[103] The success of chromatographic methods relies not only upon the differential affinity between the endotoxin and the target protein for the chromatography matrix, but also on the affinity of the endotoxin for the protein. As a result, it is a common practice to dissociate LPS–protein complexes with surfactants (e.g., alkanediol) prior to chromatographic separation.[104] Pioneered by the pharmaceutical industry, other techniques, including ultrafiltration, phase separation, and adsorption, have been developed to remove endotoxins without compromising the properties of the target protein.[105]

2.203.4. Postsynthesis Materials Processing

Eliciting appropriate biological responses often serves as a yardstick by which the success of an engineered biomaterial scaffold is measured. In turn, signal transduction to cells is significantly influenced by the nano- and microscale scaffold architecture presented at the cell–material interface.[106] Following purification, the engineered proteins are then self-assembled or chemically cross-linked to create a bulk biomaterial scaffold. These straightforward processes have produced porous materials with robust mechanical properties, but they usually result in amorphous 3D morphologies. While a recapitulation of the natural structural hierarchy of the ECM can be achieved to a certain extent by the self-assembly of engineered polypeptides into fibrillar structures, these bottom-up supramolecular assembly strategies are only applicable to specific classes of polypeptides, (e.g., helical,[50] beta-structured,[107] and amphiphilic[108]), and are incapable of supporting complex structural specifications at a length or scale that is appropriate for tissue-level organization. Additionally, nutrient perfusion and mass transport limitations (especially oxygen diffusion) render constructs larger than a few hundred micrometers pragmatically ineffective.[109] In view of these considerations, postsynthesis processing of simple porous scaffolds into intricate micro- and nanoscale structures naturally becomes an integral part of the fabrication of protein-engineered biomaterials. Similar to other polymeric materials, protein-engineered biomaterials can be processed by methods such as electrospinning, nano- or micromolding, and photopatterning. However, owing to the sensitivity of proteins to heat and pH-induced denaturation, extreme processing parameters should be avoided when working with protein-based biomaterials.

Electrospinning is one of the most straightforward and versatile tools for processing a wide variety of polymeric materials (melts or solutions; natural or synthetic) into fibrillar threads.[110] The basic setup consists of a high voltage power supply, a spinneret (a polymer reservoir, usually assembled by fitting a blunt tip needle to a syringe), a syringe pump, and a grounded collector. The polymer sample is initially held by surface tension at the tip of the spinneret. Subsequent delivery of high electric potential induces a mutually repulsive charge on the chains, causing the hemispherical liquid meniscus to morph into a conical shape known as the Taylor cone. At a critical electric potential value, where the repulsive electric force exceeds the surface tension, a charged jet of polymer solution or melt is ejected from the tip of the spinneret toward a grounded target. During its flight, the jet undergoes a whipping process, where incipient fibers begin to elongate due to electrostatic repulsion between the fiber segments. Concomitant solvent evaporation results in deposits of dry polymer fibers that range from 50 nm to 10 μm in diameter. A plethora of protein polymers such as collagen,[111] tropoelastin,[112] and silk[113] have been electrospun into continuous, high

surface area-to-volume ratio, and porous, fibrillar, matrices reminiscent of natural ECM morphologies. By adjusting parameters such as polymer molecular weight, solution viscosity, electric potential, flow rate, and collection geometry, scaffolds of various shapes, fiber orientations, and mechanical properties have been created to meet the specifications for various soft-tissue engineering applications including skin, blood vessel, tendon/ligament, cardiac patch, nerve, and skeletal muscle.[114]

Borrowing concepts from microelectronics, rapid prototyping of various micro- and nanomolded biomaterials has been propelled by the advent of lithographic techniques, particularly soft lithography, which refers to the fabrication of patterned copies using a poly(dimethylsiloxane) (PDMS) device.[115] Since its inception, several variants of the soft lithography technique have been described. These include microcontact printing (μCP),[116] replica molding (REM),[117] microtransfer molding,[118] and solvent-assisted micromolding (SAMIM).[119] Without going into the operational details, the core of these techniques can be reduced to four general steps: (1) pattern design, (2) fabrication of a topologically patterned master, (3) high-fidelity pattern transfer from a master to an elastomeric device, and (4) pattern transfer from the device to a biomaterial by printing, molding, or embossing.[120] The utility of micro- and nanomolded surface patterns in tissue engineering has been demonstrated through, for instance, the ability to align cardiac myofibers[121] and to control stem cell morphology and differentiation.[122] Although current examples are historically dominated by synthetic biomaterials, micro- and nanomolding technologies are rapidly making headway into the burgeoning field of protein biomaterials.

Optical techniques such as surface photolithography and two-photon laser scanning lithography represent another emerging class of microfabrication technology. Photopatterning hinges upon the base material's intrinsic amenability to photopolymerization or photoablation, and the ability to incorporate noncanonical amino acids into recombinantly expressed proteins has enabled the introduction of photoreactivity into protein biomaterials. For example, *para*-azidophenylalanine ($p$$N_3$Phe), a photosensitive noncanonical amino acid, was engineered into elastin-like materials to create a family of photo-cross-linkable artificial ECM films that could be surface-patterned by photolithographic techniques.[24] Through surface patterning, researchers have gleaned tremendous insight into cellular behavior when grown on biomimetic substrates. However, a complete understanding of the cellular spatial sensitivity requires complex 3D geometry, which cannot be manufactured by conventional single-mask photolithography. Layer-by-layer fabrication, which forms the basis of stereolithography, is typically required to construct patterns in 3D. Recently, dynamic mask projection stereolithography has been used in conjunction with photoactive $p$$N_3$Phe amino acids to create 3D landscapes and user-defined curvatures on elastin-based cell culture substrates.[123]

The freedom to inscribe arbitrarily shaped microstructures within a bulk substrate is also possible through photo-cross-linking or photoablation by two-photon lithography, which capitalizes on a confocal laser scanning microscope being able to deliver finely focused photons onto micron-scale focal volumes. Along the optical path, the laser focal point is the only location where the two photons converge. Therefore, photoreactive processes that are energetically driven by the simultaneous absorption of two finely focused photons are confined to the focal volume, leaving the out-of-focus regions unaltered.[124] Benefiting from this strategy, complex nerve guidance microchannels have been successfully photoablated within PEGylated-fibrinogen hydrogels to direct the outgrowth of neurites from the dorsal root ganglia.[125] Supported by their compatibility with protein materials and the geometric flexibility they afford, two-photon lithography techniques are being foreseen to be powerful tools in the 3D patterning of new protein-engineered biomaterials.

The emergence of new micro- and nanofabrication technologies is continually offering exciting opportunities for the design of biomaterial scaffolds with increasing levels of geometric and functional intricacies. The brief descriptions outlined above are meant to briefly acquaint those who are new to the field. For in-depth discussion of how such fabrication technologies are applied in tissue engineering, the reader is encouraged to consult several excellent reviews.[126–128]

2.203.5. Characterization

In order to confirm the correct synthesis of the desired material, assure batch-to-batch consistency, and assess the performance of the material, which ultimately dictates the final biological outcome, the development of novel biomaterials has to culminate in a systematic characterization scheme. At the most fundamental level, the desired chemical composition and domain functionality of the protein, which originally motivated the design considerations, must be verified. Next, postfabrication material properties such as mechanical behavior and degradation profiles have to be characterized. In addition, since cell migration and nutrient diffusion through the material are paramount to successful engraftment, an investigation of the surface properties and morphological features is integral to the series of material characterization tests. Protein-engineered biomaterials are created through an interdisciplinary convergence of protein engineering and materials science. Consequently, characterization of these materials invokes a battery of tests commonly employed in biochemistry and polymer science. Discussed in detail below are assays that investigate the composition, purity, and molecular characteristics of the target proteins, as well as the mechanical properties and mesoscopic structures of the resulting bulk materials (**Figure 3**). Downstream biological responses such as cell adhesion, migration, proliferation, and gene expression, since cells are seeded upon or within protein-engineered biomaterials, are characterized using standard *in vitro* assays described elsewhere in this textbook.

2.203.5.1. Molecular Structure Details

2.203.5.1.1. Protein sequence and composition

DNA sequencing and amino acid analysis are two methods of confirming the proper oligonucleotide sequence of the DNA template and the chemical composition of the resulting target protein. For materials that have been rationally designed and built from ground up, confirming that the components have been created as they were designed is an essential first step in

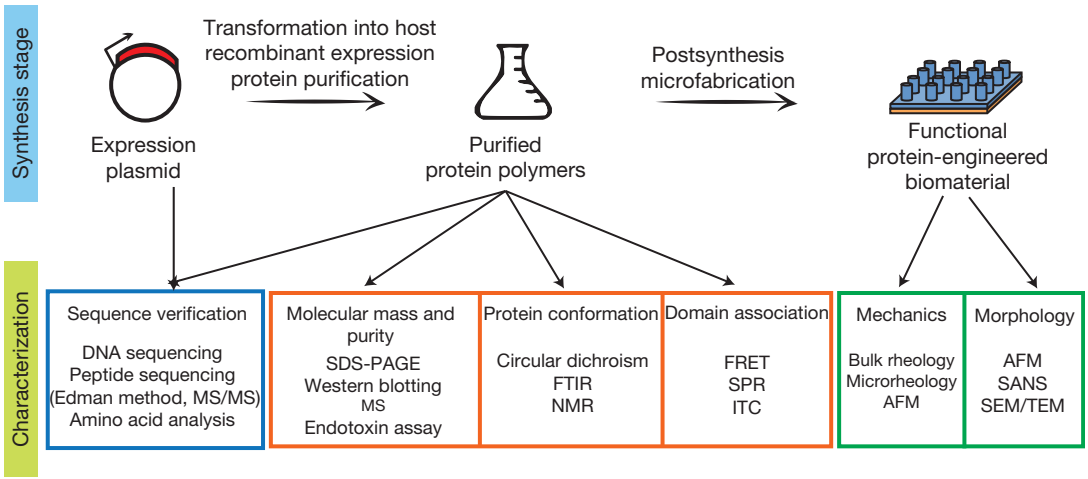

Figure 3 Flowchart for the analysis of protein-engineered biomaterials. Characterization tools are categorized according to the corresponding synthesis steps, beginning with verification of the chemical compositions, structural and functional analysis of the peptide modules, and finally mechanical and morphological characterizations of the fabricated biomaterial. This suite of material characterizations is followed by a series of *in vitro* and *in vivo* studies to determine the biological outcome of the engineered material.

their characterization. Today, DNA sequencing is performed routinely for a small fee by commercial companies, using a modified version of the chain-terminating DNA sequencing method developed in the 1970s.[129] In this technique, the DNA sample is replicated in the presence of standard nucleotides and a small amount of fluorescently labeled chain-terminating nucleotide analogs. Termination of DNA replication by the incorporation of these analogs produces new DNA fragments that are truncated at different points along the template. These fragments are subsequently size-separated by capillary electrophoresis, with the shortest sequence moving the fastest, and thus the furthest. By tracking the fluorescence signals as the DNA pieces migrate along the capillary, the sequence of the parent DNA can be deduced.

DNA sequencing is routinely coupled with amino acid analysis, which focuses on the downstream protein product. Unlike DNA sequencing, which reveals the exact nucleotide sequence, amino acid analysis gives the quantity of each amino acid that is incorporated into the full-length protein. In this process, the protein sample is first acid-hydrolyzed to release the individual amino acid residues, which are then derivatized with chromophores to facilitate their detection when subsequently separated in an HPLC system.[130] Buffers of increasing pH are fed into the HPLC column, and individual amino acids are eluted as the pH reaches their respective isoelectric points. The quantity of each eluted amino acid is determined either by comparing its average retention time and absorbance to that of an internal standard, or through the addition of a colorimetric reagent whose color change exhibits a dependence on the amino acid concentration.

Direct determination of the amino acid sequence of a protein is made possible without the knowledge of the encoding DNA through Edman degradation, and more recently, through mass spectrometry (MS). In Edman degradation, the polypeptide chain is recursively subjected to three chemical reactions. First, the N-terminal residue is reacted with phenylisothiocyanate (PITC) before it is cleaved from the polypeptide by acid hydrolysis in the second step. The resulting free amino acid residue, now existing as a cyclic phenylthiohydantoin (PTH) derivative, is then identified by chromatography or electrophoresis. The procedure is repeated with the shortened polypeptide to identify the next amino acid in the sequence.[131] Reliable sequence determination by Edman degradation can only be obtained with polypeptide chains shorter than 50 residues because such N-terminal cleavage is not 100% efficient. Thus, longer peptides are often first digested into shorter fragments using endopeptidases such as trypsin and pepsin, which cleave the proteins at distinct sites. Following sequencing by Edman degradation, the fragments are overlapped to reconstruct the full-length sequence.

Facilitated by increasing computing power and access to bioinformatics, MS has recently become the method of choice for rapid protein identification.[132] As discussed in the next section, MS analysis can be utilized to sequence amino acids under certain circumstances.[133]

2.203.5.1.2. Molecular mass and purity

Owing to the repetitive nature of engineered protein polymers, molecular weight characterization is often performed in conjunction with amino acid analysis to verify the correct length and composition of the engineered protein. The molecular weight of purified proteins is routinely characterized through polyacrylamide gel electrophoresis (PAGE), either under native or denaturing conditions.[134] Both methods rely on the electrophoretic mobility of proteins through a polyacrylamide gel as they are subjected to an electric field. Under denaturing conditions, the sample is first incubated with sodium dodecyl sulfate (SDS), an anionic detergent that disrupts noncovalently held secondary and tertiary structures, and imparts a negative charge to each protein with nearly identical charge to mass ratio. Reducing agents such as β-mercaptoethanol are often used in conjunction with SDS to eliminate disulfide linkages. In this protocol (also known as SDS-PAGE), proteins will migrate to the positive electrode at different rates and separate according to their molecular weights. In contrast, a native PAGE is run in the absence of SDS, which therefore retains protein structure. As the

individual protein conformation and charge are preserved, migration rates vary according to the hydrodynamic size and intrinsic charge of the protein at the pH of the running buffer. While not indicative of molecular weights, native PAGE is a valuable tool for studying conformation, self-association, and ligand binding. Following electrophoresis, the gel is treated with protein stains such as Coomassie Blue to identify the location of the resolved proteins. In the case of SDS-PAGE, the size of the target protein is determined by visual comparison to a protein ladder of known molecular weights.

Besides molecular weight, PAGE is often used detect protein impurities, which appear as extraneous bands on the gel. Furthermore, due to its resolving power, PAGE also constitutes the first step in immunoblotting (or western blotting), an assay that confirms a protein's identity through antibody detection.[134] For western blotting, following gel electrophoresis, proteins are transferred from the gel onto a nitrocellulose or polyvinylidene difluoride (PVDF) membrane, whereupon the membrane is treated with a dilute solution of inexpensive proteins such as bovine serum albumin (BSA) or skim milk to preemptively block nonspecific interactions between the membrane and the antibody. In the final step, the membrane is incubated with the respective antibody, which is typically linked to a reporter (e.g., a fluorescent label or an enzyme that catalyzes a colorimetric or chemiluminescent reaction) to allow detection.

More quantitative mass determination is usually achieved by MS, which begins with sample ionization, followed by acceleration and detection of the resulting ions. Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) MS is commonly used for studying macromolecules such as proteins.[135] Here, the sample is mixed with an organic solvent and dried on a metal target, which is then blasted with a laser to ionize the constituent peptides into charged gas molecules. The charged molecules are then accelerated in an electric field to a speed that is proportional to their mass to charge ratio (m/z ratio). As a molecule moves through the flight column, its retention time is recorded and used to characterize the m/z ratio, from which the exact molecular weight of the corresponding protein can be calculated. In addition to molecular weight, amino acid sequences can be deduced from a technique called tandem mass spectrometry (MS/MS). Here, the parent protein is predigested using endopeptidases into shorter peptides before being subjected to MS. Selected peaks from the resulting mass spectrum are then further cleaved and analyzed in a second round of MS. As fragmentation occurs at the peptide bond, the peptide sequence can be deduced by scoring mass differences among the fragments to identify the respective amino acids residues.[133] Sample impurities,[136] posttranslational modifications,[137] and disulfide bridges,[138] identified by the presence of uncharacteristic peaks, are other pieces of information that can be obtained by MS.

Common nonproteinaceous impurities in proteins that are produced recombinantly in Gram-negative bacteria such as *E. coli* are LPS or endotoxins. Especially, for implantable protein biomaterials, endotoxin quantities must be determined and reduced to a level that is safe for *in vivo* applications. The ceiling for acceptable endotoxin levels for intravenously introduced biologics is currently set by the United States Food and Drug Administration (FDA) at 5.0 EU per kg of body weight per hour (EU = endotoxin unit; 1 EU = 100 pg of endotoxin). To account for product-to-product dose variability, the endotoxin limit in the product is calculated as K/M, where K is 5.0 EU kg^{-1}, and M is maximum dose per kilogram that would be administered within a duration of 1 h. For example, an injected, protein-engineered drug delivery biomaterial that has a dose of 20 mg kg^{-1} must contain at most $(5.0\ \text{EU kg}^{-1})/(20\ \text{mg kg}^{-1}) = 0.25\ \text{EU mg}^{-1}$ of endotoxin. For implantable biomaterials, the endotoxin level must be below the limit for biomedical devices, which is 0.5 EU ml^{-1} of rinse volume.[139] The most popular method of endotoxin detection is the Limulus Amoebocyte Lysate (LAL) assay. Derived from the blood of horseshoe crabs (Limulus polyphemus), LAL clots upon interacting with endotoxin. Several formats of the LAL assay are commercially available, the simplest being the gel-clot assay. Here, a gel will form if the endotoxin level in the sample is above the sensitivity limit of the assay. To quantify the endotoxin level, the sample is assayed at serial dilutions until no clot formation is observed. LAL assay is also available in turbidimetric and chromogenic formats, which monitor, over time, the appearance of turbidity and a yellow color, respectively. The kinetics of turbidity and color formations, which are dependent on the amount of endotoxin, are then compared to standard curves to give accurate values of endotoxin levels in the sample.

2.203.5.1.3. Protein conformation

Despite their advantages, the previously described techniques are performed in harsh, nonnative conditions, resulting in the loss of structural information, such as folding state, which prescribes eventual protein function. Accurate assessment of a protein's conformation warrants assay conditions that closely mimic the operational environment. One technique that probes protein confirmation in its native environment is circular dichroism,[140,141] which capitalizes on the chirality of proteins. As chiral molecules, proteins exhibit differential absorption of polarized light of different handedness. Classes of secondary structures such as α-helices, β-sheets, β-turns, and random coils possess distinct degrees of chirality and, consequently, interact differently with polarized light. By monitoring the spectral signatures of these interactions, probable secondary structures of a protein can be inferred. Such structural information can then be used to ascertain the correct folding state of a domain when synthesized as part of a fusion protein, thus verifying the core assumption that underlies modular protein design strategies.

The absorption of infrared light by amide bonds in the polypeptide backbone can also be used to probe the secondary structure of a protein. Characteristic amide bond absorption frequencies have been correlated with the presence of different secondary structures such as α-helices or β-sheets.[142] By mapping the absorbance spectra, as is usually done in a technique called Fourier transform infrared (FTIR) spectroscopy, one can deduce the secondary structure of a given protein. Used in combination, FTIR and circular dichroism complement each other and give more comprehensive secondary structure information.

Another native-condition structural characterization technique is nuclear magnetic resonance (NMR), which employs a strong magnetic field to induce synchronous precession of atoms in a molecule. The decay of this precession, following the removal of the magnetic field, can be measured to unveil

the molecular environment enshrouding each atom.[143] Traditionally, such information is used to sketch the identity of interatomic covalent bonds. More recently, real-time NMR techniques have also been developed which shed light on dynamic conformational changes within a protein.[144] Presently, protein tertiary structures can be elucidated directly in solution, thanks to the emergence of sophisticated 2D homonuclear and nuclear Overhauser effect NMR modalities.[145]

2.203.5.1.4. Domain association

The mechanical properties of several protein biomaterials – especially physically cross-linked materials – hinge on the association between multiple domains. For domains that are known to associate into complexes, it is important to characterize the strength of binding, the timescale of complex assembly and disassembly, as well as the influence of external factors on these associations.

Binding interactions can be characterized by using an optical technique called fluorescence resonance energy transfer (FRET),[146] where two fluorescent moieties (denoted as the donor and acceptor), with overlapping emission and excitation spectra, are attached to each of the interacting molecules. As the domains bind, the two fluorescence moieties are brought into close proximity, triggering an energy transfer from the donor to the acceptor. This energy transfer can then be detected by measuring a shift in the frequency of the fluorescence readout (i.e., from the donor to the acceptor emission wavelengths). One disadvantage of this technique is the necessity of tagging the domains of interest with fluorescent markers; this may confound the experimental results by altering domain structure or mechanism of the domain interactions.

Surface plasmon resonance (SPR) is another method of quantifying binding interactions. In an SPR experiment, the receptor protein is first immobilized onto a sensor chip (typically made of gold) that is attached to one side of a glass prism. When a beam of light strikes the prism at a certain angle, called the resonance angle, it interacts with the cloud of electrons in the metal film to generate surface plasmons, which are electromagnetic waves that propagate parallelly to the metal–glass interface. Surface plasmons are very sensitive to the environment that is proximal to the interface, such that any changes, such as the adsorption of molecules to the metal surface, would measurably affect the resonant angle. Binding measurements are performed by making the putative ligand solution flow past the sensor chip. The association of ligand molecules onto the immobilized receptor changes the resonance angle, which is monitored in real time to derive the association rate constant (k_{on}). In the subsequent buffer wash step, the dissociation rate constant (k_{off}) is measured according to how fast the ligand detaches from the receptor. The binding association constant (K_a) is calculated from the ratio of k_{on} to k_{off}. In addition, since the signal change is proportional to the mass of the immobilized complex, relative SPR readouts are indicative of binding stoichiometry. As the receptor is immobilized, however, SPR measurements may not be representative of binding interactions that occur in solution.

A more rigorous means of measuring the strength of molecular interactions, without derivatization, is isothermal titration calorimetry (ITC).[147] Unlike SPR, which is based on the kinetics of interactions, ITC measures the thermodynamic properties of binding. ITC is performed within an adiabatic system, where the putative ligand is titrated against the receptor contained within a reaction cell. As the binding event progresses, heat will be produced or absorbed, creating a temperature discrepancy between the reaction and the reference cells. The amount of energy used to equalize the temperature of the cells is directly proportional to the binding enthalpy of the reaction, which can then be used to evaluate the thermodynamics of the binding reaction. Using ITC, interaction stoichiometry (n), as well as the characteristic thermodynamic parameters such as the association constant (K_a), the binding free energy (ΔG_b), entropy (ΔS_b), and enthalpy (ΔH_b) can be determined in a single experiment.

2.203.5.2. Material Bulk Properties

2.203.5.2.1. Mechanical properties

Depending on the time scale of observation, biological polymers and hydrogels may exhibit viscous and/or elastic characteristics when undergoing deformation. This property is called viscoelasticity, and describes the time-dependent deformation response of a material to an applied load. The ideal viscoelastic properties of a biomaterial are often specified according to its intended use. For example, hydrogels used as carriers for noninvasive drug or cell delivery are tailored to be shear-thinning and self-healing in order to promote injectability. In contrast, mechanical integrity is required for materials that are to be used as scaffolds for cell culture or substrates for patterning. In addition to the end application, it is also important to consider the effects of material mechanics on cell behavior. Recent investigations have shown that scaffold stiffness is a vital determinant of gene expression, cell phenotype, and differentiation.[46,148] Mechanical-property investigations should therefore constitute an integral part of the characterization of biomaterials including, but not limited to, protein-engineered materials.

Protein-engineered viscoelasticity is most commonly explored by rheology. The theory and practical measurements of rheological properties are described in detail in several introductory books (see **Chapter 5.502, Engineering Scaffold Mechanical and Mass Transport Properties**).[149,150] In essence, rheological tests are conducted by subjecting the bulk material to deformation, and monitoring the resulting mechanical responses. Typical test modes include oscillatory shear measurement, creep, and creep recovery tests. In the oscillatory shear mode, sinusoidally oscillating shear strain (or shear stress) is applied, and the resulting shear stress (or shear strain) is measured. To ensure that the measured variables are independent of the magnitude of imposed strain or stress, deformation is generally exerted within the material's linear viscoelastic region. Critical output parameters are the shear storage modulus (G'), loss modulus (G''), and loss factor ($\tan\delta = G''/G'$), and are monitored as a function of time, frequency, temperature, or strain. G' and G'' correspondingly represent the stored and dissipated deformation energies, and are thus used to report material stiffness and flow characteristics, respectively. $G''<G'$ ($\tan\delta<1$) indicates an elastic, solid-like behavior, while $G''>G'$ ($\tan\delta>1$) indicates a liquid-like behavior. The storage modulus G' is also proportional to the hydrogel cross-linking density,[151] as discussed in **Section 2.203.2.1**. Hence, tracking G′ and G″ over time offers a convenient, nonchemical means of studying gelation and degradation kinetics.

To serve as an injectable delivery vehicle, a hydrogel must be reversibly thixotropic, that is, its viscosity must decrease under high shear and quickly rebound when the perturbation is removed. Thixotropic investigations on a rheometer typically consist of three oscillatory test intervals. The material, in its pristine state, is first measured at a small, fixed amplitude and frequency before its structure is destroyed in the second high-amplitude shear step. In the ensuing recuperation step, the recovery of the gel structure is monitored by once again measuring the sample at a small, fixed amplitude and frequency.

Viscoelastic properties can also be probed under tensile or compressive modes, in which the specimen undergoes uniaxial elongational or compressional deformation, rather than a displacement gradient across a shear gap. Operating in the tensile mode, creep and creep recovery tests are conducted in succession to unveil the long-term responses of the viscoelastic behavior of the hydrogel. Briefly, a constant stress is applied on the specimen for a stipulated duration and it is completely removed in the subsequent recovery phase. The temporal evolution of the resultant strain is recorded in both tests to gauge the permanence of the deformation.

In the field of cell biology, genetic and soluble factors are widely perceived to be the primary determinants of cell fate and function. However, a growing body of insightful research continues to shed light on the dynamic interplay among mechanics, ECM ligands, and cytoskeletal organization as being equally important regulators of cell behavior.[152] This dynamic interplay cannot be captured by the macroscopic characterization of passive scaffold properties such as stiffness and composition, because, owing to variations in cell cycle and local scaffold degradation, cellular responses to scaffold mechanics are heterogenous and are on the nanoscale. Newer methods such as tracer particle microrheology and atomic force microscopy (AFM) are now available for probing these mechanical properties at resolutions that are smaller than the size of a cell.[153]

Recent developments in particle tracking algorithms have enabled the development of a novel characterization method called microrheology, which computes rheological properties based on the measured trajectories of tracer particles.[154] In a typical setting, monodispersed, micron-sized particles are homogenously embedded and equilibrated in the test material and then tracked using video microscopy to quantify an ensemble of passive (thermally driven) particle trajectories. Local viscoelastic parameters, within the volume of interrogation, are then calculated from the power law dependence of the average particle mean-squared displacement in time:

$$\langle \Delta r^2(\tau) \rangle \sim \tau^n \qquad [2]$$

where $\langle \Delta r^2 \rangle$ is the thermal-averaged mean-squared displacement, τ is the time interval of observation, and n is a constant. By the generalized Stokes–Einstein relationship, the creep compliance of a purely elastic material ($n = 0$) can be calculated from the power law by the following relation:

$$J(\tau) = \frac{\pi a \langle r^2(\tau) \rangle}{k_B T} \qquad [3]$$

where J is creep compliance, a is particle radius, and $k_B T$ is the thermal energy. For a liquid exhibiting a purely diffusive trajectory ($n = 1$), its viscosity (η) is related to creep compliance by:

$$\eta = \frac{\tau}{J(\tau)} \qquad [4]$$

In passive microrheology, eqn [3] is used to determine the upper limit of the measurable storage modulus ($G_{max} = 1/J$) for a given particle size, microscope resolution, and camera frame rate. The observation of subdiffusive trajectories, where $0 < n < 1$ implies a viscoelastic network. Particle motion can also be driven in stiffer materials by applying external forces and is typically facilitated by a magnetic field[155] or optical tweezers.[156] These more sophisticated methods are collectively known as active microrheology.

AFM is another convenient tool for probing the local modulus with nanoscale resolution.[157] At the heart of the AFM is a cantilever equipped with a sharp tip that probes the sample surface topography. As this occurs, forces between the sample and the tip cause the cantilever to undergo deflection, which is usually detected either by laser reflection, optical interferometry, or piezoresistive sensing. Common probing modes, in decreasing order of invasiveness, are contact mode, noncontact mode, and tapping mode. Mechanical characterization is usually performed in contact mode, where the tip is in close contact with the surface. As the probe is indented into and retracted from the surface, the force versus deflection data are converted into the surface modulus by using Hooke's law and the cantilever's spring constant. Unlike microrheology, however, AFM is limited to surfaces and hence cannot be used for investigating mechanics within the interior of a material.

2.203.5.2.2. Morphological features

Properties of biomaterials, such as hydrogel swelling, mechanical stiffness, and permissivity to diffusion, are governed on the mesoscopic level by pore size and network morphology. Extending beyond these physical properties, mesoscopic structures also critically determine the ability of the construct to support cell growth and tissue integration following implantation. For example, a study with poly(2-hydroxyethyl methacrylate) (PHEMA) has shown that angiogenesis and the maintenance of vascular ingrowth requires interconnected pores with a diameter comparable to the size of a cell ($\sim$10 μm).[146] Interesting insights can therefore be extracted by visualizing and characterizing such mesoscopic structures.

AFM, as discussed above in the mechanical characterization section, can also be used to visualize local molecular structures with subnanometer resolution. During operation in the tapping mode, AFM produces high-resolution topographic imaging of soft materials whose structures are sensitive to mechanical disruption. In this mode, the cantilever probe tip comes in contact with the sample surface by vertically oscillating at frequency ranges that are high enough to make the viscoelastic sample behave elastically. Stiff and elastic surfaces prevent sample disruption by eliminating tip-sample adhesion. Also, a unique strength of AFM imaging is its ability to investigate the sample in ambient air or liquid environments without the need for special treatment protocols.[158] An example of the topographical characterization of protein biomaterials by AFM is shown in **Figure 4**, revealing degradation pits on surface-patterned silk films due to MMP-mediated cleavage by osteogenic cells.[159]

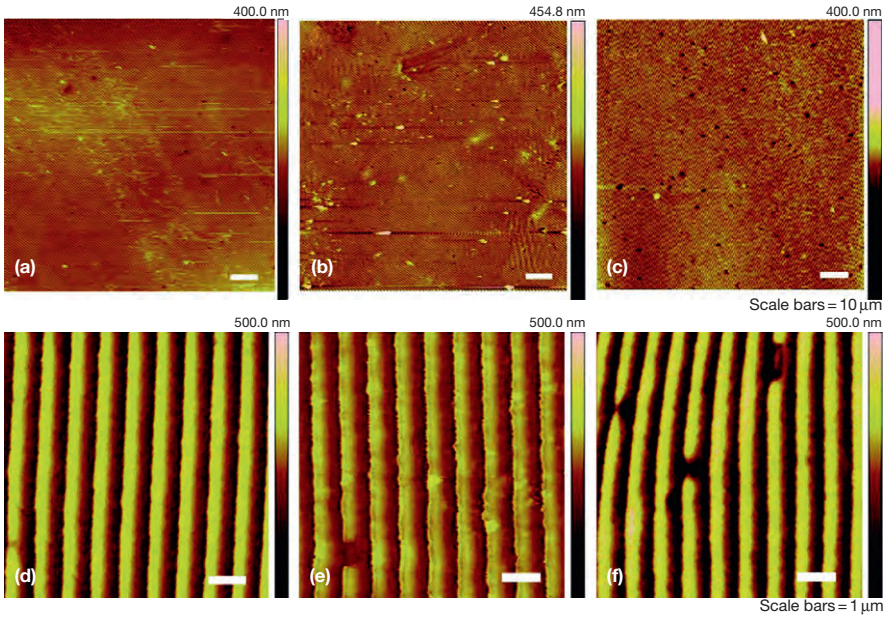

Figure 4 AFM images of degradation pits on patterned silk films caused by negative controls (a and d), osteoblasts (b and e), and osteoclasts (c and f). Scan size = 100 μm, scale bars = 10 μm (a to c); scan size = 10 μm, scale bars = 1 μm (d to f). Reprinted with permission from Sengupta, S.; Park, S. H.; Seok, G. E.; *et al*. *Biomacromolecules* **2010**, *11*, 3592–3599, with permission from ACS Publications.

Advanced scattering techniques such as small-angle neutron scattering (SANS) also provide structural information on scaffolds, from the near atomic scale (~1 nm) to the near micron scale.[160] Using Fourier transform, scattering information from the reciprocal space is fit, using different form factors, to give information on the morphology of the network. Particularly valuable for hydrogel characterization is the use of ultra-SANS (USANS), which extends the range of length scale to well beyond 10 μm.[161] Performed in ambient conditions, SANS measurements are capable of revealing real-time structure evolution, thus providing mechanistic insight into self-assembly processes. Despite its utility, SANS experiments are not as easily accessible as the other techniques because there are only a handful of neutron scattering facilities in the world.

A millimeter-scale field of view of biomaterial morphology is commonly acquired through scanning and transmission electron microscopy (SEM and TEM).[162] In a conventional setup, the biomaterial construct is mounted on a grid and dehydrated by air- or freeze-drying to accommodate the requirement for vacuum during image acquisition. In addition, contrast-enhancing agents are often deposited on the specimen to accentuate fine features. Owing to such sample preparation protocols, the utility of electron microscopy is limited to dense and fibrous protein-based materials. For biomaterials that are hydrogels, the hydrated state is a key determinant of nanostructural morphology, and electron microscopy images obtained from dehydrated samples are not representative of the true morphology. To partially circumvent this technical limitation, hydrogels are often imaged using cryoelectron microscopy, which studies the specimen at cryogenic temperatures.[163] Once secured on the grid, the hydrogel is submerged into liquid nitrogen or liquid ethylene, upon which water in the hydrogel undergoes vitrification. Another technique is environmental SEM (ESEM), which, by operating under a saturated environment, removes the high vacuum constraints and allows even fully hydrated samples to be analyzed.[164] While these process may preserve the nanostructure of some biomaterials,[165] images acquired from hydrogels must still be interpreted with caution, as the relation between the observed structure and the truly hydrated hydrogel network can be based only on educated inference.

When implemented together, the suite of characterization techniques mentioned above affords a means of analyzing the interdependence among domain sequences, structures, self-assembly, and ultimately, scaffold morphology and bulk material mechanics. This exercise not only reinforces the underlying design rationales, but is also instrumental in spawning future design iterations.

2.203.6. Biological Interactions and Immunogenicity

The design of a highly functional protein-engineered biomaterial may prove futile if it overlooks host responses subsequent to material implantation. Knowledge of how the biomaterial construct and its degradation products modulate the host immune system is critical for the safety, biocompatibility, and ultimate function of the biomaterial. Elicitation of the foreign body innate immune response by biomaterial scaffolds is relatively well known.[166] Recently, biomaterials have also been discovered to act as adjuvants for the adaptive immune response by activating antigen-presenting cells.[167]

Owing to the recombinant expression strategy, protein-engineered biomaterials carry a potential danger of exposing xenogenic contaminants to human patients. Eukaryotic hosts such as chinese hamster ovary (CHO) cells may mediate host-to-host pathogen transfer, while prokaryotic hosts may carry antigenic cellular components. Specific to the cell wall of Gram-negative bacteria such as *E. coli* is the presence of

lipopolisaccharides that are synonymously known as endotoxins. Several endotoxin removal and detection techniques, as well as acceptable FDA limits for gram-scale implantation have been described in previous sections in this chapter. Endotoxins act by activating the innate immune system, particularly the monocytes and macrophages, which in turn release a plethora of mediators including interleukins, prostaglandins, tumor necrosis factor, colony-stimulating factor, and free radicals. These factors can result in systemic inflammatory reactions, which ultimately lead to multiple pathophysiological effects such as endotoxin shock, tissue injury, and death.[168] In light of these biological hazards, recombinant synthesis schemes must satisfy stringent purification standards, and insights from the biotechnology industry may prove instrumental in developing safe and economical protein biomaterials production protocols.

As protein biomaterials are constructed from amino acid sequences, they have the potential to activate the adaptive immune response through unwelcome antigenic effects. As a preemptive measure, the domains used in the modular design of many recombinant protein polymers are constructed from amino acid sequences that either are of human origin (e.g., laminin, fibronectin, elastin), or whose biocompatibility has been established in human recipients (e.g., silk). As part of the rational design effort, spacer sequences used to stitch multiple domains together can be chosen to be nonimmunogenic. Motivated by the vaccine therapeutics field, computational algorithms now exist, which can predict epitope-free amino acid sequences that may evade recognition by the antigen-presenting cells.[169]

Ultimately, a comprehensive evaluation of material biocompatibility requires the empirical and systematic appraisal of both the innate and the adaptive immune reactions, which typically involves a battery of laboratory and preclinical tests, before taking the leap into human clinical trials. Initial stages of *in vitro* cytotoxicity and *in vivo* animal studies on elastin-like polymers and silk fibroin have shown encouraging outcomes.[170,171] Clinical trials are currently in progress to assess the compatibility of recombinant silk–elastin polymers as spinal disc replacements in patients with early-stage degenerative spinal disc disease.[172]

2.203.7. Future Directions and Conclusions

Scientists working under the rubric of recombinantly engineered biomaterials are being presented with a multitude of challenges and opportunities – some exclusive to protein-engineered biomaterials, and others more common to the larger biomaterials community – these are continually reshaping various research endeavors in the field. Particular to protein-engineered biomaterials is the call to expand the library of peptide modules that can be used to successfully design new protein-engineered materials. Despite the wealth of domains that exist in the proteomic databases, the majority of protein-engineered biomaterial designs mainly utilize short peptide modules (<50 amino acids) that exhibit spontaneous folding and robust expression in the recombinant host. Including additional peptide modules with new functionalities is a challenging task given the restrictions in both recombinant protein synthesis machinery and chemical diversity of the 20 natural amino acids. For example, the use of bacterial hosts limits domain selections to those requiring no posttranslational modifications. Major research thrusts in recombinant DNA technology and protein engineering currently seek to overcome some of these limitations.

To illustrate the above, efforts are being directed toward the bacterial recombinant production of collagen, whose post-translational hydroxylation of specific proline residues by the enzyme prolyl 4-hydroxylase (P4H) has made biosynthesis in prokaryotic hosts extremely challenging. In one approach, trans-4-hydroxyproline (Hyp) was cotranslationally incorporated in place of proline in *E. coli* by growing the culture in hyperosmotic media supplemented with Hyp.[173] Another potential scheme is to coexpress collagen precursors with the P4H enzyme within the same bacterial cell. The success of human recombinant P4H synthesis in *E. coli* is a major step forward in the realization of this strategy.[174]

In the protein engineering field, short peptide sequences have been identified and modified to recapitulate or even outperform the activity of the larger protein domains. For example, a 9-amino acid neuroprotective peptide called ADNF-9 has been identified and shown to be more potent than the parent 14 kDa ADNF (activity-dependent neurotrophic factor) protein.[175] Through combinatorial mutations and yeast surface display, 11-amino acid peptide sequences containing an RGD motif have been developed which bind to both $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins with high affinity.[176] Thanks to such developments, it may no longer be necessary to include the full-length protein sequence in modular protein-engineered biomaterial design, thus circumventing the challenges associated with complicated folding requirements.

In recent years, the ability to genetically encode noncanonical amino acids has endowed recombinant proteins with functionalities that were previously unavailable in natural proteins. Nonbiological moieties such as halogenated, photoactive, and unsaturated amino acid analogs have been incorporated into recombinant proteins to stabilize collagen-[173] and ELP polymers,[177] enable photo-cross-linking of leucine zipper–elastin fusions,[178] and allow the orthogonal chemical tethering through copper-catalyzed click reactions.[179] The variety of noncanonical amino acids, methods for their incorporation, as well as examples in protein polymer design have been discussed in great depth in several review articles.[180,181]

As the field matures, creativity in modular protein design has spawned an array of novel recombinant protein-engineered biomaterials whose functions extend beyond just acting as ECM scaffold mimics. Fusing organophosphate hydrolase to the leucine zipper domain has produced self-assembling catalytic hydrogels, which are intended for the detection, bioremediation, and prophylactic decontamination of organophosphate neurotoxins, a potent class of chemical weapons.[182] In drug delivery, the fusion of a cell-penetrating peptide and a cell-cycle inhibitory domain was tagged with an elastin-like polypeptide (ELP) to create a thermally responsive drug that targeted solid tumors via localized hyperthermia.[182] These examples demonstrate the inherent value in continuing to expand the library of peptide domains that can be designed into functional biomaterials.

In a relatively brief span of two decades, protein-engineered biomaterials have emerged at the forefront of regenerative

medicine. Endowed with highly tunable mechanical properties, diverse biochemical functionalities, and controllable degradation profiles, this new class of biomaterials offers excellent scaffolds for tissue engineering, versatile platforms for studying cell–microenvironment interactions, and exciting opportunities to design functional biomaterials for complex medical and biotechnological applications.

Glossary

Antifouling agent An antifouling agent prevents undesirable accumulation of microorganisms on wetted surfaces.

Antimicrobial peptoids Antimicrobial peptoids are designed to mimic antimicrobial peptides. Typical antimicrobial peptoids are cationic and facially amphipathic.

Chemoselectivity Chemoselectivity refers to the selective reactivity of one functional group in the presence of others.
Foldamer A polymer or an oligomer that adopts a secondary structure stabilized by noncovalent interactions.
Glycopeptoids Glycopeptoids are peptoids that contain carbohydrate moieties covalently attached to the side chains of the peptoid residues.
Heteropolymers A polymer comprising two or more monomers that are different from one another is called heteropolymer.
Lipitoids Conjugates of cationic lipids and peptoids are called lipitoids.
Peptidomimetics A peptidomimetic is a compound that is designed to mimic a biologically active peptide, but has structural differences that give advantages for its function.
Peptoid A class of peptidomimetic polymers, whose side chains are appended to the nitrogen atom of the peptide backbone rather than to the α-carbon. They are also called poly(*N*-substituted glycines).
Peptoid helix Peptoids fold into helical secondary structures by the incorporation of bulky chiral side chains. Unlike peptide helices, peptoid helices result from the repeating local steric influence of the side chain which restricts backbone rotation.
Peptoid nanosheet Amphiphilic periodic peptoids self-assemble to form well-defined 2D sheet architecture. The free-floating sheets have a thickness of 2.7 nm.
Submonomer synthesis An efficient solid-phase synthesis method to generate peptoids from simple starting materials. Instead of using monomers, two 'submonomers' are successively incorporated to form a monomer unit.

Abbreviation

AMP	Antimicrobial peptide
Apaf	Apoptotic protease activating factor
Boc	*N*-*tert*-butoxycarbonyl
BSL-2	Biosafety level 2
CD	Circular dichroism
CE	Capillary electrophoresis
CPP	Cell-penetrating peptides
DIC	*N*,*N*′-diisopropylcarbodiimide
DMF	*N*,*N*-dimethylformamide
DMPE	Dimyristoyl phosphatidyl-ethanolamine
DOPA	3,4-Dihydroxyphenylalanine
EPM	Equimolar peptide mixtures
Fmoc	Fluorenylmethyloxycarbonyl
GlcNAc	*N*-acetylglucosamine
GPCR	G-protein coupled receptor
HDM	Human double minute
HPLC	High performance liquid chromatography
HTS	High-throughput screening
Hyp	Hydroxyproline
IC_{50}	Half maximal inhibitory concentration
K_d	Dissociation constant
LC	Liquid chromatography
MAOS	Microwave-assisted organic synthesis
MBNL	Muscleblind protein
MeNPOC	(*R*,*S*)-1-[3,4-[methylene-dioxy]-6-nitrophenyl]ethyl chloroformate
MHC	Major histocompatibility complex
MIC	Minimal inhibitory concentration
MS	Mass spectrometry
NaOAc	Sodium acetate
NCA	*N*-substituted carboxyanhydrides
NHC	*N*-heterocyclic carbenes
NLeu	*N*-isobutylglycine
NLys	*N*-(4-aminobutyl)glycine
NMDA	*N*-methyl-D-aspartate
Nme (or Nmeg)	*N*-(2-methoxyethyl)glycine
NMR	Nuclear magnetic resonance spectroscopy
Nspe	(*S*)-*N*-(1-phenylethyl)glycine
OBOC	One-bead-one-compound
PITC	Phenylisothiocyanate
PMC	2,2,5,7,8-Pentamethylchromane-6-sulfonyl
PTC	Phenylisocyanate
PyBOP	Benzotriazol-1-yloxytris(pyrrolidino) phosphonium hexafluorophosphate
PyBrOP	Bromotris(pyrrolidino)phosphonium hexafluorophosphate
QD	Quantum dot
ROP	Ring opening polymerization
SDS	Sodium dodecyl sulfate
SH3	SRC (sarcoma) homology 3
SP	Surfactant proteins
TEMPO	2,2,6,6-Tetramethylpiperidine-1-oxyl
TM	Transmembrane
UPLC	Ultra performance liquid chromatography
VEGFR	Vascular endothelial growth factor receptor
VR	Vanilloid receptor

2.204.1. Introduction

2.204.1.1. Bioinspired Polymers

Sequence-specific heteropolymers are growing in importance as useful tools in chemical biology, drug discovery/delivery, and materials science. Recent advances in synthetic chemistry have made it possible to generate relatively simple protein-like structures and functions from nonbiological synthetic heteropolymers. Many of these synthetic heteropolymers are stable to biological proteases and extreme environments such as high temperatures and harsh chemical conditions. Further, they can be assembled in high yields from relatively cheap building blocks. Proteins are marginally stable; they are easily degraded by biological proteases and denatured by various chemicals

and high temperatures. Thus, there is a great opportunity to develop a new class of protein–mimetic polymers that are capable of molecular recognition and catalysis and yet are highly robust to the environment. The unusual stability properties and synthetic versatility of synthetic sequence-specific heteropolymers provide great promise for such materials and will have great impact in therapeutic, diagnostic, and materials science applications.

Researchers are making progress toward creating synthetic polymers that mimic the sophisticated structures and functions of proteins, although no synthetic polymer currently has the capacity to perform complex biological functions such as selective molecular recognition, catalysis, transport, energy conversion, etc. It has been difficult to find a single polymer system in which one can achieve stable secondary structures, sequence diversity, and long main chain lengths. It has been only the past decade since researchers have begun to mimic protein-like tertiary structures and functions.

The creation of new synthetic heteropolymers has been inspired and guided by protein folding and design principles. Advances in synthetic, combinatorial, and physical chemistry have provided a variety of useful tools to create folded protein–mimetic polymers where a variety of functionalized monomers can be arranged in a particular sequence. However, despite decades of study, the rules that govern the kinetics and thermodynamics of folding polymer chains into stable tertiary structures are not yet fully understood. Energetically, the dominant forces that drive folding of polymer chains in aqueous solution are well known,[1] and this has been useful for the design of new foldable polymer sequences. Still it has been difficult to understand the atomic structural details of the molecular interactions that drive unique and stable tertiary structures. Synthetic heteropolymers that allow detailed control of molecular interactions would help to understand folding principles on an entirely new level.

This chapter will focus on peptoids (*N*-substituted glycine polymers), one of several in the class of sequence-specific synthetic heteropolymers. Readers can find many comprehensive reviews regarding other synthetic heteropolymers.[2–4] Ever since peptoids first found utility in drug discovery,[5] many new areas of peptoid research have recently emerged as a result of their many useful properties. New structural motifs and design principles have emerged. Peptoids offer great new opportunities to create protein-like tertiary structures and functions. Peptoid polymers that spontaneously organize into well-defined supramolecular nanostructures are a promising new platform in materials science.

2.204.1.2. Properties of Peptoids as Useful Biomaterials

Peptoids are *N*-substituted glycine polymers in which the side chains are appended to the backbone nitrogen (**Figure 1**). This *N*-substitution in peptoids precludes the intra-backbone hydrogen bonding that is found in proteins, providing us the opportunity to explore polymer properties and chain folding in the absence of backbone hydrogen bonding.

Peptoids are efficiently synthesized using a solid-phase synthesis. Using the solid-phase submonomer method that we developed, 48-mer polypeptoids have been synthesized in excellent yields.[6] In terms of sequence diversity, over 300

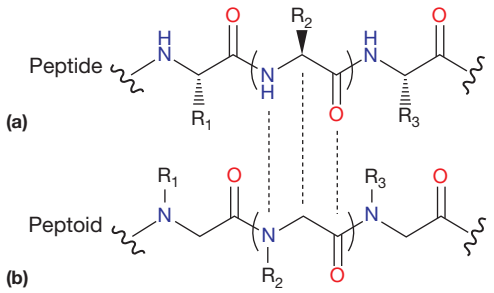

Figure 1 The comparision of (a) peptide and (b) peptoid.

primary amines are currently available that can be incorporated into peptoids as side chains. Thus, the diversity of peptoid side chains is much greater than that found in proteins.

Peptoids as short as 5-mers have been shown to adopt helical conformations when they contain chiral side chains adjacent to the main chain nitrogen.[7,8] These peptoid helical structures showed extreme stability to chemical denaturants and temperature.[9] The peptoids have been also shown to be stable to proteolysis,[10,11] opening the door to therapeutic, diagnostic, and biomaterials applications. Numerous short peptoid oligomers have been found that bind to therapeutically relevant proteins, acting as antagonists, inhibitors, or activators.[12] In this chapter, many of these useful features and examples will be discussed.

2.204.2. Synthesis

2.204.2.1. Solid-Phase Synthesis

Originally standard peptide solid-phase synthesis techniques were utilized for peptoid synthesis using Fmoc-protected *N*-substituted glycine monomers (**Figure 2(b)**).[5] This monomeric method involves tertiary amide bond formation between the existing secondary amine on the resin and the incoming monomer by the activation of carboxyl group in the monomer using benzotriazol-1-yloxytris(pyrrolidino) phosphonium hexafluorophosphate (PyBOP) or bromotris (pyrrolidino)phosphonium hexafluorophosphate (PyBroP). Then, the Fmoc group is deprotected with piperidine, generating a secondary amine for next amide coupling. This monomeric peptoid synthesis requires labor-intensive synthesis of Fmoc-protected *N*-substituted glycine monomers.

The invention of the submonomer solid-phase synthesis method for peptoids in 1992 was a major breakthrough because it greatly increased the synthetic efficiency, synthesis yields, and available side chain diversity, while also dramatically reducing time and costs.[6] As shown in **Figure 2(a)**, a secondary amine on the resin is first acylated by an activated haloacetic acid, such as bromoacetic acid, with *N*,*N*-diisopropylcarbodiimide (DIC). Then the bromine is displaced by a primary amine. In this S_N2 reaction, ~300 commercially available primary amines can be added, expanding the diversity and convenience of introducing side chains. Moreover, many new submonomers have been synthesized and incorporated into peptoids. These include *N*-BOC-tryptamine, *O*-*t*-butyl tyramine, and PMC-guanidino-propylamine to mimic natural amino acids tryptophan, tyrosine, and arginine.[13] In addition, carboxamide, carboxylic acid, and thiol derivatives of (*S*)-1-phenylethylamine

were synthesized to introduce a helical structure decorated with chemical functionalities.[14] A variety of chemoselective conjugation groups such as thiol, activated disulfides, aldehyde, aminooxy, and hydrazine groups have been also incorporated into peptoids via N- and C-terminal modification or the submonomer method that allowed an efficient ligation between peptoids.[15] Recently, amine derivatives of heterocycles such as histamine, pyridine and tryptamine were successfully incorporated into peptoids using chloroacetic acid in the acylation step.[16] Conformationally constrained cyclic peptoids can also be synthesized using the submonomer method, followed by solution-phase cyclization.[17] The submonomer synthesis is still widely used for peptoid synthesis.

2.204.2.2. Solution-Phase Synthesis

There are a couple of methods for making peptoids completely in solution as shown in **Figure 2(c)**. So far, the lengths of sequences made by this method are limited to <10 residues. One of the solution-phase peptoid syntheses is a submonomeric method using bromoacetylbromide.[18] The first step is the acylation reaction of the N-terminus of the existing peptoid chain with bromoacetylbromide. After filtration and evaporation, the crude bromoacetamide intermediate is then reacted with a primary amine. The newly formed peptoid is then isolated by flash chromatography before the next cycle of submonomer addition. Thus, this method requires labor-intensive filtration, evaporation, and chromatography, although it generates reasonably large quantities.

Another method for solution-phase synthesis is the Ugi four component reaction (4-CR) as shown in **Figure 2(d)**.[19] The Ugi-4CR is an efficient process in which a primary amine, an oxo compound, a carboxylic acid, and an isocyanide react in one pot to form a dipeptoid backbone. The Ugi-4CR has been combined with macrocyclization, generating many useful compounds such as functional macrocycles, cryptands, cages, etc.[20,21]

2.204.2.3. Other Methods for Peptoid Synthesis

Amine-initiated ring-opening polymerization (ROP) has been utilized to synthesize high molecular weight peptoid macrocycles (Figure 2(e)).[22] *N*-heterocyclic carbenes (NHCs) mediate ROP of cyclic substrates *N*-substituted carboxyanhydrides (N^R-NCA) through a zwitterionic propagating species and yield cyclic peptoid polymers in a controlled and efficient manner. This method is limited to single type of side chains in the peptoid polymers. In addition to this ROP, poly β-peptoids had been produced by the polymerization reaction of aziridines and carbon monoxide.[23,24]

The submonomer method of peptoid synthesis had been adapted for photolithographic application (Figure 2(f)).[25] A four-step monomer addition cycle was developed for the photolithographic synthesis of peptoids. Glycolic acid protected with a light-sensitive protecting group (MeNPOC) was first coupled to an amine-modified surface. The hydroxyl group was unmasked by UV irradiation and then activated with tosyl chloride. Finally, the tosylate was displaced with a primary amine to complete the construction of a monomer unit. This chemistry allows the spatially addressable synthesis of peptoids on an array by photolithography, since hydroxyl group unmasking, activation, and amine displacement will occur only at addresses that have been irradiated with UV light.

To our surprise, peptoid polymers have also been synthesized on a small scale using biosynthetic machinery. An *E. coli* cell-free translation system was used with genetically coded mRNA and artificial tRNAs charged with peptoid monomers as shown in Figure 2(g).[26] In this translation system, certain proteinogenic amino acids and/or cognate aminoacyl-tRNA synthetases are withdrawn (*withdrawn* PURE system; *w*PURE), diminishing the competing background incorporation of the proteinogenic amino acids in the translation elongation event. They prepared a wide variety of tRNAs charged with nonproteinogenic peptoid monomers using artificial tRNA acylation ribozymes. Using this method, six peptoid monomers were translated from the genetic code and purified.

2.204.3. Peptoid Structure and Characterization

2.204.3.1. Peptoid Secondary Structures: Helices and Turns

As we learned from biological polymers, efficient functions are derived from well-defined structures. One of the key strategies to forming well-defined, atomically ordered folded polypeptoids is to control the local secondary structure. Control over local and global molecular interactions can reduce the conformational freedom of the polymer chain resulting in ordered states in aqueous environment. Borrowing from nature's design principles found in proteins, many synthetic polymer systems have been developed to create protein–mimetic materials. However, most synthetic sequence-specific polymers are relatively short in main chain length, due to synthetic inefficiencies. Still, with relatively short chain lengths, many specific protein ligands have been developed. Longer sequences have been used for antifouling materials, antimicrobial agents, lung surfactant mimetics, drug delivery vehicles and protein mimicry. However, it is still in infancy to create protein-like structures and functions in purely nonbiological polymers.

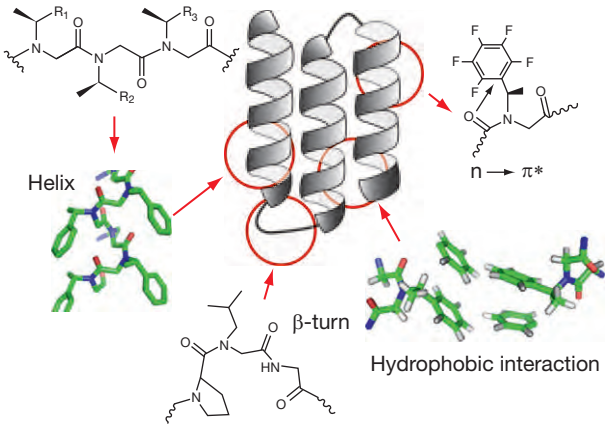

Figure 3 Schematic diagram for a hierarchical approach toward creating a tertiary structure in peptoids from local to global interactions. The local interactions include the formation of secondary structures such as helices and turns, and the tunable interactions such as n→π* interaction. The hydrophobic interaction has been utilized as a folding core of peptoid helix bundles.

A number of proteins fold up sequentially from initial secondary structures to well-defined tertiary structures. Thus, one of the methods toward unique tertiary structures in nonbiological polymers would be first to create secondary structures and then, engineer them further to assemble in three-dimension (3D). In peptoids, we have been using this sequential strategy, aiming toward unique 3D peptoid structures (Figure 3).

Like the secondary structures in proteins, helices and turns have been generated in peptoids. Peptoid helical structures are well established and exhibit extreme chemical and thermal stability.[9] Intrinsically, the peptoid backbone is more flexible than the peptide backbone due to the lack of hydrogen bond donors and main chain chirality. However, a bulky chiral side chain appended to the Nα position in peptoids significantly reduces the conformational freedom of the chain backbone and induced well-defined helical structures with three residues per turn (Figure 3).[7] The peptoid helical structures have been characterized by a range of high-resolution techniques, such as 2D-NMR, X-ray crystallography, and computational modeling.[27–29] The structural parameters including backbone ϕ and ψ angles and the distance between two helical pitches showed that the peptoid helical structures given by α-chiral steric bulk resemble the polyproline type-I helical structure in peptides. Because of the steric hindrance given by the bulky chirality at the Nα position, the backbone ϕ angle is limited to a certain range of angles to prevent the steric clash with nearby backbone carbonyl groups. This molecular steric hindrance in peptoids allows even small pentamer peptoids to form stable helical structures with extreme chemical and thermal stability. The peptoid helical structures were stable to 8 M urea and to 75 °C.[9]

The turn structures in peptoids are recently generated, but not well established comparing to the helices. A series of tripeptoids containing either *N*-methylglycine or *N*-isobutylglycine in position i + 1/i + 2 were synthesized and tested for intramolecularly H-bonded β-turn formation in chloroform solution.[30] The population of the type-II β-turn increased when they incorporated the achiral peptoids at the position $i+2$. Toward the β-turn mimic, geometrically constrained triazole ring had

been introduced into peptoids as a monomer unit, stabilizing a turn in the middle of linear peptoids. This triazole motif mimicked the β-hairpin structures in peptides.[31]

2.204.3.2. Noncovalent Local Interactions in Peptoids

Several types of noncovalent interactions have been found,[32–35] expanding significantly the scope of peptoid design and the utility of peptoids for a broad range of applications. These interactions stabilize peptoid secondary structures further and can even switch the conformation, depending on the environment such as pH and solvent.

Hydrophobic interactions and n→π* interactions have been shown to play a role in peptoid folding.[32,36,37] The conformation of the secondary structures could be tunable by these noncovalent interactions. For example, the rotameric *cis* to *trans* equilibria of the backbone amides could be controlled by n→π*, steric, and hydrogen bonding interactions (**Figure 3**).[32,34] Especially, *cis*-amides in the peptoid backbone could be exclusively formed by *N*-R-chiral acetanilide and *N*-1-naphthylethyl side chains, by $n\rightarrow\pi^*_{C=O}$/hydrogen bonding interactions and $n\rightarrow\pi^*_{Ar}$/steric interactions, respectively.[34] The pair interaction of fluoroaromatic and other electron-deficient aromatic side chain in pepoids could be an effective strategy for controlling peptoid structures.[33]

The rotameric *cis* to *trans* equilibrium of the backbone amides could be also dependent on the nearby amides in the backbone. Using NMR, the kinetics of *cis* to *trans* equilibrium of the backbone amides could be measured in monomers, di- and tri-peptoids[38] with a range of rate constants from 0.03 to 0.37 s^{-1}. These findings would be useful for understanding the transition between different conformations and developing an accurate force field in peptoids.

Previously, a threaded loop structure was found in peptoids by well-defined local interactions.[39] This structure is unique to peptoid nonamers with achiral side chains and was first identified in a homononamer of Nspe. The threaded loop structure is stabilized by three intramolecular hydrogen bonds from backbone carbonyl groups (residues 5, 7, and 9) to the N-terminal secondary ammonium, and one intramolecular hydrogen bond from a backbone carbonyl (residue 2) to the C-terminal primary amide. The peptoid threaded loop contains four *cis* and four *trans* amide bonds. Interestingly, methanol was able to disrupt the set of intramolecular hydrogen bonds, converting the threaded loop to helical structure.

L-phenylalanine *tert*-butyl ester had been utilized for the synthesis of (*S*)-*N*-(1-carboxy-2-phenylethyl)glycine oligomers.[35] These peptoids formed stable secondary structures in aqueous solution in which the conformation is dramatically responsive to variations in pH and solvent composition. The electrostatic interaction between monomer units was responsible for this pH-dependent conformational switch.

2.204.3.3. Cyclic Peptoids

Cyclization of the linear polymer chains has been developed over the past few decades as an effort to find an efficient method for conformational ordering.[40] This type of confined structures via cyclization provides a useful platform for high-affinity molecular recognition due to the gain of the entropic term in thermodynamic binding free energy. Head-to-tail macrocyclization was estabilished in peptoids, allowing the enhancement of the conformational ordering and the crystallization of cyclic peptoid hexamer and octamer.[17] The high-resolution crystal structures of these cyclic peptoids revealed that the peptoid backbone could accommodate tight turns via distorted *cis* and *trans* amide conformers in the solid state.[17] This head-to-tail macrocyclization have been utilized recently for useful alkali metal ion transporters.[41]

Another macrocyclization have been also established in peptoids via chemical linkages of side chains. Especially, the azide-alkyne cycloaddition was used widely in peptoids for macrocyclization.[42–44] Amide coupling through side chains was also developed[45,46] and employed further for cyclic peptoid arrays.[45]

2.204.3.4. Computational Modeling

Computational modeling of biological molecules has been advanced significantly in the past decade, providing a very useful tool for predicting secondary and tertiary structures in proteins and nucleic acids. This success was made possible due to the development of super-computing power and more accurate force fields in amino acids and nucleotides than ever, and the database of protein and nucleic acid structures. The computational tools are now being applied to many other nonbiological synthetic heteropolymers as an aid for the design of new molecules. However, accurate force fields are required for the success of design and understanding of synthetic heteropolymers. There are a number of computational studies in peptoids to guide us toward more accurate models of peptoid structures.[27,28,47–50] The recent high-level quantum mechanics simulation had a good agreement with available peptoid atomic-detail structures as shown in the Ramachandran plot of peptoid backbone ϕ versus ψ angle (**Figure 4**).[48] This simulation revealed that local energetics dictates the conformational preference in peptoids.[48]

Distance geometry and ensemble calculations have been carried out using the distance information from NMR data in order to refine the peptoid helical structures and understand the amide backbone *trans* to *cis* isomerism.[28,50] The *trans* conformation of the backbone amide is generally not preferred in peptoids due to the *N*-substitution.[38] Quantum mechanical *ab initio* calculations have been applied for this problem.[47,48] Although the angle of the amide backbone depends on the side chains, it is not fully understood yet about the determining factors of this amide backbone *trans* to *cis* isomerism. The accurate force field of peptoids is necessary for understanding this problem.

In order to understand the folding cooperativity in peptoid helix bundles, a dynamic programming approach was carried out using statistical mechanical partition functions of foldamer chain molecules.[51] This model showed that the peptoid three-helix bundle fold anticooperatively and predicts that two-helix bundles are unstable in proteins but stable in peptoids.

2.204.3.5. Protein-Like Structures and Functions

One of the ultimate goals in the area of bioinspired heteropolymers is to create precisely folded nanostructures with protein-like functions. There have been recent efforts to construct

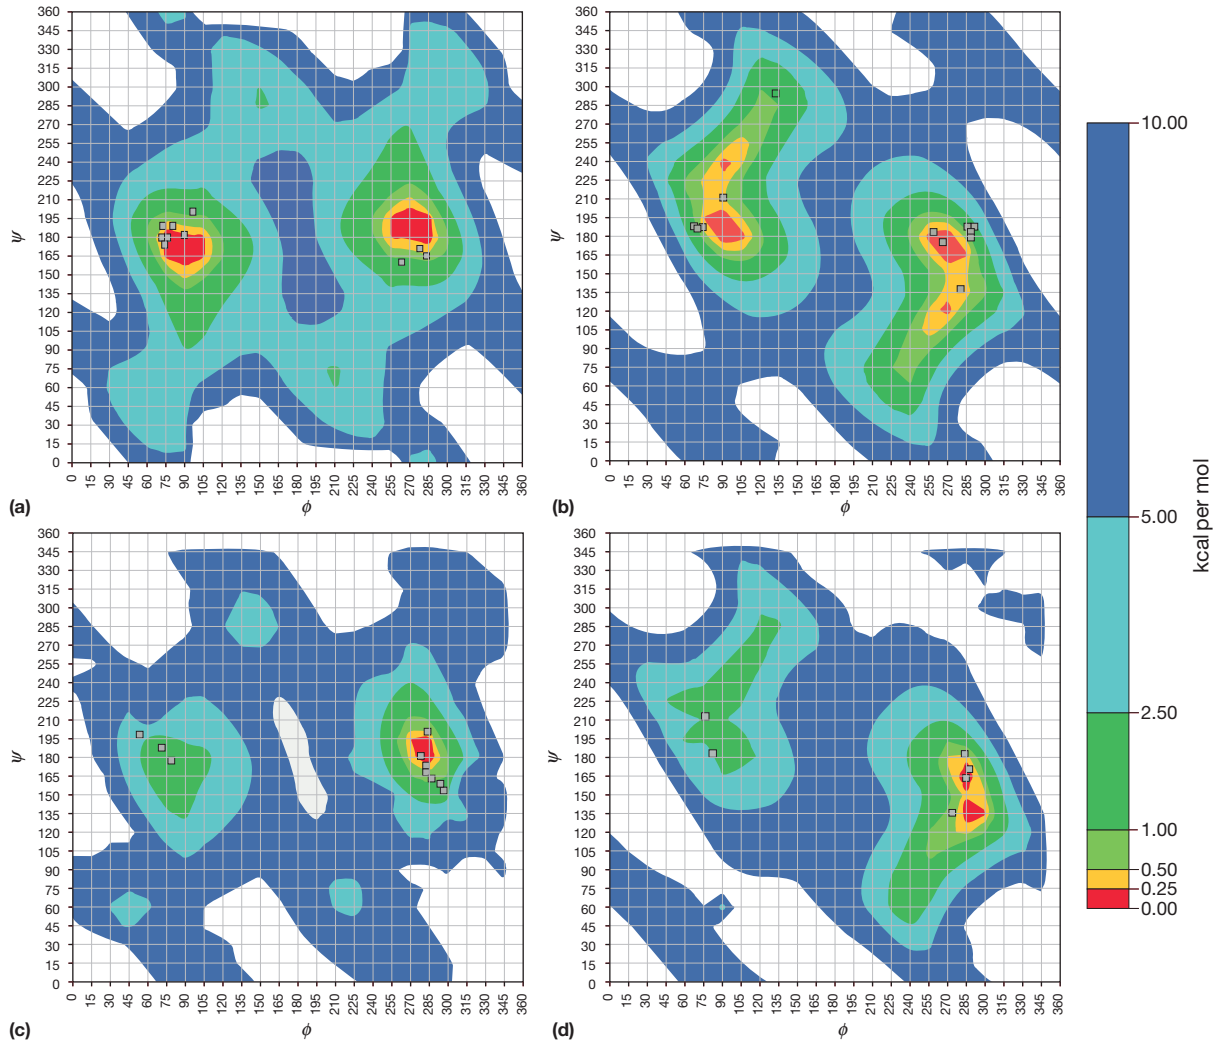

Figure 4 Ramachandran plot of peptoid backbone phi vs. psi angels revealed by a recent high-level quantum mechanical simulation. Monomeric peptoids, Ac-Nme-N(CH_3)$_2$ (a and b) and Ac-Nspe-N(CH_3)$_2$ (c and d) were calculated by the quantum mechanical calculation at the B3LYP/6-311+G(2d,p)//HF/6-31G* level. The backbone ω is *cis* at the left plots (a and c), and *trans* at the right plots (b, d). Squares are corresponding experimental residues from crystal structures. Nme and Nspe stand for *N*-(methoxyethyl)glycine and (S)-*N*-(1-phenylethyl)glycine, respectively. Adapted from Butterfoss, G. L.; Renfrew, P. D.; Kuhlman, B.; Kirshenbaum, K.; Bonneau, R. *J. Am. Chem. Soc.* **2009**, *131*, 16798–16807, with permission from American Chemical Society.

synthetic polymers that mimic protein properties. Although it has been difficult to achieve stable secondary structures, a multiletter alphabet, and long chain lengths within a single type of polymer, our group has been able to create helix bundle structures with hydrophobic folding cores and introduce one of the simplest biological functions such as high-affinity zinc binding into peptoid two-helix bundles.[36,37] The advancement of synthetic technologies and design principles would enable us to create more complicated protein-like structures and functions.

The helix bundle was the first target toward tertiary structures in peptoids because the helical secondary structures are well established in peptoids. One of the key strategies for generating protein-like helix bundles was utilizing amphiphilic self-assembled peptoid helical structures.[52] The hydrophobic groups at every third position allow the amphilicity of peptoid helices and provide a stable hydrophobic folding core inside self-assembled helix bundles. The combinatorial chemistry had been carried out to identify amphiphilic peptoid helices that have a well-defined hydrophobic core.[52] Using these peptoid helices, single-chain folded helix bundles had been created by orthogonal chemoselective conjugations between peptoid helices. By three consecutive conjugations, a 12 kDa peptoid four-helix bundle had been created previously.[37]

To mimic protein-like functions, our group was able to introduce high-affinity zinc-binding site into the peptoid two-helix bundles.[36] Borrowing from well-understood zinc-binding motifs in proteins, thiol and imidazole moieties were positioned within the peptoid two-helix bundles such that both helices must align in close proximity to form a binding site. Certain peptoid two-helix bundles bind zinc with nanomolar affinities and high selectivity compared to other divalent metal ions. This work is a significant step toward generating protein-like structures and functions.

2.204.3.6. Peptoid Self-Assembly: Nanostructures

Polypeptoids are a unique material that allows not only the mimicry of proteins, but the precise engineering of polymers. Sequence level control and the ability to synthesize relatively high molecular weights have resulted in a number of interesting applications. The nanoscale self-assembly of polymeric peptoid materials is an area of tremendous potential, as the fields of protein folding and polymer self-assembly become ever closer. Peptoid polymers have been studied as bulk solids and shown to have improved process ability over polypeptides. Recently, certain sequences of peptoids showed their ability to form nanoribbon/tapes and 2D floating sheets in aqueous solution,[53–55] gaining their potentials for useful nanostructured materials.

A series of peptoid homopolymers were studied with respect to their thermal properties as bulk solids.[56] Many of these sequences form crystalline phases with discrete melting temperatures. Interestingly, a comparison was made between a polypeptide and a perfectly analogous polypeptoid (i.e., everything in the structure was identical except for the point of side chain attachment). The peptoid was found to exhibit a reversible melting transition at modest temperatures, whereas the corresponding peptide did not melt all the way up to its decomposition temperature. This suggests that the lack of hydrogen bonding in polypeptoids is an important feature that may contribute to improved processability in the bulk.

During the development of a novel class of peptoid β-sheet breaker as amyloid inhibitors, a retro-peptoid sequence corresponding to the amyloidogenic peptide sequences amylin, SNNFGAILSS, was found to form the supramolecular nanoribbon/tape structures.[53] Due to the formation of this self-assembled peptoid nanostructures, this retro-peptoid was not efficient to inhibit the amyloid formation of amylin, but provided a useful nanostructure.

Recently, our group systematically explored the impact of amphiphilic sequence patterns in the self-assembly of peptoid polymers, and we discovered one of the largest 2D organic crystals known. Remarkably well-defined 2D free-floating peptoid nanosheets formed spontaneously in aqueous solution after mixing a 1:1 ratio of two oppositely charged peptoid 36-mers of a specific sequence.[54] A repeating, alternating sequence pattern of a polar ionic monomer followed by a nonpolar aromatic monomer was key to formation of the sheet architecture. These giant free-floating sheets were shown to have a bilayer structure (i.e., two molecules thick) and have a thickness of only 2.7 nm, yet a width and length of tens of microns (**Figure 5**). The unprecedented direct imaging of individual peptoid chains was made possible by the recent development of aberration-corrected transmission electron microscopy (TEAM 0.5) at the National Center for Electron Microscopy, Lawrence Berkeley National Laboratory. Direct observation of individual polymer chains revealed that the peptoid chains are fully extended in structure and run parallel to one of the sheet edges. Further, the chain–chain spacing of 4.5 Å could be directly imaged, which corresponded well to the spacings observed by X-ray and electron diffraction experiments. It was further demonstrated that the peptoid nanosheets could be functionalized with biologically active ligands and that they could specifically bind their protein target with high specificity.

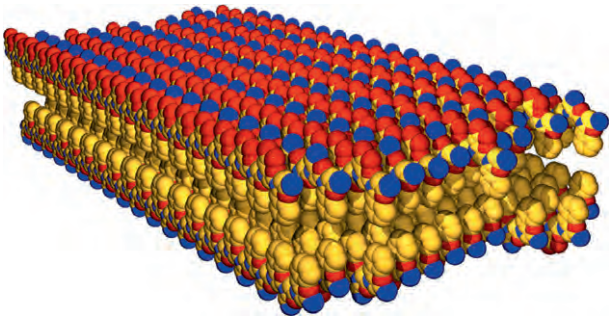

Figure 5 Free-floating nanosheets can be formed by the self-assembly of two oppositely charged peptoid 36-mers of a specific sequence pattern. The peptoid sequence is a repeat of an alternating sequence of a polar ionic monomer and a nonpolar aromatic monomer. The peptoid nanosheets consist of a bilayer, which is <3 nm in thickness, yet many tens of microns in length and width. Adapted from Nam, K. T.; Shelby, S. A.; Marciel, A. B.; *et al*. *Nat*. *Mater*. **2010**, *9*, 454–460.

Importantly, this is the first demonstration that biological sequence information (a beta-sheet-like alternating sequence) can be introduced into a synthetic polymer to generate an atomically defined biomimetic structure. Interestingly, because the peptoids are achiral, these peptoid nanosheets are completely flat, in contrast to peptidic beta sheets, which have an inherent twist in their structure that is a result of the amino acid chirality. Thus, the synthetic flexibility and biocompatibility of peptoids provide a flexible and robust platform for integrating functionality into defined nanostructures.

2.204.4. Combinatorial Discovery of Peptoid Ligands

Molecular diversity as a source of potential drug candidates, protein–mimetics, and various other functional materials has been of enormous interest. Combinatorial library synthesis provides an efficient route to achieve great molecular diversity and has been extensively used both in academic and industrial research.[12] Inspired by nature's intrinsic molecular diversity provided by biopolymers (i.e., proteins), researchers at Chiron Corp, now part of Novartis AG, pursued new drug discovery technologies employing a peptoid combinatorial library platform.[5] The invention of the solid-phase submonomer synthesis methods facilitated the library synthesis and enabled peptoids to be an ideal class of molecules for combinatorial library synthesis. First, the solid-phase peptoid synthesis allows the resin-splitting methods, which are crucial for mix-and-split type combinatorial library synthesis where equimolar compound mixtures can be synthesized. Second, each residue incorporation step is composed of highly efficient bromoacetylation and amine displacement reactions. These reactions provide high yields and are not sensitive to air and moisture; therefore, the chemistry is automatable. Third, due to the availability of a number of peptoid submonomers as primary amines, a wide variety of chemical functionalities can be incorporated. These favorable aspects of peptoids for combinatorial library synthesis along with the availability of state-of-the-art lab automation instruments, the synthesis of millions of peptoids now became a straightforward process. In addition, the ability to screen and analyze peptoids

rapidly and inexpensively from the libraries has been a primary tool in modern peptoid research.

2.204.4.1. Synthesis Technologies

2.204.4.1.1. Automated synthesis

Solid-phase synthesis techniques have been introduced in the early 1960s by Bruce Merrifield, a Nobel laureate in 1984, and have been applied to biopolymer synthesis including peptides, oligonucleotides, nonnatural peptides, and oligosaccharides. In the case of peptide synthesis, the key steps of the synthetic cycle, namely deprotection and coupling, are repeated until the complete sequence is assembled on the solid matrix. Afterward, the crude product is cleaved from the support, purified, and characterized.[57] Nowadays the synthesis of peptides is fully automated and routinely performed on automated synthesizers. Because the peptoid monomer addition cycle is also two steps, peptoid synthesis can be carried out by most commercial peptide synthesizers with only a few minor programming changes.[58] In the automated synthesis of peptoids, amine solutions are placed in the 'amino acid' reservoirs. Depending on the synthesizer's specification, (1) many samples are handled in parallel (up to ~30 wells) on a typical scale of 0.1 mmol per well; or (2) one-bead-one-compound (OBOC) peptoid libraries of tens to hundreds of thousands of compounds can be synthesized using an automated resin mix-and-split step.[59,60]

2.204.4.1.2. Parallel synthesis

In parallel synthesis, each library member is synthesized in a separate reaction vessel. For the synthesis of 16 peptoid dimers, 16×2 cycles of peptoid monomer unit incorporation is required. For the same number of peptoid dimer synthesis, a mix-and-split method needs only 8 cycles and is well suited for a large size library synthesis to cover larger chemical space.[61] However, the advantages of the parallel synthesis are that the entities in the library are known and that a large amount of peptoid can be prepared in each reaction vessel. A library prepared by the mix-and-split method often requires additional deconvolution or encoding steps to identify peptoid on a specific resin.

Microwave-assisted organic synthesis (MAOS) was originally developed for simple organic transformations such as hydrolysis. Then the technique has been successfully applied to the synthesis of peptides, peptidomimetics, and carbohydrates.[62] The microwave irradiation for peptoid library synthesis has been reported and has shown advantages in terms of both higher purity and dramatically shorter reaction time.[63,64] The optimal conditions for the bromoacetylation step involved irradiation for 30 s and heating to 35 °C using temperature control probe, and for the amine displacement, irradiation for 90s and heating to 95 °C again using the temperature control (at room temperature, typical reaction time for bromoacetylation is 20 min and for amine displacement is 60 min). The MAOS is being used actively in the preparation of peptoid library synthesis either in the parallel synthesis or in the mix-and-split library synthesis.

2.204.4.1.3. SPOT synthesis

The SPOT synthesis technique employs the parallel synthesis method mentioned above, but the difference is that the synthesis is carried out directly on a cellulose membrane rather than on resin beads in a reaction vessel.[65] The SPOT method follows the standard peptoid submonomer synthesis protocol: preparation and functionalization of the cellulose membrane, stepwise bromoacetylation and amine displacement, and cleavage of the side chain protecting groups. If necessary, peptoids can be cleaved from the cellulose membrane by the incorporation of appropriate linkers between the membrane and the peptoid. Peptoid synthesis on cellulose allows the parallel synthesis of large numbers of positionally addressable peptoids in small quantities, and the cost of SPOT synthesis is far cheaper than that of conventional resin-based synthesis.

Wenschuh *et al.* first reported the SPOT synthesis of peptomers (peptide–peptoid hybrids) and peptoids.[66–68] They used Whatman 50 cellulose membranes and modified by treatment with epibromohydrin and 4,7,10-trioxa-1,13-tridecanediamine to provide homogeneous terminal primary amines on the cellulose membrane. Slight modification on conventional peptoid submonomer protocol was employed by using bromoacetic acid 2,4-dinitrophenyl ester instead of commonly used bromoacetic acid/DIC, and selective bromoacetylation on the terminal secondary amines over residual hydroxyl groups on cellulose was achieved. For the dry state cleavage of peptoids, the authors used a photo-labile linker system to cleave membrane-bound peptoids via UV irradiation. The peptoid SPOT array consisting of 8000 peptoids and peptomers are screened for the monoclonal antibody Tab-2, and micromolar affinity ligands were identified demonstrating the potential utility of this method for the rapid identification of novel nonpeptidic protein ligands.

2.204.4.1.4. Split/mix synthesis

In the early 1990s, the OBOC combinatorial library method was first introduced by Lam and coworkers.[69,70] With the OBOC library technique, tens of thousands to millions of compound beads could be rapidly prepared and then screened for a specific biological activity. For the synthesis of OBOC libraries, a mix-and-split synthesis method is utilized such that each bead displays only one compound.[71] Originally, Lam *et al.* developed the OBOC library technique for the synthesis of short linear peptides. Afterwards, led by Zuckermann and Kodadek, the application of the technique was expanded to the preparation of the peptoid libraries.[58,72]

Prior to the library synthesis, the size of the library including the length of the oligomer and the number of amine submonomers must be considered. If nothing is known about the target protein, diverse sets of amines are used. However, the information about the target-binding site can help design the library and significantly reduce the number of amine submonomers to be used. Typically, 6–30 amine submonomers are used to conveniently prepare an OBOC library. The scale of the library synthesis depends on the amount of material needed for screening. Generally, for the synthesis of peptoid trimer library, 2.4 mmol of resin is used, yielding about 1 ml of each of 24 pools, each at a concentration of 100 μM per compound. This quantity is sufficient for hundreds of screens when screened at 1 μM per compound.

In 1992, Zuckermann and coworkers introduced a fully automated peptoid synthesis protocol that is capable of synthesizing equimolar peptide mixtures (EPM).[59] Equimolarity

was achieved by employing the resin-splitting method, namely isopycnic slurry method, where the resin was suspended as slurry in a solvent system that had a similar density to resin, causing the resin particles to settle very slowly. The authors suspended a polystyrene resin (100–200 mesh and 1% cross-link with divinylbenzene) as a 3% w/v free-flowing slurry in 65% 1,2-dichloroethane/DMF. The resin slurry was then transferred by a robotic pipet hand into separate reaction vessels (up to 36). When short peptides/peptoids were synthesized, the equimolarity of the library was well maintained after repeated split-and-pool processes. With the automated EPM synthesizer on hand, the authors prepared ~5000 peptoid dimers and trimers to identify high-affinity ligands for 7TM/GPCR (see Section 2.204.5.1 for further discussions).[73] In this work, iterative deconvolution method was successfully employed for the structural determination of the peptoid hits. This method is based on an iterative process of screening and resynthesis of smaller sublibraries in an attempt to fractionate a mixture into its most active constituents. Popularized by Houghten *et al.*,[71] iterative deconvolution has been used as a screening method to identify hits from non-OBOC libraries.

2.204.4.2. Analytical Methods

2.204.4.2.1. Separations

In combinatorial chemistry, a vast number of diverse compounds are generated by robotic instruments; for example, thousands of compounds can be synthesized daily. Due to the increase in the rate of compounds synthesized, the demand for rapid analysis and characterization of the library is high. For separation purposes, widely used analytical instruments are LC/MS (liquid chromatograpy/mass spectrometry), HPLC (high performance liquid chromatography), and more recently UPLC (ultra performance liquid chromatography). Typically, liquid chromatography separations are carried out on a reverse phase mode; C18 or C4 supports are used as stationary phase, and water/acetonitrile gradients are eluted as mobile phase. Technical advances in this field have enabled high-resolution separations of mixtures and high sensitivity detection of compounds in small quantity.

One active area of investigation is in the development of capillary electrophoresis (CE). CE is designed to separate species based on their size to charge ratio in the interior of a small capillary filled with a matrix. The advantages of CE are the requirement of small sample quantity and the wide variety of separation mechanisms modulated by types of matrices and by mobile phase solutions. The superior separation efficiency of CE makes it a powerful tool for many of the analytical challenges in biopharmaceutical research.

Lunte and coworkers evaluated the utility of the CE technique for the separation of a combinatorially synthesized peptoid mixture.[74,75] The mixture consisted of 24 trimeric peptoids that ranged in molar mass from 392 to 699 with pK_a values ranging from 3 to 10. With reverse phase HPLC, separation of this mixture posed a significant challenge. Hence, the authors used a fused-silica capillary electrophoresis and surveyed different types of mobile phase buffers and additives for efficient separation. Significantly enhanced separation was achieved when they used a combination of heptane sulfonic acid (25 mM) and methyl-β-cyclodextrin (40 mg ml^{-1}) in 250 mM sodium phosphate buffer at pH = 2.0. As for the additives, heptane sulfonic acid was used as an ion-pairing agent to reduce hydrophobic intramolecular interactions and to disrupt electrostatic interactions with the capillary wall, and methyl-β-cyclodextrin was used to provide host–guest interactions and resolve very hydrophobic components of the peptoid mixture. Later the authors reported the use of SDS micelles in conjunction with methyl-β-cyclodextrin, and the additives in the same sodium phosphate buffer (pH = 2.0) provided dramatic improvement in the separation of the peptoid mixture.

Lunte and coworkers demonstrated the potential advantages of CE over conventional HPLC for the analysis of complex peptoid mixtures. Only nanoliters of sample are injected for each analysis, and this offers tremendous benefit when extremely small amounts of sample are available as is typical with OBOC combinatorial chemistry.

2.204.4.2.2. Characterization

Numerous techniques have been applied for the characterization of combinatorial libraries. For libraries prepared by parallel synthesis, all compounds in the library are addressed individually, and characterization process is relatively straightforward. However, evaluation of libraries prepared by mix-and-split synthesis is much more challenging. Taking into account that an OBOC library is composed of individual beads containing unique chemical entities, the first approach to characterize the mix-and-split library is to analyze the individual beads. This approach is often limited because each bead contains only a picomolar quantity of a compound; therefore, highly sensitive analytical methods have to be used. Generally, the methods of choice are mass spectrometry, microsequencing and amino acid analysis. Sensitivity of modern automatic microsequencers is greatly improved and allows the characterization of the small quantity of compound on a single bead. Sequencing based on Edman degradation can be combined with mass spectrometry, and evaluation of mixtures generated by the degradation using mixture of phenylisothiocyanate (PITC) and phenylisocyanate (PTC) can be performed. The use of PTC does not cleave the N-terminal amino acid: this amino acid is capped and the resulting phenylcarbamoyl peptide (or peptoid) resists further degradation. Repeated cycles of this procedure provide a mixture of peptide (or peptoid) fragments differing by a single peptoid monomer unit, which can be characterized by mass spectrometry. For peptoid Edman degradation, Kodadek *et al.* noted the importance of a strong denaturing wash (with hot 1% SDS buffer) of peptoid beads prior to sequencing; this step eliminated any undesirable interference of bound proteins on sequencing reactions. With minor modifications, peptoid Edman sequencing protocol was well established using a standard peptide sequencer.[72,76]

Using the Edman degradation, peptide/peptoid structures can be determined directly on resin without being cleaved; however, only 3–4 peptides/peptoids can be sequenced each day with an automated sequencer.[69,77,78] Analysis of unnatural amino acids by Edman degradation is especially slow because it requires the synthesis and analysis of standards for each unnatural residue.[78] Mass spectrometry (MS) offers both high sensitivity and speed for characterizing peptoid combinatorial library. Tandem MS (or MS/MS) has been routinely used for

the sequence determination of peptides, and this technique was shown to be readily applicable to analyze peptoids.[79,80]

Zuckermann and coworkers developed a method for the rapid identification of sequence of hit compounds from OBOC peptoid libraries.[81] They used a cleavable hydrophilic linker to reduce nonspecific binding to biological samples and allows for the attachment of a halogen tag, which facilitates postscreening sequencing by tandem mass spectrometry (MS/MS). The linker is based on a tartaric acid unit and produces a C-terminal aldehyde upon cleavage from resin. Then the aldehyde can be derivatized with a bromine-containing aminooxy compound that serves as an isotope tag for subsequent MS/MS analysis. The authors showed a number of peptoids can by synthesized using the linker and demonstrated very low levels of nonspecific binding to proteins in a bead screening and sequencing step. Another strategy for rapid and robust sequencing of peptoids and peptomers from OBOC libraries was developed by Pei and coworkers.[82] In this strategy, beads were subjected to multiple cycles of partial Edman degradation by treatment with a 1:3 molar mixture of phenyl isothiocyanate (PITC) and 9-fluorenylmethyl chloroformate (Fmoc-Cl) to generate a series of N-terminal truncation pruducts for each resin-bound peptoids. After the partial Edman degradation step, the Fmoc groups were removed by piperidine treatment. The resulting mixture of the full-length peptoid and its truncation products was analyzed by mass spectrometry, and the full-length peptoid was sequenced. The authors showed this method was also readily applicable to peptomers (peptide–peptoid hybrids).

2.204.4.3. Screening Methods

A reliable high-throughput assay is essential to successfully screen a combinatorial library. A systematic screening of diverse compound collections has proved to be a fruitful source of a number of pharmaceutical lead compounds.[83] For combinatorial library screening, solid-phase and solution-phase assays have been developed. In the solid-phase assays, the ligands are still attached to the resin, and the assay involves either (1) direct binding of molecular target to the bead-attached ligand or (2) detection of functional properties of the bead-attached ligand such as identifying the activity of the ligand as a substrate to a protein. Solution-phase assays require cleavage of ligands from the beads, and the ligands have to be spatially separated such as in 96-well plates.

In peptoid research, major advances in screening technology have enabled combinatorial peptoid libraries to be mined quickly and inexpensively for specific protein binders.[76] Kodadek and colleagues focused on the discovery of peptoid binders for proteins, with the purpose of using the high-affinity binders for the construction of protein-detecting microarrays. The primary approach they used was the OBOC peptoid library screening. The screening was conducted by binding a fluorescently-labeled target protein to the OBOC peptoid library beads. After trial and error to find an optimal system for peptoid library screening, they found a Texas Red-labeled protein to a library of tens to hundreds of thousands of peptoids displayed on TentaGel beads worked well for their purpose.[77] A visual examination and identification of the beads that contained peptoids and the Texas Red-labeled protein were performed under a fluorescent microscope, and the fluorescent beads were isolated manually using a micropipette. Technical improvement was made to increase the visual contrast between hits and nonhits by employing a biotinylated protein and detecting its binding to the bead by subsequent hybridization with a streptavidin-coated quantum dot. The intense signal from the quantum dot made it easier to distinguish hits from nonhits (autofluorescent beads), and the sequence of the peptoid on the bead was determined by Edman degradation and mass spectrometry. For the sequencing step after this on-bead screening, bound proteins were stripped from the bead by the treatment of 1% SDS solution, and the bead was subjected to an automated Edman sequencer. If peptoids are not attached on beads, the sequence can be determined by tandem mass spectrometry[81] or partial Edman degradation and mass spectrometry.[82] Recently, Kodadek *et al.* reported a new bead screening technique for the identification of specific peptoid ligands for cell surface receptors.[84] Because of the difficulty of handling membrane receptors (i.e., poor solubility and/or lack of stability when isolated), the standard screening methods developed for soluble proteins could not be easily employed for membrane receptors. Therefore, cell-based assay techniques have been developed based on the use of live cells carrying target receptor.[85] Kodadek *et al.* used a two-color, cell-based screening method to isolate peptoid hits to exhibit specificity for a membrane protein, VEGFR-2 (vascular endothelial growth factor receptor-2). They labeled cells lacking VEGFR-2 with a green quantum dot (QD), and cells carrying VEGFR-2, but were otherwise identical, were labeled with a red QD. The QDs did not contaminate the cell surface because they were taken up into cells by endocytosis. The cells were then incubated with ~300 000 OBOC beads displaying nonameric peptoids under carefully controlled conditions to minimize nonspecific adhesion of cells to the beads. The binding of cells on beads were then inspected under fluorescent microscope. Hundreds of beads were observed to bind both red and green cells implying that the peptoids were not specific ligands for VEGFR-2. Five beads bound only red cells, meaning that the peptoids were likely to be specific VEGFR-2 ligands. Subsequent *in vitro* assay confirmed the five peptoids were specific ligands for VEGFR-2 with binding affinity of low-micromolar range. Later, the authors used the hits to develop peptoid 'antibody surrogate' with extremely high specificity toward VEGFR-2 (see **Section 2.204.5.1**). Solution-phase assays, usually in the 96-well plate format, have been used for synthetic compounds or natural products that are added as a soluble form into each individual well for biological testing. In principle, all solution-phase biological assays including competitive receptor-binding assays, antibacterial assays, and anticancer assays can be adapted to combinatorial library screening. Because the numbers of compounds are enormous, the current screening strategy is to use miniaturized and automated solution-phase assay set-ups. Ligands are attached to the beads via cleavable linkers; then the ligands are released from the each bead into solution phase, and the biological assays are carried out. The released compounds are subsequently identified (or sequenced).

Researchers have mimicked a biological event where the genetic material encoding molecules with superior functions survives natural selection and propagates to next generations. Harbury and colleagues utilized the concept of evolutionary mechanism and DNA-programmed combinatorial chemistry to

prepare a large library of peptoids individually associated with specific DNA sequences, enabling amplification of compound hits.[86] The authors adopted the bioinspired but completely abiotic approach to prepare a collection of 100 million distinct peptoids. The library was then subjected to a selection process for binding to the N-terminal SH3 domain of the proto-oncogene Crk, and novel ligands were discovered after six amplification steps. The hits bind to the protein tightly with affinities similar to those of peptide SH3 ligands discovered from phage display libraries.

2.204.5. Drug Discovery

In general, peptides possess distinctive advantages including (1) relatively straightforward synthesis and modification; (2) high affinity and specificity of peptides for different molecular targets such as receptors, antigens, and enzymes; and (3) low toxicity relative to synthetic small molecules. However, peptide drugs often exhibit poor oral bioavailability, a short plasma half-life, a potential for immunogenicity, and unfavorable pharmacokinetic profile; therefore, considerable effort has been directed to the design and development of nonnatural surrogates for peptides. Peptoids exhibit enhanced stability toward proteolysis relative to peptides,[10] significantly different lipophilicity and physicochemical properties, better cell penetration,[87] and low immunogenicity. Hence peptoids find interesting applications in biological probe development as well as in drug discovery.

2.204.5.1. Protein Receptor Ligands

2.204.5.1.1. Protein–protein interaction inhibitors

Protein–protein interactions play a crucial role in cellular and biological processes. Consequently, the chemical intervention of protein–protein interactions would enable new therapeutic possibilities. Targeting protein–protein interactions often can be a challenging task for small molecules that satisfy Lipinski's rules because of the large protein surface area to cover. High-throughput screening (HTS) programs can sometimes lead to the discovery of small molecules that are capable of disrupting certain protein–protein interactions; however, the eventual success of these compounds as drugs remains uncertain. Peptides and peptidomimetics, which are larger molecules than the small molecules, have been identified as high-affinity binders to protein–protein interaction surfaces and are currently being developed as drug candidates.

Apoptosis, a critical biological process that is strongly regulated by protein–protein complex formation, is implicated in human disease states such as cancer, ischemic injuries, and neurological disorders. Development of an apoptosis modulator through inhibition of apoptosome assembly formation has been reported by Pérez-Payá and coworkers.[88,89] Apoptosome, a multi-protein complex consisting of cytochrome c, apoptotic protease activating factor-1 (Apaf-1), procaspase 9, and dATP, mediate the caspase cascade and apoptosis. From the screening of a positional scanning diversity-oriented library (~5000 peptoids) and further chemical optimization process, Pérez-Payá and coworkers identified peptoid oligomers (**Figure 6, (1)** and **(2)**) that directly bind Apaf-1 and showed the decrease in the apoptotic phenotype in mitochondrial-mediated models of

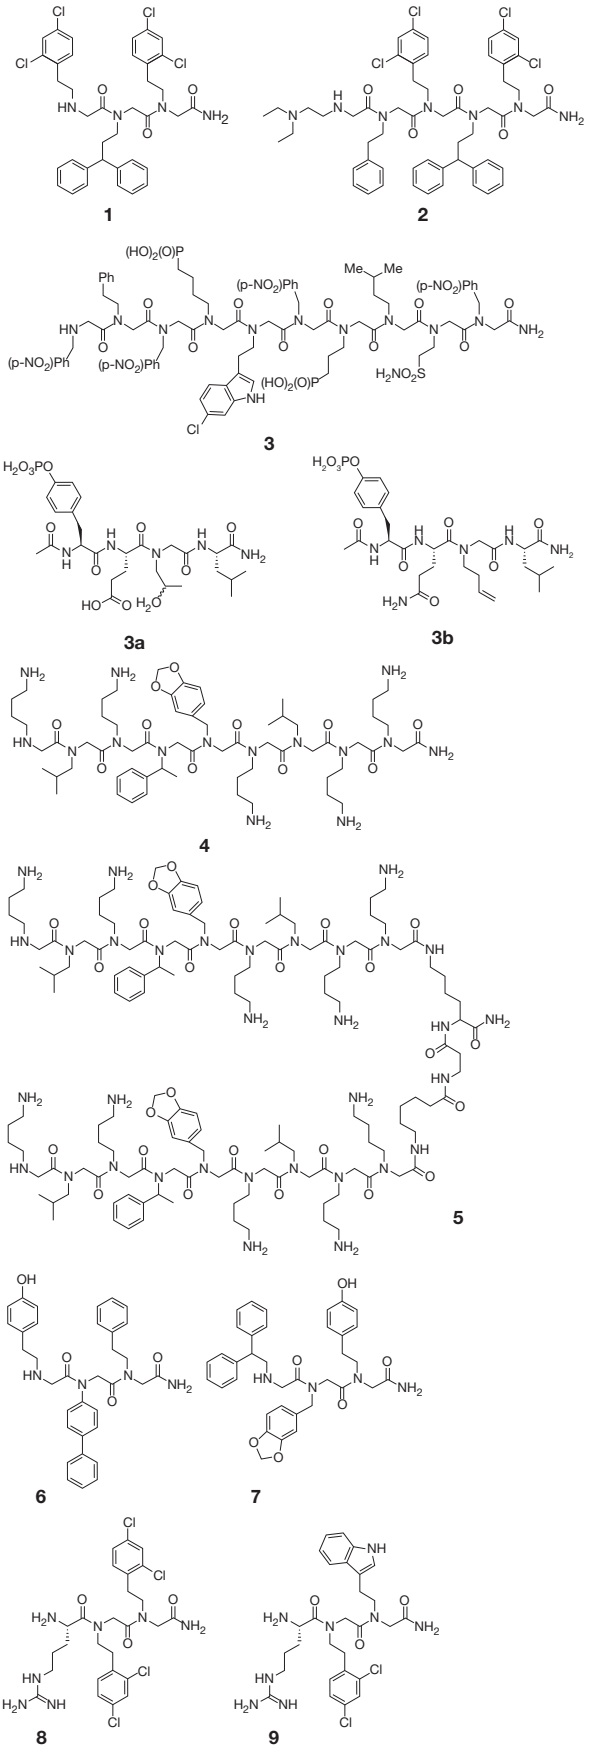

Figure 6 Peptoid ligands that bind to protein receptors.

cellular apoptosis. To increase antiapoptotic activity of **1**, the authors conjugated the peptoid trimer to poly-L-glutamic acid (pL-Glu), and the resulting peptoid-polymer conjugate not only enhanced the antiapoptotic activity but also lowered cytotoxicity of **1** in various cell lines. Further studies include conjugation of **1** to cell-penetrating peptides (i.e., penetratin and HIV-tat) and cyclization of **1**. Along with the pL-Glu-**1** conjugate, penetratin-**1** and cyclo-**1** indicated better cell permeability and efficacy in an *ex vivo* assay, and the authors are moving forward to examine the effectiveness of Apaf-1 inhibitors for *in vivo* myocardial infarction model.[90]

Connections between cancer and protein 53 (or p53) have been well established.[91] Protein 53 is a tumor suppressor protein that regulates the cell cycle and prevents cancer; therefore, when p53 is inactive, cells are able to grow and proliferate. Human double minute 2 (HDM2), which has emerged as an independent anticancer drug target, downregulates p53 function and inactivates the protein. Overexpression of HDM2 has been linked to tumor aggressiveness, and inhibition of HDM2 can restore p53 function and prevent tumor growth. The crystal structure of a p53 peptide bound to HDM2 provides useful information for the design of HDM2 inhibitors. Using structure-guided design, Appella and coworkers designed peptoid-based HDM2 inhibitors.[92] To mimic the p53 peptide fragment bound to HDM2, the authors initially prepared peptoid helices as HDM2 binders. However, their best inhibitor (**Figure 6**, **(3)**) lacked a helical structure but still maintained good binding affinity against HDM2 ($IC_{50} \approx 6.6\,\mu M$). Dissociation constants measured by isothermal titration calorimetry indicated that the binding affinity of **3** ($K_d \approx 1.23\,\mu M$) was about a half of the p53 (15–29) peptide fragment ($K_d \approx 0.62\,\mu M$). From their experience, the authors concluded that starting with rigid peptoid scaffold may not always be optimal to develop new inhibitors.

Alternatively, Kodadek and coworkers used peptoid combinatorial library screening to identify an inhibitor of HDM2 protein.[77] Constructed by standard mix-and-split synthesis on TentaGel, their peptoid libraries were composed of one- to five-hundred thousand peptoid hexamers. They used 13 peptoid submonomers with distinct functionalities, so their peptoid library was chemically diverse. On-bead screening using Texas Red-labeled HDM2 protein provided a peptoid octamer with $K_d \approx 37\,\mu M$.

Src homology 3 (SH3) and WW protein interaction domains participate in diverse signaling pathways, and their functional roles in cancer, osteoporosis, and inflammation are implicated. The SH3 protein domains recognize a specific proline-rich sequence motif, PXXP, where P is proline and X is any amino acid. In addition, it is known that these domains broadly accept amide N-substituted residues instead of recognizing only the critical prolines. In comparison to natural peptides which have proline as the only *N*-subsituted amino acid, peptoids provide enormous number of *N*-substituted nonnatural amino acids. Lim *et al*. exploited the diversity offered by peptoid residues, screened a series of ligands in which key prolines were replaced by nonnatural *N*-substituted residues, and discovered a ligand that selectively bound the Grb2 SH3 domain with 100 times greater affinity than natural peptide.[93] The authors carried out further variation of the peptoid residues and created highly domain-specific peptide–peptoid hybrids.[94] Members of the Src homology 2 (SH2) family have also been targeted with peptide–peptoid hybrids. The structures of the peptomer ligands for Syk[95] and Shc[96] domains are shown in **Figure 6** (**(3a)** and **(3b)**, respectively). The peptomer ligands were discovered by a peptoid scan which provided a useful method to examine to what extent a peptide sequence can be transformed into a peptoid (or a peptomer) while maintaining its binding affinity.

The binding of vascular endothelial growth factor (VEGF) to the receptor VEGFR is an important signaling event in angiogenesis, and inhibition of the hormone-receptor binding can lead to a possible treatment of cancer. Monoclonal antibodies such as Avastin® and Erbitux® have shown to block the VEGF signaling pathway; however, more effective VEGFR antagonists will help increase patients survival time significantly.

Employing mix-and-split combinatorial peptoid library as a source of receptor-binding ligands, Kodadek *et al*. screened on-bead peptoid oligomers for VEGFR2 using a two-color, cell-based screening technique.[84] From the screening of ~300 000 size peptoid library, they discovered peptoid nonamer **4** (**Figure 6**) with low-micromolar-binding affinity to VEGFR2 *in vitro* ($K_d = 2\,\mu M$). Because VEGFR2 functions as a homodimer, the authors envisioned that homodimer of **4** would increase the binding affinity and, indeed, found homodimer **5** had a binding affinity of $K_d = 30$ nM for VEGFR2. The peptoid antibody surrogate was proven to be active in a mouse model and inhibited tumor growth *in vivo*. In the following study, the authors identified three side chains in the peptoid nonamer as minimally required pharmacophore and found backbone amide atoms participated in the binding with VEGFR-2.[97] Interestingly, the peptoid ligand did not bind to the anticipated site and did not compete with VEGF for binding to VEGFR-2. The authors proposed an allosteric mechanism of the peptoid antagonist that might prevent the receptor from acquiring the proper conformation to propagate downstream signals.[98]

2.204.5.1.2. Receptor ligands

Highly potent peptoid ligands for 7-transmembrane G-protein-coupled receptors (7TM/GPCR) were identified from a peptoid combinatorial library.[73] Peptoid timers **6** and **7** (**Figure 6**) showed low-nanomolar-binding affinities for α_1-adrenergic receptor ($K_i = 5$ nM) and μ-opiate receptor ($K_i = 6$ nM), respectively. This study was the first demonstration of the generation of high-affinity ligands for a pharmaceutically relevant receptor from a synthetic combinatorial library. The peptoid library design was based on an analysis of known GPCR ligands, which revealed that each peptoid should contain at least one aromatic hydrophobic side chain and one hydrogen-bond donating side chain. This rational design strategy lowered total number of peptoids in the library (~5000 peptoids), and successfully provided tight binders to GPCR receptors.

Following the Zuckermann's discovery of the peptoid GPCR ligands, a vast number of peptoids or peptomers were reported as ligands for various receptors. Adan and coworkers reported discovery of peptomers targeting the melanocortin receptors.[99,100] The melanocortin receptors are G-protein-coupled receptors with five different isoforms, MC1R–MC5R. Particularly, MC4R are known to be an excellent drug target for the treatment of obesity. The authors used a peptoid scan to transform an MC4R selective peptide heptameric ligand into peptomers, assayed the 31 peptomers for binding toward melanocortin subtypes, and found that the peptomers generally

retained selectivity for MC4R. Although introduction of peptoid moieties resulted in a decrease of affinity, many of the peptomers were still active at submicromolar concentrations. In addition, the authors observed increased bioavilability of the peptomers when three or more of the seven peptide residues were substituted with peptoid residues.

The vanilloid receptor subunit 1 (VR1), also known as the capsaicin receptor, plays essential role in inflammatory pain in the peripheral nervous system. Ferrer-Montiel *et al*. synthesized and screened trimeric peptoid library to discover novel VR1 antagonists.[101] Compound **8** in Figure 6 showed submicromolar potency and *in vivo* analgesic and anti-inflammatory activities. Using the scaffold for further optimizatoin, Albericio *et al*. synthesized 20 indole-containing peptoids and evaluated the biological activity of the peptoids as novel VR1 antagonists.[102] In this series, compound **9** (Figure 6) showed the best potency and selectivity: ~4-fold stronger potency and 10-fold higher selectivity than the parent peptoid **8** was obtained.

Other than the peptoid or peptomer ligands introduced here, there are a vast number of peptoids or peptomers discovered as ligands for various receptors and proteins. Cholecystokinin receptor antagonists,[103] hsst2 receptor-binding somatostatin mimics,[104] Tachykinin NK_3 receptor antagonists,[105] concanavalin A-binding oligomannopeptoids,[106,107] P-glycoprotein-binding multi-drug resistance reversal peptoids,[108] NMDA (*N*-methyl-D-aspartate) receptor antagonists,[109] VLA-4 inhibitors,[110] MHC-II ligands,[111] maltose-binding protein ligands,[112] and urokinase plasminogen activator receptor ligands[113] are all included in this category. All these works demonstrated that peptoids were an excellent source of biologically active receptor ligands. Most of the compounds isolated in these efforts had potency in the low-micromolar range. But there are some lessons learned from the earlier works regarding peptoid ligand discovery: (1) Simple transformation of a known peptide ligand to a peptoid (or to a peptomer) may not always retain binding affinity of the parent peptide. Often a significant conformational change occurs upon single mutation of a peptide residue to a peptoid residue. In addition, the unavailability of backbone–NH proton in peptoid can lead to a loss of an existing hydrogen bonding interaction. (2) Peptoid ligands identified in library screening do not always bind to expected binding sites and may have different mechanism of action from that of natural ligands as was shown by Kodadek's VEGFR-2 ligand.[98] (3) Generally, peptoid library that is highly diverse, but modestly sized (i.e., 5000 ~ 10 000 compounds from 20 different amines), was sufficient to provide high-quality ligands.[12]

2.204.5.2. Nucleic Acid Binders

Antisense oligonucleotides have been used in biological studies for the determination of gene function and in medicine for the suppression of disease-related genes.[114] More recently, synthetic molecules are being used to target RNAs. Most of the RNA targeting synthetic molecules have been discovered by high-throughput screening of a library for binding therapeutically relevant RNAs. Disney *et al.* prepared peptoid microarrays that were composed of peptoid scaffolds with moieties known to bind RNA.[115] They screened the library for inhibiting the group I intron RNA from Canadida albicans, an opportunistic pathogen that kills immunocompromised host. Each peptoid ligand identified from the screening inhibited self-splicing in the presence of 1 mM nucleotide concentration of bulk yeast tRNA with IC_{50} values between 150 and 2200 μM. Based on the structural features of the peptoid binders, second generations of peptoids were designed and synthesized; all second generation peptoid inhibitors showed enhanced potencies with IC_{50} values lower than 100 μM. The best peptoid in this study had an IC_{50} of 31 μM and contained one phenylguanidino- and three indole-functionalities (**1** in Figure 7). Peptoid **1** was sixfold more tightly binding to the RNA than pentamidine, a clinically used drug that inhibits self-splicing. This study is a successful example of rational library design and screening to identify a synthetic RNA binder.

The same group reported the discovery of RNA binders through rational design of peptoid RNA binders solely based on the information about the ligand-binding site in RNA. They employed modularly assembled ligands targeting the RNA that causes myotonic dystrophy (DM), an inherited disease that is characterized by wasting of muscles.[116,117] 6′-*N*-5-Hexynoate kanamycin A is known to bind 2 × 2 nucleotide, pyrimidine-rich RNA internal loops. Multiple copies of such loops are found in the RNA hairpin that causes DM2. The authors displayed 6′-*N*-5-hexynoate kanamycin A on a peptoid scaffold with various degrees of multivalency and spacing to target several internal loops simultaneously. The multivalent display of 6′-*N*-5-hexynoate kanamycin A on a peptoid scaffold yielded a peptoid that inhibited the interaction of DM2 RNA and muscleblind protein (MBNL-1). The most potent binder displays three 6′-*N*-5-hexynoate kanamycin A modules, each separated by four spacer peptoid monomers (**2**, Figure 7). The peptoid showed an IC_{50} value of 25 nM for the inhibition of the RNA-protein complex formation, and binds the DM2 RNA at least 30 times more tightly than related RNAs and 15 times more tightly than MBNL-1. In addition, they showed peptoid **2** could penetrate cell membrane by an uptake study into a mouse myoblast cell line.

2.204.5.3. Antimicrobial Agents

Over the past decades, a broad class of antimicrobial peptides (AMPs) has been identified as an intrinsic defense in animals, plants, and in a wide variety of organisms. AMPs have been of great interest to researchers not only because AMPs belong to the innate host-defense immune system, but also because they are promising candidates for the development of antibiotics. The antimicrobial activity of AMPs encompasses diverse species including Gram-positive and Gram-negative bacteria, fungi, and virus. The mechanism of action for most AMPs is permeabilization of the bacterial cytoplasmic membrane, which is facilitated by their cationic amphipathic structure.[118,119] Another possible mechanism of AMPs is that the peptides penetrate cell membrane and target intracellular substances such as nucleic acids.[120] Both mechanisms do not necessarily involve specific receptors, so the chances for bacteria to develop resistance for AMPs are thought to be slim.

AMPs are typically short (10–50 amino acids) sequences with α-helical, β-hairpin, extended or loop structures and usually have a cationic amphipathicity. Bacterial membranes are composed of an excess of phosphatidylserine over phosphatidylcholine and are negatively charged; hence, the cationic

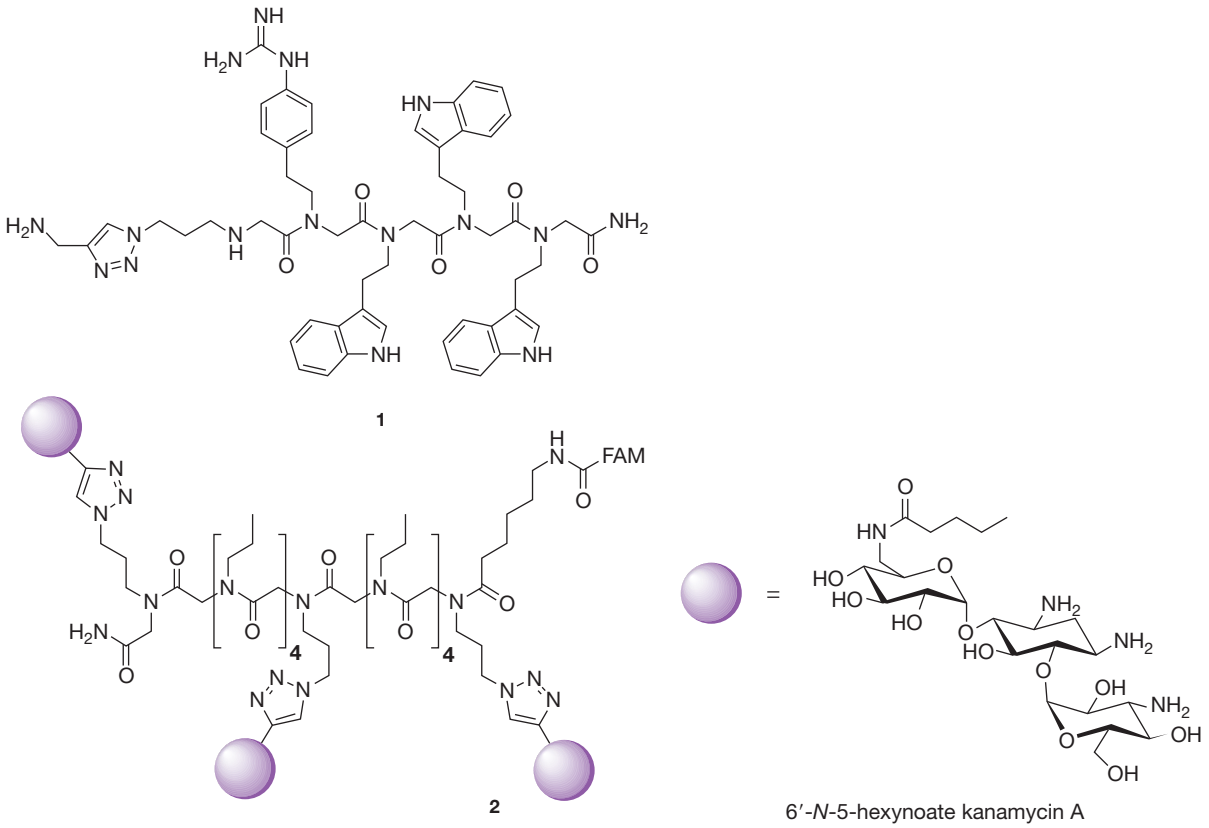

Figure 7 Peptoids that target nucleic acids.

region of AMPs provides a degree of selectivity toward the bacterial membranes over mammalian membranes. The hydrophobic portions of AMPs are believed to play a role for the insertion or penetration into the bacterial cell membrane.

Discovery of antimicrobial agents has been a very active area in peptoid research. Although AMPs possess a number of positive aspects, they have not been developed as drugs due to the poor pharmacokinetics. This problem motivates the effort to develop peptoid mimics of AMPs as antibiotics.

Magainin-2, a linear, cationic, facially amphipathic helical AMP, was successfully mimicked by Barron and coworkers using peptoid helices.[121–124] Several members of antimicrobial peptoids or ampetoids were discovered with low-micromolar MIC (minimal inhibitory concentration) value and relatively low toxicity (**1** and **2**, Figure 8). Peptoid **1** is composed of a helix-inducing and hydrophobic residue, Nspe, and a cationic residue NLys. The latter was incorporated every third position to create a cationic face on the helix (peptoid helix has a periodicity of three residues per turn). Peptoid **2**, a variant of peptoid **1**, was created by replacing the Nspe at position 6 with L-proline. Circular dichroism (CD) study indicated that L-proline is well accomodated in right-handed type-I polyproline-like peptoid helices, and **1** and **2** showed similar helical intensity. Compared to the parent peptoid, **2** exhibited similar antimicrobial activity while less hemolysis and less cytotoxicity were observed. Broad spectrum activities of these ampetoids against clinically relevant BSL-2 pathogens including *Staphylococcus aureus* were also shown in their study. Carefully designed structure–activity relationship study by Barron and coworkers provides some important information: (1) excessive hydrophobicity and helicity in a peptoid leads to greater hemolysis and toxicity; (2) number of cationic charges needs to be higher than +3; and (3) selective peptoids appear to have induced helicity increase upon interaction with negatively charged membrane. These design strategy will help the development of more selective antimicrobial peptoids in the future.

Earlier than Barron's work, Winter and coworkers used combinatorial library screening to discover peptoid trimers that inhibit bacterial growth.[125,126] The MIC of the representative peptoid (**3**, Figure 8) showed 5–40 μM. Excessive hydrophobicity, however, caused the peptoid to be hemolytic.

Mutations of AMPs with various peptoid residues generated selective AMP analogs.[127] Melittin (**4**), an active component of bee venom, is a highly potent AMP, but at the same time, it is nonselective. Melittin contains leucine zipper motif, two leucine residues and an isoleucine are positioned at 7-residue intervals, and the motif promotes dimerization of melittin. Shin and coworkers generated a series of melittin mutants by replacing Leu-6, Leu-13, and Ile-20 with Nala, Nleu, Nphe, or Nlys (**5**, **6**, **7**, **8**, respectively), and investigated their secondary structure, dimerization capability, antimicrobial activity, and cell selectivity.[128] CD study demonstrated that the substitutions disrupted the helical integrity of melittin, and Nleu, Nphe, or Nlys substitution disturbed the dimerization of melittin in an aqueous media. Compounds **5**–**8** maintained the interaction with negatively charged bacterial membrane but lost the interaction with

zwitterionic mammalian cell membrane providing significant selectivity increase. In their study, melittin analogs **7** and **8** showed the best selectivity toward bacterial cells. The authors concluded that the peptoid substitution changed melittin's mode of action from membrane-targeting mechanism to possible intracellular component targeting mechanism.

2.204.5.4. Lung Surfactants

Surfactant proteins (SP) play an important role for innate host defense and are essential for physiological lung function. Four pulmonary SP have been identified so far, known as SP-A, -B, -C, and -D. SP-B and -C are small, hydrophobic proteins that function in conjunction with lipids to reduce surface tension at the air-liquid interface of the lung.[129] A deficiency of SP-B and -C, frequently observed in premature infants, results in impaired lung function and gas exchange known as infant respiratory distress syndrome (IRDS). SP-A and -D are hydrophilic collagen-like lectins that bind oligosaccharides on the surface of microorganisms.[130] As members of innate immune system, these two proteins opsonize and aggregate bacteria and viruses; therefore, SP-A and -D enhance uptake of pathogens by immune cells such as alveolar macrophages and neutrophils. Reduced levels of SP-A and -D make the host susceptible to bacterial and viral infections.

Surfactant replacement therapy (SRT) using exogenous lung surfactant (SP-B or SP-C) has been an effective treatment for IRDS, and premature infant survival has improved significantly. However, there are drawbacks regarding the usage of the current animal-derived surfactant proteins (SP-B and SP-C) such as high production costs, batch-to-batch variability, and possible transfer of cross-species infectious agents, which has prompted investigation into the discovery of synthetic SP preparations.

Development of synthetic and biomimetic surfactants utilizing peptoids has been actively investigated by Barron and colleagues.[129] First, sequence-specific peptoid analogs of SP-C (5-32) have been reported.[131–133] The sequences of the peptoid-based SP-C mimics were designed to adopt key structural features of the natural protein; (1) a helical and hydrophobic region and (2) an N-terminal amphipathic achiral region were incorporated. The peptoid comprising 22 monomers acted as an excellent mimic of SP-C protein (**1** and **2**, Figure 9). When integrated into a lipid film, the amphipathic helical peptoid SP-C mimic captures the essential biophysical surface-activity of the natural protein. The authors carried out a systematic structure–function relationship study and characterized the peptoid mimics using various biophysical characterizations including CD, Langmuir-Wilhelmy surface balance, fluorescence microscopy, and pulsating bubble surfactometry. They concluded that (1) the aromatic-based SP-C peptoids have superior surface activity and film morphology than the aliphatic-based peptoids and (2) increased activity was observed upon increasing helical length.

Along with the biomimetic SP-C, Barron group actively developed peptoid-based SP-B mimics.[134] Initially, they designed and synthesized simple amphipathic peptoid helices (**3** and **4**, Figure 9). Surface pressure-area isotherms, surfactant film phase morphology, and dynamic adsorption behavior indicated that the peptoids were promising mimics of SP-B$_{1\text{-}25}$. The helicity and lipophilicity of the peptoids were shown to be important in the activities of the SP-B mimics. Later, the authors attempted to mimic natural SP-B protein in a more precise way: (1) the incorporation of a hydrophobic, helical insertion region with aromatic side chains showed significantly improved *in vitro*

2.204.5.5. Peptoid Pharmacology

As described earlier, peptoids differ from peptides only in that peptoid side chains are attached to the backbone amide nitrogen instead of the α-carbon. This unique structure of peptoids leads to quite different pharmacological properties from peptides: (1) they are highly stable against proteases or peptidase;[10,11] (2) they lack a backbone hydrogen-bonding donor, which prevents backbone-driven aggregation and thus increases bioavailability; and (3) they showed increased cell permeability over peptides.[87]

To assess the potential of peptoids as useful therapeutic agents, pharmacokinetic profile of small peptoid was investigated.[137] In this study, radiolabeled tripeptoid and tetrapeptide which had similar physicochemical properties (molecular weight, hydrogen-bonding capacity, and octanol–water partition coefficient) were compared for their *in vivo* pharmacokinetic behaviors. Both compounds showed similar adsorptive clearances, but different absorption and disposition characteristics in the rat. Their comparable intestinal permeability was likely from their similar physicochemical properties. However, the structural difference between peptide and peptoid appeared to be the reason for their dissimilarities in *in vivo* absorption and disposition. As was expected, it was observed that the tetrapeptides was rapidly metabolized, but the tripeptoid was stable in the body. The authors in this study concluded that the peptoid appeared to have advantages over the peptide in terms of metabolic stability, but its low oral absorption and rapid biliary excretion still present challenges.

Pharmacological study was carried out for the peptoid ligand of α_1-adrenergic receptor (compound **6** in Figure 6). The peptoid trimer was demonstrated to be soluble and metabolically stable *in vitro* and to have receptor antagonist activity in animals.[138] The intravenous administration of **6** to dogs antagonized the epinephrine-induced increase in intraurethal pressure. In both rats and guinea pigs, **6** antagonized the epinephrine-induced increase in mean arterial blood pressure

in a dose-dependent manner. The rates of systemic clearance of 6 following intravenous administration were 60 and 104 ml $min^{-1} kg^{-1}$ in rats and guinea pigs, respectively. Another peptoid trimer, CHIR-5585, which was discovered as a potent inhibitor of the urokinase plasminogen activator receptor, was also shown to be an active antagonist *in vivo*. Intranasal administration of the peptoid to rats and subsequent tissue distribution study demonstrated the significant delivery of the peptoid throughout the central nervous system and deep cervical lymph nodes.[113] The results suggest that intranasal administration of peptoids may provide a way to bypass the blood–brain barrier.

2.204.6. Cellular Delivery/Uptake Vectors

2.204.6.1. Cell-Penetrating Peptoids

In recent years, methods to enhance or control selective passage of therapeutics or diagnostics through cell membrane have been actively investigated. Research in this area introduced a variety of delivery vectors and enabled the intracellular uptake of various molecular cargoes (e.g., antisense oligonucleotides, plasmid DNA, siRNA, prodrugs, peptides, proteins, imaging agents, and nanomaterials). Cell-penetrating peptides (CPPs) have become widely used vectors for such delivery and hold great potential in basic and applied biomedical research.[139] Among many CPPs, HIV-tat is the most popular CPP; the sequence responsible for the cellular uptake of the HIV-tat peptide consists of the highly basic region, amino acid residues 49–57 (RKKRRQRRR). Poly-lysine, another effective cellular transporter, is also composed of highly basic amino acids.

Using the structure–function relationships obtained with CPPs, Wender and coworkers designed a series of polyguanidine peptoid derivatives.[140] Significantly enhanced cellular uptake was observed for guanidine peptoid 9-mer over R9 (L-Arg 9-mer) and r9 (D-Arg 9-mer), and the stability of peptoid could explain this result (peptoid > D-peptide > L-peptide). The authors also found both the number of guanidine residues and the length of side chain spacer affected the function of cell-penetrating peptoids; more number of guanidino groups and longer side chain spacer appeared to be beneficial for higher cellular uptake. The best cell-penetrating peptoid discovered in this study is shown in Figure 10 (compound **1**).

Instead of using guanidine-containing side chains, Bradley and coworkers focused on amine-containing side chains and evaluated the polylysine-like peptoids for cellular uptake.[141,142] A series of fluorescein-labeled polylysine-like peptoids were synthesized, and their uptakes into HeLa, L929, and K562 cell lines were examined via flow cytometry. As was observed in guanidino-peptoids, longer cationic peptoids showed greater cellular penetration.

Bräse and coworkers compared the two types of peptoids, one with guanidino-side chains and the other with amino-side chains, and compared their cellular uptake (**2** and **3**, Figure 10).[143,144] In this study, the authors found that amino-peptoid **2** required longer times to complete translocation into the cell, while the uptake rate for guanidino-peptoid **3** was much faster, and reasoned that different translocation mechanisms were involved for the two types of peptoids. Intracellular localization of the two peptoids was also different; amino-peptoid **2** resides in the cytosol, but guanidino-peptoid **3** accumulated preferentiallies in the nucleus. Hence, they showed the interesting possibility that the uptake rate and cellular localization of the peptoid transporter can be fine-tuned by simple modification on the peptoid side chain. Notably, no significant cytotoxicities of **2** and **3** were observed.

Membrane permeability of peptoids has led the design of peptoid-based transcription factor mimics, allowing for upregulation of targeted genes. Kodadek and coworkers screened a peptoid library to identify oligomers capable of binding a transcriptional co-activator. A peptoid hit sequence was conjugated to a polyamide to provide specific binding to a target region of DNA.[145,146] The biological activity of the conjugate was facilitated by the membrane permeability of cationic peptoid.

An elegant method to measure the relative cell permeability of synthetic compounds was reported by the Kodadek group.

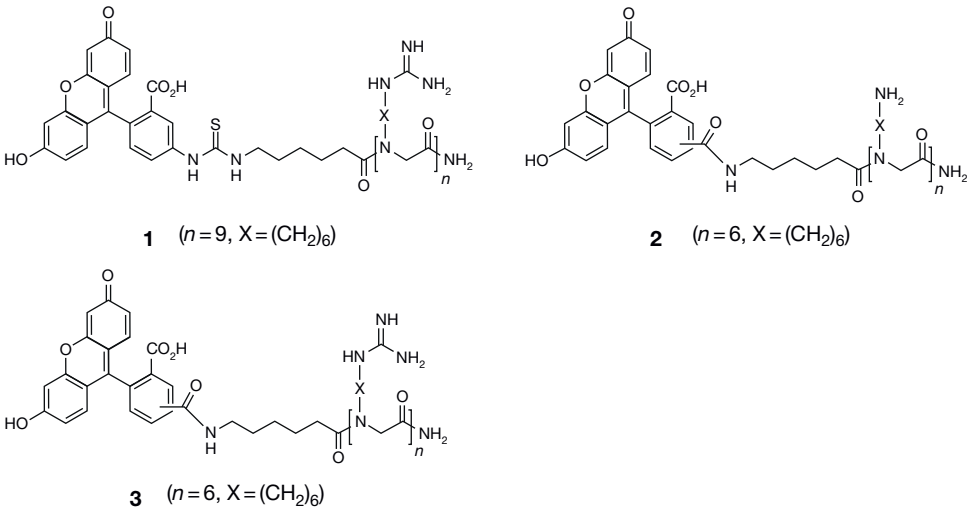

Figure 10 Peptoids with cell-penetrating activity.

The compound of interest was conjugated to a dexamethasone derivative. Upon entry of the conjugate into living cells, the Gal4-responsive luciferase gene was activated. The level of luciferase expression was therefore quantitatively proportional to the cell permeability of the conjugate. Using this reporter gene-based assay, the cell permeability of peptide and peptoid was compared,[87] and general trend showed superior cell permeability of peptoid over peptides. The authors reasoned the lack of backbone–NH protons in peptoids resulted in the increased lipophilicity and therefore membrane permeability. The authors also compared relative cell permeability of linear and cyclic peptides. Generally, cyclic peptides are thought to be more cell permeable than their linear counterparts due to the conformational rigidity. However, the authors proved that cyclic peptides were not generally more cell permeable than linear peptides.[147]

2.204.6.2. Lipitoids for Cellular Delivery of Nucleic Acids

Although synthetic nonviral vectors have shown promise for the delivery of plasmid DNA, their efficiencies in gene transfer have not matched those of viral vectors. Therefore, the need for developing a new class of synthetic nonviral vectors is high. Zuckermann and coworkers first showed the ability of peptoids to serve as nucleic acid delivery vector.[148] Simple mimicry of peptide transporters (e.g., poly-lysine) did not directly lead to active gene delivery peptoids. Employing a library screening method, they found 36-mer peptoids with a specific triplet motif was the most active transfection agent. The triplet motif was composed of two hydrophobic residues and a cationic (i.e., *N*-2-aminoethyl glycine) residue. The cationic peptoids were able to form complexes with DNA and facilitated cell transfection with efficiencies similar to that of commercial cationic lipids. After the discovery, Zuckermann *et al*. systematically investigated the structure–activity relationship of cationic peptoid–lipid conjugates (or lipitoids); they prepared a small library of lipitoids and evaluated their ability as gene transfer agents.[149] The authors showed that several lipitoids condensed plasmid DNA into very discrete and uniform 100-nm particles and protected DNA from nuclease digestion. The best lipitoid in the study was DMPE-(Nae-Nmpe-Nmpe)$_3$ (**1**, **Figure 11**). Lipitoid **1** was active in the presence of serum and exhibited remarkably low cellular toxicity, indicating its potential for *in vivo* studies. Further, **1** showed better efficiency than lipofectin or DMRIE-C, two commercial cationic lipid transfection reagents. Later, Kirshenbaum *et al*. demonstrated this reagent's effectiveness as an siRNA (short interfering RNA) transfection reagent.[150] The lipitoid proved to have remarkably low toxicity and be highly effective in specific siRNA-mediated gene silencing across several cell lines, including primary cells.

2.204.7. Biomimetic Materials

2.204.7.1. Collagen Mimicry

Collagen is the most abundant fibrous protein in the body. It is responsible for providing the scaffolding matrix upon which complex biological structures are supported. So mimicry of collagen and pursuit of novel collagen-like materials has been a major area of biomimetic materials research. The collagen mimics have diverse potential applications in drug delivery, biomedical devices, and tissue engineering (i.e., wound healing); therefore, major research has been performed to understand how its conformation is controlled by its typical Gly-X-Y repeats.

Goodman *et al*. first reported the incorporation of peptoid residues into the collagen-like triple helical structures. Initially, they focused on a bulky hydrophobic peptoid residue *N*-isobutylglycine (or Nleu) and introduced the submonomer as a proline surrogate.[49,151,152] A series of peptide–peptoid hybrids were synthesized based on (Gly-Pro-Nleu), (Gly-Nleu-Pro) or (Gly-Nleu-Nleu) sequences, which were then coupled to KTA scaffold (cis, cis-1,3,5-trimethylcyclohexane-1,3,5-tricarboxylic acid, also known as the Kemp triacid).[153] Biophysical analysis revealed that the sequences $(\text{Gly-Pro-Nleu})_n$ and $(\text{Gly-Nleu-Pro})_n$ ($n \geq 9$ and $n \geq 6$, respectively) formed stable triple helices. Interestingly, $(\text{Gly-Nleu-Pro})_n$ formed more stable triple helices than $(\text{Gly-Pro-Nleu})_n$ did, and the authors explained with molecular modeling that the isobutyl side chain of Nleu could have more hydrophobic contact with Pro in triple helices composed of $(\text{Gly-Nleu-Pro})_n$ than in those composed of $(\text{Gly-Pro-Nleu})_n$.

Unlike the other two sequences, $(\text{Gly-Nleu-Nleu})_n$ did not form a triple helical conformation; it had to be included in a host–guest fashion within sequences such as $(\text{Gly-Pro-Hyp})_n$ to adopt the triple helix conformation.[154] An example of the sequence is Ac-$(\text{Gly-Pro-Hyp})_3$-$(\text{Gly-Nleu-Nleu})_3$-$(\text{Gly-Pro-Hyp})_3$-NH_2, and the guest–host structure reatined triple helicity. Another sequence that behaved like Gly-Nleu-Nleu was Gly-N_x-Pro sequences where N_x was composed of a variety of alkyl peptoid residues. Using these guest–host collagen mimetic structures as model systems, the authors elucidated the contributions of steric and hydrophobic effects that are important for the triple helix formation.

2.204.7.2. Antifouling Agents

Exposure of medical devices to biological fluids is often accompanied by undesirable accumulation of proteins, cells, and microorganisms on the surface. Biofouling of surfaces can result in compromised device performance and in some cases may be life threatening to the patient. Various antifouling polymers have been used as coating materials for such medical devices and have

proven to be efficient in preventing protein and cell adsorption; however, few are ideal for providing long-term biofouling resistance. In this regard, Messersmith and Barron introduced a novel strategy to develop an efficient biomimetic antifouling system that was composed of a water-soluble inert peptoid and an anchor derived from mussel adhesive proteins.[155] The methoxyethyl side chain (Nmeg) of the peptoid portion was chosen for its chemical resemblance to the repeat unit of the known antifouling polymer poly(ethylene glycol) (PEG), and the 5-mer anchoring peptide was chosen to mimic the DOPA- and Lys-rich sequence of a known mussel adhesive protein (**1** in **Figure 12**). Peptide–peptoid conjugate **1** was found to be highly soluble in aqueous solution and adsorbed strongly onto TiO_2 surfaces by simple immersion process. Both modified and unmodified TiO_2 surfaces were then exposed to whole human serum, and the modified surface showed dramatic reduction of protein adsorption and resistance to mammalian cell attachment for over 5 months. Hence, these new antifouling polymers showed potential as long-term control of surface biofouling in physiological environments.

Numerous pathogenic microorganisms are capable of attaching and aggregating themselves on a surface and forming

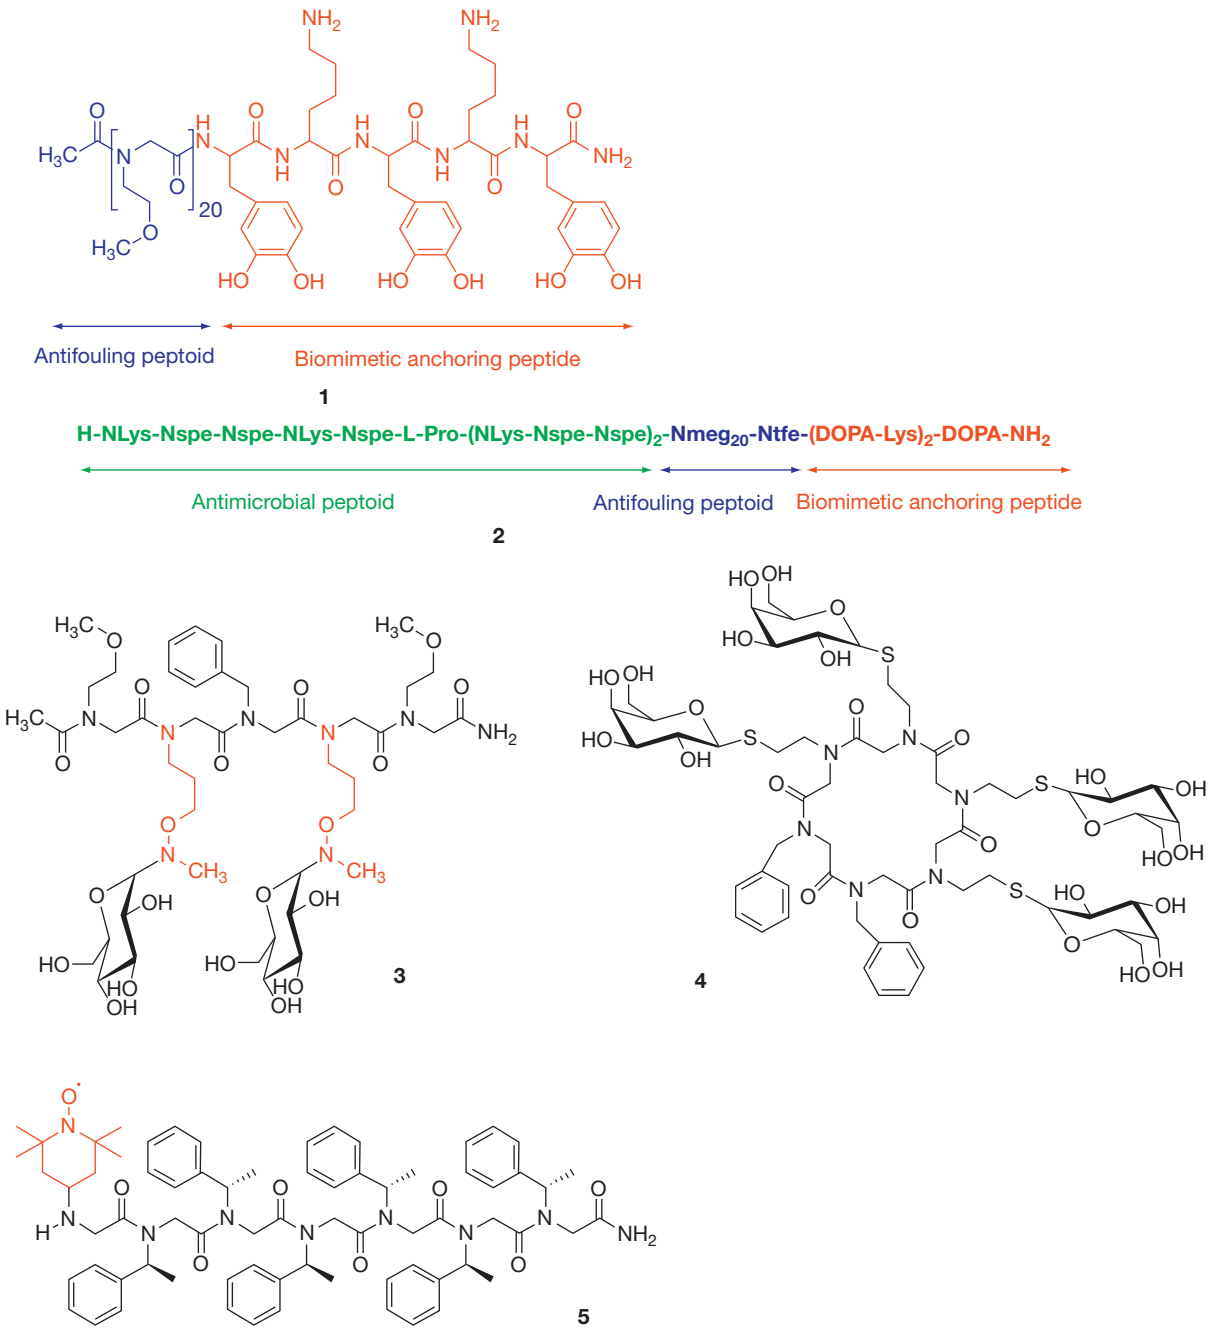

Figure 12 Peptoid-based biomaterials.

biofilm. Biofilms are known to be extremely difficult to eradicate and have been found to be involved in a wide variety of microbial infections in the body. Messersmith, Barron, and coworkers advanced their original antifouling peptide–peptoid hybrids by attaching antimicrobial peptoids at the N-terminus (**2** in **Figure 12**).[156,157] Surface modifications with this peptide–peptoid hybrid created a surface that was both antimicrobial (active) and antifouling (passive), and this material provided a promising solution to infections associated with implantable medical devices.

2.204.7.3. Glycopeptoids

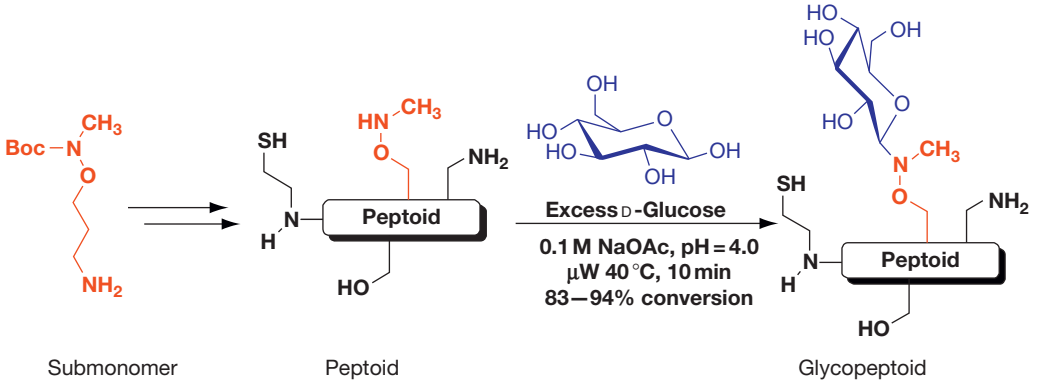
Glycosylation, a ubiquitous posttranslational modification in proteins, plays critical roles in protein folding, stabilization, trafficking, and recognition. Owing to the inherent complexity of carbohydrates, glycosylation can produce enormous structural diversity in proteins and induce a variety of functional changes. In an attempt to decipher these structure–function relationships, protein and peptide chemists have developed various chemical and enzymatic methods for the synthesis of homogeneous and well-defined glycoconjugates. Among the glycosylation methods, the *N*-alkylaminooxy-strategy is attractive because it employs native, completely unprotected sugars to glycosylate *N*-alkylaminooxy-containing peptides.[158] Carrasco and coworkers synthesized an *N*-methylaminooxy-containing primary amine as a peptoid submonomer, incorporated the submonomer into various peptoid chains, and demonstrated glycosylation of the peptoids using native sugars (**Scheme 1**).[159] The authors optimized the glycosylation conditions: a mildly acidic aqueous solution (0.1 M NaOAc, pH = 4.0) and a gentle microwave heating at 40 °C for a short time (~10 min) worked well for D-glucose, D-maltose, D-melibiose, D-lactose, maltotriose, and GlcNAc. Carbohydrates that contain an axial hydroxyl group such as galactose (C4 position) or D-mannose (C2 position) did not provide pure glycopeptoid products; they contained a portion of furanose by-products. Next the authors showed a divalent glycopeptoid was readily prepared using microwave conditions (**3** in **Figure 12**). The chemoselectivity of the glycosylation was also demonstrated using a peptoid that contained hydroxyl, amino, sulfhydryl, and carboxamido functionalities in addition to the *N*-methylaminooxy group. This N-methoxyaminooxy-strategy provides an efficient way to generate an extensive range of biologically functional glycopeptoids and multivalent glycopeptoids.

Another strategy of preparing glycopeptoids is to use protected carbohydrate-containing monomer units[160,161] or submonomeric units[106,162] as building blocks. This strategy is amenable for the synthesis of glycopeptoids that contain more than two different types of sugars in a single peptoid chain. But the potential drawback of this strategy is that a large-scale preparation of the peptoid monomers (or submonomers) can sometimes be cumbersome. Several groups reported *O*-linked, *N*-linked or *C*-linked glycopeptoid synthesis using this strategy.[107,163–165] Also Comegna *et al.* recently reported a method for an inexpensive and rapid synthesis of linear and cyclic *S*-linked glycopeptoids (**4** in **Figure 12**).[162] These glycopeptoids provide well-defined glycopeptide or glycoprotein mimics and are useful in many applications such as lectin-binding ligands, glycopeptide antigen mimics, multivalent carbohydrate display, and antifreezing protein mimics.

2.204.7.4. Other Applications

2.204.7.4.1. Enantioselective catalysts

Proteins form tertiary structures and provide chiral microenvironments required for asymmetric catalysis. Since Whitesides pioneered the conversion of a protein to a homogeneous enantioselective hydrogenation catalyst, artificial enzymes have been developed for various asymmetric reactions.[166,167] Mimicry of this effect with peptoid polymers has been achieved by Kirshenbaum and coworkers by positioning a catalytic center in a chiral microenvironment using peptoid helices.[168] Substrates that meet the spatial arrangement can access the active site and are converted to desired products. They used TEMPO (2,2,6,6-tetramethylpiperidine-1-oxyl) as the catalytic center for the oxidation of secondary alcohols to ketones and incorporated this active site into either middle position or N-terminal position of various peptoid sequences. Interestingly, best result was obtained when TEMPO was positioned at the N-terminus of peptoid helix (**5** in **Figure 12**); 84% conversion with >99% ee was achieved when 1% peptoid catalyst **5** was loaded. The reaction was carried out at 0 °C for 2 h. When TEMPO was incorporated into peptoid helix with the opposite handedness, the catalyst exhibited the opposite enantioselectivity with similar reaction conversion. This work



Scheme 1 General synthesis of glycopeptoids using *N*-methylaminooxy functionality.

provides a nice proof-of-concept study: a well-defined conformational ordering created by synthetic foldamers can mimic the asymmetric microenvironment produced by protein secondary or tertiary structures. This is an important step toward emulating protein function.

2.204.8. Summary and Future Directions

Peptoids are a bioinspired material whose properties lie in-between natural biopolymers and nonnatural synthetic polymers. Like biopolymers, they are information-rich polymers, offering precise control of main chain length, side chain functionality, and monomer sequence. Because peptoids are synthesized one monomer at a time from readily available building blocks, an almost infinite sequence-space awaits to be explored. The structural similarity to polypeptides has been responsible for the impressive diversity of biological activity observed for peptoids. The ability to precisely engineer polypeptoid structure is unprecedented for a synthetic polymer and will open up many fundamental studies in polymer physics and polymer self-assembly. The lack of a hydrogen-bond donor in the backbone holds great promise for polypeptoid-based self-assembly.

An impressive body of work on peptoids has been achieved in the past 20 years. Advances in the chemistry of peptoid synthesis have enabled a better understanding and control of peptoid secondary and tertiary structure. Computational methods to model and predict polypeptoid conformation are at an early stage, and improvements in these tools are greatly needed. Combinatorial synthesis and screening methods of peptoid libraries have been developed for a variety of functions, ranging from drug discovery and drug delivery to materials science.

Ultimately, as the understanding of peptoid conformational control, chain folding, and self-assembly continues to grow, we expect to be able to generate a new family of advanced materials that rival the structure and function of proteins. Such protein–mimetic materials would be capable of sophisticated functions like molecular recognition and catalysis, and yet would have enhanced stability to biological, chemical, and environmental stresses.

The accelerating efforts in peptoid research described in this chapter are a result of the practical nature of their synthesis, as well as in their intriguing properties. Yet the field is actually in an unusual situation; synthesis of polypeptoids is not limiting the field. These tools are well developed and easily adopted. The challenges are now centered on how to design molecules with the desired properties and activities. Combinatorial screening methods will continue to be important while the tools for prediction of peptoid structure and function catch up. It is a very exciting time for the field, as we see the immense gap between biopolymers and synthetic polymers begin to close.

2.205.1. Introduction

Molecular self-assembly can be defined as the spontaneous transition of initially disordered molecules into predictable supramolecular structures, usually driven by specific noncovalent interactions. Much of biology is a result of self-assembly, which taken to an extreme, produces the high molecular weight networks that constitute the cytoskeleton and the extracellular matrix. Self-assembling strategies in biomaterials can likewise produce highly structured, compositionally defined, multicomponent, multifunctional materials from a discrete set of molecular building blocks.

Self-assembly has become a prominent strategy in chemistry and materials science as a whole. It has become significant in highly diverse applications, in fields ranging across electronic materials, synthetic biology, structural materials, chemical biology, and biomaterials. The objective of this chapter is to generally outline several of the concepts and strategies based on molecular self-assembly that have received particular interest in the past several years for designing biomaterials. Specifically, the chapter focuses on biomaterials that self-assemble in two-dimensional (2D) structures, primarily self-assembled monolayers, and biomaterials that self-assemble in 3D structures, primarily those based on peptides and proteins. Bioconjugates of peptides and polymers are addressed, but purely polymeric self-assembling materials are outside the scope of the chapter and have been covered in several recent reviews.[1,2]

The forces that direct molecular self-assembly tend to be weak intermolecular interactions between molecules in solution. These include hydrogen bonding, hydrophobic interactions, Coulombic interactions, π-stacking, and van der Waals forces. Accordingly, self-assembling systems tend to be highly dependent on solution conditions such as pH, ionic strength, concentration, temperature, and solvent polarity, aspects that have been exploited to produce conditionally assembling or stimulus-sensitive materials. In addition to controllable stimulus-sensitivity, self-assembling approaches provide a set

of unique advantages that make them useful as biomaterials. First, large, relatively complex supramolecular structures and objects such as fibrils, networks, and membranes can be formed from synthetically accessible, small molecular weight components. In this way, the chemical definition of the material can be highly controlled, even when multiple co-assembling constituents are present. In comparison with structurally and compositionally heterogeneous biomaterials such as biologically sourced polymers, such definition is a significant advantage. Second, by identifying molecules that can self-assemble and be functionalized with ligands or chemical groups either postassembly or preassembly, materials displaying complex combinations of molecular features can be produced from an easy-to-synthesize initial set of molecules. In this way, multifunctional materials can be systematically produced and optimized. In the sections below, 2D and 3D biomaterials that take advantage of these properties are discussed.

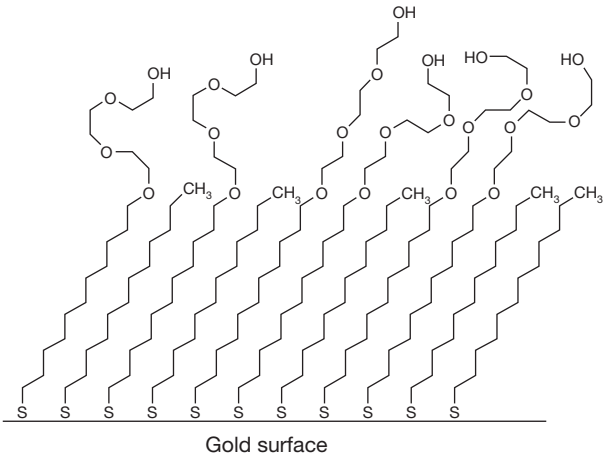

Figure 1 A self-assembled monolayer (SAM) displaying nonfouling oligo(ethylene glycol) terminal functionalities.

2.205.2. Planar Self-Assembling Systems

Although almost all physiological processes operate in three dimensions, planar surfaces have been the *de facto* substrate for adherent cells for most of the history of cell culture. Planar systems are useful because of their chemical definition, simplicity, cost-effectiveness, and compatibility with a wide range of imaging methods. However, traditional glass or polystyrene tissue culture surfaces mediate cell adhesion through an adsorbed layer of proteins. This layer can be derived from serum proteins in the culture medium, from proteins secreted by the cells themselves, or by purposefully precoating the surface with matrix proteins such as fibronectin or collagen. Such adsorbed layers are complex, presenting varied and dynamic mixtures of conformations for different proteins, making the precise engineering or study of cell–surface interactions challenging. Many 2D self-assembling biomaterials have been developed in order to improve upon these simple, poorly defined substrates. As described below, one of the main goals of 2D self-assembling biomaterials is to provide surfaces for which the identity, density, availability, spatial positioning, and dynamic properties of specific cell–surface interactions may be specified. Strategies that allow the lateral motion of surface functionalities, such as supported lipid bilayers, have been extremely useful for modeling cell–surface interactions, for studying proteins and structures associated with cell membranes, and for producing functionalized culture surfaces. However, this section focuses primarily on strategies for which lateral diffusion is minimal or nonexistent, owing to the robustness and applicability of such surfaces within many biomaterials contexts. Supported bilayers have been reviewed recently and are addressed in other chapters of this comprehensive volume as well.[3–5]

2.205.2.1. Self-Assembled Monolayers

Self-assembled monolayers (SAMs) are molecular layers that assemble on a surface by adsorption, usually from solution. Their formation is mediated by a specific functional group that has a strong affinity for a particular surface. Several different SAMs have been developed for a range of different materials including medically related metals such as titanium,[6] but the most extensively investigated have been SAMs utilizing alkanethiolates and gold.[7–9] When a gold surface is immersed in a solution of alkane thiolates, the sulfur atoms coordinate to the gold (111) surface in a densely packed array (Figure 1). The alkane portion extends from the surface, and it can be functionalized with a wide range of chemical modifications, either preassembly or postassembly, to provide surfaces with defined chemistries. Useful properties of SAMs include their optical transparency when applied to thin gold layers and their electrical conductivity, which makes them applicable to electrochemical modulation of surface properties. Mixed SAMs of multiple different alkane thiols may also be produced by incubating gold surfaces under mixed solutions of different alkanethiolates. In this way, ligands, chemical functionalities, or nonfouling alkane thiols can be applied to a surface in defined formulations, as described below. In this chapter, several overarching concepts in the development of SAMs will be discussed, citing relevant examples from the literature. For a more complete recent discussion of the various approaches used, the reader is referred to Robertus *et al.*[9]

2.205.2.2. Functionalized SAMs for Modulating Cell Attachment

As an alternative to the poorly controlled adsorbed layers of proteins that are a general feature of traditional cell culture systems, SAMs displaying precise combinations of biochemical features have been developed. One of the initial steps involved in creating such defined self-assembled surfaces has been to first reduce or eliminate the protein adsorption that naturally complicates traditional culture surfaces. In this regard, SAMs displaying terminal oligoethylene glycol groups have been the most thoroughly investigated, though SAMs terminated with other nonfouling groups such as oligosarcosines, permethylated sorbitol groups, or oligophosphorylcholines have also demonstrated good resistance to protein adsorption.[9–11] Such monolayers are stable in cell culture for several days.

Early work with functionalized SAMs utilized oligoethylene glycol monolayer backgrounds containing around 1 mol% or less of a functionalized alkane thiol. For example, a small amount of RGD peptide-terminated alkanethiolates was mixed

with triethylene glycol-terminated alkanethiolates to promote cell adhesion via integrin binding.[12] This system has also been used with other peptide ligands of interest, such as the PHSRN peptide from the ninth type-III domain of fibronectin.[13] The ability to adjust the relative amounts of each ligand on the surface has been utilized to study the mechanism of integrin binding to these fibronectin fragments. Mixed SAMs have also been employed to produce gradients of cell adhesion molecules for investigating cell adhesion and migration.[14,15] One potential concern, however, is that it is possible that phase-separated domains may form in such mixed monolayers, but it has been found that such phase separation can usually be avoided if the density of the functionalized alkanethiolate is kept below 1% of the total alkanethiolate.[8]

2.205.2.3. Patterning and SAMs

SAMs are natural complements to surface patterning techniques such as microcontact printing (μCP), which uses an elastomeric stamp to transfer 'ink' to defined patterns of a planar surface.[16] Stamps are produced by casting an elastomer, typically polydimethylsiloxane, onto a high-aspect-ratio topographical pattern fabricated via photolithography. The stamp is then inked with an alkane thiol of choice and placed in contact with a gold surface, whereby the alkanethiol is transferred to the gold. A second alkane thiol can then be applied to nonstamped regions by immersing the surface in a solution containing the second alkane thiol. In a foundational report of using this technique to control cell behavior, Chen and coworkers produced cell-adhesive islands with varying sizes surrounded by a nonadhesive background. Cells restricted to small islands became apoptotic, whereas apoptosis was progressively diminished as island size increased.[17] μCP and SAMs have since been utilized to explore a wide range of cell behaviors, including differentiation, cell division axis orientation, epithelial monolayer growth, proliferation, and others (for review see Ruiz and Chen[16]). In more recent work, μCP has been used to control the subcellular shape of the cytoskeleton, which in turn exerts strong influences on cell contractility and differentiation.[18–20] For example, Mrksich and coworkers developed pentagonal patterns on which single cells could be maintained, where the concavity of the pentagonal features were modulated (Figure 2).[18] They found that rounded features (producing a flower-like pattern) promoted the differentiation of mesenchymal stem cells into adipocytes, whereas pointed features (a star pattern) promoted osteoblastic differentiation. One of the critical features of the highly defined SAM substrates used in this study was the reproducibility of both the pattern and the surface chemistry supporting each individual cell. Owing to these features, the cytoskeletal organization of dozens of cells exposed to extremely similar microenvironments could be overlaid so as to statistically compare them and generate averaged structures of their cytoskeletons (Figure 2). It is anticipated that these and similar methods of reducing population heterogeneity in biological samples will prove to be powerful techniques in fields ranging from cell biology to drug discovery in the coming years.

In addition to sharply defined patterns such as those produced with techniques like μCP, gradated patterns on SAMs are also of significant interest, especially for studies of cell migration. Methods for producing gradients include electrochemical desorption of alkanethiolates from SAMs,[21] photochemistry,[22] and microfluidic manipulation. In an example combining microfluidics with SAMs displaying short chemically defined peptide ligands, one recent approach created patterns of 33-μm squares containing gradients of cell-adhesive peptide ligands within each square. The squares were placed within a background of a nonfouling tri(ethylene glycol)-terminated SAM. Gradients of RGD ligands were produced by flowing gradated mixtures of functional RGD peptides and nonfunctional scrambled RDG peptides onto patterns of maleimide-terminated SAMs using a microfluidic system. The gradient produced within the solution phase of the microfluidic system was reflected by a similar gradient immobilized to the maleimide-terminated SAMs, and the total peptide immobilized to the surfaces was kept constant.[23] When cultures of mouse melanoma cells were seeded onto these substrates, the RGD gradients were reflected in a proportional distribution of the focal adhesion protein vinculin, demonstrating that the gradients influenced the spatial organization of cellular adhesive complexes.

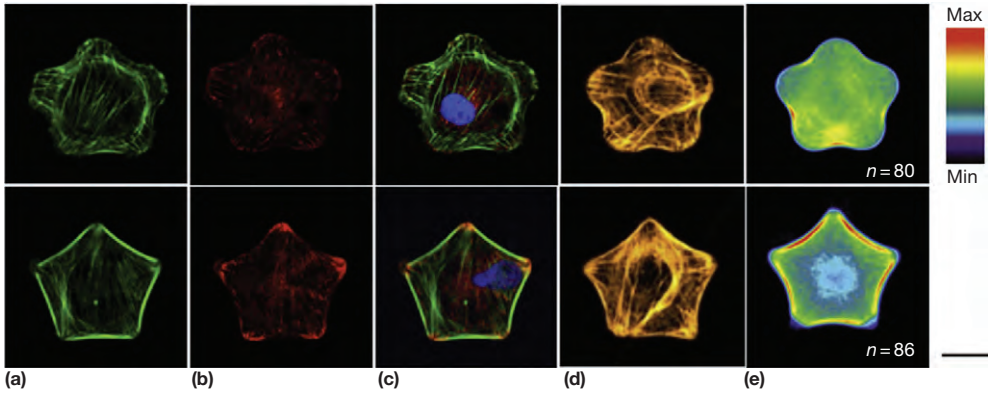

Figure 2 Defined two-dimensional self-assemblies such as self-assembled monolayers provide the opportunity to place individual cells in highly repeatable chemical and geometric environments. Shown are immunofluorescent images of human mesenchymal stem cells in flower and star shapes stained for F-actin (green), vinculin (red), nuclei (blue), and myosin IIa (orange) (a–d). Heat maps of >80 different overlaid images of myosin IIa can be used as a quantitative measure of contractility (e). Scale bar = 20 μm. Reproduced with permission from Kilian, K. A., Bugarija, B., Lahn, B. T., Mrksich, M. *Proc. Natl. Acad. Sci. USA* **2010**, *107*, 4872–4877, with permission from Mrksich.

Further, although micropatterning approaches have significantly utilized SAMs, micropatterned culture surfaces have also been explored using a wide range of other patterning approaches, including those based on photolithography,[24,25] photolithographically patterned polymer coatings,[26] anisotropic surfaces,[27,28] and microfluidics.[29]

2.205.2.4. Responsive Elements and Dynamic SAMs

Planar self-assembled biomaterials such as SAMs are amenable to modification with a range of chemical approaches, including oxidation, electrochemistry, photochemistry, and other regio- or chemoselective techniques. Either singly or in combination, such strategies have been utilized to produce biomaterials with dynamic control over their interactions with cells. A goal of these techniques is to produce surfaces for which a specific biological activity, such as engagement of a specific cell or receptor, can be turned 'off' or 'on.' Such 'switchable' surfaces are valuable in applications ranging from basic biological investigations to cell-based devices and sensors. They have been particularly useful in combination with patterning techniques, which allow the switching of spatially resolved areas of culture surfaces.

Owing to the inherent electrical conductivity of the gold layers on which SAMs are immobilized, electrochemical approaches in particular have been exploited to develop switching strategies. In one example, nonfouling SAM constituents were desorbed by application of a reductive potential, switching the surface from one that resisted protein and cell adhesion to one that supported cell adhesion and migration.[30] By initially confining cells within micropatterned areas of cell adhesiveness and then rendering the entire surface adhesive by desorbing the nonfouling triethylene glycol SAM regions, a useful migration assay was produced. Electrochemical desorption has also been utilized to release cells captured to the SAM via SAM-linked antibodies. In a recent example, T cells were captured on a SAM presenting anti-CD4 antibodies. Subsequently, an applied reductive potential could be used to trigger detachment of the SAM and a corresponding cell detachment.[31] Such processes could be useful for capturing, concentrating, and releasing specific cells from heterogeneous mixtures. Another example of switching a SAM surface from displaying a ligand to releasing it focused on SAMs displaying biotin tethered via a quinone propionic ester, which upon application of a reductive potential released the biotin into the solution.[32] A similar approach was later applied to SAMs displaying RGD peptides instead of biotin. This chemistry was patterned into circular regions using μCP and displayed on the same surface as other regions displaying RGD peptides tethered to the SAM via an *O*-silyl hydroquinone, which could release the ligand under oxidative potentials instead of reductive ones.[33] By patterning the two different chemistries into different regions of the surface, and by also including a third nonelectroactive RGD-bearing SAM, cells could be selectively released in one region by application of a reductive potential, in a second region by application of an oxidizing potential, or maintained on the surface within the nonelectroactive regions. Other means for switching cytophobic surfaces to cell-adhesive surfaces have included the use of microelectrodes to locally generate Br_2 to degrade oligoethylene glycol-terminated SAMs, leaving alkyl-terminated SAMs.[34] In this work, the local degradation of the otherwise protein- and cell-resistant oligoethylene glycol termini of the SAM rendered the remaining alkyl-terminated SAMs able to adsorb proteins.[34,35] By using a microelectrode as a 'pen,' patterns could be drawn on culture surfaces in a customizable manner. Surfaces switchable via UV illumination have also been developed for silane-based monolayers on glass, in which SAMs terminated with photocleavable 2-nitrobenzyl groups were employed.[36,37] When these SAMs were coated with Pluronic block copolymers, they were non-cell-adhesive, but irradiation by UV light resulted in the development of a carboxy-terminus on the SAM. This switch desorbed the Pluronic coating, allowing subsequent fibronectin adsorption and the rendering of the surface cell-adhesive. This chemistry has been utilized to study the process of cell migration in single-cell microarray formats.[37]

Techniques for selectively attaching ligands to SAM surfaces have also been developed using both electrochemical and photochemical approaches. In an early example of an electrochemical strategy for doing so, monolayers presenting hydroquinone groups against a background of triethylene glycol groups could be switched with an oxidizing potential to present benzoquinone groups, which could subsequenty be reacted with cyclopentadiene-terminated peptides via a Diels–Alder reaction to afford peptide-terminated SAMs.[38] In this way, surfaces could be switched from being nonadhesive to being cell-adhesive (**Figure 3(a)–3(c)**). This approach has been useful in constructing migration assays and spatially organized co-cultures. In the fabrication of co-cultures, one cell type was allowed to attach to a specific pattern, after which the remaining surface was rendered cell-adhesive to support the attachment of a second cell type. In an example of a photochemical approach for creating switchable surfaces, monolayers presenting NVOC-protected hydroquinone groups were developed (**Figure 3(d)**). Deprotection of the hydroquinone could be achieved by illumination with 370 nm light. Conversion of the hydroquinone groups to quinones via chemical oxidation and subsequent conjugation of cyclopentadiene-terminated RGD peptides then produced the RGD-terminated SAMs in photopatterned arrays.[39] An exhaustive discussion of the strategies developed to date for designing switchable SAMs is beyond the scope of this chapter; for a more extensive review, the reader is referred to Robertus *et al.*[9]

Collectively, SAMs and other planar self-assembling systems provide surfaces that are highly defined chemically. This precise definition enables a wide range of electrochemical, photochemical, microstamp-based, or microfluidic manipulations that can be used to position specific functionalities and to switch them dynamically.

2.205.3. 3D Self-Assembling Systems

Molecular self-assembly into 3D structures has become an increasingly common synthetic route in applications ranging from electronics to 'smart' materials to composites. Self-assembling approaches can employ aqueous conditions, organic solvents, inorganic materials, organic compounds, or even macroscopic objects. Despite this wide range of strategies available, within the biomaterials field a subset of self-assembling materials has received the most intense interest: those that assemble in aqueous solutions, and those that are

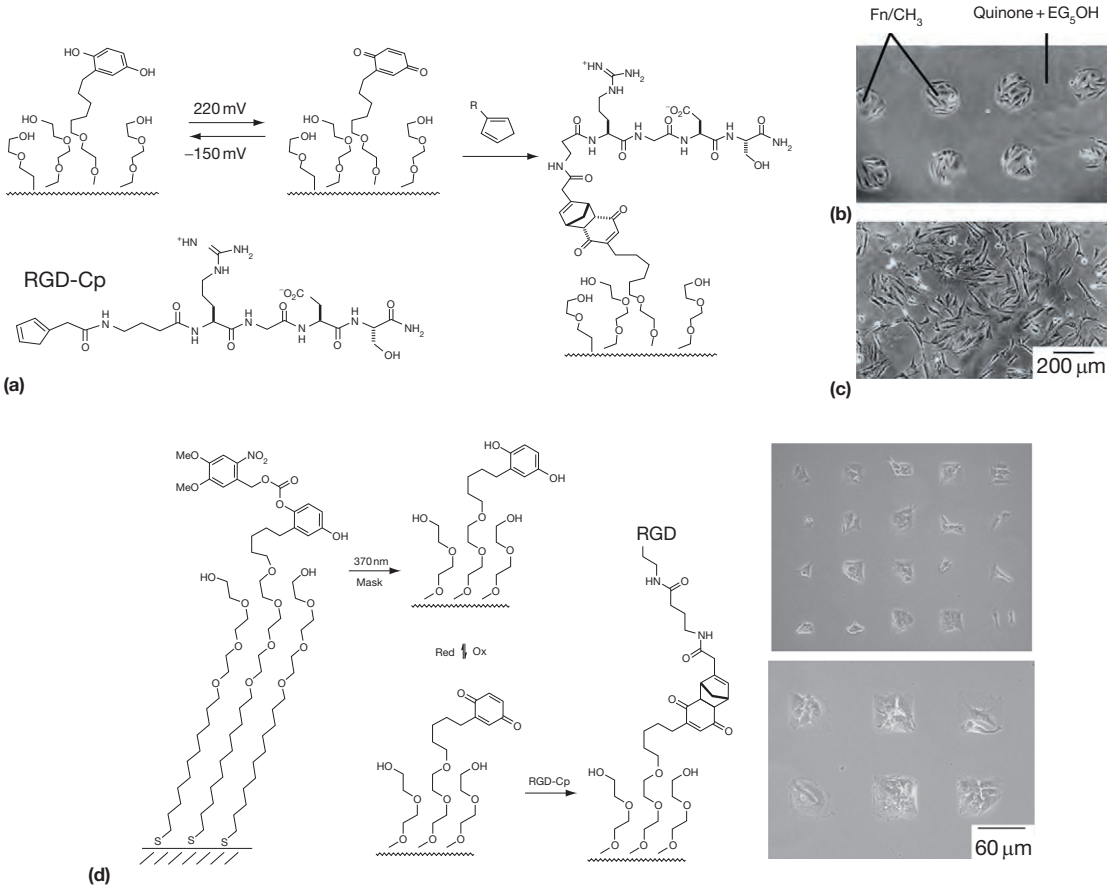

Figure 3 Self-assembled monolayers (SAMs) presenting electrically active groups (a–c) and photoreactive groups (d). In electrically switchable SAMs (a), inert monolayers presenting hydroquinone groups mixed with penta(ethylene glycol) groups were converted to monolayers that support cell attachment and spreading by application of a positive potential, which converted the hydroquinone groups to quinone groups. The quinone groups then underwent a Diels–Alder reaction with RGD–cyclopentadiene (RGD–Cp) to conjugate the peptide onto the surface. Fibronectin was adsorbed on to the methyl-terminated regions and initially cells attached only to the fibronectin-coated regions (b), but after oxidation of the substrate in the presence of RGD–Cp, cells were able to migrate and then grow to fill the entire monolayer (c). Photoreactive SAMs have included those presenting photosensitive NV OC-protected hydroquinone groups in a background of oligoethylene glycol groups (d). Illumination by 370 nm light revealed hydroquinone groups, which could be converted to quinones by applying tetramethylbenzoquinone and functionalized further with RGD-Cp (left, d). 3T3 fibroblasts could be patterned on RGD-functionalized islands of the substrate (right, d). based on native biopolymers, especially peptides and proteins. Aqueous conditions are required for interfacing with biological processes, and polyamino acids afford bioactive structures that can, in principle, approach the functionality of native proteins.

2.205.3.1. Self-Assembling Peptides

Peptides have been extensively employed in self-assembling biomaterials strategies owing to their native biofunctionality, their ease of synthesis, and their chemical definition. Standard synthesis and purification techniques allow for significant control over structure and purity, and they provide opportunities for chemically modifying the peptide termini, for chemically modifying side chains, for conjugating peptides to other macromolecules such as polymers, or for incorporating any number of commercially available nonnative amino acids. The construction of supramolecular structures from peptides has also been enhanced by the elucidation of design rules that can be exploited to direct peptide folding into several useful secondary and tertiary structures, including coiled coils, β-sheet fibrils, collagen triple helices, and other more specifically folded domains. Each of these structures is stabilized by multiple noncovalent forces that act in concert, including hydrogen bonds, hydrophobic interactions, van der Waals forces, or the stacking of aromatic groups. The following sections will discuss these structures in greater detail.

2.205.3.2. Coiled Coils

As one of the fundamental secondary structures in nature, the α-helix is a useful building block for self-assembling biomaterials. However, α-helices tend not to be stable as monomers in solution owing to the ability of water to interact with their backbone N–H and C=O groups, providing an entropic cost for helix formation. This entropic penalty can be overcome by designing peptides where multiple noncovalent intermolecular

interactions are used to stabilize helical folding. To accomplish this in biomaterials strategies, the coiled coil has been the most heavily investigated structure. Coiled coils (Figure 4(a) and 4(b)) are common motifs found in a wide range of proteins,[40,41] including fibrous proteins,[42] transcription factors,[43] extracellular matrix proteins,[44] load-bearing proteins,[45] and membrane spanning proteins.[46,47] Most coiled coils exist as a supercoil of 2–5 helices,[41] and their primary structures tend to possess a regular pattern of polar and nonpolar residues in a well-known heptad repeat denoted by $(abcdefg)_n$, where residues in the *a* and *d* positions are nonpolar, and the other positions are polar (Figure 5). The average spacing between nonpolar residues is thus 3.5 residues, and the 3.6-residue pitch of the α-helix leads to the formation of a hydrophobic stripe that spirals around the helix. Burial of this hydrophobic stripe by oligomerization with other helices then forms a supercoil with a left-handed twist. While residues in the *a* and *d* positions form the hydrophobic contacts between different coils, residues in the *b*, *c*, and *f* positions are exposed to the solvent, and residues in the *e* and *g* positions can participate in interhelical electrostatic interactions that modify the topology or oligomerization state of the helices (Figure 5).

Coiled coils can be parallel or antiparallel, and the packing of *a* and *d* residues differs between the two topologies. In parallel coiled-coil dimers, residues in *a* positions form close contacts with *a* residues of the second helix, whereas in antiparallel dimers, residues from *a* positions pair most closely with residues in *d* positions of the second helix (Figure 5(a)). Likewise, the pattern of electrostatic interactions between *e* and *g* residues differs with antiparallel versus parallel topology. In parallel coiled-coil dimers, electrostatic interactions exist between *e* residues on one helix and *g* residues on the other, whereas in antiparallel coiled coils, interhelical interactions occur between *g*–*g* pairs and *e*–*e* pairs (Figure 5(b)). Knowledge of these intermolecular interactions between residues in the $(abcdefg)_n$ heptad repeat are the basis of many design strategies that have been utilized to construct coiled-coil self-assembling biomaterials.

Additional levels of design rules have also been developed for specifying coiled-coil assembly. First, the identity and packing of the *a* and *d* residues in the hydrophobic core can be tuned to specify oligomerization state. In general, aliphatic residues have been the most heavily utilized in this regard owing to the steric constraints of aromatic residues. Aromatic residues are relatively uncommon in *a* and *d* positions of natural coiled-coil structures, although Trp zippers and Phe zippers have been designed and produced.[48,49] For the formation of dimers, *a* positions containing β-branched residues (Ile and Val) and *d* positions containing Leu have been found to be particularly stabilizing.[50,51] This is thought to be a result of the ability of these branched residues to pack appropriately to fill the space between the two helices. In contrast, it has been shown in some models that if all *a* and *d* residues are Ile, trimers are favored, whereas Leu in *a* positions and Ile in *d* positions favors tetramers.[52,53] Electrostatic pairing between *e* and *g* residues can also influence the oligomerization state, especially when used in conjunction with strategies for packing residues in the hydrophobic core.[54] Studies of amino acids in

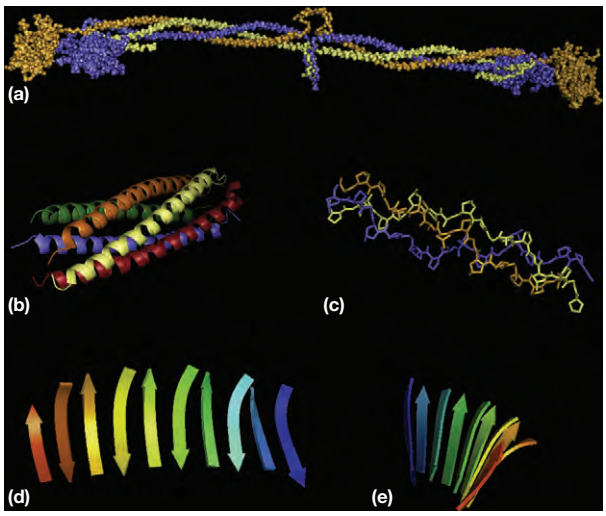

Figure 4 Peptide folding that has been utilized in self-assembling biomaterials. Networks of extracellular matrix proteins are constructed through hierarchical levels of self-assembly. As an example, the symmetrical dimer of trimers forming the protein fibrinogen (a, chicken fibrinogen shown) forms a long fibrous protein in part by the oligomerization of long stretches of triple-helical coiled coils. A pentameric coiled-coil bundle (b). Self-assembled synthetic collagen triple helices (c) have been utilized for producing collagen-mimetic biomaterials. β-sheet fibrillization ((d) side view; (e) axial view illustrating twist) has been a heavily investigated mechanism of self-assembly for peptide biomaterials. Figures created using PyMOL, Delano Scientific.

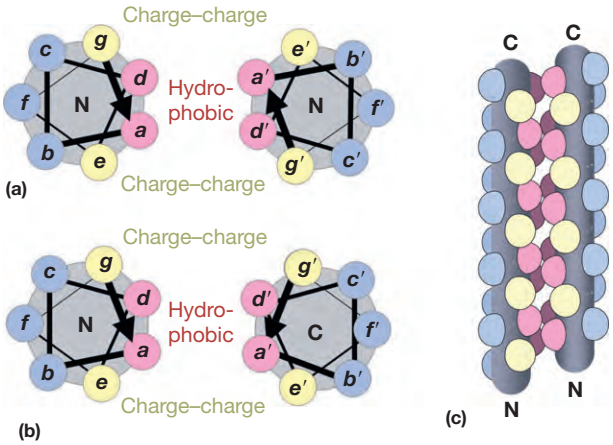

Figure 5 Coiled-coil helical wheel projections (a, b). Residues in *a* and *d* positions form hydrophobic contacts between helices. In parallel coiled-coil dimers (a), residues in *d* positions make closest contacts with those in *d*′ positions, located diagonally across the hydrophobic interface when depicted in helical wheel diagrams (the prime denotes the second helix). Residues in *a* positions make closest contacts with residues in *a*′ positions. Conversely, in antiparallel coiled-coil dimers (b), residues in *d* positions make close contact with residues in *a*′ positions (again located diagonally across the hydrophobic interface in helical wheel projections), and vice versa. Residues in *g* and *e* positions participate in Coulombic interactions to stabilize coiled-coil folding, with residues in *g* positions interacting with residues in *e*′ positions in parallel bundles (a). In antiparallel bundles, *g*–*g*′ contacts and *e*–*e*′ contacts are made. Part (c) adapted from Arndt, K. M.; Pelletier, J. N.; Müller, K. M.; Alber, T.; Michnick, S. W.; Plückthun, A. *J. Mol. Biol.* **2000**, *295*, 27–639, with permission from Elsevier.

the ***e*** and ***g*** positions have shown that a Lys-Glu pair is more stabilizing in the E***e***–K***g*** position as compared to K***e***–E***g*** position,[55] and amino acids in ***b***, ***c***, and ***f*** positions can be specified to guide lateral assembly into higher-order coiled-coil structures.[56–58]

To specify the alignment of helices with respect to each other axially, one strategy has been to place polar residues, such as Asn, in putative nonpolar ***a*** or ***d*** positions. Alignments between multiple helices that position two or more of these nonpolar residues together in the hydrophobic core are then less destabilizing than independently acting buried polar residues.[53,59] Even when buried polar residues are paired, however, some degree of destabilization results, so a compromise must be made between coiled-coil stability and registration in this design strategy. Peptide length is also a factor that impacts coiled-coil stability, and it is generally challenging to produce stable coiled-coil bundles with fewer than three complete heptads.[60] Peptides as short as fourteen amino acids have been designed de novo, however, and in some cases lengthening a coiled-coil peptide can destabilize it if it is only moderately stable to begin with, illustrating some exceptions to this rule.[61,62] For a more extensive discussion of coiled-coil folding and design in the context of biomaterials construction, see Apostolovic *et al.*[63]

2.205.3.3. Biomaterials from Coiled Coils

The relative simplicity of coiled-coil structures compared to more complex folding of proteins has led to extensive use of coiled coils as components of self-assembling biomaterials. Several computational programs like 'COILS,'[64] 'PAIRCOIL,'[65] and 'MULTICOIL'[66] have been developed that aid in the selection and design of such peptides. For biomaterials, one of the critical issues regarding the use of coiled coils as oligomerization domains is how to connect them into extended networks. To this end, several strategies have been developed for producing fibers, fibrils, or cross-linked structures capable of behaving as gels. These approaches can be categorized into several groups, including expressed proteins, peptide–polymer conjugates, and short peptides that form coiled-coil fibers (**Figure 6**). In high enough concentrations, each of these types of molecules is capable of forming gels that can be used as biomaterials.

Peptide–polymer conjugates and proteins capable of forming gels through coiled-coil assembly have been based significantly on designs having terminal helical peptide sequences flanking a central hydrophilic and disordered sequence (**Figure 6(b)**). Oligomerizaiton of the helical portion of such proteins into coiled coils in water produces viscoelastic materials.[68] Hydrophilic polymers with side chain helical peptides have also been developed (**Figure 6(a)**), and assembly of the helical peptides into coiled coils likewise can produce hydrogels.[67] Combining peptide sequences with polymers not only provides control over structure but also allows the incorporation of biologically interactive materials. In tissue engineering applications, hydrogels based on the coiled-coil peptide motif conjugated to HPMA[67,71,72] and PEG[69] have been reported by Kopecek and coworkers and Collier and coworkers, respectively. Properties such as temperature responsiveness, swelling behavior, and viscoelasticity can be tuned on the basis of peptide design and the number of peptide grafts on each polymer chain.[71–74] Since their introduction in the late 1990s, the designs of both protein-based and peptide–polymer coiled-coil biomaterials have been systematically improved.[73] Recent advances have included strategies for regulating the interconnectivity between the coiled-coil domains, including minimizing the formation of short loops or intramolecular helical bundles. Both intramolecular assembly and loops can

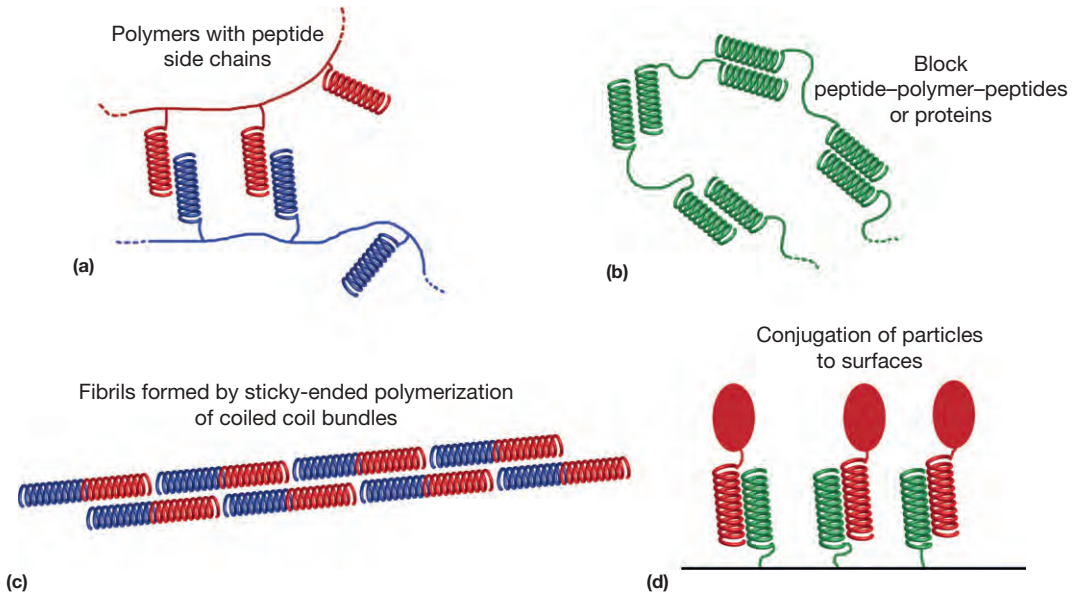

Figure 6 Coiled coils as oligomerizing domains for self-assembled biomaterials. Strategies that are capable of forming biomaterials and gels include polymers with side chain helical peptides that cross-link via coiled-coil oligomerization (a),[67] peptide–polymers or expressed proteins that have terminal helical peptides separated by a random-coil central domain (b),[68,69] and long fibrous bundles formed by the 'sticky-ended' noncovalent polymerization of coiled-coil bundles (c).[56] Coiled coils may also be used to attach proteins or particles to surfaces (d).[70]

compromise the gels' mechanical properties, so strategies for reducing them have been important for enhancing the robustness and lifetime of coiled-coil materials.[75] Also, covalent cross-linking has been employed to minimize any rearrangements in the supramolecular assemblies that could cause individual molecules to pull out of the extended network. Such covalently linked coiled-coil assemblies have been used to generate stable coatings for biomaterials.[76]

Although most approaches for producing gels have utilized polymers or randomly structured protein chains to link coiled coils together into extended networks, a recent strategy utilized coiled-coil peptides as the sole structural components (**Figure 6(c)**). Peptides were designed that polymerized via coiled-coil bundles with 'sticky ends,' or single-helix overhangs, and the fibrils themselves further assembled to form fibers and other laterally entangled networks.[56,77] By specifying the extent of lateral assembly through the selection of appropriate ***b***, ***c***, and ***f*** residues, hydrogels could be produced that were amenable to cell culture. Variants of this strategy have also been developed for introducing kinks,[78] branches,[79] and fiber-recruiting peptides into these scaffolds,[80] illustrating the diverse topologies that may be possible in this system. Beyond their use as gel materials, coiled coils have also been used for the controlled oligomerization of nanoparticles[70] and proteins,[81] for the attachment of proteins onto surfaces,[82] and the binding of nonbiological cofactors.[83]

2.205.3.4. Self-Assembling Peptides Based on β-Sheet Fibrils

The β-sheet fibril has received considerable attention as an engineered biomaterial. β-sheets are formed by adjacent parallel or antiparallel peptide strands that are hydrogen bonded in a 'pleated' conformation.[84,85] In β-sheets, the backbone N–H and C=O of one strand hydrogen bond with the C=O and N–H of an adjacent strand, respectively, and the side chains project alternatively above and below the plane of the sheet. Although this hydrogen bonding pattern between peptide backbones is the defining characteristic of β-sheets, the structure is also reinforced by hydrophobic interactions, van der Waals forces, and electrostatic interactions that occur between the side chains and between the side chains and backbone. Most sheets also have a twist of 0–30° between consecutive strands.

It is known that certain patterns of polar and nonpolar amino acids favor the formation of β-sheet structures.[86] Peptides with strictly alternating polar and nonpolar residues, for example, can produce β-sheet fibrils, and many such peptides have been utilized in the construction of self-assembling biomaterials.[87] In a β-sheet with alternating polar/nonpolar sequences, all hydrophobic residues are placed on one side of the sheet, and all hydrophilic residues are placed on the opposite side, providing an amphiphilic surface that drives assembly into tertiary structures such as fibrils. However, alternating sequences do not always result in well-defined sheets,[88] and many β-sheet fibrillizing peptide sequences that do not strictly adhere to the alternating polar/nonpolar design have been described.[3,4,89–97] Despite the wide range of primary sequences that can form β-sheet fibrils, once they are fibrillized, they can be very difficult to distinguish on the basis of their morphology. β-sheet fibrils are highly consistent in their morphology, even when constructed from unrelated peptides or proteins. The fact that there exist so many peptides of varying sequences, lengths, and patterning of polar and nonpolar residues that form β-sheet fibrils suggests that β-sheet assemblies can tolerate a variety of appended sequences or other modifications. This property has been capitalized on in recent years to produce functionalized β-sheet fibrillar biomaterials, as described below. β-sheet fibrils tend to be relatively unbranched, laterally entangled, about 8–15 nm wide, and up to several microns long. Individual peptide strands run perpendicular to the fibril axis, although the parallel-versus-antiparallel topography can vary, as can the presence of turns or hairpins at the fibril edge. In millimolar concentrations, such peptides tend to form gels in water.

One of the most useful features of β-sheet fibrillizing peptides is that their assembly is highly dependent on solution conditions, including ionic strength and pH. This sensitivity can in turn be used to design systems that assemble under defined stimuli or triggers.[98] Salt-sensitive assembly was systematically studied for the peptide $(FKFE)_3$. For this peptide, it was found that the critical salt concentration for inducing assembly was highly dependent on the salt's valency, with higher valencies inducing assembly at lower concentrations.[99] These findings were in agreement with the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory and the Schultz–Hardy rule. It was also found that increasing the hydrophobicity of the residues in the nonpolar amino acid positions decreased the critical salt concentration, also consistent with DLVO theory.[99] Such salt sensitivity also has a unique advantage with regard to β-sheet peptide use as biomaterial scaffolds, as it enables *in situ* gelation when injected into the body. For example, Lee and coworkers utilized the conditional gelation of RADA-16 peptides to deliver injectable peptide scaffolds to the myocardium in small animal models.[100,101]

Early work developing β-sheet fibrillar biomaterials was conducted in the 1990s based on peptides having strictly alternating polar/nonpolar sequences and electrostatic complimentarity between residues in the polar positions.[87,102] These materials produced hydrogels, which in subsequent years have been explored in many different contexts and with many different modifications. Among these materials has been the commercially available PuraMatrix™. β-sheet fibrillizing peptides can be extended at either the C-terminus or the N-terminus with a variety of ligand sequences (e.g., RGD, IKVAV) so as to integrate specific functionality into the scaffold. Successful applications of such ligand-decorated fibrils include their use to specify the adhesion and proliferation of fibroblasts[92]; the proliferation of endothelial cells[3,4,103]; the proliferation, differentiation, and migration of osteoblasts[104]; or the adhesion and differentiation of neural cells.[105,106] Currently, it is not precisely known in detail what structural impact such terminal decoration of β-sheet fibillizing peptides may have on their topology, strand orientation, and lateral aggregation, but in many cases any disruption of fibrillization appears to be minimal. As an example, the self-assembly of the peptide Q11 (QQKFQFQFEQQ) appears to tolerate the inclusion of N-terminal ligand sequences without significant disruption of fibrillization (**Figure 7**). Co-assembly of ligand-bearing Q11 peptides (e.g., GGRGDSGGG-Q11 or GGIKVAVGGG-Q11)

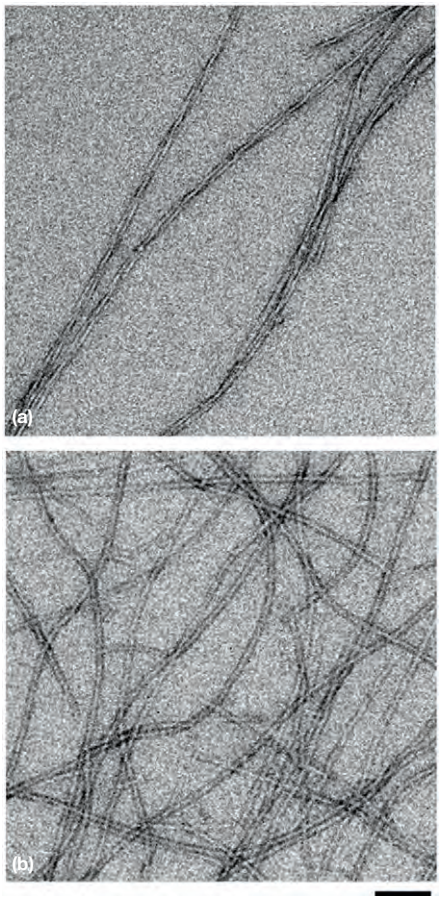

Figure 7 TEM images of β-sheet fibrillar peptide assemblies. Shown are Q11 (a), and OVA-Q11 (b). Scale bar = 100 nm. Reproduced with permission from Rudra, J. S., Tian, Y., Jung, J. P., Collier, J. H. *Proc. Natl. Acad. Sci. USA* **2010**, *107*(2), 622–627.

into backgrounds of unmodified Q11 in ratios of up to at least 10% afforded mixed fibrils with similar secondary structure by CD, similar mechanical properties by oscillating rheometry, and similar nanostructure by TEM compared to 100% unmodified Q11 fibrils.[3,4] The fibrillization of Q11 is also tolerant to the inclusion of N-terminal Cys residues and C-terminal thioesters for covalent stabilization via native chemical ligation,[93] or even 17-residue immune epitopes (Figure 7).[97] In all of these cases, nanofibers are formed in physiological buffers that are morphologically similar to those of unmodified Q11. As discussed below, this enables the production of multipeptide materials with modular construction via noncovalent coassembly.[107] There is also strong evidence that Q11 sequences bearing N-terminal ligands or epitopes display a significant proportion of the epitope sequence on the surface of the fibrils, confirmed with ELISA[97] and immunogold labeling[3,4,97] (Figure 8). For these reasons, β-sheet fibrillizing peptides appear to be a versatile system for the display of a multitude of ligands or chemical functionalities on nanofibers. Other self-assembling biomaterials employing β-structure have included peptide–polymers such as tetraphenylalanine–PEG conjugates.[108,109] Such materials assemble into fibrils, nanotubes, and hydrogels via the formation of antiparallel β-sheets

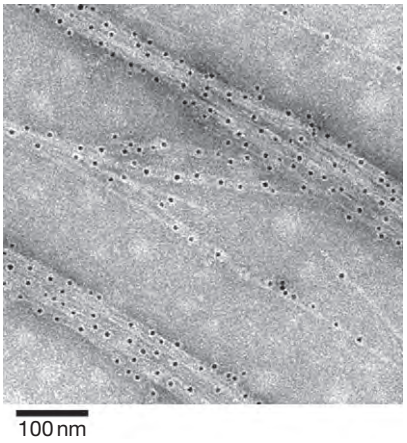

Figure 8 β-sheet fibrillizing peptides bearing functional amino acid ligands on their termini are capable of displaying those ligands on the surface of the self-assembled fibrils. Shown is biotinylated GGRGDSGGG-(Q11), labeled with avidin-conjugated gold particles in a TEM image.

and π–π interactions. Superstructures of hybrid copolymers containing β-strand peptides and PEG in alternating blocks have also been investigated by Klok and coworkers.[110]

2.205.3.5. Self-Assembling Peptides Based on Collagens

Although β-sheet fibrils and α-helical coiled-coil materials have been two of the most intensively investigated peptide-based self-assembling biomaterials, other peptide folds have been employed, including collagen-like folding. Collagens are defined by their characteristic triple helix structure, in which three peptide strands form left-handed polyproline II-type helices that coil around each other to form a right-handed triple helix (Figure 4(c)). Collagens have a primary structure of XaaYaaGly tandem repeats, Gly being required in every third position owing to the tight packing between the helices. Amino acids in the Xaa positions tend to be proline, and amino acids in the Yaa positions tend to be hydroxyproline, with Pro-Hyp-Gly being the most common XaaYaaGly repeat in fibrillar collagens (Figure 4(c)). In contrast to β-sheet fibrils and coiled coils, which are substantially reinforced by hydrogen bonding and hydrophobic interactions, collagen triple helices are noncovalently stabilized by stereoelectronic effects and by only one interstrand hydrogen bond per triplet (for review, see Shoulders, and Raines[111]). Self-assembly of triple helices during natural collagen production in tissues is initiated intracellularly by the binding of the C-terminal regions of the collagen propeptides, which brings the three chains in proximity and templates the coiling and winding of the triple helix towards the N-terminus. During this process, prolyl hydroxylases and lysyl hydroxylases modify proline and lysine residues, respectively, producing hydroxyproline and sites for glycosylation. Once the trimer is folded, it is exported to the extracellular space, where the globular domains of the N- and C-termini are cleaved, an event that enables the fibrillization of the collagen into the classic banded structure observable by transmission electron microscopy (TEM), atomic force microscopy (AFM), and other techniques. Owing to the involved

process by which collagen is synthesized naturally and the relative inability of small collagen-like peptides to template their own self-assembly in the absence of such processes, it has been somewhat challenging to produce gelled self-assemblies of short peptides based entirely on the folding of the collagen triple helix. Strategies to provide additional structure stabilization are necessary to assemble short collagen-like peptides into network-forming biomaterials.[112] This is reflected by the relatively fewer examples of successfully synthesized collagen peptide-based gels in comparison to those based on β-sheet fibrillar peptides or coiled-coil peptides. Nevertheless, the centrality of collagens as the most abundant protein in animals, their usefulness in tissue engineering applications, and the difficulty of producing them recombinantly make collagen-mimicking peptide biomaterials extremely attractive targets for synthesis. One early example of synthetic peptide-based collagen-like fibrils utilized native chemical ligation to polymerize collagen-related peptides into long polymers, which formed fibers (Figure 9(d)).[116] In another approach analogous in some ways to the production of sticky-ended coiled-coil bundles described above, Raines and coworkers designed trimers of collagen-related peptides linked by a disulfide knot such that they contained single-helix overhangs (Figure 9(a)).[113] This covalent preorganization of the collagen peptide trimers enabled the assembly of fibers over 400 nm long. Similar sticky-ended disulfide-linked trimers have been utilized recently to produce hydrogels,[117] and to host the integrin-binding, collagen-derived sequence GFOGER for improved cell attachment.[118] Other strategies for stabilizing the folding and assembly of short collagen peptides have included the use of electron-poor pentafluorophenyl groups and electron-rich phenyl groups at either terminus of the peptide to promote assembly via π-stacking (Figure 9(c)),[114] or the inclusion of charged residues at the peptide termini to similarly promote assembly through electrostatic interactions (Figure 9(b)).[115] In another strategy that combined the chemical definition of synthetic peptides with the mechanical stability of full-length collagen, functionalized collagen-mimetic peptides were intercalated into collagen fibers by thermally unfolding the collagen and cooling it in the presence of the peptides. In this way, the peptides co-assembled into the full-length protein to provide decorated collagen fibrils.[119,120]

2.205.3.6. Self-Assembling Peptide Amphiphiles

Peptide amphiphiles (PAs) are molecules that contain a hydrophilic peptide head group and one or more hydrophobic alkyl tails. They can self-assemble into a variety of nanostructures including micelles, vesicles, bilayers, and nanofibers.[121] Fibrillizing systems in particular have received the most interest as biomaterials, owing to their ability to form gels by fibril entanglement at low millimolar concentrations. Such materials have been extensively studied as 3D substrates for cell culture and as matrices for regenerative medicine.[122–126] Several features of PAs have been shown to be important in their assembly.

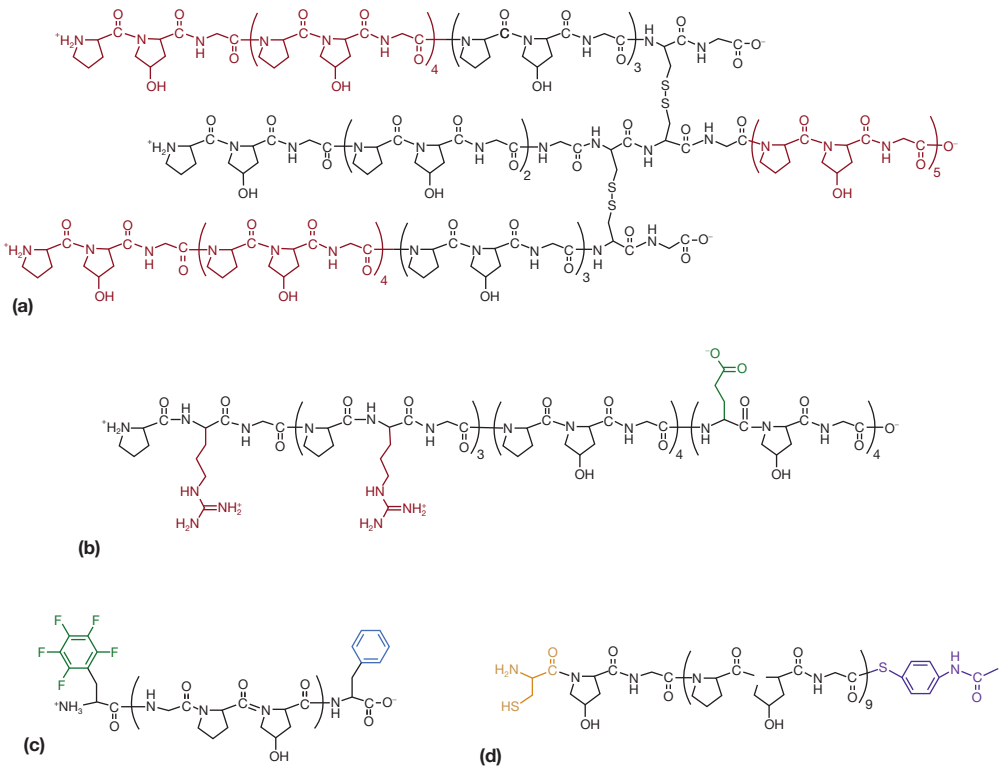

Figure 9 Strategies for producing biomaterials from synthetic collagen-mimetic peptides. Long fibrils can be produced via the sticky-ended assembly of disulfide-linked trimers with staggered single helix overhangs (a).[113] Peptide alignment and templating of triple helix formation can be achieved for collagen-mimetic peptides with charged residues placed at the peptide termini (b)[114] or through π-stacking between electron-poor pentafluorophenyl groups and electron-rich phenyl groups (c).[115] Long polymers of collagen-mimetic peptides have been obtained through the polymerization of such peptides by native chemical ligation (d).[116]

First, clustering of the hydrophobic tails of peptide amphiphiles stabilizes the 3D structure of the peptide head group, and an overall conical shape of the molecule favors fibrillization rather than membrane or micelle formation.[127–129] At the same time, recent studies have shown that the secondary structure of the peptide domains also plays an essential role in PA self-assembly.[130] Residues closest to the hydrocarbon tail, and thus closest to the nanofiber core, are involved in hydrogen bonding similar to β-sheets. By investigating peptide amphiphiles with N-methylated amino acids, it was shown that disruption of hydrogen bonding in this region resulted in spherical micelle formation rather than fibrillar assembly.[131] In addition, the morphologies of the fibrils produced by both PAs and by β-sheet fibrillizing peptides lacking hydrocarbon tails are similar when viewed with AFM or TEM.[107]

One of PAs' most useful features has been their demonstrated amenability to terminal functionalization with a wide variety of ligands and chemical groups. For example, several different cell-binding peptide ligands such as RGDS and IKVAV have been incorporated into the head groups of peptide amphiphiles and have been shown to promote cell adhesion and differentiation.[123,125,132] More recently, PAs displaying peptide sequences having cytotoxic characteristics have been investigated as cancer therapeutics,[133] and PAs with other terminal functionalities including heparin-binding peptides, growth factor-binding peptides, and hydroxyapatite-nucleating peptides have been explored in a variety of applications within regenerative medicine.[124,126,134–136] Within these investigations, one particularly useful modification of the basic PA design has been to incorporate enzyme substrates that allow them to be degraded by matrix metalloproteinases *in vivo*.[137] Given the generally slow degradability of β-rich assemblies, this is a significant advancement.

2.205.3.7. Self-Assembling Peptides with Aromatic Groups

Short peptides containing aromatic groups have been shown to assemble into fibrils. For example, diphenylalanine can self-assemble to form peptide nanotubes through a combination of hydrogen bonding and π-stacking.[138–141] Because of the combined effects of these noncovalent forces, at sufficient concentrations aromatic short peptides can form gels having storage moduli between 2 and 10 kPa.[142] The fibrillar morphology of these types of materials can be variable with pH[138,142] and solvent polarity,[139,143] and their assembly can be triggered through stimuli such as enzymatic action.[144] Xu and coworkers have utilized a complementary pair of kinase/phosphatase enzymes to assemble and dissemble Fmoc-tyrosine and napthyl-pentapetides.[71,72,140] The tyrosine residues can be dephosphorylated by a phosphatase to induce gelation, and a kinase can be used to reverse the process. The structures obtained through enzyme-mediated assembly were found to be more uniform than those obtained with pH switching.[71,72] In another work, enzyme substrate activity was provided for self-assembling Fmoc-peptides using the thermolysin substrate Gly-Phe-Cys. In this work, the Fmoc-peptides were conjugated to gold particles to produce optical enzyme sensors.[145] For biomaterials applications, short peptides with aromatic groups form gels capable of supporting cell culture. Gels of Fmoc-FF supported the growth of chondrocytes in 2D and 3D cell cultures.[138] These systems, like longer β-sheet fibrillizing peptides, are also amenable to modification, as shown by the fact that mixtures of Fmoc-FF peptides and Fmoc-RGD peptides could be co-assembled in order to present the RGD ligand on the surface of the fibrils. Such fibrils were competent for modulating the adhesion of dermal fibroblasts through specific RGD-integrin binding, with subsequent cell spreading and proliferation.[146] Short dipeptides that self-assemble through aromatic interactions are attractive alternatives to longer peptides and folding motifs, as the small size of the molecules can reduce synthesis costs while still providing for mechanisms of stimulus-responsiveness, bioactivity, and gel formation.

2.205.3.8. β-Hairpins

β-Hairpins are secondary structures formed by two antiparallel β-sheet strands with only 2–5 intervening residues forming a turn between them. Schneider, Pochan, and coworkers have designed and investigated MAX1, a peptide containing alternating lysine and valine residues on either side of a β-turn on the basis of a D-Pro-L-Pro sequence.[88,147] Other variations of the MAX1 peptide include MAX2/MAX3[148] and photocaged MAX7,[149] whose gelation properties can be triggered by heat and light, respectively. Gelation of these β-hairpins can be induced by the addition of cell culture media, and rheological studies have shown that under various conditions they possess storage moduli in the 1–10 kPa range or greater, making them attractive as tissue engineering scaffolds.[150] β-Hairpins are noncytotoxic and biocompatible with mammalian cells, but some have been shown to be selectively toxic to gram-positive and gram-negative bacteria, making them attractive candidates for regenerative medicine applications under conditions that may not be entirely sterile.[151] Mesenchymal stem cells have also been encapsulated within β-hairpin hydrogel networks, which were then shear-thinned and delivered to target sites via a syringe. After injection, the cells remained viable and the resolidified construct remained intact.[152] To achieve stiffening of β-hairpin networks in a reversible fashion, borate ion complexation has been employed to form physical cross-links between lysine residues.[153] Other means to modulate the materials' viscoelasticity has included substitution of lysine residues with negatively charged glutamic acid residues, which has led to faster gelation and stiffer gels.[152] Controlling the gelation rate in this way enabled cell encapsulation without cell aggregation or sedimentation. In sum, β-hairpins have proven to be a flexible, modifiable platform for producing chemically defined self-assembled biomaterials.

2.205.3.9. Proteins

Although the bulk of self-assembling biomaterials to date have focused on synthetic molecules such as peptides and peptide–polymers, or proteins that oligomerize through discrete peptide folds such as coiled coils, these materials fall short of biological supramolecular assemblies in terms of complexity and exquisite control over folding and specificity. In contrast, biological assemblies such as viral capsids (see Chapter by Schaffer *et al.*), extracellular matrices, and the cytoskeleton are formed by the self-assembly of multiple protein constituents with highly specific affinities for each other.

Inspired by these natural protein networks, a number of strategies have been developed to induce or control self-assembly into materials using designed proteins. A few examples will be provided here. For a more detailed review, see Papapostolou and Howorka.[154] One approach has been to place cysteine residues on opposing sides of a protein, which can be further functionalized with specific ligands such as biotin. This bivalent unit can then be self-assembled with tetravalent streptavidin to form a network of proteins.[155] Another approach has been to remodel patches on protein surfaces into contact sites. Using site-directed mutagenesis, the contact sites for the naturally occurring octamer Rua-B were engineered to assemble into fibers of associated octamers.[156] In other approaches, self-assembling proteins with different oligomerization valencies were fused recombinantly, and the resultant fusion proteins could be self-assembled into geometrically defined nanoscale polyhedra.[157] In biomedical applications, self-assembled proteins have been useful as epitope carriers for vaccine development. As an alternative to inactive viruses, noninfectious adenoviruses,[158,159] tobacco mosaic virus capsids,[160] and planar S layer lattices[161] have been used as carrier proteins for pathogen-specific epitopes. The spatial repetition of the epitope is known to enhance immune responses relative to the free antigen.[162] Self-assembling proteins have been exploited in variety of other biologically relevant applications, including biotemplating of nanoparticles,[163] selective removal or concentration of ions,[164] and templates for metallic nanotubes.[165,166]

2.205.4. Modulating the Mechanics of Self-Assembling Systems

It is increasingly appreciated that viscoelasticity can play a fundamental role in the behavior of cells in contact with materials.[167,168] In 3D self-assemblies, recent work has focused on modulating viscoelasticity so as to provide a means, along with ligand presentation, for directing cell behavior. One challenge associated with self-assemblies is that they are constructed predominantly with noncovalent bonds, so their strength, elasticity, and moduli tend to be somewhat lower than those of gels or materials made from higher molecular weight polymers. This poses a practical problem for creating devices that can mechanically withstand the forces involved in their placement and operation within specific tissue sites, and it also reduces the ability to adjust stiffness to favor particular cell behaviors.

In 3D self-assemblies, viscoelasticity can be controlled through several routes, including modulating the stiffness of individual self-assembled components (e.g., fibrils), controlling the strength and degree of lateral interactions of these fibrils, and establishing covalent cross-linking between fibrillar elements. Before such strategies are employed, however, often an initial goal is to render the mechanical properties of a self-assembly consistent, regardless of the types of ligands or functionalities co-assembled into it. To accomplish this, the most common approach has been to dope ligand-bearing or otherwise functional peptides into a background of nonfunctionalized base material. Ligand-bearing β-sheet peptides or peptide amphiphiles can be co-assembled with unfunctionalized β-sheet peptides or peptide amphiphiles to entrap the ligands within the self-assembles while minimally perturbing gel mechanics.[3,4,146,169] Such a strategy has been applied to β-sheet peptides,[3,4] peptide amphiphiles,[169] and short peptides with aromatic sequences.[146] For example, the β-sheet fibrillizing peptide Q11 can tolerate the inclusion of N-terminal cell binding peptide ligands such as RGDS or IKVAV in concentrations that significantly modulate cell attachment and growth without influencing storage modulus.[3,4] An analogous approach in SAMs is to dope a ligand-bearing alkanethiol into a background of nonfouling oligo(ethylene glycol)-terminated alkane thiol, but in this case the goal is to minimally perturb the SAM's nonfouling character, not its mechanics.[8]

Once a reproducibly stiff matrix has been established, modulation of its viscoelastic properties can be achieved either by adjusting the noncovalent lateral associations of self-assembled elements, or by establishing covalent bonds within the network. One of the simplest ways to increase the stiffness of self-assembled matrices is to increase the peptide or protein concentration.[93,146,169] The mechanics of most fibrillar self-assemblies are significantly dependent on total peptide concentration, although the topographical details of fibril entanglement as a function of concentration have not yet been worked out for most systems. Although concentration modulation can be an effective way of specifying mechanics, an upper limit of stiffness is reached at the point where the peptides are no longer soluble. Large changes in total peptide concentration are also undesirable if there is a need to control matrix stiffness without affecting other parameters such as network topology or porosity.

Efforts to specify the lateral aggregation of self-assembled fibrillar elements have included work with the MAX1 β-hairpin system, in which single amino acid substitutions have been employed to modulate the Coulombic interactions involved in intramolecular folding and fibrillization.[152,153,170] By installing a Glu residue at a previous Lys position in the $(Lys\text{-}Val)_2$ β-strand portion of the molecule, intramolecular folding could be significantly accelerated, leading to faster gelation kinetics and stiffer gels. Overall, the morphology of the β-sheet fibril did not change with this Lys→Glu substitution, indicating that the number of physical cross-links may have been increased owing to the faster gelation kinetics. Importantly, the speed with which the modified hairpin gelled and the ultimately stiffer material enabled cell encapsulation in 3D. In contrast, the unmodified MAX1 hairpin gelled so slowly that cells sedimented before they could be encapsulated.[152] In an example of modulating lateral assembly in self-assembled gels based on coiled coils, Woolfson and colleagues modified the charged and polar residues found in ***b***, ***c***, and ***f*** helix positions so as to avoid fiber coarsening.[56] The resultant materials formed hydrogels with rapid enough gelation kinetics to allow 3D cell encapsulation. Viscoelasticity can also be modulated through ion complexation, as has been demonstrated with MAX1 β-hairpins and borate complexation[153] as well as with β-sheet fibrillizing peptides and the complexation of phosphate or magnesium ions.[171]

Several covalent strategies have been reported for stiffening self-assembling biomaterials, including disulfide bond formation[171] and native chemical ligation.[93] In the native chemical ligation strategy, matrix stiffening was achieved by engineering a C-terminal thioester and an N-terminal cysteine into the

self-assembling peptide Q11. Ligated Q11 gels showed a five-fold increase in storage modulus and were able to support significantly enhanced endothelial cell proliferation compared to less stiff gels. The chemistry was also orthogonal to the inclusion of ligand-bearing Q11 derivatives, and gels doped with RGD-Q11 showed even greater endothelial cell proliferation and CD31 expression compared to those with RGD or ligation alone.[93] Such a co-assembling strategy enables increasingly systematic fine-tuning of scaffolds for applications ranging from 2D cell culture scaffolds to tissue engineering, and the degree of functionalization that can be incorporated into these materials has only begun to be exploited.

2.205.5. Advantages Provided by Self-Assembled Systems for Biomaterials Applications

One of the most significant advantages of self-assembling strategies is that they can lead to complex, multicomponent materials starting with a discrete, chemically defined set of molecules. Chemical definition in turn enables precise investigation, experimentation, and optimization in applications ranging from cell culture to *in vivo* cell therapies. Contrasting with the chemical definition of self-assemblies, the most utilized materials for providing multicomponent scaffolds for cells have traditionally been biologically derived biopolymers. For cell culture, such materials include collagens, alginates, and the mixture of proteins that constitutes Matrigel. Matrigel is a heterogeneous mixture of glycoproteins secreted by Engelbreth–Holm–Swarm mouse sarcomas.[172,173] It is rich in laminins and other basement-membrane proteins, and it has been a centrally important material for the development of 3D cell culture models and cell–matrix investigations. Its usefulness in these contexts cannot be overstated, but at the same time, Matrigel's compositional heterogeneity, its incomplete definition, and its batch-to-batch variability have made it a challenging material for engineering applications. Moreover, its xenogeneic nature makes it problematic for use in humans. Self-assembling materials contrast with the heterogeneity of such naturally derived biopolymer matrices. What chemical definition affords is the ability to choose to include, at a predetermined dose, any number of therapeutic or biologically active ligands or chemical groups of interest, while at the same time definitively excluding any other molecules that may confound investigation of the biological process of interest. Small molecular weight contaminants, opsonins, residual growth factors, cytokines, and unknown low-concentration matrix components are all possible constituents in naturally derived biopolymers that can significantly derail or complicate both basic investigations and development efforts. Further, given that biological processes occur in an extremely complex milieu of soluble and insoluble factors, any opportunity to reduce or specify such complexity facilitates the engineering of these systems. For both 2D and 3D self-assembled biomaterials, such considerations have been a major driving force behind their development. As one example, SAMs with chemically and spatially defined regions of cell adhesiveness allow one to force a population of cells to assume nearly identical geometries, so that statistical distributions in the precise arrangement of multiple cells' cytoskeletons can be revealed.[18] In unpatterned substrates, such analyses cannot be accomplished in a straightforward manner.

On the other hand, instead of rendering culture surfaces highly uniform, the modularity of many 3D self-assembling systems can also enable combinatorial or high-throughput analyses of multicomponent matrices. The noncovalent construction of scaffolds that are created from the co-assembly of more than one molecular constituent enables the production of a limitless range of different ratios of assembled ligands or chemical features, simply by mixing and inducing co-assembly. For ligand-bearing β-sheet peptides, this can be achieved by dissolving them in water, mixing them in specified ratios, and gelling the mixture with buffers or culture media.[3,4] Many other 3D cell culture matrices currently used or under development such as polymer hydrogels are produced as integrated, covalently connected materials, so production of a range of formulations would be less straightforward than in co-assembling systems. In addition, many advantages of synthetic systems, including the possibility for incorporating nonnative amino acids or chemical modifications, are retained in self-assembling biomaterials.

Noncovalent interactions are sensitive to solution conditions, including pH, temperature, ionic strength, and others, providing opportunities for rendering self-assembling biomaterials stimulus-sensitive. As an example, β-sheet fibrillar self-assembly could be rapidly triggered under the stimulus of warming from room temperature to body temperature, or by near-infrared light.[98] In this approach, calcium ions capable of inducing self-assembly were sequestered away from the peptide within liposomes that had been engineered to be either light- or temperature-sensitive. Application of the relevant stimulus initiated the release of the ions into the extravesicular space, leading to rapid gelation. Triggered gelation through the addition of salt-containing buffers has also been widely used to produce 3D cell culture matrices.[3,4,88,93,106,125,137] Similarly, delivery of unassembled peptides to tissue sites can induce gelation upon contact with the high osmolarity and neutral pH of the physiological milieu.[100,101,126] Stimulus-sensitive peptide self-assembly has been reviewed recently.[174]

A final advantage of self-assembled biomaterials is that they are highly multivalent. This can be used to enhance the activity of ligands or peptides that have relatively low affinities. For example, high epitope density has been utilized to promote neuron regeneration using peptide amphiphiles bearing the laminin-derived IKVAV sequence.[124,126] It is also likely that the antibody production elicited by OVA323-339-conjugated Q11 peptides was a result of the materials' high degree of multivalency.[97] As another example in α-helical designed proteins, multivalency and control over the precise distance between charged groups or saccharides have been utilized to significantly increase affinities for biological toxins, such as the cholera toxin.[175,176] Highly multivalent materials have also been reviewed for targeted delivery recently.[177]

2.205.6. Immune and Inflammatory Responses to Self-Assembling Materials

All biomaterials have a potential to interact with inflammatory or immune processes, and such interactions will be decisive factors regarding their clinical usefulness.[107,178] Initial

investigations of self-assembled biomaterials *in vivo* have been encouraging as almost all reported studies have found them to be minimally immunogenic.[3,4,100,101,106] RAD16-II peptide fibrils injected within rat[101] or mouse[100] myocardium have been found to elicit negligible immune or inflammatory responses. Low antibody titers have also been reported for RAD16 peptides in rabbits and goats,[106] and nitric oxide-releasing peptide amphiphiles were well tolerated in rats.[179] Both the self-assembling peptide Q11 and the RGD-bearing variant GGRGDSGGG-Q11 were nonimmunogenic when delivered to mice subcutaneously.[3,4] In sum, almost all reports of self-assembled peptide biomaterials *in vivo* have indicated minimal or negligible responses. These findings prompted a study to test the extent to which even known T and B cell epitopes presented on self-assembled peptide fibrils could be tolerated (**Figure 10**). This series of experiments sought to clarify whether or not the minimal immunogenicity of self-assembled fibrils was a general property. Interestingly, when a peptide from chicken egg ovalbumin ($OVA_{323–339}$) containing known B and T cell determinants was fused to Q11 and delivered subcutaneously to mice, strong antibody responses were observed without any adjuvant.[97] The anti-OVA titers were comparable to the free peptide administered in complete Freund's adjuvant (CFA), one of the strongest adjuvants known. In contrast, the unmodified self-assembling peptide Q11 was nonimmunogenic by itself, even when administered in CFA, illustrating that Q11 was a very poor immunogen without an attached epitope. Furthermore, these high antibody titers were completely abrogated when mice were immunized with mixtures of free OVA peptide and Q11, suggesting that self-assembly and fibrillization were critical to the observed antibody responses. No cytokine production was detected in peptide-challenged cultures of splenocytes of mice immunized with OVA-Q11, which might have indicated that T cells were not significantly involved in the response, but this mechanism continues to be under investigation.

In the absence of strong epitopes, self-assembled peptides are useful as scaffolds for regenerative medicine, as has been demonstrated in several animal models.[100,101,126,179] As these efforts move forward, continued avoidance of strong epitopes may be a significant factor to consider, and it may even be possible that a mild antibody response could be acceptable in the context of the regenerative processes that many of these materials seek to promote. At the same time, owing to their ability to act as adjuvants for strong epitopes, self-assembled peptides may also be useful in immunotherapies or for raising antibodies in animals. Currently, the development of peptide-based vaccines is complicated by the heterogeneous nature of currently available adjuvants. The mechanism of action of even clinically approved adjuvants such as alum is still not well understood.[180] Several other adjuvants like oil-in-water emulsions, toll-like receptor agonists, and immunostimulating complexes have been investigated for adjuvanting peptide immunotherapies, but their molecular heterogeneity makes it challenging to fully understand or modulate their mechanism of action.[181] In contrast, self-assembling peptides may be produced with more precise chemical definition.[3,4] Taken together, the picture that is emerging is that self-assembling peptides may be engineered for nonimmunogenicity or targeted immunogenicity, depending on the nature of the epitope conjugated to them, and this distinction may be exploited for applications in both regenerative medicine and immunotherapies.

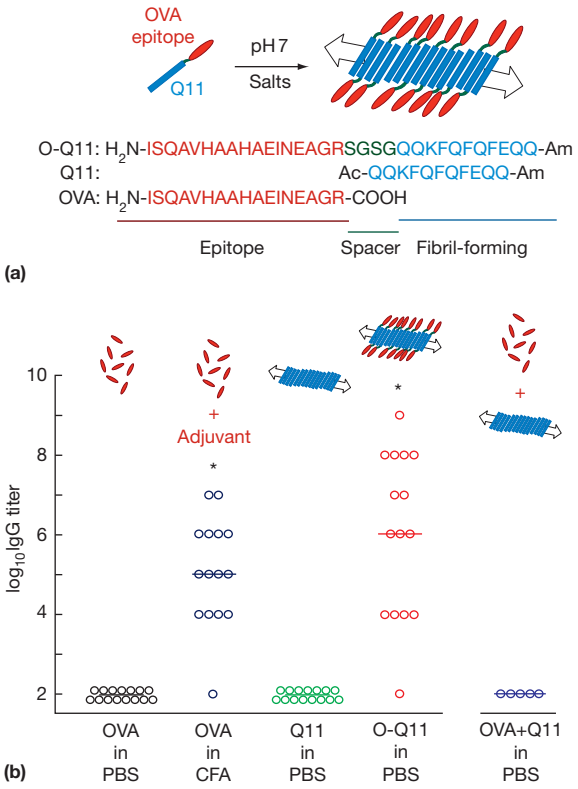

Figure 10 Self-assembling peptides can be well tolerated immunologically or can elicit antibody responses, depending on the epitope peptide attached to them. The peptide Q11 was nonimmunogenic by itself or when conjugated to RGD peptides.[3,4] However, when it was placed in tandem with a peptide from the protein ovalbumin (OVA) containing known T and B cell epitopes (O-Q11, a), it elicited the production of high titers of specific antibodies in mice without the co-administration of any adjuvant (b). Total IgG titers determined by ELISA; groups correspond to peptides shown in (a), delivered to mice either in PBS or in complete Freund's adjuvant (CFA), as indicated. The OVA+Q11 group corresponds to mice that received a mixture of soluble OVA peptide and unmodified Q11 in PBS. Adapted with from Rudra, J. S., Tian, Y., Jung, J. P., Collier, J. H. *Proc. Natl. Acad. Sci. USA* **2010**, *107*(2), 622–627.

2.205.7. *In vivo* Applications of Self-Assembled Biomaterials

Throughout the preceding sections, a few examples of clinical uses of self-assembled biomaterials have been touched upon to illustrate chemical or structural aspects of the materials. In this section, these efforts will be discussed in terms of their promise for tissue engineering and regenerative medicine (**Figure 11**). One of the most common uses of self-assembled biomaterials in regenerative medicine approaches has been to employ them as relatively inert carriers for injected cells in various tissues. As mentioned above, Lee and coworkers have investigated RADA16 peptides as carriers for cardiomyocytes or embryonic stem cells delivered to damaged myocardium. In these studies,

suspension of the cells in soluble peptide prior to injection allowed delivery via a needle, after which gelation (triggered by the physiological environment) entrapped the cells at the tissue site.[100,182] Delivery of the cells in this way promoted cell survival or the recruitment of progenitor cells from the nearby tissues. Transplanted embryonic stem cells also showed signs of differentiation into cardiomyocytes when injected with the fibrillizing peptides. The full range of functions that the peptides may be performing as carriers for cells is not completely known, and the critical interactions that ultimately lead to improved regeneration are also not entirely clear. Possible mechanisms include retaining cells at the injection site, providing an open network that facilitates cellular infiltration and angiogenesis, eliciting a mild inflammatory response that aids in regeneration, or some other mechanism. Other studies have investigated acellular injections of self-assembled materials designed specifically to promote the infiltration of regenerating tissues, for example, peptide amphiphiles bearing IKVAV ligands for use in neural regeneration applications.[124,126] In this study, evidence of healing in spinal cord compression injuries was observed for rats in which ligand-bearing peptide amphiphiles were delivered to the injury site, but the specific processes responsible for such observations have not yet been clarified. The potential tissue responses to self-assembled biomaterials may be complex and dependent on the species, tissue site, inflammatory responses, or other parameters. Beneficial tissue responses have been reported in several cases, however, making them interesting and highly useful to clarify these materials' mechanism of action in the coming years.

Self-assemblies that release drugs have a conceptually more direct mechanism of action, although some of the other possible mechanisms listed above may also play roles as well. Using nitric oxide-releasing gels of peptide amphiphiles, neointimal hyperplasia could be diminished in a rat carotid artery insult model.[179] In this study, nitric oxide-releasing peptide amphiphile gels were applied around the adventitia of arteries that had been damaged by balloon angioplasty. The most successful formulation tested reduced neointimal hyperplasia by over 70% compared to untreated controls, and led to a reduction in smooth muscle cell proliferation and an increase in endothelialization. In another example of a combination therapy, peptide amphiphiles have been utilized in the pores of titanium foams in order to improve bone integration within orthopedic implants.[135,136] Combining soft self-assemblies as coatings or

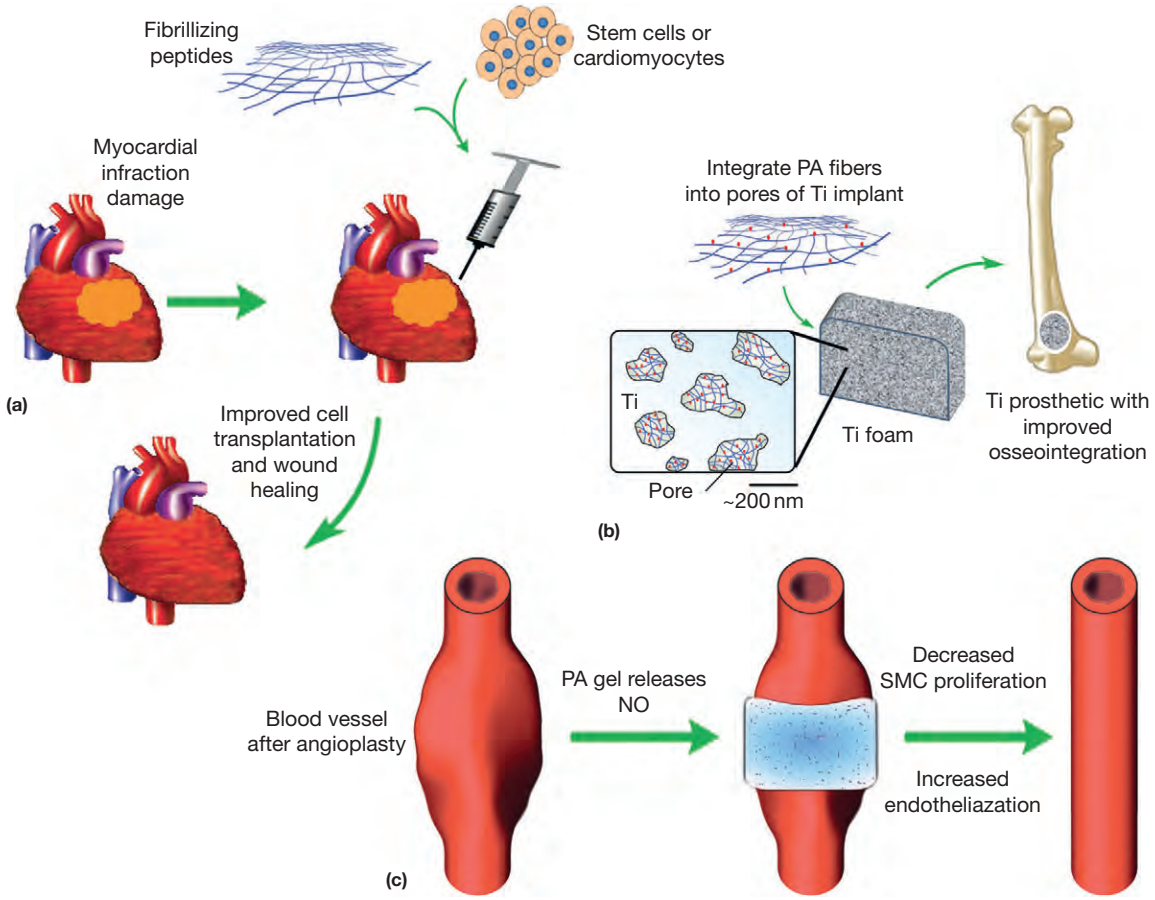

Figure 11 Potential clinical applications of fibrillar peptide gels. (a) Cell-based therapies. Fibrillizing peptides were mixed with cardiomyocytes or undifferentiated stem cells and injected into damaged myocardium.[100,182] (b) Improvement of prosthetics. PAs were integrated into the pores of titanium foam to create bioactive composites that induced mineralization and vascularization around and within orthopedic implants.[135,136] (c) Direct application of a therapeutic-releasing gel. Following angioplasty, a nitric oxide-releasing PA gel was applied directly to the exterior of the vessel at the site of injury, reducing smooth muscle cell proliferation and increasing endothelialization compared with untreated controls.[179] Reproduced with permission from Jung, J. P., Gasiorowski, J., Collier, J. H. *Biopolymers* **2010**, *94*, 49–59, with permission from Wiley.

pore-filling matrices on stiff materials may be a simple and useful way of improving the mechanics of self-assemblies while still retaining their biological activity. In addition, modifying existing devices and biomaterials may be a useful platform for gaining more mechanistic insight into the biological activity of some self-assemblies by virtue of being able to build from models and devices that already benefit from some mechanistic understanding.

2.205.8. Concluding Remarks

The use of noncovalent self-assembly has been a significant trend in the development of many classes of materials, including electronic materials, environmental materials, structural materials, and biomaterials. Their modularity, ability to mimic native structures, ability to assemble multiple components into defined matrices, and ability to create complex structures from comparatively simple starting compounds all make them exciting materials to be used in biological contexts. These properties, along with their multivalency and stimulus-sensitivity, provide opportunities and experimental systems for understanding how materials interact with physiology. It is anticipated that the both these materials' biotechnological development and their use as defined model systems will continue to be interesting and productive research areas in the coming years.

Glossary

Bacteriophage Bacteriophage (phage) is a prokaryotic virus that can infect bacterial host cells. The name 'bacteriophage' can be translated as 'bacteria eater' in Greek.

Directed evolution Directed evolution is a method of utilizing the power of natural selection at the molecular level to evolve proteins or RNA that are customized to meet desired specifications.

Molecular recognition element The molecular recognition element is a specific amino acid sequence that binds to a particular molecular target which can be discovered through directed evolution processes.

Nanobot The nanobot is a new future machinery concept proposed by Dr. Eric Drexler in his book *Engines of Creation* in 1983. He coined the term 'Nanobot (Nanoscale Robot)' for systems that can self-assemble, self-evolve, and self-replicate – serving as fabricators of the next generation of improved future machine systems.

Phage display Phage display is an accelerated evolutionary screening process that allows one to isolate peptides that bind specifically to a particular target material.

Phage therapy Phage therapy is the therapeutic use of bacteriophage to treat bacteria-related disease.

Phagemid The phagemid is a hybrid cloning vector from the filamentous phage M13 and plasmids. The vector can grow into a plasmid and also can be packaged as a single-stranded DNA in viral capsids. In order to enable single-stranded DNA replication and packaging of the phagemid DNA into phage particles, bacterial host containing phagemid is subjected to infection with a helper phage to provide the viral components.

Virotronics The Virotronics is a novel virus-based material design technology that can be used to create novel functional materials with precise molecular-level structural and functional control using unique biological advantages of viruses, such as specific molecular recognition, evolution, and self-replication.

PSMA	Prostate-specific membrane antigen	**TNT**	1,3,5-Trinitrotoluene

2.206.1. Introduction

Nanotechnology is an interdisciplinary science and engineering field that enables us to observe, measure, and control matters at the molecular level. Its development has allowed us to envision clean and efficient energy conversion devices,[1,2] super-computers operated by light,[3] and tissues and organs regenerated by smart tissue scaffolding.[4] Despite the existence of various methodologies to manipulate atoms and molecules into exquisite new functional materials, designing new materials with well-defined structures and desired functions is still a challenge in materials science.[5] Conventional materials are developed through rational design and intensive characterization. Based on the results, new materials with improved physical and chemical properties can be designed. Many new materials are generated by this iterative design and performance characterization process. Nature, however, solves such material design issues using an evolutionary approach. Nature prepares a diversified set of candidates and tests them in a given environment through mutation. The best candidates are then selected and propagated through generations over the course of millions of years. Examples of advanced biological materials with well-defined structures and functions include glass sponges (optical fibers),[6] brittle stars (optical lens array),[7] diatoms (sophisticated periodic structures), abalone shells (fracture-resistance materials),[8] bones (support structure for vertebrates),[9] and cells (exquisite self-replicating biomachines).[10] Efforts to mimic the unique biological structures in nature have provided a variety of tools and resources that are useful to scientists and engineers.[11,12] However, whole organisms have complex functions and self-templated hierarchical structures that cannot be easily mimicked. These unique characteristics, which have accumulated through evolution, are inherited genetically. Genetic information is translated into proteins, which work as molecular machines to control precisely programmed processes in biosystems. Although protein-based 'bottom-up' synthesis of nanoscale functional materials and devices is one of the most promising areas in the newly emerging field of nanotechnology,[13] identifying active basic building blocks from biological examples is still a challenge because of their complex and encrypted sequence structure. Genetic engineering of phage viruses provides opportunities for building novel bio-nanomaterials by integrating biology, chemistry, physics, materials science, electric engineering, and other disciplines. By mimicking the evolutionary process in nature, phages can be used as an information-mining tool to identify functional peptide (or protein) sequences that can specifically recognize desired materials at the molecular level.[14,15] These recognition elements can be used to guide the design of unprecedented materials such as semiconductor and metallic materials. Additionally, because of their well-defined shape, viral particles can be used to catalyze self-assembly of ordered nanostructures, which is useful in applications including energy,[16–18] biosensors,[19] electronics,[14] and tissue regenerating materials.[20,21] In this chapter, we introduce the unique features of viruses, recent accomplishments in the development of virus-based materials for use as tools to fabricate functional nanomaterials, and review the potential future applications of this emerging technology.

2.206.1.1. Introduction of Bacteriophage

Bacteriophage (phage) is a prokaryotic virus that can infect bacterial host cells.[22] The name 'bacteriophage' can be translated as 'bacteria eater.' As its name implies, once a bacteriophage infects the bacterial host, the virus exploits the host's biosynthetic machinery in order to produce many identical copies of itself. Phages are some of the most common organisms on earth.[23] Phages are commonly composed of a protein capsid, or shell, which encapsulates and protects the virus's genomic material (DNA or RNA) (**Figure 1**).[24] There are many types of phages, each having differing genomic materials, replication processes, and shapes. Genomic materials can be either DNA or RNA in a single-stranded or double-stranded form.[25] With regard to the replication processes, phages can be lysogenic or lytic.[25] Lysogenic phages infect the host cells by injecting their genomic materials. The genetic materials uptake the host cell metabolisms and reproduce the same genetic materials and corresponding proteins. These protein products are delivered to the host cell membranes, where new phages are packaged and released without disruption of the host cell walls. On the other hand, lytic phages are replicated and accumulate inside the host cells rather than at the cell membrane. Following replication, the newly amplified phages destroy the host cell wall and can infect other host cells. There are many different shapes of phages such as linear (M13, Fd, F1)[26] or spherical (MS2)[27] (**Figure 1**). Some shapes are quite sophisticated. For example, T4 and T7 phages possess an icosahedral head and a long tail connected through a cylindrical body. Regardless of differences in shape, composition, and life cycle, all phages share the capacity to make exact copies of themselves with incredible structural precision. Because of this property, phages are great candidates to aid the development of novel bio-nanomaterials. Thanks to the commercially available genetic tool kits, M13 phage, in particular, has been extensively used as evolvable nanoscale material. Therefore, we discuss mainly M13 phage and introduce other phages whenever applicable.

2.206.1.2. Structure of M13 Phage

M13 phage is a bacterial virus that comprises a single-stranded DNA encapsulated by several major and minor coat proteins.

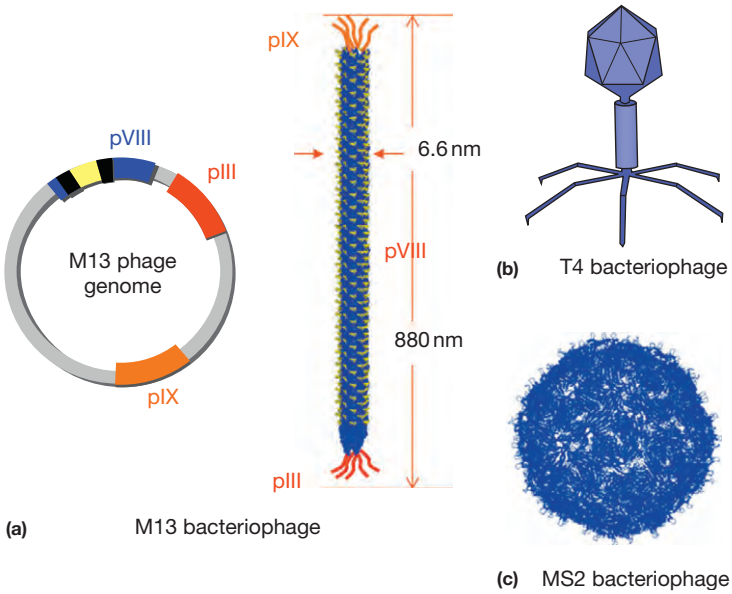

Figure 1 Schematic diagram of various distinct structures of various phages. (a) Long-rod structure of M13 bacteriophage with genomic schematic diagrams to show the each protein expressed on the M13 phage surfaces. (b) Structure of T4 bacteriophage with icosahedral head and long tail connected through cylindrical body. (c) Sphere structure of MS2 bacteriophage.

It has a long-rod filament shape that is approximately 880 nm in length and 6.6 nm in diameter (**Figure 1(a)**).[28,29] The viral capsid is composed of 2700 copies of helically arranged major coat protein, pVIII, and 5–7 copies of the minor coat proteins, pIII, pVI, pIX, and pVII, located at either of its ends.[28,29] M13 phage can only infect and propagate within bacteria displaying F-pili, such as *Escherichia coli*.[30] It is a nonlytic bacterial virus, meaning that it does not break the bacterial cell membrane upon exit, but instead is secreted through a protein pore channel in the bacterial membrane.[28,31,32] Bacterial host growth is slowed down because of the increased metabolic demands of phage production, but continues after infection.[33] These qualities allow for easy mass amplification of the bacteriophage in bacterial culture. Over the past 2 decades, the biochemical landscape of the phage structure has been greatly expanded through genetic engineering of the phage[21,34–36] and site-specific organic synthesis approaches.[37–40] Through genetic engineering, many foreign or synthetic DNA have been integrated into phage genome and expressed at various sites of the phage body.[36,41] Nonnatural amino acids have been expressed on the phage surfaces using amber codon tRNA approaches.[42,43] In addition, reactions have been developed that enable site-specific modification of phage surfaces with chemicals such as fluorescent dyes or chromophores for various applications including biochemical imaging and energy harvesting.[38–40]

2.206.1.3. Directed Evolution of Phage

One of the most remarkable features of phage-based materials, which distinguishes them from traditional engineering materials, is their ability to be chemically evolved in a directed fashion. Evolution mainly consists of genetic diversification, functional selection, and replication processes. In nature, mutation can occur during gene replication, resulting in diversified species with various new functions. By mimicking this natural process, phage can be used as a template to perform directed evolution through a technique called phage display.[36,41] Phage display is an accelerated evolutionary screening process that allows one to isolate peptides that bind specifically to a particular target material. All the phage coat proteins can be genetically modified to display relatively short (<8–20 amino acid) peptide sequences. Insertion of randomized DNA sequences at specific locations within the phage genome enables one to generate a highly diverse library of peptides (up to 10^{11} random sequences) expressed on the viral particle surface.[36,44]

To select the functional peptide sequence for a given target material, the engineered phage library pool goes through several rounds of selection, which is typically based on affinity for the target material (**Figure 2**). As for the affinity selection, the phages are first allowed to bind to the target. The nonbound phages are then washed away, and the bound ones are eluted separately. The eluted phages are then amplified through *E. coli* bacterial host infection. This is repeated for several rounds with increasingly stringent binding conditions in order to enrich the phage pool with high-affinity peptides. Finally, the dominant binding peptides emerge and are identified through DNA analysis of the phage genome. Phage display on pIII is most often utilized, as it is the biggest phage coat protein and allows for greater peptide sequence variability. pIII is also conducive for display of constrained libraries.[36,45] The lower valency of the protein (only 5 copies as opposed to 2700 for pVIII) allows for the selection of peptides with higher affinity toward the target, because of the lack of avidity effects.[35] Recently, major coat engineered libraries have been developed and used for inorganic material syntheses involving semiconductors, metallic materials, and conjugation of phage with carbon nanotubes.[14–16,18,46] By applying microelectromechanical system (MEMS) techniques, Liu *et al.* have recently developed a microfluidic device that performs phage display in an automated manner on a microliter scale.[47]

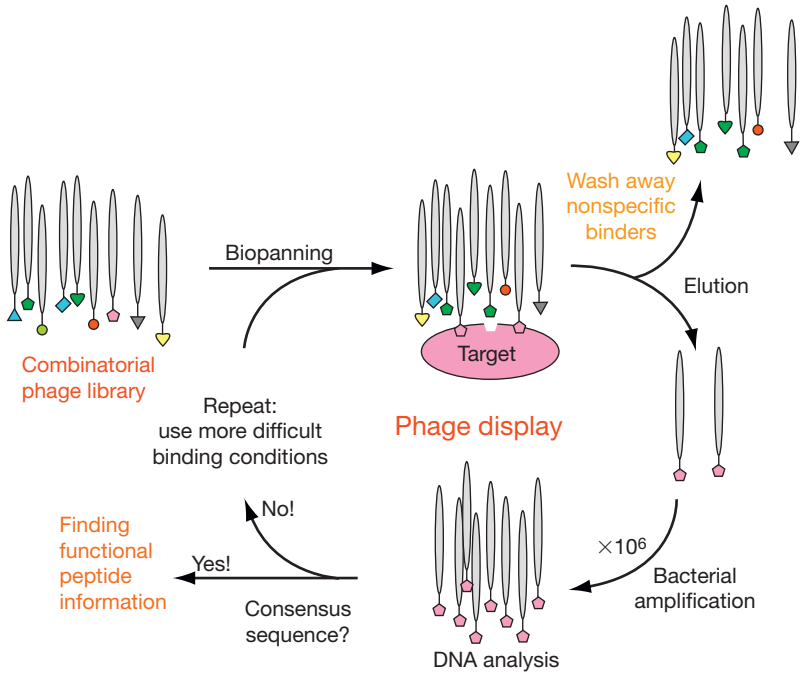

Figure 2 Schematic diagram of the phage display processes to identify the functional recognition peptide motifs.

The phage display technique was originally developed for small peptides and antibodies and for identifying epitope-like ligands. The main advantage of this approach is that the use of an amino acid library allows for identification of an epitope sequence from a protein that is not necessarily in sequential order, but could assemble and become functional through protein folding.[35] Further, presentation of such a library on a phage protein allows for a direct connection between the peptide identified and its encoding genetic sequence.[34,35] Since the inception of this method, a variety of peptide ligands have been discovered that are involved in interactions including specific protein binding,[48–50] DNA binding,[51] receptor binding,[52,53] and cell and tissue binding.[53] Further, through the use of phage-display, short peptide motifs can be further matured for enhanced binding against the target of interest.[54,55] For example, phage display was instrumental in determining the best binding conformation for the well-known RGD motif, as well as elucidating the different sequences of RGD flanking residues which confer binding specificity for certain classes of integrins.[53] However, identified peptide sequences should be carefully confirmed with appropriate binding assays. Results from nonspecific binding can mislead the interpretation, particularly when panning phage libraries against cell surfaces, which include many of their molecules as well as the target receptor.

2.206.2. Phages for Inorganic–Organic Hybrid Materials

Phage display has also been utilized to identify affinity peptide sequences for a variety of inorganic substances, such as semiconductor and magnetic and metallic materials.[14,46,55–57] Specific binding peptide sequences identified through such directed evolution screening methods have been summarized in recent reviews.[58–60] Phage display performed with inorganic substrates can uncover novel information about the particular binding interaction between inorganic crystals and organic peptides. Belcher and coworkers have demonstrated that a genetically engineered phage can specifically recognize inorganic semiconductor substrates. For example, Whaley *et al.* demonstrated that the phage could be selected for binding to GaAs (III–V semiconductor) (Figure 3).[15] The resulting phages and corresponding peptide sequences exhibit remarkable specificity in their binding to different crystallographic orientations, such as (100) and (111), and similar surface structures,

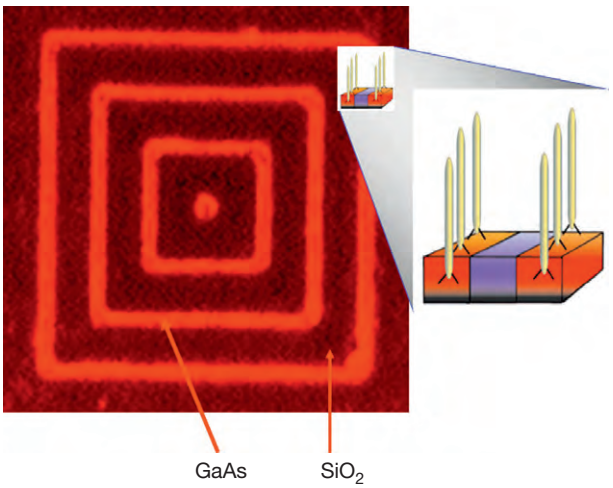

Figure 3 Specific recognition of phage onto semiconductor surfaces. Fluorescence image of the phage can bind to square patterned GaAs semiconductor surfaces. Reproduced from Whaley, S. R.; English, D. S.; Hu, E. L.; Barbara, P. F.; Belcher, A. M. *Nature* **2000**, *405*, 665–668, with permission from Nature. © 2000 Macmillian Publishing Ltd.

such as (111)A (gallium-terminated) or (111)B (arsenic-terminated) face of GaAs.[15] Another study of phage display screening using carbon nanotubes and graphite surfaces showed that selective binding of sequences with multiple tryptophan residues could be attributed to aromatic ring interaction between the peptides and nanotubes.[57,61] Recently, similar display screening methods, such as bacterial cell surface display[60,62] and yeast display,[63] have also been applied to identify the specific binding peptide against the various inorganic seminconductor and metallic materials and uncover the specific binding peptides and proteins.

By mimicking the biomineralization processes in nature, the phages and their peptides discovered from phage display can also be used for the synthesis of inorganic materials. In nature, specific binding proteins against various inorganic crystals, such as silica in diatoms,[64,65] iron oxide in magnetotetic bacteria,[66] calcium carbonate in abalone shells,[67] or calcium phosphate in bones and teeth,[68,69] play a critical role in the synthesis of hybrid organic–inorganic materials.[70] Similarly, specific recognition peptides identified through phage display for desired crystal surfaces can be exploited in order to template the growth of various target inorganic crystals. Flynn *et al.* identified specific binding peptide motifs with high affinity for II–VI semiconductor materials (ZnS, CdS, PbS, etc.) and used them to direct mineralization of different phases of the inorganic crystals in controlled shape and morphology.[55] The researchers showed, for example, that linear and constrained binding peptides selected for zinc sulfide crystal surfaces are capable of nucleating cubic (zinc blende) and hexagonal (wurtzite) phases of ZnS nanocrystals, respectively.

Genetic engineering of functional peptides with crystal-nucleating or recognition capabilities on multiple phage coat proteins has allowed for construction of many interesting functional nanomaterials and nanostructures. Single or multiple genetic modification schemes are depicted in **Figure 4**. Single modification of pIII minor coat protein was used to synthesize ZnS and CdS nanoparticles at the terminus of the phage.[14,55] Nam *et al.* modified both the end minor coat proteins (pIII and pIX) with six histidines and HPQ (His-Pro-Gln) streptavidin-binding peptide motifs. These phages were then used to construct nanoscale viral ring structures through specific binding of chemically conjugated streptavidin and Ni-NTA linkers.[71] By incorporating complementary leucine zipper sequences on both ends of the phage, Sweeney *et al.* programmed phage to self-assemble into linear structures.[72] By expressing the semiconductor- and metal-binding peptides on the major coat proteins using phagemid vectors, one-dimensional polycrystalline semiconductor and magnetic and metallic nanowires can be synthesized on viral templates.[46] After high-temperature annealing processes, high-quality single-crystal ZnS or CdS nanowires with uniform size and shape could be fabricated on the templated phage

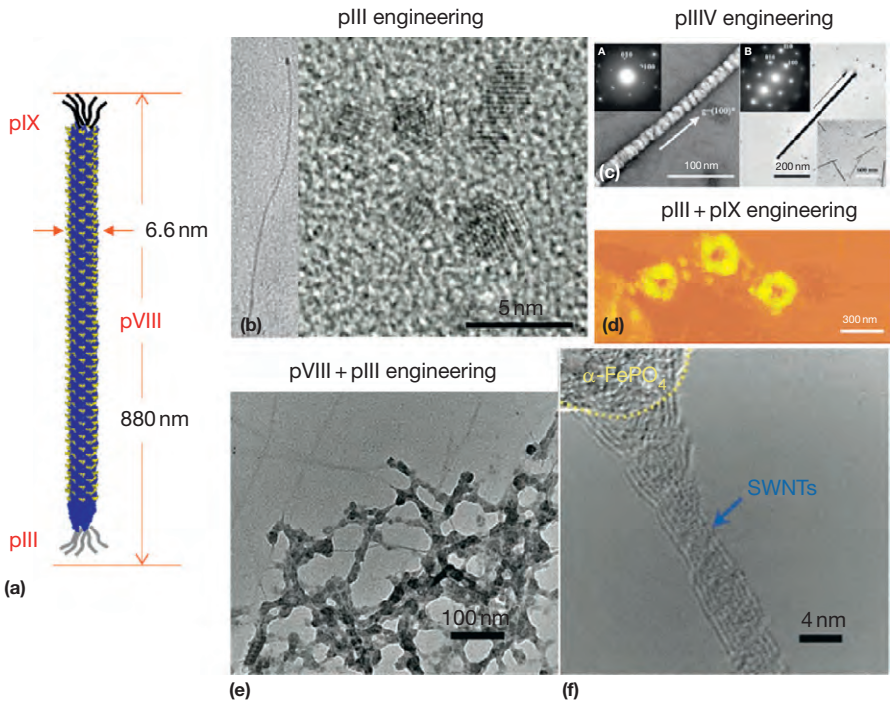

Figure 4 Engineering of M13 phage for programmed functionalization from material synthesis to specific conjugation. (a) Schematic diagram of M13 phage. Single engineering: (i) pIII engineering: specific nanoparticle synthesis on minor coat proteins (b); (ii) pVIII engineering: major coat protein engineering for the synthesis of ZnS nanowires which can be used for the semiconductor synthesis or energy producing nanoscale nanowired materials (c). structures. These nanowires exhibited promising electrooptical and magnetic properties.[46] By inserting multiple major coat protein genes in the phage genome, Nam *et al.* demonstrated that the phage can nucleate gold and metal oxides simultaneously.[17] A variety of architectures of phage-templated nanostructures have been successfully demonstrated using concurrent modification of pIII and pVIII coat proteins.[73] Both ends and major coat protein-engineered phage might conduct multiple programmed operations. Such engineered phages are expected to be able to serve as electronic components and wires, potentially resulting in self-assembled, self-interconnected, self-fabricated electronic devices. As a proof of concept, Huang *et al.* showed that exquisitely programmed materials can perform electronic functions.[73] They fabricated two terminal electrodes, which were interconnected by virus-based conductive gold nanowire, and measured *I*–*V* behaviors, which exhibited ohmic behaviors of the viral nanowires.

2.206.2.1. Self-Assembly of Inorganic Materials using Phage

Because of their monodispersity and long-rod shape, many filamentous viruses have been extensively studied as liquid crystalline model systems.[74,75] By changing variables such as concentrations, ionic strength, and external fields, viruses are able to form ordered liquid crystalline structures (Figure 5). At a low concentration range (below 5 mg ml^{-1}), phages are randomly ordered in an isotropic liquid crystalline phase. With increasing concentration (10–20 mg ml^{-1}), the distance between neighboring viral particles becomes smaller than their length. The virus particles begin to sterically hinder each other and align into orientationally ordered configurations called nematic phase liquid crystals. In the nematic concentration range, the helicity exhibited by viral particles such as M13, F1, and Ff phages is conserved in the nematically ordered phage layer. Therefore, each nematic layer becomes twisted about the normal axis of the layer below it. In the concentration range between 20 and 80 mg ml^{-1} (cholesteric phase), the rotation of nematic layers generates optically distinguishable periodic structures, which may resemble finger print textures in the optical micrographs (Figure 5). Finally, above 100 mg ml^{-1}, the viral particles acquire both positional and orientational order (smectic phase).[74] Some viral particles such as M13 viruses have been studied at much higher concentration ranges as solid phase two-dimensional thin films[14,75] and one-dimensional fibers.[76] Two-dimensional viral liquid crystalline films grown at the air–liquid–solid interfaces of a meniscus have been shown to exhibit a chiral smectic C structure (Figure 5).[75]

The use of polymeric templates and surface patterning tools has greatly expanded the self-assembly capabilities of phages. Yoo *et al.* developed a novel M13 phage patterning methodology by combining M13 phages with polyelectrolytes such as polyethyleneimine and poly acrylic acid.[77] In this approach, M13 phages were segregated from the bulk charged polymers when deposited on the surface of a suitable substrate. The resulting aligned films exhibited a high degree of positional and orientational order and could be further modified with inorganic nanomaterials such as cobalt and gallium nitride thin films. Using solvent-assisted capillary molding methods, Yoo *et al.* showed that phage can be densely packed atop micropatterned surfaces. Surface feature size was dependent on phage length as well as the swelling properties of the underlying electrolyte polymers.[78] Solis *et al.* also showed that, by combining soft-lithography techniques with phage antibodies, they could first pattern phage antibodies on the gold substrates. By tuning the concentration of the phage solution, they could immobilize phages on the gold substrates on a large scale in a controllable manner.[79] In the future, these

surface patterning techniques may be useful for biosensor development, semiconductor fabrication, and energy storage and conversion devices.

Phage self-assembly combined with peptide display via genetic modification has been exploited to organize a variety of nanocomponents into periodically ordered films and fibers.[14,55,76] After the identification of ZnS-specific binding peptides through phage display, ZnS nanoparticles were self-assembled into periodically ordered film structures. Similarly, anti-streptavidin viruses were used to align gold nanoparticles, organic dyes, and biological molecules.[80] Magnetic nanoparticle–virus composite films (FePt, CoPt, etc.) were constructed using both phagemid and pVIII engineering of viruses.[81] Finally, spontaneously ordered virus-based thin films integrated with semiconductor (GaN) and metallic (Au) nanoparticles have been fabricated on multilayered electrolyte polymer films using layer-by-layer deposition.[17]

Besides electronic and magnetic particles, viruses can also be used for the assembly of biological tissues. Merzlyak *et al.* engineered M13 phage with RGD (integrin-binding peptide) and IKVAV (neural cell stimulating peptides) displayed on the major coat proteins.[21] Following formation of the liquid crystalline suspensions, these phages were spun along with target cells using a micropipette. The resulting microfiber structures contained aligned phages, which served as scaffolds for the controlled growth of fibroblasts and neural stem cells. Mechanically sheared thin films composed of liquid crystalline phages can also exhibit directional organization and serve as substrates that direct cell growth processes.[20]

2.206.3. Phage for Energy Materials

In recent times, there has been a rising demand for novel materials that can generate, store, and utilize energy with performance levels exceeding those of current technologies. In this research area, the ability to nucleate nanocrystals and self-assemble long-range ordered phage structures has attracted much attention.

2.206.3.1. Phage for Energy Storage Materials

One of the advantages of the use of engineered viruses as molecular templates is the fact that they permit nanomaterial synthesis and assembly in an energy-efficient and environmentally friendly manner. Nam *et al.* demonstrated that engineered M13 phages can be used to synthesize and assemble nanowires of cobalt oxide at room temperature, which can then be used as materials in lithium-ion batteries.[17] In this work, tetraglutamate (EEEE-, 4E) was first inserted into the N-terminus of the pVIII major coat protein. This phage was further engineered to express gold-binding peptide motifs. Both gold and cobalt oxide nanoparticles nucleated on the major coat protein, which resulted in hybrid nanowire structures composed of cobalt oxide with spatially interspersed gold nanoparticles (**Figure 6(a)**). These cobalt oxide nanowires mineralized by the M13 virus in aqueous condition at room temperature exhibited a high degree of crystallinity that was comparable to that of cobalt oxide nanoparticles prepared using conventional high-temperature (>500 °C) methods. When these virus-based hybrid composite Au–Co_3O_4 nanowires were applied to lithium battery electrode materials, the resulting electrodes showed improved energy storage capacity compared to the pure Co_3O_4 nanowires (>30% greater). This was mainly because of the enhanced conductivity and catalytic activity of the gold nanoparticles that participated in the redox reaction of Li with cobalt oxide. In order to integrate these hybrid nanomaterials into a thin and flexible energy storage system, M13 viruses (4E) were assembled in a two-dimensional polyelectrolyte using layer-by-layer assembly (linear poly(ethyleneimine)/poly(acrylic acid)). Spontaneously assembled viruses were then transformed to cobalt oxide nanowires in a similar fashion, enabling fabrication of lightweight, flexible, and transparent anode electrode films. The resulting self-assembled virus-based lithium-ion battery film exhibited enhanced battery performance in comparison to commercial batteries and displayed a cycling rate remarkably close to the theoretical limits. The main reason for the improved performance of novel virus-based battery materials is that the monodisperse nanowires templated by engineered viruses enable assembly of close-packed layered structures with a high surface area to volume ratio, and thus charge carrying capacity. The Belcher group has also developed a method for spatial positioning of virus-based electrodes using microcontact printing.[18] After coating a PDMS template (4-μm diameter circular patterns) with alternating layers of positive and negative polyelectrolytes, the engineered virus (4E) solution was dropcasted on the multilayers. The whole assembly was dipped into the cobalt oxide precursor solution and cobalt oxide nanowires formed on the micropatterned regions. Stamping the template onto a platinum microband current collector (cobalt oxide side down) produced a patterned array that served as the anode electrode component of an effective battery. In order to fabricate cathode materials needed for a full virus-based battery system, Lee *et al.* developed a novel multigene engineered virus.[16] The new cathode-fabricating viruses were engineered to nucleate iron phosphate on the pVIII major coat protein and to bind to carbon nanotubes on pIII minor coat proteins. The resulting viral particles successfully mineralized iron phosphate and interconnected the conductive carbon nanotubes, forming a conductive network cathode material (**Figure 6(b)**). It was found that incorporating carbon nanotubes increases the cathode's conductivity without adding much weight to the battery. By combining virus-based cathodes and anodes (viral silver Ag nanowires), the Belcher group has demonstrated complete virus-based 3-V batteries that can be used to power light-emitting diodes (LEDs).

2.206.3.2. Phage for Energy Producing Materials

Inspired by the natural photosynthetic systems, the well-defined structure of viral protein shells has also been used to develop biomimetic photosynthetic materials. In natural photosynthetic systems, several types of chromophores are spaced precisely so that the resulting structures can transfer absorbed solar energy in a highly efficient manner.[81] Thus, in manmade systems, the spacing between individual energy transferring components should be regulated with nanometer precision. In order to accomplish this, the well-defined structure of viral particles such as MS2 phage has been taken advantage of for precise spatial tuning of self-assembled structures that mimic

natural energy transfer systems.[38,83] The protein structure of viral particles can be modified by genetic engineering or chemoselective bioconjugation approaches for incorporating specific functional groups at desired locations.[21,40] Using such techniques, photocatalytic materials such as porphyrins can be conjugated to genetically engineered M13 bacteriophage for investigation of virus-based energy transfer reactions.[84] Scolaro *et al.*, for example, have genetically modified M13 phage to express inserted peptides containing tryptophan (Trp) residues at the exposed N-terminal region of the pVIII major coat protein. Cationic porphyrin derivatives were then electrostatically immobilized to the negatively charged M13 phage surface. Fluorescence quantum yields of the resulting porphyrin–virus hybrid structures were examined at three different wavelengths (295, 400, and 438 nm) in order to observe energy transfer events from the external tryptophan residues of M13 to the contiguous porphyrins. In the presence of M13 with Trp residues, fluorescence quantum yields at 295 nm were found to be approximately two times higher than those observed with wild-type M13 phage. This only happened at 295 nm, which indicated that Trp residues were actively involved in the donor–acceptor coupling and energy transfer processes.

Site-specific chemical reactions have also been developed to precisely control the protein shell structure for design of well-defined multifunctional viral particles used in photosynthetic systems. Stephanopoulos *et al.* used viral capsids of sphere-shaped MS2 viral particles, which can be assembled in a hollow 27-nm diameter shell, to arrange fluorescent dyes (Oregon green) and zinc-porphyrin through chemoselective reactions (**Figure 7(a)**).[39] The maleimide-containing donor dyes were targeted to the interior surface of MS2 phage, which was modified with cysteine residues. The dyes were chosen to have emission spectra that overlapped with the porphyrin absorbance band. The exterior of the capsid was modified through an oxidative coupling reaction on the aniline residue[37] to introduce an aldehyde functional group, which was further modified with the aminooxy-containing derivative of Zn-porphyrin to form an oxime linkage. This arrangement enables fluorescence resonance energy transfer from the dyes inside to the porphyrin on the outside through the 2-nm-thick protein shell. The electron-transfer ability of the complex was monitored by photoreduction of methyl viologen by excited-state Zn-porphyrins (**Figure 7(b)**). The addition of 2-mercaptoethanol completed the catalytic cycle by reducing the porphyrin cations. Viral capsids with both fluorophore donors and porphyrin acceptors showed a 3.5-fold increase in the photoreduction of methyl viologen upon illumination at 505 nm for 15 min in comparison to the capsids without donor (**Figure 7(c)**). The results indicate that well-designed nanostructures incorporating donor dyes and porphyrins at

specific locations can perform energy transfer from the inside to the outside of the capsids.

2.206.4. Phage for Sensing Materials

Phages have been used extensively in sensing applications over the course of the past 2 decades. Because of their genetically tunable chemical surface properties, self-assembling capabilities, and biological activity, phages have emerged as valuable tools for detection of various targets including small molecules,[85–87] biomolecules,[88–93] and whole cells.[94–104] Phages have been applied to biological and chemical sensor development in three fundamental ways[19]: First, phage display techniques have been used for rapid evolutionary screening of peptide molecular recognition elements (MREs) capable of binding to a particular target of interest. Once their sequence is identified, these MREs can be chemically synthesized and applied to assays for further development of integrated sensor systems. Second, engineered target-binding phages can be mass produced using a bacterial host and used, intact, as a sensing probe. Serving as a nanometer-scale scaffold, a phage probe is capable of displaying MREs in high copy numbers with controlled orientation. Finally, the biological activity of lytic phages can be utilized for detection of host bacteria. In this case, high phage replication rates and unique phage–host interactions enable rapid and specific sensing of microorganisms.

2.206.4.1. Phage-Based Molecular Recognition

The success of the use of phages for chemical and biological sensing can be attributed to their broad adaptability and ease of genetic manipulation as a molecular recognition agent; capacity to enhance target binding by serving as multivalent scaffolds for MREs; and natural ability to recognize, replicate inside of, and sometimes destroy microorganisms. Phages are thus versatile sensing probes with incredible chemical diversity and structural complexity. They can be applied for chemical and biological sensing much in the same way as antibody,[105] peptide,[106] aptamer,[107] or imprinted polymers.[108]

Both phage display and rationale modification have emerged as convenient tools for the development of sensing probes. As discussed in the previous chapter, by insertion of the randomized gene sequences into phage genome, it is possible to express billions of peptide-based receptor candidates. These peptide libraries enable rapid evolutionary screening for receptors. There are many reviews related to receptor development using phage display.[19,36,109–112] As an illustration, we briefly introduce one example of rapid receptor discovery performed using trinitrotoluene (TNT) explosive as a molecular target. Jaworski *et al.* identified TNT- and DNT-binding peptide motifs using phage display processes.[86,113] These two explosive molecules possess very similar chemical structures with one nitro functional group difference. After four rounds of TNT screening using phage display, the researchers identified TNT-binding sequences with the consensus motif of Trp-His-Trp-X (X: hydroxylated, amine, or positively charged side chain) at the N terminus of the receptor (**Figure 8**).[86] From competitive screening experiments, 95% of the strong binding phage exhibited the same tetrapeptide motif: Trp-His-Trp-X. The most abundant sequence was assigned as the best TNT-binding peptide candidate (Trp-His-Trp-Gln-Arg-Pro-Leu-Met-Pro-Val-Ser-Ile: TNT-binding peptide (TNT-BP)). Similarly, consensus DNT-binding motifs were identified after five rounds of screening (**Figure 8(a)**). Among the subset

W.; Raorane, D.; Huh, J. H.; Majumdar, A.; Lee, S. W. *Langmuir* **2008**, *24*, 4938–4943, with permission from American Chemical Society. © 2008 American Chemical Society.

of TNT-binding sequences, several exhibited varying affinity for DNT. In order to enhance the selectivity between TNT and DNT targets, negative screening was performed for the DNT molecules using the isolated TNT-binding peptides. The TNT-binding peptides with the lowest affinity for DNT exhibited remarkable selectivity for the TNT target (Figure 8(b)). This result demonstrates that M13-linked receptor sequences identified from phage display can selectively bind a predetermined target. Through investigation using fluorescent binding assays and peptides with alanine substitutions in the N-terminal region, it was shown that the conserved tryptophan and histidine residues are critical for effective TNT binding. The tryptophan replacement resulted in a 58% decrease in affinity, while the histidine replacement reduced binding by 48%. By comparing the identified TNT-binding sequence, scrambled sequence, histidine substitute, and tryptophan substitute for different substrates, the investigators provided evidence of substrate selectivity through multivalent binding. Cerruti *et al.* later demonstrated that these TNT receptor peptides have a remarkable selectivity for target TNT molecules following immobilization on quartz crystal microbalance (QCM) liquid sensing platforms.[113] The rapid receptor discovery technique for the TNT and DNT explosive introduced here is one of many examples of the application of the phage display for molecular sensing. With its evolutionary capabilities, phages can be generalized as tools for the discovery of novel molecular receptors for environment-, terrorism-, and health-related target toxicants in a rapid and convenient manner.

2.206.4.2. Phage for a Sensing Platform

Phages have been used in combination with many transducing modalities not only for the discovery of receptors for various target analytes but also as functional sensor components. In order to generate an observable output signal as a result of a specific molecular recognition event, phage particles have been coupled with nano- or micromechanical, electrochemical, and optical sensing platforms, which have recently been reviewed.[19] Using many of the self-assembly approaches discussed in the previous section, it can be convenient to fabricate phage-based sensor systems with highly dense and customizable molecular recognition elements. Both whole-phage and phage-derived probes can be implemented in several sensing formats, for example, as alternatives to antibodies in solution-based and surface-based assays,[109,110] or as a biochemical signal amplifier in bacterial culture-based assays.[100,101,114] A variety of useful sensing systems and devices that utilize phage have emerged since the development of phage display for molecular biopanning.[86,113] These can be based on the measurement of mechanical, electrical, or optical signals in response to the presence of molecular or cellular targets (Table 1).

2.206.4.3. Micro- and Nanomechanical Sensing

Phages have been used to coat materials for various micro- and nanomechanical sensing platforms. Since their original development for microweighing applications,[118] quartz crystal microbalances (QCMs), nano-cantilevers, and magnetoelastic

Table 1 Classes of phage-based sensing systems

Mechanism	*Platform*	*Probe*	*Target*	*References*
Nano/ micromechanical	Quartz crystal microbalance	pVIII-engineered Fd phage	*S. typhimurium*, β-galactosidase, prostate-specific membrane antigen (PSMA)	89,91,98,101,114
	Magnetoelastic resonator	pVIII-engineered Fd phage	*S. typhimurium*, *B. anthracis*	95–97
Electrochemical	Amperometric sensor	Phage λ; M13 phagemid/ALP	*E. coli* K12 (MG1655); *E. coli* TG-1	99,100
	Impedance sensor	T4 phage, λ phage, pVIII-engineered M13 phage	*E. coli*, *Salmonella* spp., anti-M13 IgG, PSMA	91,93,102,115
	Light-addressable potentiometric sensor	pIII-engineered M13 phage	Human phosphatase of regenerating liver-3 (hPRL-3) marker carcinoma cell (MDAMB231)	87,103
Optical	Fluorescence, ELISA	pVIII-engineered Fd phage, pIII-engineered M13 phage	*B. anthracis*, staphylococcal enterotoxin B 2,4,6-trinitrotoluene, *S. typhimurium*, hepatitis B surface antigen	84,88,90,94,116
	Surface plasmon resonance	pVIII-engineered M13 phage, pVIII-engineered M13 phage	β-Galactosidase, L-monocytogenes	89,98
	Opto-fluidic ring resonator	Bifunctional (pVIII and pIII-engineered) Fd phage (RGD and HPQ)	Streptavidin	92

resonators have been used widely for real-time, label-free studies of biomolecular interactions and cellular adhesion.[119,120] Detection is typically based on the accumulation of mass at the sensor surface and a corresponding shift in the vibrational resonance of the transducer.

Commercially available piezoelectric transducers such as QCMs are commonly functionalized with target-binding receptors such as engineered phage and implemented for sensing.[92,102,115] On the application of an alternating electric field, coated QCMs undergo mechanical vibrations at a frequency that is dependent on the amount of accumulated target. In one comparative study of label-free QCM and standard ELISA-based molecular sensing,[115] Nanduri *et al.* demonstrated the efficacy of physically adsorbed pVIII-engineered Fd phage as a target-binding agent against a model protein, β-galactosidase. They found that, while immobilized phage performed similarly to monoclonal antibodies in a standard ELISA format, QCM-based measurements yielded a fundamentally different dose–response curve (~12-fold lower K_d value and a ~3-fold lower Hill coefficient), perhaps indicating a relative improvement in target accessibility and thus sensing capability.

Another means of inducing vibrational resonance in a mechanical sensing platform is through the use of magnetoelastic (ME) materials. When subjected to megahertz-range oscillating magnetic fields, submillimeter ME 'ribbons' oscillate, generating a corresponding alternating current in a remote pickup coil. This technique allows for wireless measurement of frequency shifts and thus remote sensing.[96–98] In a recent demonstration of multiplexed detection of pathogenic organisms,[97] Huang *et al.* determined the concentrations of pathogenic *Salmonella typhimurium* and *Bacillus anthracis* simultaneously using phage-functionalized ME ribbons with two different resonance frequencies (**Figure 9**). Separately functionalized ME platforms were highly specific with no detectable cross talk between frequency channels.

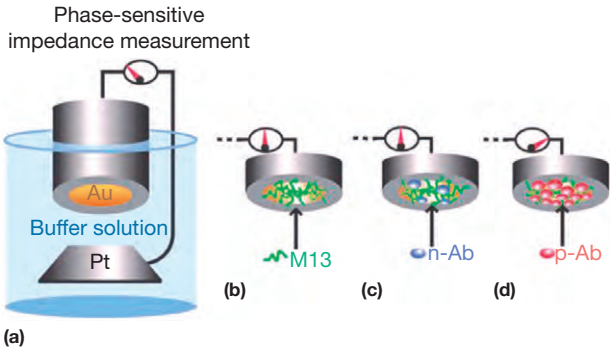

Figure 9 Phages as sensor coating materials. Schematic diagram of virus-based impedance measurement setup. (b) A dense virus layer was covalently bonded to the gold surface that produces a dense phage layer that completely electrically insulates the gold surface from contact with the buffer solution. (c) Exposure of this virus electrode to a 'negative' antibody (n-Ab, blue) causes no change to either the imaginary component of impedance, Z_{Im} or to $Z_{Re.}$ (d) Exposure to a 'positive' antibody (p-Ab, red) that is selectively recognized and bound by the phage causes a significant increase in the high-frequency Z_{Re}. Reproduced from Yang, L.-M. C.; Tam, P. Y.; Murray, B. J.; *et al. Anal. Chem.* **2006**, *78*, 3265–3270, with permission from American Chemical Society. © 2006 American Chemical Society.

2.206.4.4. Electrochemical Sensing

Molecular recognition of specific targets by phage peptide receptors can be detected using electrochemical sensors. Electrochemical sensing systems are useful because they allow for direct interrogation of the sample on a compact, integrated platform. Detection is typically based on the simple readout of changes in currents, impedances, and potentials associated with the presence of target species. Amperometric sensing systems measure current flow in a solution undergoing an oxidation–reduction reaction. In conjunction with such

systems, phages can be utilized for highly specific detection of their bacterial host (target) on generation of an electrochemically active reporter. In one example, phage λ was used as a lysing agent for a specific strain of *E. coli*. Release of β-D-galactosidase enzyme and subsequent conversion of an added substrate (*p*-aminophenyl-β-D-galactopyranoside) to an electroactive product allowed for detection of cells at concentrations as low as 0.01 colony-forming units per milliliter.[101] Detection without lysis of the target microorganism has also been demonstrated using a phagemid system to express alkaline phosphatase as a reporter.[99]

Impedance spectroscopy is one of the most well-developed electrochemical techniques used in combination with engineered phage for sensing applications.[92,94,103,116,121] Impedance measurements are easy to conduct over a range of frequencies and are highly sensitive to perturbations (e.g., target binding) at the surface of the sensing electrode. In one example of such a sensor,[92] Yang *et al.* covalently attached a dense layer of pVIII-engineered M13 phage to a gold electrode, which was then immersed in a test solution. Measuring time-dependent changes in electrical impedance of the circuit at the kHz frequency range resulted in a target (PSMA) detection limit of ~120 nM and signal to noise ratios greater than 10. More recently, the authors used the same technique to thoroughly characterize binding of anti-M13 antibodies to the phage-coated electrode and determined 4–140 kHz as an optimal driving frequency for the sensing circuit.[116] Additional examples of impedance sensing involve detection of *E. coli* on screen-printed carbon electrode arrays functionalized with T4 bacteriophage,[103] and real-time observation of salmonella infection and lysis by bacteriophage.[94]

Phages have also been used as a bioresponsive coating for light-addressable potentiometric sensors (LAPS).[88,104] Composed of a semiconductor–insulator base (e.g., $Si–Si_3N_4$), which can be activated by directed light pulses, these devices allow for interrogation of surface potentials generated as a result of ion gradients, redox reactions, or pH changes.[122] Such devices have been coated with engineered phage for label-free detection of human phosphatase marker and cancer cells.[88] More recently, LAPS were covalently modified with four different phages selected against metastatic SW620 cells.[104] When tested with other highly metastatic lines (e.g., MDAMB231) added to a plasma sample, the system was able to detect as few as 100 cancer cells with almost no background from healthy leukocytes.

2.206.4.5. Optical Sensing

Employing phenomena such as colorimetric amplification, fluorescence, and photonic resonance, optical sensing modalities are quite versatile. Detection can be based either on signals associated with optical labels or on changes in the optical properties of a sensor–sample interface.[19] In either case, optical systems are extremely sensitive, with high signal-to-noise ratios and, sometimes, single-molecule resolution.

ELISA-like assays are commonly carried out on microtiter plates using engineered phage or phage-derived affinity peptides.[85,89,91,95,117] This allows for rapid assay development and the use of standard absorbance or fluorescence-based plate readers. For example, Sorokulova *et al.* performed intensive landscape phage screening against *S. typhimurium* using both phage-capture and target bacteria-capture sandwich ELISAs.[117] Secondary labeling of captured target with alkaline phosphatase-conjugated antibodies allowed for colorimetric measurements of binding affinities. Fluorescently labeled phage can also serve as the reporter in these assays.[85,123] In addition, fluorescent labels allow for microscopy, FACS analysis,[117] and Förster resonance energy transfer assays, whereby distance-dependent, nonradiative energy transfer from a donor fluorophore to an acceptor allows for the detection of highly specific biomolecular interactions (e.g., between phage-derived antibody fragments and morphine[124]). Fluorescent quantum dot labels have been used in conjunction with engineered phage in order to carry out detection of host bacteria.[114] Here, phages were engineered to display a peptide tag, which could be biotinylated by the host's biotin ligase protein. After being released into solution, biotinylated phage progenies were then labeled by streptavidin-conjugated quantum dots. Viral infection thus served as a means of signal amplification, as quantum dot fluorescence was directly correlated with phage infectivity. Because of rapid replication, a 100-fold amplification was observed within 1 h, allowing for a detection limit of 10 bacterial cells per milliliter of sample.

Label-free optical sensing platforms that employ surface plasmon resonance (SPR), waveguides, interferometers, and ring resonators allow for real-time detection of target-binding events.[125] These systems measure refractive index changes at a surface functionalized with MREs. For example, pVIII-engineered phage can be used for highly sensitive SPR detection of β-galactosidase, a model protein,[90] or for kinetic binding analysis of *Listeria monocytogenes*, a pathogenic bacterium.[99] In these studies, this technique was easily adaptable, as engineered phages specific to the target of choice were simply adsorbed onto a commercial SPR chip. Whispering gallery mode resonators represent another class of versatile optical biosensors that have been implemented on microspheres, microtoroids, planar ring waveguides, and cylindrical optofluidic devices.[126] Because of recirculation of resonant light modes, these systems are extremely sensitive. In one example,[93] Zhu *et al.* developed a phage-based optofluidic microring resonator by depositing streptavidin-binding phage on the interior of a pulled microcapillary tube. The resonator was coupled to a light source and photodetector via a tapered optical fiber. Shifts in the resonant frequency peak of circulating whispering gallery modes corresponded linearly to both phage deposition and target binding, and allowed for a streptavidin detection limit of 100 pM.

Each of the sensing modalities described above exists because of a unique combination of sensitivity, specificity, speed, cost, and adaptability. No single system is 'best' overall – optimality depends on the particular sensing application of interest. However, at least for the purpose of sensor development, an engineered phage may be advantageous over other probes because of its broad adaptability. The ability to develop MREs specific to almost any molecular or cellular target of interest is extremely powerful, as it allows investigators to focus on the detection systems rather than the probe, alone.

2.206.5. Phage for Biomedical Application

Over the past century, phages have been used in biomedical applications including antibiotics, drug delivery, gene therapy, and tissue engineering. As mentioned, the word 'bacteriophage' (directly translated from Greek as 'bacteria eater') implies that we can use it as an antibacterial drug. The first description of bacteriophages in scientific literature originated from a British bacteriologist, Ernest Hankin, in 1896, when he observed that a substance present in the waters of the Ganges and Jumna rivers in India significantly reduced the titer of *Vibrio cholerae* bacteria when grown in culture.[127,128] Twenty years later, two independent scientists, Fredrick Twort in 1915 and Felix d'Herelle in 1917, conducted more conclusive studies to characterize such bactericidal effects. It was at that time that d'Herelle reported that they were caused by a bacteria-infecting virus and coined the term 'bacteriophage.' Soon after this discovery, d'Herelle and his contemporaries began using bacteriophage preparations as a medical therapy against the bacteria that caused diseases such as dysentery and cholera.[128,129] Despite early clinical success and even commercialization by several well-known companies including Eli Lilly[128,129] phage therapy failed to take off. Several factors led to its early demise, including lack of in-depth knowledge of phage–bacteria interactions, failure to efficiently purify the phage from lysed bacterial solution, and rapid clearance of the phage from the body's circulation.[128,129] Another factor that led most Western researchers to abandon the advancement of phage therapy was the coming of an antibiotic era. While most phage-bacteria interactions are species specific, antibiotics can have a blanketing bacteriocidal effect on bacterial populations. Thus, at the time, they were more effective and attractive for eliminating bacteria.

2.206.5.1. Phage Therapy

During the past 60 years, phage therapy investigations continued in centers across Eastern Europe and the former Soviet Union. Today, with the rise of antibiotic-resistant bacteria[130] and further developments in molecular and microbiology, the idea of phage therapy is becoming more popular among the scientific[127,128,131] as well as business communities. Previous problems associated with phage therapy are now being addressed, and scientists are expanding on molecular biology knowledge of phage–host interactions and infective mechanisms. For example, it has been shown that M13 bacteriophage are only able to infect Gram-negative bacterial cells that display the F pilus protein on the outer membrane, such as *E. coli*. Specific interactions between the TolQRA bacterial receptor and the pIII and pVIII proteins facilitate virus penetration and DNA transfer.[132–134] This specificity allows for the use of *E. coli* for effective replication and amplification of the virus but ensures that M13 will not infect or replicate within a human patient's indigenous bacterial population or eukaryotic cells, which lack the necessary tropism. Another major problem that previously led to failure of administered phage therapy was contamination of phage mixtures with either bacterial particles or endotoxins, which can incite potentially harmful immunogenic reactions.[135] At present, advanced purification methods including ultracentrifugation, precipitation, and ion chromatography allow for solutions of phage to be prepared that are free of bacteria and related particles.[128,129,136]

Phages can be cleared from the body through two pathways. Composed of proteins foreign to the body, a virus may evoke an immune system response that would inactivate and destroy it. Alternatively, phage particles may be rapidly cleared by the reticuloendothelial system (RES), which includes filtering organs such as the liver, spleen, kidneys, and cells therein that are responsible for phagocytosis of bacteriophages and other foreign particles.[137] The RES may be the more prominent mechanism for phage clearance. For example, when mice or rats were injected with phages, neutralizing antibodies could not be detected in the animal's blood,[137,138] suggesting that phages were removed from the circulation before an immune response could be initiated. To allow the virus to perform its designated function and remain in the circulation longer, directed evolution approaches have proven effective for bypassing neutralizing antibodies[138] as well as reducing RES clearance.[140] In these cases, the virus coat protein was either allowed to mutate during the selection process[140] or chosen from a recombinant virus library.[139] The fittest candidate after several rounds of stringent selection had only a few amino acid differences in its coat protein. However, it was either 96 times more resistant to antibody opsonization[139] or was able to avoid RES entrapment 16 000 times better 24 h after injection.[140]

Several recent articles have reviewed the potential of medicinal phage therapy along with the obstacles that still need to be overcome before widespread use.[127–129,131] One challenge is the intensive regulatory approval process that any phage-based application will have to face.[131] A step in this direction is the FDA's recent approval of the use of a phage mixture to combat *Listeria* bacterial growth on meat and cold cuts. The first of its kind, this approval was granted in August 2006 to Intralytix, Inc. based in Maryland[141] and may pave the way for future human-based phage applications.

2.206.5.2. Phage for Drug and Gene Delivery

In addition to therapies centered on bacterial lysis, medical applications that harness the ability to alter phage surface proteins through either genetic engineering or chemical conjugation are also being developed. Several groups are investigating engineered filamentous bacteriophage for *in vivo* screening via phage display within organs[53] or cancerous tissue,[142,143] for targeted drug delivery,[138,144] or as an imaging agent.[145] At this time, behavioral and histological evaluations of animals post-therapy, as well as previous reports of humans treated for infection with phage solutions, have not indicated the existence of any harmful side effects of phage therapy.[128,138,143,145]

For gene delivery applications, therapeutic genetic material can be incorporated into phage DNA and carried into cells following receptor uptake.[146] Phage can be locally targeted to cell receptors (i.e., via RGD or other ligands) by incorporation of specific targeting and/or internalization peptides. To make phage even more effective as DNA delivery vehicles, they can be further decorated with peptides that facilitate endosomal escape or nuclear localization motifs that target the nuclear envelope.[147] The most widely used bacteriophages for gene

delivery are M13 filamentous phages[148–150] and lambda phages.[151] In general, these can be engineered to incorporate targeting ligands without undergoing significant structural change. To enhance gene delivery efficiency, phage with multifunctional peptides can be produced using a phagemid system, which facilitates manipulation of expressed proteins on the viral vectors.[149] Phage display technology has allowed for identification of novel homing peptides that target unknown cell surface proteins. The targeting peptides can be incorporated into bacteriophage coat proteins through the genetic engineering techniques described previously.[146] These include peptides (RGD, glioma-binding peptide),[149,152] HER2 receptor targeting antibody,[150] growth factors (EGF, FGF2),[148,153,154] and the penton base of adenovirus.[151]

Eukaryotic viruses such as adeno-associated virus (AAV) have fantastic transgene delivery capabilities, but they require elimination of native tropism for mammalian cells. In contrast, M13 bacteriophages have no tropism for mammalian cells; however, their gene delivery efficiency is poor. Thus, there has been an effort to combine the advantageous aspects of AAV and M13 bacteriophages into a single system.[146] Hajitou *et al.* constructed hybrid phage with two genes from phage and nucleus integrating gene from AAV, called inverted terminal repeats. Additionally, these phages were engineered integrin-binding peptides on minor coat proteins. Therefore, the RGD peptide-induced internalization of the phage through integrin-mediated endocytosis process and the inverted terminal repeats (ITR) led to improved transgene delivery in the cytoplasm. The resulting AAV/phage system provided superior tumor transduction over phage alone. Nucleic acid cargo can also be incorporated into scaffolding materials for delivery to cells. It has been shown that DNA materials that are tethered to a matrix, rather than simply encapsulated, are more effectively transferred to the cell.[155]

2.206.5.3. Phage for Tissue-Engineering Materials

The unique biochemical and structural features of genetically engineered phage can be also used in the context of tissue engineering in order to control cellular growth (**Figure 10**). Merzlyak *et al.*, for example, have explored the use of genetically modified M13 phage as a novel building block for tissue engineering materials.[21] This was accomplished by engineering the phage to display specific cell signaling motifs and then assembling the viral particles into a macroscopic scaffolding material.[21] Many peptide expression systems have previously been demonstrated on the various capsid proteins of the phage through creation of peptide libraries.[36,44,156] However, as biological particles for peptide display, phages possess the inherent limitation of having to be successfully expressed and assembled within the *E. coli* bacteria host, which restricts the type and number of peptides that can be displayed.[45,157–159] In order to expand the utility of M13 for phage display, Merzlyak *et al.* developed a novel cloning approach for display of an integrin-binding RGD motif on every copy of the pVIII major coat protein. The researchers constructed the phage using a partial library, in which an engineered octamer insert for pVIII included a constrained RGD group that was surrounded by flanking degenerate residues.[21] This allowed for expression of inserts that retained the desired function of the RGD motif and yet were biologically compatible with *E. coli* during the intricate phage replication process. After construction of engineered phage that stably displayed either RGD- or IKVAV-peptide groups on every copy of the pVIII protein, Merzlyak *et al.* constructed aligned two- and three-dimensional scaffolding materials containing phages and tested their applicability for tissue engineering. First, the investigators verified the biocompatibility of the materials by growing NIH-3T3 fibroblast and neural progenitor cells on phage films and in phage containing media. Both cell types showed normal morphology and proliferation when in direct contact with phage materials. Neural progenitor cells either retained their progenitor state or differentiated toward the neural cell phenotype depending on media conditions. It was then demonstrated that three-dimensional phage materials could support proliferation and differentiation of neural progenitor cells. Both RGD- and IKVAV-phage matrices facilitated colony formation of neural progenitor cells, which sustained a viability of over 85% during the 7-day observation period. In comparison to RGE and wild-type phage controls, RGD and IKVAV phage resulted in enhanced binding and spreading of neural progenitor cells with high specificity. Finally, by simple extrusion or spinning of phage solution, the researchers constructed aligned three-dimensional phage fiber matrices with embedded neural progenitor cells. The resulting phage fibers encouraged neural cell differentiation and directed cell growth parallel to the long axis of the fibers.[21] Mechanical shearing of phage solution on a glass substrate resulted in two-dimensional directionally oriented films. These oriented films were shown to direct the alignment and morphology of fibroblasts, osteoblasts, and neural cells.[20] The Grinstaff group has worked in panning phage-displayed combinatorial peptide libraries against biomaterials[160] and implantable biomedical devices[161,162] to identify binding peptides usable in surface modification. They have synthesized heterobifunctional peptides which include a cell-adhesion promoting sequence (RGD) along with an identified binding sequence for the target surfaces. The interfacial biomaterial coating for polymers (polyglycolic acid, polystyrene)[160,163] and the metal surface (titanium)[162] using as-prepared peptides enabled the material to guide endothelialization on the coated surface. In the same groups, the HKH tripeptide motif was identified as the titanium-binding contributor using a phage display screening process.[161] A synthetic peptide containing three repeats of HKH was conjugated with PEG. The pegylated analogue of the peptide was shown to adsorb to the titanium surface, preventing nonspecific protein adsorption and bacterial colonization which can cause orthopedic implant failure.

2.206.6. Summary and Future Perspectives

Viruses are unique in their intrinsic ability to self-replicate within a cellular host and self-assemble into highly ordered two- and three-dimensional nanostructures. By combining these self-replicating and self-assembling functions, virus-based materials can be used to construct nanomaterials and devices with novel structure and function. Moreover, in order to improve the performance of the desired function, it is possible either to evolve these materials toward a directed endpoint or to incorporate rational design modifications

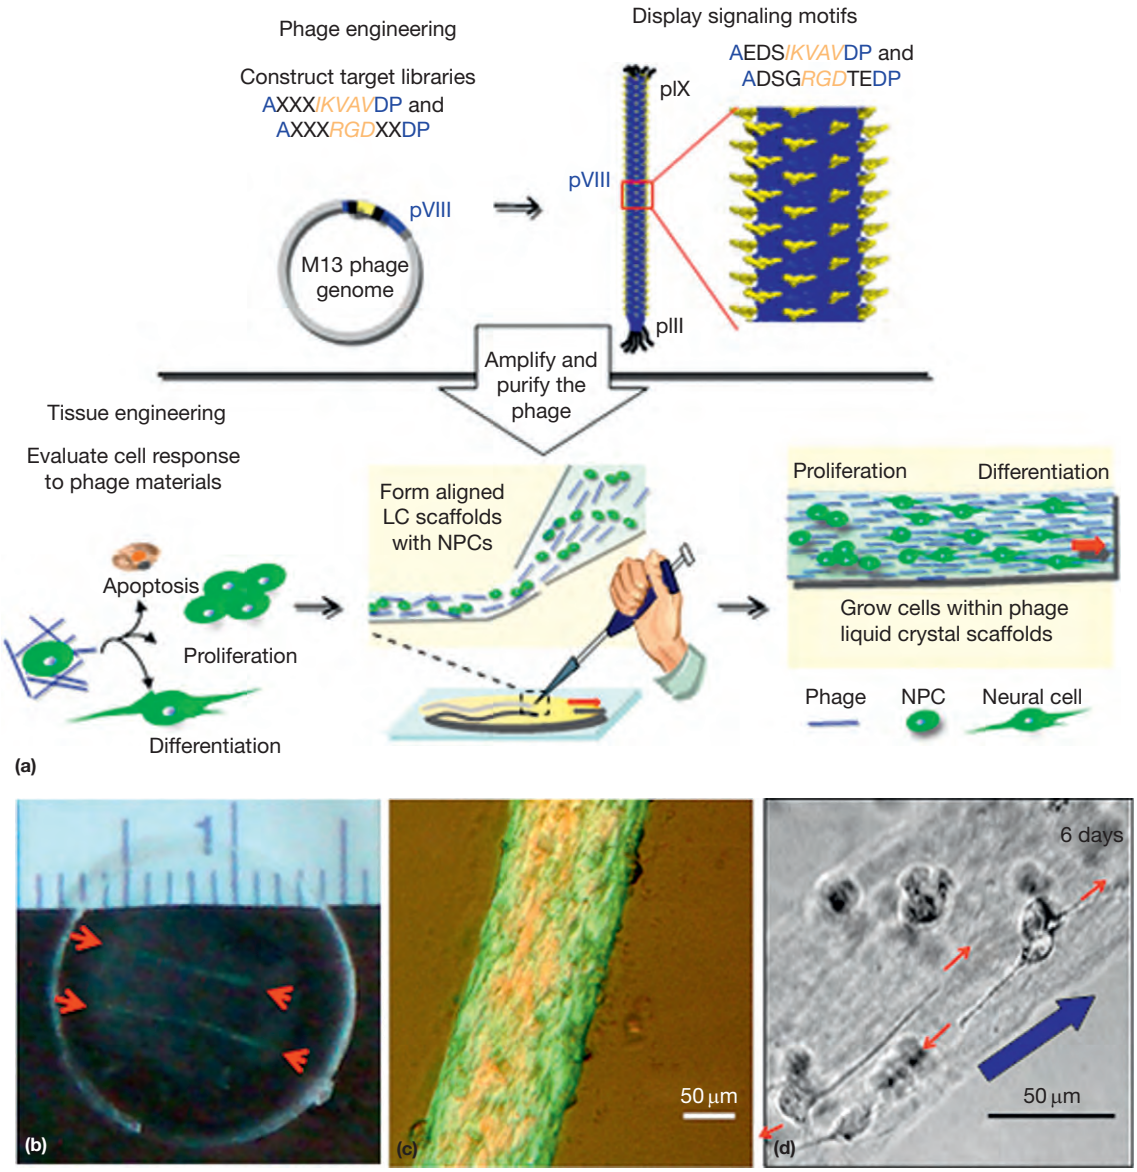

Figure 10 Phage-based tissue engineering materials. (a) Schematic diagram of developing M13 phage tissue engineering process to depict phage engineering, cell response characterization, and aligned fiber matrix fabrication. Directional guidance of neural cells using the liquid crystalline phage matrices. (b) Photograph of the phage microfiber (1 cm in length) spun in agarose, shown with a centimeter scale ruler. (c) POM image shows nematic liquid crystalline structure of the phage microfiber, scale bar = 50 μm. (d) Polarized optical microscopy images of the differentiated neural cells within aligned RGD-phage matrices after 6 days. Reproduced from Merzlyak, A.; Indrakanti, S.; Lee, S. W. *Nano Lett*. **2009**, *9*, 846–852, with permission from American Chemical Society. © 2009 American Chemical Society.

through genetic engineering. Over the past couple of decades, we have witnessed the emergence of a new class of virus-based nanomaterials and nanotechnologies. As discussed in this chapter, viruses have been developed as templates for fabrication of exquisite nanostructures including electronic or semiconductor materials, energy storage materials, sensors, and biomedical materials. They can be deposited as functional coatings for existing devices used for applications such as biological and chemical sensing. The resulting novel materials and devices benefit from the unique biological, physiochemical, and structural features of viruses such as self-replication, self-assembly, directed-evolution, and target recognition.[14,21,55,76,86]

Through eons of evolution, nature has arguably mastered the process of biosynthesis. There are several reasons for this: First, biological systems can replicate with remarkable precision at molecular, cellular, and macroscopic scales. Second, these systems can self-organize in a hierarchical fashion, generating structures and exhibiting behaviors that extend beyond the capabilities of a single subunit. Third, through diversification (mutation) and selection processes, these systems progressively evolve and adapt in order to maintain fitness in the presence of environmental pressures. This information is recorded genetically and passed to future generations. Inspired by these exquisite biological systems and their apparent ability

to self 'design,' Dr. Eric Drexler proposed several characteristics of future materials and machinery in his book *Engines of Creation* in 1983.[164] He coined the term 'Nanobot (Nanoscale Robot)' for systems that can self-assemble, self-evolve, and self-replicate – serving as fabricators of the next generation of improved nanobots. To our knowledge, synthetic systems that exhibit these behaviors do not currently exist, and it is difficult to imagine them in the near future. Virus-based materials and devices, on the other hand, may be the best representations of the nanobot concept proposed by Dr. Drexler. Through the application of techniques described in this chapter, along with methodologies that have not yet been developed, we might witness a real nanoscale 'robot' that is capable of performing intricate programmable tasks. We have termed this emerging science and engineering field '*virotronics*' because it seeks to exploit the unique properties of viruses for human benefit.[59] *Virotronics* represents a novel virus-based design technology that can be used to create new materials with precise molecular-level structural and functional control. As we described throughout this chapter, *virotronics* incorporates the unique biological advantages of viruses, such as specific molecular recognition, evolution, and self-replication with engineering principles including information mining, data storage and processing, as well as structural self-assembly, self-templating, and organization of various materials into functional devices at multiple length scales. In the near future, we strongly believe that products derived from *virotronics* will be used regularly for data mining, storage, and computation, for generation of clean and green energy, for sensing of chemical toxicants and biological pathogens, for regeneration of damaged tissues, and for other unforeseen applications which will have an impact on human health and quality of life.

Glossary

Affinity (protein-ligand) Characteristic binding strength between a single protein and ligand; commonly described by the dissociation constant.

Allogeneic immunologic response Immune response to cells or other materials derived from a genetically nonidentical donor of the same species (allograft).

Angiogenesis The process by which new blood vessels are grown from preexisting vessels.

Anisotropy A property of a material having directional dependence.

Avidity (protein-ligand) Strength of binding derived from multiple bond interactions.

Basement lamina Characteristic extracellular matrix found under epithelial or endothelial cells consisting of the fusion of two distinct layers: the basal lamina and the reticular lamina.

Bioderivation Extracting certain components/information from the biological system and then applying that to a different area of use.

Bioinspiration Deriving strategies different from that employed by nature to achieve the same function and properties.

Biomimicry Learning the principles governing the function of a biological system and then using that same strategy to create a synthetic system that functions with a similar precision.

Bioresorption A form of resorption in which materials degrade when they come into contact with one or more specific biological molecules.

Cell differentiation Process by which a cell becomes more specialized through modifications in gene expression that can lead to alteration in morphology and activity.

Collagen Primary structural ECM protein family. All collagen subunits initially organize into triple-helical fibers and then these fibers associate further to form fibrillar, sheet-like, or fibril-associated structures.

Cytokine Small cell-signaling proteins, peptides, or glycoproteins which are released into the extracellular environment by various cell types for intercellular communication.

Cytoskeleton Intracellular protein scaffolding which plays important roles in cell morphology, cellular mobility, intracellular transport, and cellular division.

Denaturation The process through which proteins or nucleic acids lose either tertiary or secondary structure due to the application of an external stress. A loss of function is typically seen in conjunction with this loss of structure.

Electrospinning Process by which continuous nano- to microscale fibers are formed by using electric forces to overcome surface tension and thereby elongate droplets of polymer melt or solution into a stream.

Excitation threshold Minimum amount of stimulus necessary to create an action potential in a nerve cell.

Extracellular matrix (ECM) The native cell microenvironment composed of specific proteins, proteoglycans, small molecules, water, etc. depending on the cell type and resident tissue. Through adhesion to the ECM, cells are exposed to physical, mechanical, and biochemical cues capable of altering cell differentiation, activation, migration, and adhesion strength.

Fibrillogenesis Creation of thin fibril structures present in the collagen fiber architecture.

Filopedia Nanoscale cellular extensions capable of interacting with nanoscale physical cues.

Glycoprotein Proteins which contain covalently attached oligosaccharide chains.

Glycosaminoglycan (GAG) Long, unbranched polysaccharides consisting of repeating disaccharide units.

Hydrogel Water-swollen, polymeric structures containing either covalent or physical cross-links. Hydrogels are highly varied in composition, construction method, and the resulting chemical and physical characteristics.

Hydrolysis A chemical process in which a molecule, such as a polymer, is split into two parts through the addition of a molecule of water.
Hydrophobicity/hydrophilicity A physical property which characterizes the ability of a molecule to repel/attract water molecules.
Hydroxyapatite The naturally occurring mineral form of calcium apatite. A modified form of this substance is a primary component of bone tissue.
Integrins A large family of heterodimeric transmembrane proteins which serve as the primary receptors between cells and ECM proteins.
Isotropy A property of a material being homogeneous in all directions.
Ligand Substance capable of forming a complex through binding to another molecule or binding site. Typically in biology, ligands are small molecules or functional groups which are able to bind to specific sites on proteins.
Mechanotransduction Mechanism though which cells convert mechanical stimuli into chemical activity.
Microablation Microscale removal of material from a surface.
Microstructure Structural features of a material which can be visualized using a microscope at 25× magnification.
Morphogenesis The process by which an organism, tissue, or cell develops its shape and/or structure.
Morphology Form or structure of an organism including shape, size, and structural features.
Motif Characteristic sequence or structure found in a protein which performs a biological function or results in specific higher-order structures, respectively.
Nanocomposite A solid multiphase material in which the size of the phases, the distance between the phases, or the structural repeats have nanoscale dimensions.
Nanopatterning Fabrication of a nanoscale pattern on a surface.
Nanostructure Structural features which range in size between molecular and micrometer dimensions.
Osteogenesis The process by which new bone tissue is developed through the laying down of new bone material by osteoblasts.
Phenotype Observable physical, biochemical, or behavioral characteristics of an organism.
Porosity A measure of the void spaces within a material.
Protease An enzyme which can catalyze the breakdown of peptide bonds within the primary protein structure.
Proteoglycans A diverse family of molecules whose structure consists of a core protein covalently attached to multiple glycosaminoglycan chains.
Recombinant DNA/recombinant protein Engineered DNA which is developed by combining sequences which would not normally occur in nature. Often this process is accomplished by introducing foreign DNA into an existing organismal DNA, such as the plasmids of bacteria. Recombinant DNA technology is used to manufacture recombinant proteins.
Tangent modulus The slope of the compression stress–strain curve as a specified stress or strain. Typically, the tangent modulus is used to describe the behavior of materials beyond their elastic regions.
Topography The composition and configuration of physical features on a surface.
Ultimate strength Maximum load or stress a material can withstand before necking of the material occurs.
Ultrastructure Detailed biological structure of a specimen not able to be visualized using a light microscope.
Viscoelasticity A property of materials that demonstrate both viscous and elastic characteristics when undergoing deformation.
Xenogeneic immunologic response Immune response to cells or other material derived from a donor of a different species (xenograft).

Abbreviations

3D	Three-dimensional
DNA	Deoxyribonucleic acid
DRG	Dorsal root ganglia
ECM	Extracellular matrix
FAK	Focal adhesion kinase
GAG	Glycosaminoglycan
HAp/Col	Hydroxyapitite/collagen nanocomposite
hMSC	Human mesenchymal stem cell
MCL	Medial collateral ligament
MMP	Matrix metalloproteinase
PCL	Poly(ε-caprolactone)
PEG	Poly(ethylene glycol)
PGS	Poly(glycerol sebacte)
PLGA	Poly(DL-lactic-*co*-glycolide)
rhBMP	Recombinant human bone morphogenetic protein
RT-PCR	Reverse transcriptase polymerase chain reaction
SIS	Small intestinal submucosa
SLRP	Small leucine-rich proteoglycan

2.207.1. Introduction

Of all the advances in science, technology, and engineering in the past few decades, the deeper understanding of biological systems has led to an ever more intimate contact between individuals and technology. This personal impact of biology-based technologies has been demonstrated to be a very powerful force in shaping the scientific community. The creation of biology-centered enablers is the result of the pursuit of three general research paradigms: biomimicry, bioinspiration,

and bioderivation. *Biomimicry* is defined as "learning the principles governing the function of a biological system and then using that same strategy to create a synthetic system that functions with similar precisions." Examples of this are protein/cell-based biosensors for detecting (bio)hazards and self-assembled materials with unprecedented responsiveness, complexity, and ability to interact and evolve. *Bioinspiration* is defined as "devising strategies different from that employed by nature to achieve the same function and properties." Examples of this are novel light harvesting methods based on nanotechnology and microorganism-based air/water filtration systems to control pollution including greenhouse gases. *Bioderivation* is viewed as extracting certain components/information from the biological system and then applying that to a different area of use. Examples of this are also plentiful: alternative fuel sources, incorporation of biologically derived molecules for targeted drug delivery, and biofunctionalized materials for advanced cellular and molecular medicine such as stem cell and gene therapies.

Earlier biomaterial research has mainly focused on biocompatibility and application-specific macroscale requirements such as mechanical, adhesive, or optical properties. The design constraints were therefore primarily concerned with preventing adverse effects on the body caused by a foreign material. Although these subjects remain to be critical issues in biomedical research with incomplete mechanistic insights, the advancement in biological sciences have influenced and expanded current biomaterial research and design. By applying biological principles through biomimicry, bioinspiration, or bioderivation to material design, the overall rationale and motivation is to expand the property and to improve the biological interaction of these materials. This chapter focuses on how the structural and functional principles derived from the native cell microenvironment, the extracellular matrix (ECM), have been applied to biomaterial design and construction. By mimicking the ECM, researchers are able to take inspiration from defined cell–matrix interfaces to subsequently control cell–biomaterial interactions. Furthermore, the hierarchical structure of ECM architecture is a desirable characteristic to incorporate into material design. Several methodologies are covered ranging from directly incorporating ECM proteins to utilizing self-assembly principles to construct materials. An overview of basic ECM structural and functional features is given followed by selected examples throughout the chapter that illustrate how these bioactive attributes are incorporated into biomaterials.

2.207.2. Overview of ECM Structure and Function

The interplay between cells and the surrounding ECM establishes a dynamic tissue microenvironment capable of performing the varied functions seen in biological systems. Cells secrete ECM molecules and maintain the matrix through continuous remodeling of the structure. The ECM, in turn, supports and maintains the cells by providing nutrition and indirectly mediating cell–cell communication. Furthermore, in some tissues, the ECM also acts as the structure responsible for carrying out the central function of a tissue. The organization and composition operate cooperatively to balance strength, flexibility, and complexity to establish specific tissue properties. ECM-inspired biomaterials attempt to mimic the bioactive and bioresponsive relationship between cells and ECM as well as the ECM's hierarchical structure through the incorporation of ECM-derived biochemical and structural components. This section focuses on the basis for such mimicry by providing an overview of how the main constituents and structural characteristics of native ECM contribute to overall tissue function (for a more in-depth examination of the ECM structure–function relationship, see Plopper[1]).

The tissue-specific ECM is composed of a unique combination of water, glycoproteins, proteoglycans, and sequestered signaling molecules integrated into a highly complex three-dimensional (3D) cell scaffold. The individual properties and subsequent configuration of these components play multiple roles in the tissue hierarchy. Proteoglycans are a diverse family of molecules whose structure consists of a core protein covalently attached to one or more glycosaminoglycan (GAG) chains. The anionic nature of the GAG leads to electrically driven association with cations and these, in turn, attract water molecules. The association of a large amount of water with the GAG chains causes overall structural rigidity as well as hydration. As such, large interstitial proteoglycans, for example, aggrecan, are able to maintain tissue hydration and establish tissue structure. Proteoglycan-mediated hydration allows diffusion of small molecules and increases the tissue's ability to resist compression forces. The relatively rigid and large structure helps define ECM architecture and can also act to prevent bacterial infiltration. Additionally, the ability of proteoglycans to bind other components facilitates organization of the ECM into functional structures. For example, binding of small leucine-rich proteoglycans (SLRPs) to collagen helps stabilize and align fibers leading to mechanical anisotropy. Soluble factors, such as cytokines or proteases, are sequestered through interactions with proteoglycans creating depots or gradients of these regulatory molecules throughout the ECM. Subsequent cell-mediated degradation of the matrix results in liberation and/or activation of these soluble proteins, enabling bioresponsive cell signaling.

The principal structural ECM proteins, collagens, are organized into a variety of functionally relevant configurations. All collagen subunits initially organize into approximately 1.5-nm triple-helical fibers and then these fibers associate further to form fibrillar, sheet-like, or fibril-associated structures. Fibrillar collagens are formed through bundling of progressively larger fibers along a single axis till eventually fibers with diameters up to approximately 3 μm are achieved. The final structure displays directionally dependent mechanical properties, for example, increased strength in the direction of alignment. Sheet-like collagens, on the other hand, are organized into defined planar networks and are better able to withstand forces in multiple directions. Collagen is often paired with elastin in tissues requiring flexibility, because of collagen's strength and elastin's ability to resist structural deformation. Alternating regions of hydrophobic and hydrophilic peptide sequences in the structure of elastin's subunit allow it to return to its original coil shape without any loss of energy. This property is advantageous for tissues undergoing constant deformation, such as blood vessels and skin because the tissue superstructure is maintained without excessive expenditure of energy. Similar association of collagens with other cell-adhesive ECM proteins, such as the bifunctional

glycoproteins, fibronectin, and laminin, may also influence mechanical properties of tissues by defining the arrangement of mechanically active cells.

Through adhesion to the ECM, cells are exposed to physical, mechanical, and biochemical cues capable of altering cell differentiation, activation, migration, and adhesion strength. Collagen, fibronectin, laminin, and other ECM proteins contain adhesive motifs within their structure to which cells can bind through transmembrane integrin receptors (Figure 1). Integrin activation through binding can in itself trigger a variety of downstream effects through intracellular signaling pathways. Increased understanding of cell–ECM interactions, however, has revealed a more complex relationship with spatial, temporal, and multisignal components. The spatial arrangement of the ECM components leads to cell interaction with differential densities and types of adhesive motifs, 3D constructs, and micro- and nanoscale topographical features. Furthermore, mechanical characteristics of the ECM are able to alter cell behavior to a similar degree as biochemical signals.[2] This concept is true not only for the overall mechanics of the tissue but also for the mechanical differences established by cellular and subcellular scale ECM structural features such as fibers or pores. All of these different types of signals coalesce to create a niche with the ability to control the adhesion strength, rate of proliferation, differentiation state, migration, and morphology of cells.

Cells, in turn, are able to manipulate and remodel the ECM environment. For example, after injury, through complex, yet coordinated, phases of healing, a temporary fibrin scaffold must be established and then quickly degraded to be replaced by fibrous tissue consisting mainly of loose bundles of type III collagen as well as new vascularization. To fully regain tissue function, this fibrous tissue must be remodeled into the native ECM of the injured tissue. Throughout these phases, a continuous progression of cell-mediated degradation, synthesis, and organization of ECM molecules occurs. Degradation is mediated by recognition of cleavable peptide sequences contained within the ECM molecules by proteases released from or located within the membrane of cells. Assembly of ECM structures is primarily driven through extracellular protein–protein interactions; however, cells participate by drawing together and orienting higher-order ECM structures through application of traction forces to the networks to which they are bound. For example, mechanical loading of collagen scaffolds stimulates cells to align collagen fibers in the direction of tension. The ECM's ability to influence and respond to the cellular environment makes it a crucial factor in important biological processes such as tissue development, blood clotting, wound healing, and cancer metastasis, all of which are targets for biomaterial applications.

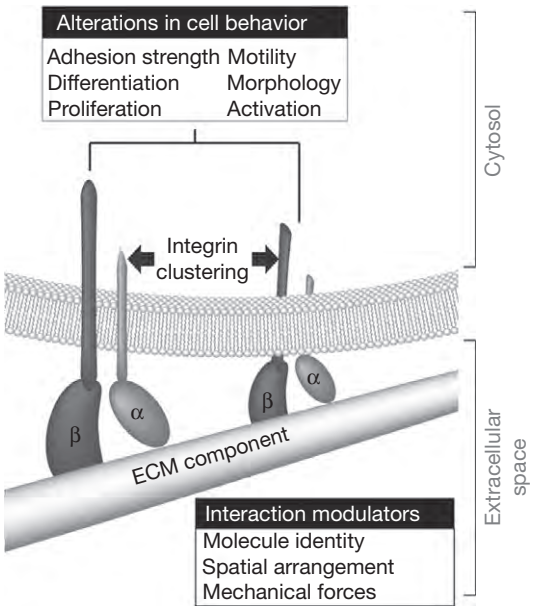

Figure 1 Integrin binding to the extracellular matrix (ECM) and subsequent extra- and intracellular clustering can lead to a variety of downstream effects causing changes in cell behavior. The ECM properties participate in the determination of cellular responses.

2.207.3. Types of ECM Mimicry

In order to take advantage of both the structural and biological functions of ECM, material design has drawn inspiration from the structure–function principles of ECM. There are various approaches in which both natural and synthetic materials can be formulated to mimic either the function and/or structure of the ECM (Figure 2). In this section, an overview of main methods of mimicry is given and selected case studies are presented to demonstrate different methods of incorporating ECM-derived biological principles (for an excellent review of tissue engineering focused ECM mimicry, see Place *et al.*[3]).

2.207.3.1. Mimicking ECM Functions by Using ECM Components

2.207.3.1.1. Full/direct copy

The most straightforward methods to achieve ECM mimicry involve incorporating native ECM components into biomaterials as structural and/or functional factors. The vast array of both

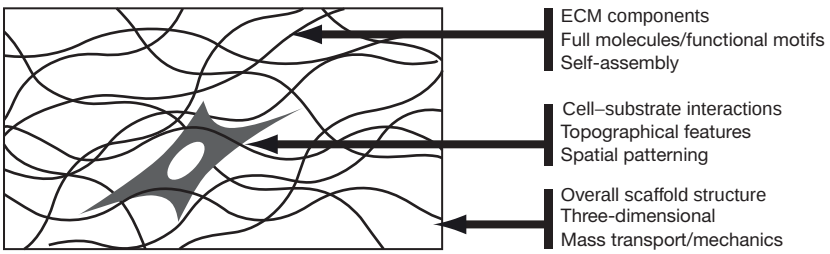

Figure 2 Extracellular matrix properties targeted for mimicry.

the types of ECM components and methods of incorporation provides a flexible and relatively controllable platform to incorporate bioactivity into material design. For example, structural proteins, mainly collagen type I or III, may be manipulated to form 3D matrices or combined with synthetic materials as a bioactive component. Soluble factors, such as growth factors, are often sequestered into a matrix, to be delivered to the surrounding tissue upon implantation or to cells encapsulated within or adhered to the biomaterial. Full versions of the molecules have the potential to retain complete functionality in terms of physical properties and/or the ability to interact with the cellular environment. By controlling the presentation of these molecules, the correct cues for various cell processes, for example, differentiation, may be accomplished through biomaterial applications (reviewed in Abraham *et al*.[4]). ECM molecules for use in biomaterial production are derived from a variety of harvested tissues, typically from animal sources, or through chemical synthesis or biosynthesis using recombinant DNA technology. The primary challenge of this methodology is maintaining the bioactivity of full copies of ECM components, in particular proteins, during material construction or processing where denaturation and loss of higher-order structures are common. Additionally, simply incorporating individual native ECM components may not fully represent the complexities of the ECM to the extent needed for certain cell interactive applications.

The multicomponent, hierarchical structure of the ECM can be more closely mimicked by decellularized ECM scaffold material derived from intact mammalian tissue (see Badylak *et al*.[5] for a more in-depth review). A variety of tissues can be used as source material including small intestinal submucosa (SIS), heart valves, blood vessels, ligaments, nerves, and tendons. After removing the cellular material to avoid adverse allogeneic or xenogeneic immunologic responses, what remains is a scaffold consisting of a preformed 3D matrix composed of the necessary ECM molecules and architecture appropriate for a particular tissue. Despite their xenogeneic source, decellularized ECM scaffolds stimulate a minimal inflammatory response[6] and demonstrate prominent host cell infiltration leading to successful engraftment and resolution of the inflammatory response. Facilitation of tissue reconstruction in both animal and preclinical models occurs though the scaffold's ability to affect cell proliferation, migration, and differentiation as well as stimulating angiogenesis. These effects are attributed to the presence of a combination of different types of collagen, sequestered growth factors, bifunctional glycoproteins, and other soluble and insoluble bioactive molecules. Additionally, the degradation products of these scaffolds have also been shown to stimulate cell proliferation and cell migration. However, the decellularization process can lead to alterations in the structure, composition, and type of host response that these materials elicit.[7] For example, the loss of water may lead to changes in the scaffold's mechanical properties caused by alterations to collagen fiber morphology or creation of physical bonds between proteins. Lack of proper hydration may also lead to reduced bioactivity because of protein denaturation or the aforementioned creation of physical bonds. Conversely, maintaining the ECM scaffolds in a hydrated state could lead to other consequences including the loss of proteoglycans or other sequestered soluble factors. A few options exist to manipulate the ECM scaffolds' mechanical and functional properties including introducing cross-links between proteins within the matrix, creating multilaminate constructs from several ECM scaffold sheets, preloading the tissue to cause collagen fiber alignment, or combining powdered (50–200 μm particles) or gel forms of the ECM scaffold material with synthetic materials with the appropriate mechanical and/or degradation properties. These methods, however, may also lead to changes in the bioactivity of the material and alter the host immunological response.

2.207.3.1.1.1. Case study: hydroxyapatite/collagen nanocomposite based material for bone regeneration

Skeletal bones consist of a complex hierarchical porous structure comprised of mainly collagen type I and hydroxyapatite crystals ranging in size from 30 to 120 nm. Bone defects resulting from injury or disease have the ability to self-repair due to the osteoconductive nature of the native ECM components. When the defect size is large, however, the tissue framework is too damaged to effectively support the regrowth of bone tissue. Tissue engineering strategies to induce bone formation often incorporate native ECM components in order to take advantage of their ability to stimulate osteogenesis as well as for their natural biocompatibility. For example, collagen I isolated from xenogenic tissues such as skin, bone, tendons, ligaments, and cornea are able to be employed after undergoing a purification process to remove a majority of the antigenic components such as the telopeptide regions. Hydroxyapatite can also be derived from xenogenic tissues, but is more commonly obtained through direct precipitation of calcium and phosphate ions. Chemical methods, however, may result in an impure product or nonmimetic crystal sizes. Third, the delivery of recombinant bone morphogenic proteins (BMPs) has been shown to stimulate complete bone morphogenesis and has been approved by the USDA for clinical applications. The success of these individual native ECM components in supporting and enhancing repair of large bone defects has prompted creation of scaffolds containing various combinations and arrangements of these molecules to more closely mimic native bone ECM.

In a study by Sotome *et al.*,[8] a hydroxyapatite/collagen nanocomposite (HAp/Col) and alginate hybrid material was investigated as a bone filler and BMP delivery system using a rat model. Previous work had demonstrated the bone-like nanostructure of the HAp/Col composite with hydroxyapatite crystals of up to 50 nm aligned along the collagen fibers. However, the density of the blocks of the HAp/Col composite prohibited tissue invasion and thus, limited its efficacy. By combining a powder form of the HAp/Col nanocomposite with alginate, they were able to create an injectable, porous scaffold. Application of this scaffold to holes in a rat femur demonstrated enhanced proximal bone formation and tissue ingrowth over 8 weeks compared to both porous HAp scaffold and alginate gels. Additionally, recombinant human BMP-2 (rhBMP-2)-induced ectopic bone formation showed dose dependent amounts of bone growth throughout almost the entire matrix as compared to the isolated small area of bone growth seen with rhBMP-2 loaded collagen scaffolds. Coupled with the scaffold's ability to maintain its shape in the compressive environment of bone tissue, the results

suggest that the HAp/Col-alginate scaffold would be a more effective BMP delivery vehicle in bone tissue than traditionally employed collagen matrices.

By incorporating multiple native components, the material more closely mimicked the native structure of bone ECM in both structural features and the ability to direct cell behavior *in vivo*. The results of this study, however, represent preliminary comparisons of feasibility and do not examine the quality of the regenerated tissue. While the material may have been able to stimulate cellular ingrowth and some bone formation, the ideal outcome of scaffold replacement with functional bone tissue was not demonstrated within the time frame or with the materials employed. The dependence of tissue ingrowth on swelling limits the possible applications of this material and may lead to an eventual lower rate of healing. Thus, while the use of ECM molecules provides advantageous bioactivity through stimulation of osteogenesis, further consideration must be given to mimic the mechanical and cell permissive properties of native ECM to achieve optimal tissue regeneration.

2.207.3.1.1.2. Case study: use of ECM scaffolds to repair ligaments

Ligaments are highly hydrated tissues featuring closely packed fibers composed of mainly collagen type I as well as collagen types III, V, and SLRPs. Type I collagen dominates the structure and is the main component responsible for the tissue's mechanical properties. Variations in the relative quantities or organization of these components can lead to significant differences in the mechanical properties of the tissue. Injuries to ligament tissue in the form of ruptures or tears usually result in regenerated tissue with significantly inferior mechanical properties to normal ligaments because of alterations in composition and ultrastructure even after years of remodeling. In particular, increases in the relative concentration of collagen type V and the amount of proteoglycans as well as a decrease in fiber diameter are commonly seen in the healed tissue.[9]

One strategy employed to improve healing efficacy is surgically implanting a SIS-derived biological scaffold into the site of ligament injury. In a series of investigations, a single layer of SIS was sutured into a 6 mm gap medial collateral ligament (MCL) injury in a rabbit model and compared to nontreated injuries and a sham control of undermined, but not injured, ligament.[10,11] After 12 weeks, SIS-treated MCL had greater collagen density, cellularity, overall collagen fiber diameter (**Figure 3**), and fiber alignment than nontreated controls. Additionally, RT-PCR investigations of the healed tissues demonstrated lower relative concentrations of collagen type V and certain SLRPs in SIS-treated conditions than in nontreated conditions. These compositional differences corresponded to at least 50% increases in the stiffness, tangent modulus, and ultimate strength of the SIS-treated healing tissue compared to nontreated controls. Such effects are attributed to cell signaling through the presence of growth factors and the degradable collagenous cell scaffold material as well as to the SIS scaffold's ability to maintain hydration within the wound environment.

Despite the improvements seen in SIS-treated healing tissue as compared to nontreated tissue, the composition and mechanical properties of the healed tissue from each condition were still vastly different from those of the sham controls even after 26 weeks. One important requirement of scaffolds

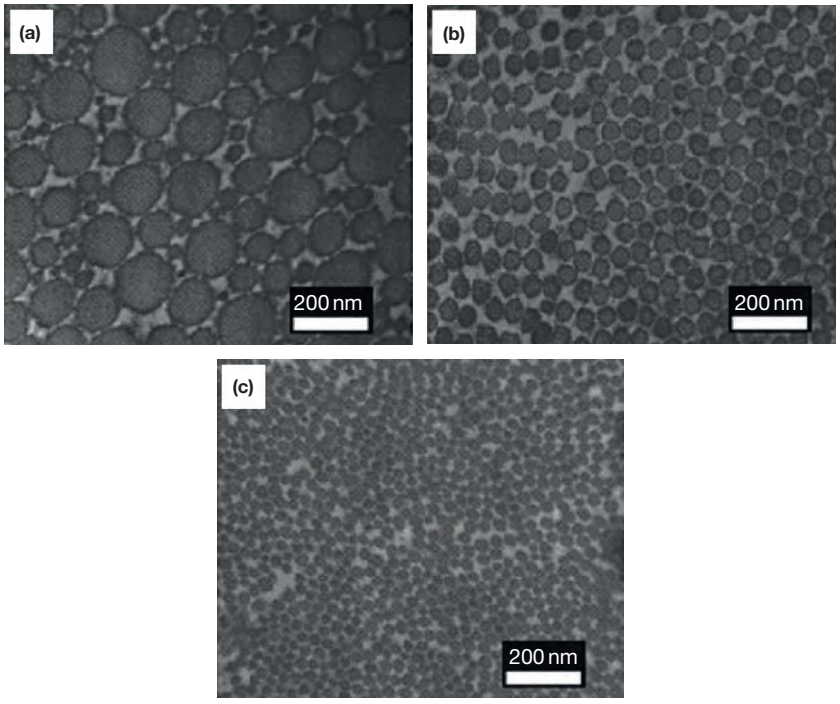

Figure 3 Transmission electron micrographs (70 000×) of cross-sectional collagen fibrils in (a) sham-operated medial collateral ligament (MCL), (b) small intestinal submucosa-treated MCL, and (c) nontreated MCL at 12 weeks post-6-mm gap injury. Adapted from Woo, S. L. Y.; Abramowitch, S. D.; Kilger, R.; Liang, R. *J. Biomech.* **2006**, *39*, 1–20.

employed to regenerate tissue is to be able to transmit the mechanical forces across the injury. This requisite not only provides the replacement of lost function but also allows for mechanical conditioning of the regenerating tissue. As ECM scaffolds, including SIS, reflect the composition and architecture of the source tissue, application of these materials to different types of allogenic or xenogenic tissue may not fully replicate the environment necessary to restore functioning tissue. In this case, SIS lacking some crucial characteristics of ligaments, such as collagen fiber orientation in space, may have limited its ability to fully stimulate remodeling of the healing tissue despite containing many of the same structural molecules. Some current research focuses on mechanically preconditioning cell-seeded ECM scaffolds that reorient fibers and increase mechanical properties.[12] Such steps may allow ECM scaffolds from more accessible tissues to be more effective in mimicking the properties of ECM from different tissues.

2.207.3.1.2. Partial copy

Using full-length copies of proteins is not always feasible or appropriate for certain biomaterial applications. ECM scaffolds may not fulfill either the required mechanical or bioactive role or the rapid degradation may compromise the material efficacy. Individual ECM proteins are often not sufficiently stable to successfully retain bioactivity after incorporation into the biomaterial and the amount of source material or the cost of production to achieve the required bioactive concentration can be prohibitory. Additionally, full proteins may stimulate undesired cell responses, especially in cases where certain cell differentiation states must be maintained (reviewed in Carson and Barker[13]). As mentioned previously, ECM–cell interactions and interactions between ECM proteins are mediated by recognition of small peptide sequences contained within ECM proteins. Exploiting this relationship provides an alternative method to attaining the desired protein–protein interaction though incorporating a fraction of the native ECM protein in the form of a functional motif. Through these protein–protein interactions, changes in cell behavior and ECM structure can be stimulated through alterations of protein configuration, formation of membrane-proximinal protein clusters, transmission of mechanical forces between cells and ECM, and organization or enzymatic cleavage of ECM proteins. By taking advantage of the relatively low complexity of these recognition motifs, bioactivity and bioresponsiveness can be incorporated and controlled in synthetic or natural biomaterials.

The techniques used to modify biomaterials with these functional peptide motifs generally fall into two categories: 'surface modification' and 'incorporation' into the scaffold structure. Surface modification methods, as opposed to bulk material modification, are typically employed with materials having a lower surface to volume ratio where cell–material interactions occur within a limited surface area. This approach is also advantageous in *in vivo* settings as it allows the material to maintain its bulk mechanical properties while adding surface bioactivity. The major methods of immobilizing peptides to the biomaterial surface include electrostatic interaction (e.g., adsorption, self-assembled monolayers), ligand–receptor interactions (e.g., biotin–avidin, antibody–antigen), and covalent attachment (e.g., silanization, polymer tethering; see Garcia,[14] Goddard and Hotchkiss,[15] Raynor *et al.*[16] for more detailed reviews). Limited availability of the ligand due to surface rearrangement, nonspecific adsorption of proteins, and changes in ligand conformation is a common challenge that reduces the efficacy of these techniques. To overcome some of these limitations, one common strategy is to introduce a spacer group, typically in the form of a hydrophilic polymer, between the surface and the bioactive molecule to increase availability, prevent denaturation, and reduce nonspecific protein adsorption. For highly porous materials, typically hydrogels or other polymeric scaffolds, ECM mimetic ligands are often incorporated directly into the polymeric structure. Peptide sequences can be covalently attached to polymer chains prior to formation of the scaffold or a peptide sequence can be incorporated on formation of the scaffold through the attachment of cross-link-susceptible chemical groups or interactions with proteins. For example, SLRP-mediated collagen fibrillogenesis has been mimicked in collagen scaffolds by incorporating a small peptidoglycan containing collagen-binding peptide sequences derived from these SLRPs.[17] In this way, functional peptide sequences are presented throughout the scaffold in a similar manner, as seen with surface modification, or as an integral, bioresponsive segment of the polymeric chains.

2.207.3.1.2.1. Case study: multiple ligand–integrin interactions alter intracellular signaling

Integrin binding to adhesive motifs that are present in a variety of ECM proteins may direct cell phenotypes and guide various cell processes such as adhesion, intra- and intercellular signaling, and cell death. Affinity between the ligand and integrin, avidity of the ligand, and integrin specificity are all influential factors in the subsequent downstream cellular effects. One of the first and most commonly employed peptide motifs in biomaterial design is the ECM ubiquitous integrin-binding tripeptide sequence arginine-glycine-aspartic acid (RGD). RGD was first employed to increase or control adhesion to materials which normally may not support adhesion, but has been found to influence a variety of cell behaviors including cell phenotype. For example, variations in monocyte behavior seeded onto poly(ethylene glycol) (PEG)-based hydrogels with or without incorporation of a tethered RGD motif demonstrate possible implications toward modifying the host response using functional motifs.[18] Both adhesion of and inflammatory cytokine and protease release from primary monocytes were shown to be modulated by the presence and density of RGD within the scaffold. While the ability of simple peptide sequences, such as RGD, to bind multiple integrin pairs is advantageous for increasing cell adhesion, in cases where unambiguous downstream outcomes are desired, integrin-specific binding is necessary. Moreover, additional complexity present in the native protein may provide further bioactivity than is seen with binding to just a simple, small peptide sequence. For example, presentation of the collagen I derived adhesive motif, GFOGER, in a triple-helical conformation similar to that of native collagen is critical for $\alpha_2\beta_1$ integrin binding. By incorporating integrin-specific protein fragments into biomaterials, researchers hope to exploit individual integrin-mediated bidirectional transfer of biochemical signals.

Both $\alpha_2\beta_1$ and $\alpha_5\beta_1$ integrin pairs have been shown to play integral roles in mediating the interaction of several cell types,

for example osteoblasts, fibroblasts, and chondrocytes, with their native ECM. Most studies, however, deviate from what is seen in the ECM by incorporating only a single adhesive motif. In a study by Reyes *et al.*,[19] surfaces combining two specific integrin-binding motifs were employed to elucidate possible synergistic effects on fibrosarcoma cell adhesion, integrin binding, and integrin-mediated signaling responses. Biotinylated triple-helical GFOGER and a fibronectin fragment (FNIII7-10) were attached in various ratios to avidin-adsorbed tissue culture polystyrene surfaces using the well-known high-affinity interaction between avidin and biotin. The fibronectin fragment spanned the 7th–10th type III repeats containing the adhesive motif RGD and its synergistic binding domain PHSRN. Previous work had demonstrated the increase in $\alpha_5\beta_1$ binding specificity of this fragment as compared to that of the linear RGDS peptide. The presentation of both GFOGER and FNIII7-10 demonstrated synergistic enhancement of cell adhesion, FAK activation (implicated in integrin-mediated intracellular signaling), and cell proliferation as compared to single ligand or no ligand surfaces (**Figure 4**). The use of ligand mimics providing specific integrin binding as well as antiintegrin antibody controls point to specific coordinated integrin binding of the adhesion motifs leading to membrane-proximal clustering of the two integrin types and possible further downstream interaction between signaling pathways.

The results of these studies demonstrated intracellular convergence of integrin-activated signaling pathways through use of fibronectin and collagen mimetic ligands presented on a material surface. Such synergistic effects demonstrate some of the complexity involved in mimicking cell–ECM adhesive interactions. While there are prevalent examples of incorporation of the single ECM mimetic ligands into biomaterial scaffolds, cell-responsive benefits may be gained by expanding the number and types of motifs. However, further material development and cell-based studies are needed to determine if multiligand materials could be employed to improve material efficacy in an *in vivo* or in a clinical setting.

2.207.3.1.2.2. Case study: enhancement of chrondrogenic differentiation by MMP-13 degradable hydrogels

Differentiation of stem cells to dedicated cell types requires highly coordinated processes integrating multiple types of signals derived from growth factor–receptor binding to mechanotransduction. An additional level of complexity is also presented in the form of temporal synchronization of these varied signals. As such, while stem cells hold much promise as a tool for research and clinical purposes, many challenges remain concerning both stimulating and inhibiting differentiation. Designing and constructing biomaterials to act as platforms for controlling differentiation states will require a similar level of complexity as seen in the native ECM environment which normally mediates stem cell fate. While research into this field is still in its infancy, several promising bioactive materials have been developed by incorporating ECM functional motifs.

Temporal principles of chondrogenesis were applied to enhance human mesenchymal stem cells (hMSC) differentiation seeded on an enzymatically responsive PEG hydrogel.[20,21] Differentiation of hMSC into chrondrocytes has been shown to require an increase in fibronectin, specifically the RGD adhesive motif, during preliminary phases of chondrogenesis, likely to stimulate cell–cell interactions. A subsequent decrease in fibronectin is then seen as differentiation proceeds and cells adapt a more spherical shape. In fact, the persistent presence of fibronectin may be inhibitive to chondrocyte function as was seen in *in vitro* work from another group using RGD-conjugated alginate gels. Incorporation of RGD into a PEG hydrogel was shown to support hMSC viability and initiate chondrogenic differentiation; however, results also demonstrated that extended incubation of the hMSC reduced the percent differentiation. On the basis of studies which demonstrated matrix metalloprotease-13 (MMP-13) upregulation at 7–12 days of hMSC chondrogenesis, a MMP-13 cleavage site, derived from the cartilage ECM component aggrecan, was incorporated into the PEG hydrogel. By integrating a 12-mer peptide containing both

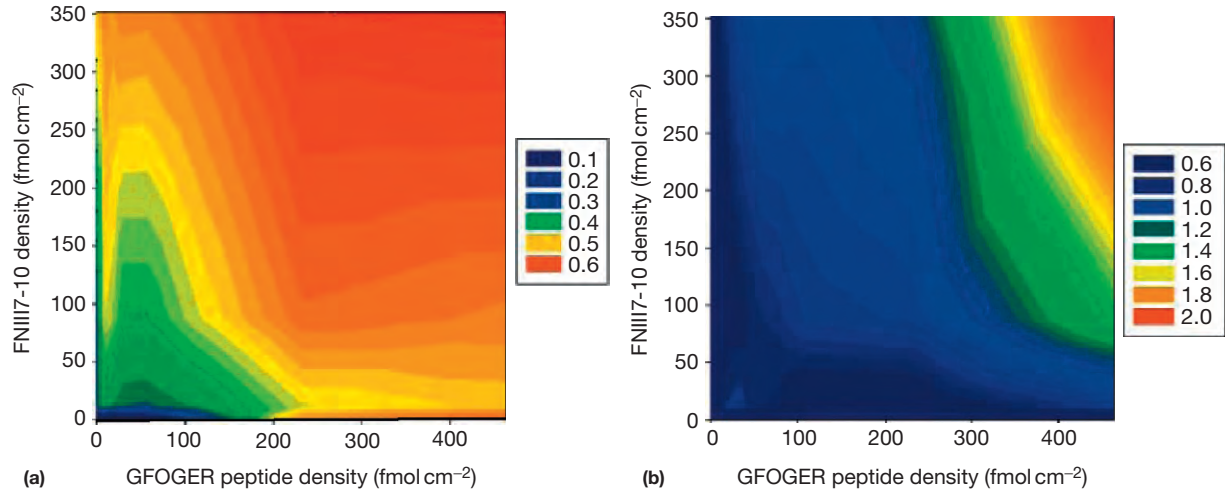

Figure 4 Contour plots displaying the effect of the GFOGER and fibronectin fragment mixed densities on adhesion ligands on fibrosarcoma; (a) adhesion and (b) FAK phosphorylation. Results are presented as (a) postcentrifugation calcein-AM signal normalized to the precentrifugation signal and (b) activated FAK normalized to total FAK detected for those conditions. Adapted from Reyes, C. D.; Petrie, T. A.; Garcia, A. J. *J. Cell Physiol*. **2008**, *217*, 450–458.

the cleavage site, PENFF (proline-glutamic acid-asparagine-phenylalanine-phenylalanine), and RGD into the PEG hydrogel, bioresponsive enzymatic cleavage of the RGD sequence was achieved. While there was a loss of viability of hMSC encapsulated in hydrogels containing the cleavage site after 11 days, likely because of the loss of adhesion sites, there was a dramatic increase in glycosaminoglycan deposition, an indicator of chondrogenesis, compared to RGD-only controls.

These studies demonstrated effective temporal and bioresponsive presentation of ECM cues to modulate differentiation of hMSC through incorporation of biological principals to material design. While these studies address mimicking down-regulation of signals in the extracellular environment, one important function of native ECM, maintenance of cell viability, was not achieved, and it demonstrates the need for further material development to fully realize how materials can control cell fate. Furthermore, additional levels complexity must be considered for possible future *in vivo* applications of bioresponsive materials. For example, levels of MMP-13 may be altered in an inflammatory environment as compared to an *in vitro* hMSC culture system leading to possible incorrect timing of RGD cleavage.

2.207.3.2. Mimicking ECM Function Through ECM Architecture and Topography

While specific ligand–receptor interactions between ECM components and the cellular environment are the primary interface responsible for mediating ECM functions, the way in which these components are organized play a major role in controlling both the downstream cellular effects and overall function of the tissue. The hierarchical configurations of the ECM ultrastructure establish macrolevel mechanical and mass-transport properties in a tissue. Well-defined nanostructural topographical and mechanical cues are able to influence cell–material interaction by promoting cell proliferation, differentiation, adhesion, and migration. Additionally, nanopatterning of cell-adhesive motifs provides a secondary level of cell behavioral control. In this section, an overview of how these ECM features are replicated and employed in material design is discussed.

2.207.3.2.1. Hierarchical microstructure and porosity

The core structure of the ECM across tissues consists of a 3D, highly hydrated, porous matrix. This configuration allows for water retention, mass transport of nutrients such as glucose and oxygen, as well as directed cell migration and soluble factor storage. For example, cell migration efficiency has been found to be optimal at pore diameters that are the same or slightly smaller than the diameter of polarized cells (reviewed in Friedl and Wolf[22]). Larger and smaller pore sizes lead to reduced cell migration rates because of decreased amounts of cell–ECM contacts and steric hindrance, respectively. Also, the additional complexity incorporated into the porous structure of the ECM creates differential physical properties of a tissue. Simple architectural features, such as fibers (see **Section 2.207.3.2.2**), are able to undergo further organization to form multifunctional lattice structures with specific densities and spatial arrangements. Developing these hierarchical arrangements establishes tissue-specific directionally dependent mechanical properties and cell arrangement (see Isenberg and Wong[23] for further review). For example, helical arrangement of successive layers of collagen- and elastin-embedded smooth muscle cells provides enhanced circumferential load-bearing properties and high torsional stability in arterial walls. Another widespread example is the organization of the basement membrane in a variety of endothelial tissues: the high density of structural ECM components forms nearly a 2D platform for cell attachment and organization through steric- and adhesion-based inhibition of endothelial cell migration. Mimicking the structural properties of the ECM in biomaterial design can range from simply imitating the properties of the core structure to incorporating mechanically effective higher-order lattice construction.

A major biomaterial application requirement is to support cell viability and growth, particularly in tissue engineering and wound healing applications. Hydrogels composed of both hydrophilic synthetic polymers (e.g., PEG) and natural macromolecules (e.g., collagen) have garnered attention for their similarity to the ECM core structure in terms of possessing basic cell-supportive properties including providing hydration, mass transport, and a 3D environment. This broad class of materials is highly varied in terms of polymer chemistry, construction methods, and types of functional modifications (see Andriola Silva *et al.*,[24] Jia and Kiick,[25] and Tibbett and Anseth[26] for relevant reviews) allowing extensive customization of hydrogels for different applications. By controlling the material chemistry and the porosity, specific mechanical properties and transport characteristics can be achieved. For example, hydrogels or similar systems can act as local reservoirs for soluble proteins where diffusion of soluble factors can be controlled, in part, by pore size and interactions with the polymer backbone similar to what is seen in native ECM. Additionally, controlling the density of physical or chemical cross-links will alter mechanical properties of the hydrogel. However, highly porous materials are traditionally limited in both the strength and complexity of the mechanical characteristics they can achieve. Additionally, pore size is typically heterogeneous and not able to be precisely controlled using simpler scaffold construction techniques. Therefore, while the core structural characteristics of the ECM are able to be mimicked with relative ease, achieving coordinated mass transport and mechanical properties requires adaptation of more complex architectural features.

Approaches in scaffold design are able to mimic higher-order ECM architecture through creation of hierarchical or micropatterned porous structures that provide the desired mechanical and mass-transport properties. Possibly the simplest methodology to achieve porous structures with anisotropic mechanical properties is through the mechanical conditioning of existing porous scaffolds. For example, scaffold alignment can be achieved through cell- or temperature-mediated mechanical cycling of collagen or synthetic polymer hydrogels, respectively.[12,27] Alignment of electrospun fibers can also be employed to create anisotropic materials while at the same time presenting important topographical cues to cells (see **Section 2.207.3.2.2**). These techniques, however, often do not achieve cell permissive pore sizes or physiological mimetic mechanical properties. More complex techniques are available to create 3D structures with defined pore size and shape

ranging from microablation of pores into polymer membranes to computational-driven layer by layer manufacturing of complex 3D scaffolds from polymer, hydrogel, ceramic, and metal materials (see Hollister[28] for in-depth review). The latter technique provides rigorous control of the scaffold architecture, allowing construction of materials with a single pore size or wavy fibers, for example. By varying the shape, orientation, and distribution of the pores, porosity can thereby be used to create direction-dependent mechanical properties instead of relying solely on material chemistry.

2.207.3.2.1.1. Case study: anisotropic honeycomb structure for ventricular myocardium repair

Ventricular myocardium is structurally highly complex, requiring directionally dependent mechanical and electrical properties for its proper function. In native tissue, cardiomyocytes are interwoven into a multifaceted network of collagen fibers which display honeycomb-like organization. This type of organization produces mechanical and electrical anisotropy. Damage to the ventricular myocardium, typically as a result of a cardiac infarction, leads to cardiomyocyte death and replacement of native tissue with nonfunctional fibrous tissue. Previous attempts to repair myocardial tissue using 3D scaffolds has failed to effectively regenerate functional tissue due to structural and mechanical variances from native tissue. For example, scaffolds were unable to promote more than isolated regions of cardiomyocyte alignment or effectively transmit physiological mechanical forces. More recent efforts borrow from native ECM collagen fiber orientation to more closely mimic directionally dependent myocardial structural and mechanical characteristics.

In a study by Engelmayr *et al.*,[29] a polymeric scaffold exhibiting anisotropic characteristics was designed and evaluated for use in cardiac tissue engineering. An accordion-like honeycomb structure was created by laser microablating two overlapping $200 \times 200\,\mu m$ square pores oriented at 45° into approximately 250-μm-thick poly(glycerol sebacte) (PGS) wafers. The resulting accordion-like scaffold exhibited anisotropic mechanical properties more closely mimicking that of right ventricular myocardium than scaffolds constructed with square or rectangular pores. Further manipulation of the mechanical characteristics could be achieved by reducing the polymer curing time, cyclic loading, and culture with heart cells. While in some cases, this modulation helped to achieve better-matched properties, cell interaction reduced the stiffness of the scaffold to levels below what is seen in native tissue after one week. Cardiomyocytes and cardiac fibroblasts cocultured on the accordion-like scaffolds demonstrated cell alignment and slightly lower excitation thresholds in the preferred direction than more isotropic materials. Additionally, an initial attempt to create a bilayer structure by combining a partially and a fully excised PGS wafer resulted in cell penetration and interpore connectivity.

Mimicry of mechanical properties in tissue engineering scaffolds is important for correct transmission of mechanical forces across repairing tissues. This study demonstrates that use of a geometrically controlled porous structure can better match the mechanical characteristics of native tissues than heterogeneous or isotropic scaffolds. Creation of directionally dependent mechanical properties also provided cues that were able to partially guide cell alignment and thereby, cell-mediated electrical properties. The authors also attempted to address *in vitro* to *in vivo* scaling issues by layering the PGS wafers to create additional thickness. Scaling is a major hurdle to translating these types of precise material construction techniques from the miniature *in vitro* cell culture environment to implants used in considerably larger areas of tissue in *in vivo* environments. For scaffolds to successfully function at the tissue level, materials must be able to be constructed with a variety of shapes and sizes, typically much larger than what is used *in vitro*.

2.207.3.2.2. Topographical features and patterning

The ECM contains a considerable amount of cell-instructional information within micro- and nanometer scale topographical and biochemical details. In native ECM, these features are established through the arrangement and configuration of ECM components creating geometric cues or differential densities of functional motifs. Cells interact with simple physical cues, such as varying elevations or nanoscale pores, through nanoscale cellular extensions, known as filopedia. Although the mechanism by which these physical cues influence cell behavior is not completely understood, one contributing factor is the significant increase in the surface area-to-volume ratio and overall complexity of the surface. These features facilitate contact guidance phenomena and subsequent changes in cell morphology and migration. Concentration gradients of growth factors or proteins containing adhesive motifs also function to direct cell migration and alignment along the gradient. Additionally, specific ligand clustering or patterning of dissimilar motifs or signaling proteins can lead to alterations in cell behavior beyond what is seen for disorganized ligand–integrin binding. Although the exact mechanism by which adhesive ligand clustering affects intracellular signaling is unknown, it is generally thought that subsequent spatial proximity of integrins leads to further intracellular protein interaction, particularly with various cytoskeleton proteins. The addition of nanometer scale details in biomaterials can be accomplished by mimicking native ECM structures or can be imitated using surface modification techniques to add topological or patterned biochemical cues.

One of the most common methods to replicate micro- and nanoscale structural features of the ECM is to mimic the fibrillar construction of the ECM scaffold. In addition to influencing cell behavior through topological details, interactions between cells and ECM nanofibers also play an important role in mechanotransduction through viscoelastic deformation of the fibers in response to external and internal stresses. Nanofiber-based biomaterials can be manufactured using several different techniques, the most commonly employed being phase separation, self-assembly, and electrospinning (see Nisbet *et al.*[30] and Madurantakam *et al.*[31] for relevant reviews). Thermally induced phase separation involves partitioning of a polymer phase from a solvent phase through controlled or, more frequently for nanofiber formation, rapid cooling. Self-assembly of nanofibers can be accomplished by driving assembly of carefully designed monomers using hydrophobic or ionic interaction. For example, Hartgerink *et al.*[32] constructed a biofunctional nanofibrillar network containing fibers with an average diameter of 7.1 nm on the basis of hydrophobic interactions between akyl chains linked to

functional polypeptides (for more examples of self-assembled structures, see **Section 2.207.3.3**). The more common current approach for forming fibrous scaffolds because of its relative ease of use, versatility, and scalability, is electrospinning. Electrospinning involves forming continuous fibers by using electric forces to overcome surface tension and thereby elongate droplets of polymer melt or solution into a stream. Using this technique, natural or synthetic polymers can be employed as substrates for fiber formation and by varying process, environmental, and substrate parameters, fibers with a vast diversity of properties can be constructed. For example, while traditional methods produce nonwoven, randomly oriented fiber mats, using a rotating, electrified collector results in fiber alignment and thereby improved mechanical and cell-guidance properties. Recent work has also explored increasing the fiber's bioactivity by incorporating the delivery of drugs or growth factors and even cell encapsulation within the fiber structure.[33]

While electrospinning provides a versatile construction method for mimicking ECM architecture, several limiting design constraints remain. Processing conditions, in particular the use of volatile solvents, have been shown to cause denaturation of the native protein structure. For example, collagen type I-based nanofibers demonstrated a loss of triple-helical structure, lack of crystallinity, and lower denaturation temperature suggesting that the collagen had been reverted to a gelatin-like state.[34] Moreover, the resulting pore sizes of the 3D fibrous scaffold often prohibit cell migration into the matrix. Steps can be taken to increase porosity such as the addition of easily removable components to the structure, for example, salts or highly degradable polymers. Finally, while electrospinning is typically associated with production of nanofibers able to mimic the fibers of the ECM, most current production methods achieve fibers with larger diameters than native tissue. Typical electrospun fiber diameters are >500 nm; however, several methods do exist to achieve dimensions closer to native ECM. Furthermore, increases in the understanding of parameters relevant to fiber diameter coupled with technological advances promise closer ECM fiber mimics.

Using ECM structural mimics, such as nanofibers, to construct biomaterials currently does not provide the level of control or bioactivity needed to fully investigate and/or exploit microscale or nanoscale cell–material interactions. To accomplish these goals, the material design parameters are commonly focused to the area of cell–material interface through use of surface modification techniques. Methods to incorporate nanoscale features onto the surface can be categorized on the basis of the level of user-specific control of the resulting patterns they provide. Unordered topographies can be manufactured using techniques such as polymer demixing, colloidal lithography, and chemical etching (see Norman and Desai[35] for a more detailed review). These methods allow a small amount of user control over the type and number of nanofeatures obtained through variations in processing parameters, but cannot create structures with complex prescribed geometries or organization. In exchange, these methods are capable of rapid coverage of large substrate surfaces. The resulting unordered surface topographies are able to mimic the nanoscale features of the ECM but may not present the same amount of complexity and therefore cell-instructional information of native tissue.

Ordered topographies can be developed using laser ablation, microfluidics, or a variety of lithographical techniques (for more extensive reviews, see Christman *et al.*,[36] Hook *et al.*,[37] Mrksich,[38] and Schmidt and Healy[39]). Through molecule removal from the surface, molecule addition to the surface, or surface group modification, organized nanopatterns can be attained. Both physical and biochemical cues can be patterned by adding motifs directly to the surface or manipulating the chemical composition of the surface to prevent or accept biofunctional molecules through adsorption or covalent binding. Alternatively, imprint lithography and microcontact printing use nanopatterned rigid masters, manufactured using the previously mentioned techniques, to topographically mold surfaces or stamp proteins onto surfaces. However, the relatively high cost, low throughput, and lack of available equipment needed to employ these techniques limit the application of ordered nanopatterning to biomaterial design. All of these methodologies are able to spatially control molecule placement on biomaterial surfaces allowing creation of more complex biomaterials. Yet, currently, the main advantage of being able to define surface nanopatterns is derived from the ability to gain a better understanding of how individual nanoscale topographical and biological patterns affect cell behavior and phenotype at an *in vitro* level.

Patterning of functional motifs onto biomaterial surfaces has been used extensively to study how engineering material surfaces can be used to alter cell adhesion strength, spreading, migration, and differentiation. Initial and continuing work in this area involved micropatterning of proteins, such as fibronectin, through preferential adsorption to certain chemical domains patterned onto the substrate or lithographic printing methods.[40,41] Cell morphology and adhesion strength, for example, were shown to be controlled by modulating the area of cell–material contact.[14] Development of more sophisticated nanopatterning techniques has shifted the focus to creating subcellular arrangements of proteins or, more commonly, functional motifs. For example, a density gradient of RGD causes preferential migration and alignment of cells.[42] Additionally, the density and spatial proximity of nanoscale RGD clusters can modulate differentiation, spreading, proliferation, and motility of cells.[43,44] One reason for the observed variations was demonstrated by a series of studies where a spatial limit between RGD clusters was established for the formation of focal adhesions.[45] The limitations of these techniques revolve around the 2D system necessary for the creation of these nanoscale patterns. Therefore, while the existence of nanoscale features in the ECM is known, the level of knowledge and technology needed to mimic these aspects to control cell–biomaterial interactions in a more clinical setting has not yet been achieved.

2.207.3.2.2.1. Case study: electrospun nanofibers for repair of peripheral nerves

The peripheral nervous system consists of bundles of neuronal axons (nerve fibers) typically surrounded by a myelin sheath formed by layers of Schwann cells, a type of glial cell. Damage to peripheral nerves usually presents as a severance of an axon and can be repairable without intervention with significant restoration of function. In cases where there is extensive loss of tissue, however, random nerve sprouting at the site of injury because of a lack of directional cues is insufficient to effectively

regenerate the lost tissue. Infiltration of inflammatory cells and eventual establishment of granulation tissue at the site of injury create an inhibitory microenvironment for nerve regeneration. Several different types of tissue engineering approaches have been attempted to create a more permissive environment for nerve regeneration.[46] Conventional treatment involves insertion of nerve autografts or allografts; however, autograft material is limited and allografts may lead to immunological rejection. Polymer nanofiber-based biomaterials are promising for neural cell–material applications because of their resemblance to native ECM and ability to directionally guide neurite outgrowth. Of particular interest are nanofibers constructed out of poly(α-hydroxy esters) because of their bioresorbable and biocompatible nature.

Poly(DL-lactic-*co*-glycolide) (PLGA) and poly(ε-caprolactone) (PCL) nanofibers have been used for *in vitro* and *in vivo* neural tissue engineering applications concerning neurite outgrowth for damaged peripheral nerve reconstruction. When whole dorsal root ganglia (DRG), dissociated DRG cells, Schwann cells, and fibroblasts were seeded on aligned PCL and PCL/collagen blend nanofibers (500–600 nm diameter), greater alignment of neurite growth parallel to the fiber orientation was demonstrated as compared to nonfibrous poly-D-lysine surfaces (**Figure 5**).[47] The addition of collagen to the nanofiber composition led to an increased fiber orientation, glial cell migration, and elongation of fibroblasts, but decreased rate of neurite elongation, likely attributed to stronger cell–material interactions due to the presence of collagen. Furthermore, on PCL/collagen nanofibers, there was evidence of neurite growth on top of Schwann cells suggesting indirect directionality conveyed by the nanofibers to the extending neurites. In a separate *in vivo* study, tubes constructed with both PCL microfibers (2.5–8 μm diameter) and PCL/PLGA blend nanofiber tubes (140–500 nm diameter) were used to treat a 10-mm gap wound in the sciatic nerve in a rat model.[48] Improved rat sciatic nerve regeneration was achieved as compared to both transected nerve and nontreated 10-mm gap injury controls. After 4 months, regenerated tissue consisting of neural fibers, glial cells, fibroblasts, and ECM consistent with regenerating basal lumina was observed throughout the length of the scaffold. Meanwhile, the nerve stumps never reconnected in the case of the two controls; instead, random neurite sprouting led to attachment to the surrounding muscle tissue. Evidence of partial reinnervation was seen on the basis of transmission of neural tracers across the regenerated tissue as well as behavioral and neurophysiological tests. The success of the scaffold was attributed to increased cell adhesion and directional migration across the fibrous structure as well as a lack of excess inflammatory response. The fibrous structure provided high flexibility, porosity, and surface-to-volume ratio allowing higher levels of protein adsorption and an absence of mechanical microinjury as seen with stiff continuous tubes. In addition to serving as a guide for the regenerating nervous tissue, the relatively close-knit structure of the fibers prevented unwanted tissue infiltration while still allowing passage of nutrients.

Despite the success of the employment of nanofibrous tubes over nontreated controls, full function was not restored to the tissue. Myelination was not seen throughout the regenerated nervous tissue and the restored basement lamina was disorganized compared to uninjured tissue. In this *in vivo* study, the

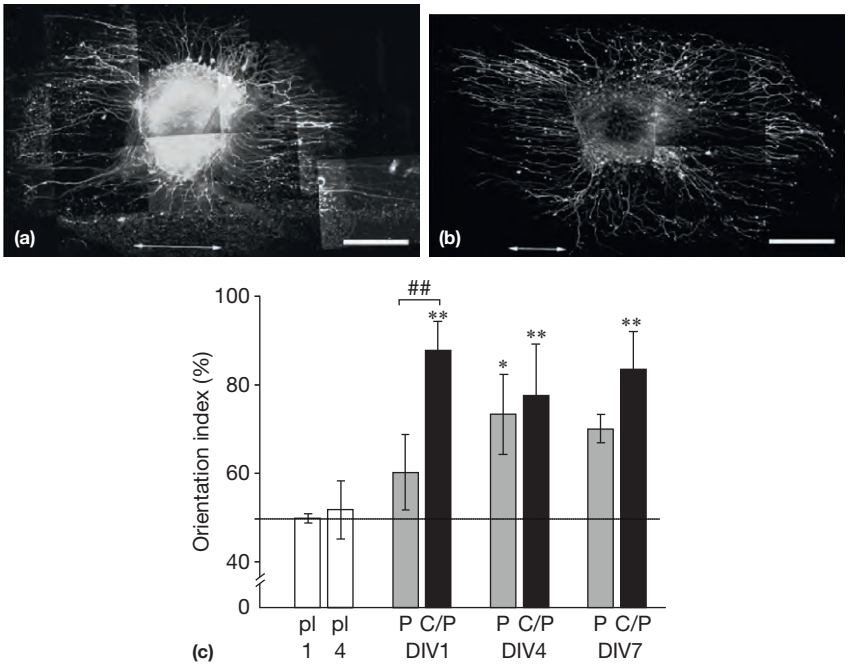

Figure 5 Orientation of neurite growth from dorsal root ganglia explants. (a,b) Neurofilament staining at 4 days on (a) poly(ε-caprolactone) (PCL) nanofibers and (b) PCL/collagen blend nanofibers; scale bar = 500 μm. Arrows indicate direction of nanofibers. (c) Comparison of axon orientation on poly(lysine)-coated coverslips at 1 and 4 days *in vitro* (DIV) and on PCL and PCL/collagen nanofibers at 1, 4, and 7 DIV; orientation index of 50% indicates random orientation of neuritess, 100% complete alignment with nanofibers, 0% orientation perpendicular to nanofibers. Significantly different than 50% $*p < 0.01$, $**p < 0.05$; $\#\#p < 0.01$. Adapted from Schnell, E.; *et al*. *Biomaterials* **2007**, *28*, 3012–3025.

fibers were randomly oriented and relied on the tube structure to direct longitudinal growth of the neurites. Improvements may be seen by applying the *in vitro* results discussed previously by increasing geometric directional cues and incorporating native ECM components into the material. In either case, however, tissue engineering approaches incorporating ECM architectural principles to peripheral nerve regeneration are relatively novel and further development will be needed before clinically efficient demonstrations can be achieved.

2.207.3.3. Mimicking ECM Protein Design and Assembly

Biological polypeptides are, in essence, complex copolymers which derive their properties from the precisely organized sequences and compositions of the basic amino acid monomers. Depending on the properties of the amino acid side chains, proteins will adapt various secondary, tertiary, and quaternary assemblies. Furthermore, through controlled associations between motifs incorporated into different polypeptide molecules, ECM proteins have the ability to self-assemble into complex 3D scaffolds. The design versatility, synthetic homogeneity, and biocatalytic assembly of biopolymers are attractive attributes to incorporate into material design and construction. In this section, a brief overview of how concepts of ECM protein design and self-assembly are both mimicked by and incorporated into biomaterials is provided (for more in-depth reviews, see Deming[49] and Maskarinec and Tirrell[50]).

Advances in recombinant DNA technology and chemical peptide synthesis techniques have stimulated interest and provided the necessary tools to explore *de novo* designed polypeptide sequences with material application potential. Designing proteins which assemble into higher-order structures using recombinant DNA technology is the most complex adaptation of mimicking protein assembly into material design. By designing novel polypeptide sequences from first principles utilizing sequence-based structural elements, researchers hope to be able to control higher-order structures or interactions between proteins. Successful cases of achieving functional tertiary structures are rare; however, greater progress has been made utilizing sequence-to-structure concepts on a smaller scale. Artificially created amino acids can be substituted to change the overall properties of the polypeptide. Incorporation of fluorine-containing amino acid analogues, for example, has been used to integrate properties seen in fluorinated synthetic polymers, such as low surface energy, low friction coefficient, and good hydrolytic stability, into polypeptides. Thus, multi-monomer, well-defined polypeptides can assimilate desirable chemical properties normally seen in polymers with heterogeneous molecular weight distribution and less complex chemical composition. The configuration of small polypeptide sequences has also been altered to perform a non-native function. For example, introducing different sequence mutations into functional domains has been used to artificially confer specificity. Richards *et al.*[51] produced a FNIII10 fragment with an RGDWXE sequence that demonstrated enhanced affinity and specificity to the $\alpha_v\beta_3$ rather than the $\alpha_5\beta_1$ integrin. Finally, controlled periodicity of sequence structure can stimulate thermodynamic folding into higher-order structures such as fibers or sheets. By exploiting structural and ionic characteristics of amino acids, peptide sequences without chemical modification have been designed to fold into β-sheets or α-helical structures. Further modification of the peptide sequence can lead to systematic interactions between polypeptide chains leading to the formation of coiled-coil or stacked structures. For example, in a study by Banwell *et al.*,[52] modifications to a repeating heptad peptide sequence capable of self-assembling into α-helical structures were able to control the formation of higher-order materials (Figure 6). That is, more specific

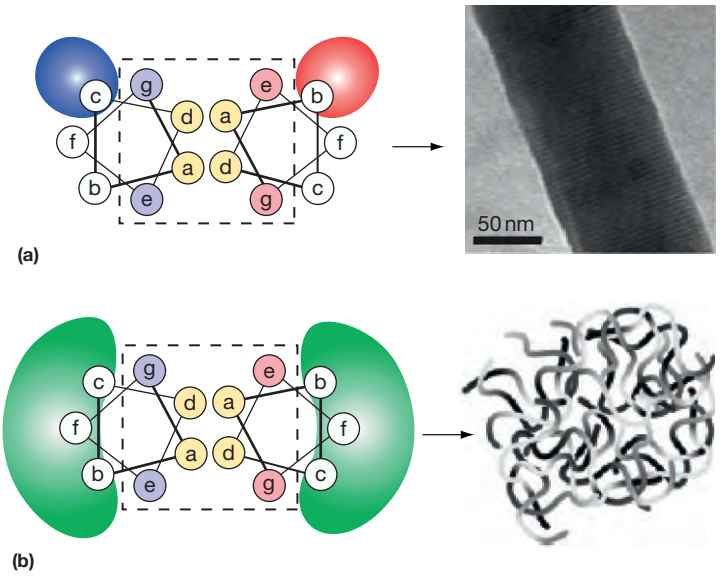

Figure 6 Schematic representation of design principles behind the hierarchical assembly of polypeptide chains containing the coiled-coil heptad sequence repeat, abcdefg. By incorporating specific interactions between amino acids at positions b and c, the α-helical structures further organized to form thicker fibrils. Alternatively, incorporation of more general, weaker interactions at positions b, c, and f led to the formation of thinner, more flexible fibers which could form hydrogels based on physical interactions between chains. Adapted from Banwell, E. F.; *et al*. *Nat*. *Mater*. **2009**, *8*, 596–600.

interactions between chains led to α-helical dimer association to form larger fibrils or more general interactions led to hydrogel formation containing more flexible chains. Such a work exhibits potential for creating highly controllable and biocompatible materials by translating nanoscale structural principles.

2.207.4. Future Directions

The merging of material and biological principles allows for the creation of materials that function as cooperative parts of the biological environment. As shown in this chapter, particular promise lies in incorporating principles derived from the native ECM into biomaterial design. Contained within the ECM is a complex regimen of spatial and temporally controlled cellular cues and structural elements responsible for maintaining and adapting to changes in the biological environment. In addition to multiple biomaterial applications benefiting from the addition of structural and functional ECM-derived principles, this design approach can also provide new insights into biological mechanisms that are not fully understood. While many strategies exist for incorporating these features, mimicry of the complex multicomponent, spatially and temporally controlled system has not been truly achieved in biomaterial design. The future lies in increasing the specificity and control of the presentation of multiple types of signals and structures. However, incorporating this type of complexity into biomaterials requires an additional level of inquiry into scalability issues and possible host modification once the material is applied to *in vivo* clinical settings. Furthermore, when nanoscaled or technologically complicated techniques are used to construct the materials, additional consideration must be paid toward the long-term efficacy and impact versus 'traditional' biomaterial in the face or regulatory hurdles, clinical availability concerns, and potentially high costs of production. Nonetheless, ECM mimicry holds much promise in advancing biomaterial research into controlling host–biomaterial interactions and creating new ways to construct materials.

Abbreviations

aECM	Artificial extracellular matrix
ALP	Alkaline phosphatase
AT-III	Antithrombin III
BMP	Bone morphogenetic protein
C1q	Complement factor 1q
CAM	Cell adhesion molecule
CNS	Central nervous system
CS	Chondroitin sulfate
CS-PG	Chondroitin sulfate proteoglycans
DDR	Discoidin domain receptors
DG	Dystroglycan
DNA	Desoxyribonucleic acid
DPS	D-periodic symmetry
DS	Dermatan sulfate
ECM	Extracellular matrix
EDC	1-Ethyl-3-[3-dimethylaminopropyl] carbodiimide hydrochloride
EGF	Endothelial growth factor
EGF-R	EGF-receptor
ePTFE	Expanded polytetrafluoroethylene
ERK	Extracellular signal regulated kinase
FAC	Focal adhesion complex
FACITs	Fibril-associated collagens with interrupted triple helices
FAK	Focal adhesion kinase
FGF	Fibroblast growth factor
FGF-R	Fibroblast growth factor receptor
FN	Fibronectin
GAG	Glycosaminoglycan
GF	Growth factor
GM-CSF	Granulocyte macrophage colony stimulating factor
GPI	Glycosylphosphatidylinositol
GTP	Guanosine triphosphate
HARE	HyA receptor for endocytosis
HB-EGF	Heparin-binding EGF
hESC	Human embryonal stem cells
HGF	Hepatocyte growth factor
HGF-R	Hepatocyte growth factor receptor
hMSC	Human mesenchymal stem cells
HS	Heparan sulfate
HS-PG	Heparan sulfate proteoglycans
HyA	Hyaluronic acid, hyaluronan
IGF	Insulin like growth factor
IGF-R, IGF-IR	IGF receptor, IGF-I receptor
IL	Interleukine
KS	Keratan sulfate
LAIR	Leucocyte-associated immunoglobuline receptor
LRR	Leucine-rich repeats
LYVE-1	Lymphatic vessel endothelial HA receptor 1
MAPG-1	Microfibril-associated glycoprotein 1
MAPK	Mitogen-activated protein kinase
MCP-1	Monocyte chemoattractant protein
MIP2	Murine IL-8 analogon
MMP	Matrix metalloprotease
mRNA	Messenger ribonucleic acid
MSC	Mesenchymal stem cell
N-CAM	Neural cell adhesion molecule
NF-κB	Nuclear factor κ-light-chain-enhancer of activated B cells
NHS	*N*-hydroxysuccinimide ester
OB	Osteoblastic cells
OPN	Osteopontin
PAI-1	Type 1 plasminogen activator inhibitor
PDGF	Platelet-derived growth factor
PDGF-R	PDGF receptor
PECAM	Platelet/endothelial cell adhesion molecule 1
PG	Proteoglycan
PI3K	Phosphoinositide 3 kinase
RANTES	Regulated upon activation, normal T cell expressed and secreted
RHAMM	Receptor for hyaluronan-mediated motility
RPTG-γ	Signal transducing receptor-type tyrosine phosphatase
SLRPs	Small leucine-rich proteoglycans
TES	*N*-Tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid
TGase	Transglutaminase
TGF-β	Transforming growth factor-β
TLR	Toll-like receptor
TN	Tenascin
TNFα	Tumor necrosis factor α
TSG	Twisted gastrulation
TSP	Thrombospondin
uPAR	Urokinase type plasminogen activator inhibitor
VCAM	Vascular cell adhesion molecule
VEGF	Vascular endothelial growth factor
VEGF-R	VEGF receptor
VN	Vitronectin
vWF	Von Willebrand factor
WISP-I	Wnt1 inducible signalling pathway protein

2.208.1. Introduction

A key process in the integration of implants and scaffolds into the host tissue is the interaction of the host tissue cells with the implant surface. Achieving a surface that guides these interactions is therefore a prime goal of biomaterial development.

Guiding cellular reactions is no trivial thing: *in vivo* cells exist in a highly complex environment, their fate being determined by information received from soluble factors, from other cells, and from the physical network they adhere to. This physical network that provides structure and support is the extracellular matrix (ECM), a viscoelastic milieu rich in biological information that plays an important role in guiding development, maintaining homeostasis, and directing regeneration, and thus constituting the gold standard for an environment that can steer and determine cellular reactions.

What is the ECM, and how does it achieve this? The term 'extracellular matrix' comprises a large and very heterogeneous set of components that are assembled locally into an ordered, highly site-specific network, and through the differences in composition the ECM takes an active part in regulating the cellular processes and responses in specific situations and tissues. ECM structure varies widely depending on the tissue and developmental stage of the collagen fibril as the central building block that is modified by other collagen types or noncollagenous components. The organic part of bone for instance consists to 90% of collagen type I, with small additions of type V and at times type III, as well as associated proteins such as decorin, osteopontin (OPN), and bone sialoprotein, which in mineralized tissues are also involved in the process of biomineralization. Cartilage, on the other hand, is made up largely of collagen type II and proteoglycans (PGs) (mainly aggrecan) that are responsible for osmotic swelling and elastic properties,[1] while blood vessel walls have to be elastic to support a pulsatile flow and consequently are made up of collagen I, type III, and elastin.

The mentioned proteins belong to certain component groups of the ECM (which will be discussed in detail in the following chapter): collagens, noncollagenous glycoproteins, PGs, and glycosaminoglycans (GAGs). Collagens are the most abundant proteins in the body, making up the lion's share of the structural network. They are modified in their structure and function by glycoproteins and PGs; these usually consist of a protein core to which one or more GAG chains are attached. GAGs are unbranched chains of repeating disaccharide units, and with few exceptions they occur only bound to the mentioned protein cores. Members of these different groups not only associate with each other in a defined manner but also specifically interact with cells and soluble proteins.

One very basic characteristic of the structural protein components of the ECM is that they confer cell adhesion, which is of vital importance for almost all cells, and the first use made of ECM components – mainly of collagen and fibronectin (FN) – was to increase cell adhesion to biomaterial surfaces not optimally suited to it. While a sound strategy, it does not do justice to the true functions and possibilities of the ECM. Cell adhesion to the ECM is a complex process and conveyed by specific adhesion receptors, enabling the cells to 'see' their surroundings and respond to them. Consequently, adhesion is intimately coupled to signal transduction, with most adhesion receptors functioning as signaling molecules. Engagement of these different receptors gives rise to a wide variety of intracellular signals that in turn influence proliferation, differentiation, and apoptosis (see Section 2.208.3 for details).

The direct interaction of the ECM with cellular receptors is by no means the only mechanism for influencing cells, as many of the structural components associate with growth factors and cytokines. These soluble factors are potent regulators of cell function, and the matrix components in turn regulate their functions: storing, activating, or inactivating them, protecting them from degradation, and retaining them at one place, thus generating gradients that cells can follow as in the case of vascular endothelial growth factor (VEGF). Without the matrix, there would be no gradient and therefore no ordered growth of blood vessels.

What now needs to be understood is the term 'artificial ECM' (aECM), which is the topic of this chapter? An aECM is a matrix consisting of isolated ECM components that have been reconstituted *in vitro* to construct a microenvironment that mimics the ECM in its ability to guide morphogenesis in tissue repair and engineering. It does not mean perfectly reconstructing the host tissue, a task that is beyond us as yet, but using those parts of the complex whole that elicit a specific response. This biomimicry may include, depending on the purpose, biochemical composition, fibrillar structure, and mechanical properties, as well as bioadhesive character, proteolytic susceptibility, and growth factor binding capacity.[2] Although both bioderived and biosynthetic materials can be applied, this chapter focuses mainly on the use of naturally derived materials (**Chapter 2.207, Extracellular Matrix: Inspired Biomaterials** and **Chapter 4.414, Molecular Biomimetic Designs for Controlling Surface Interactions**).

2.208.2. Components to Be Used for aECM

Some ECM components lend themselves more readily to use in artificial matrices than others. In this section, the main focus is placed on those proteins and polysaccharides that either have already been used in such a way, or are of potential interest; it does not constitute a comprehensive overview of the ECM. Materials which do not naturally occur but have been adapted to use in an artificial construct are included in a few exemplary cases only, for while of interest in this field, they are beyond the scope of this chapter (**Chapter 2.205, Self-Assembling Biomaterials** and **Chapter 2.203, Protein-Engineered Biomaterials: Synthesis and Characterization**).

2.208.2.1. Collagens

Collagens are the most abundant among the structural proteins. In humans, 28 collagens and collagen-like proteins have been identified so far,[3,4] although the defining line between collagen and collagen-like is blurred. In general, the term collagen encompasses all proteins containing regions characterized by the repeating amino acid motif (Gly-X-Y) that form a right-handed triple-helical structure and have a role in tissue assembly or maintenance. The collagen family can be subdivided into the following: fibrillar collagens, fibril-associated collagens (FACITs), beaded filament-forming collagens, basement membrane collagens, transmembrane collagens, collagens forming hexagonal networks and anchoring fibrils, and multiplexins (**Table 1**).[5] Among them, there is a considerable degree of complexity in structure, splice variants, presence of nonhelical domains, assembly, and function. The most abundant collagens are those of the fibril-forming subfamily with about 90% of the total collagen,[6] and these are the ones of the most interest for application in aECM (**Chapter 2.215, Collagen: Materials Analysis and Implant Uses**).

The fibril-forming collagens are I, II, III, V, XI, XXIV, and XXVII, and they are characterized by their ability to assemble into highly organized aggregates with a typical suprastructure, the quarter-staggered fibril-array with diameters between 25 and 400 nm. This results in a banding pattern with the so-called D-periodicity between 64 and 67 nm (depending on the tissue) on the basis of the staggered arrangement of the collagen monomers (for more detail see Section 2.208.4).

Table 1 Collagens and their receptors

Family	*Type*	*Receptors*	*Occurrence*
Fibril forming	I	Monomers: $\alpha2\beta1$, $\alpha1\beta1$, $\alpha10\beta1$, $\alpha11\beta1$ Fibrils: $\alpha2\beta1$, $\alpha11\beta1$ Denatured: $\alpha5\beta1$, $\alpha v\beta1$ DDR1, DDR2 Glycoprotein VI LAIR-1	Noncartilaginous tissues, bone, tendon, skin, ligaments, cornea, vasculature, interstitial connective tissues
Fibril forming	II	Monomers: $\alpha2\beta1$, $\alpha1\beta1$, $\alpha10\beta1$, $\alpha11\beta1$ DDR1, DDR2 Glycoprotein VI	Cartilage, vitreous body, nucleus pulposus, intervertebral disk
Fibril forming	III	Monomers: $\alpha2\beta1$, $\alpha1\beta1$, $\alpha10\beta1$, $\alpha11\beta1$ DDR1, DDR2 Glycoprotein VI LAIR-1	Embryonic skin, lung vasculature, vessel wall, elastic tissues
Network forming	IV	$\alpha1\beta1$, $\alpha10\beta1$, $\alpha2\beta1$, $\alpha11\beta1$ $\alpha1$(IV): $\alpha1\beta1$ $\alpha2$(IV): $\alpha v\beta3$, $\alpha v\beta5$ $\alpha3$(IV): $\alpha v\beta3$, $\alpha3\beta1$ DDR1	Basement membranes
Fibril forming	V	Monomers: $\alpha2\beta1$, $\alpha1\beta1$, $\alpha10\beta1$, $\alpha11\beta1$ DDR1, DDR2 Glycoprotein VI	Cornea, embryonic tissues, bone, interstitial matrix
Beaded filament forming	VI	$\alpha1\beta1$, $\alpha10\beta1$, $\alpha2\beta1$, $\alpha11\beta1$ DDR1	Muscle, dermis, cartilage, placenta, lung, vessel wall, invertebral disk
Anchoring fibrils	VII	$\alpha2\beta1$	Dermal–epidermal junction, skin, oral mucosa, cervix
Network forming	VIII	$\alpha1\beta1$, $\alpha2\beta1$ DDR1	Descement's membrane, endothelial cells
FACIT	IX	$\alpha1\beta1$, $\alpha2\beta1$, $\alpha10\beta1$, $\alpha11\beta1$	Cartilage, vitreous humous, cornea
Network forming	X	$\alpha2\beta1$ DDR2	Hypertrophic cartilage
Fibril forming	XI	Glycoprotein VI	Cartilage, vitreous body
FACIT	XII		Ligaments, tendon, perichondrium
Transmembrane	XIII	$\alpha1\beta1$	Neuromuscular junction, skin, epidermis, liver, lungs, chondrocytes
FACIT	XIV	$\alpha1\beta1$, $\alpha2\beta1$	Dermis, tendon, vessel wall, placenta, lungs, liver
Endostatins (multiplexins)	XV		Muscle, microvessels, eye, fibroblast, pancreas, kidney, smooth muscle cells
FACIT (multiplexins)	XVI		Fibroblasts, aminon, keratinocytes
Transmembrane	XVII	Denatured: $\alpha5\beta1$, $\alpha v\beta$ LAIR-1	Epithelia, dermal–epidermal junction
Endostatins (multiplexin)	XVIII	$\alpha5\beta1$, $\alpha v\beta3$, $\alpha v\beta5$	Basement membranes, lungs, liver
FACIT	XIX		Basement membranes
FACIT	XX		Corneal epithelium, embryonic skin, sternal cartilage, tendon
FACIT	XXI		Widespread distribution, vessel wall
FACIT	XXII		Tissue junctions, cartilage–synovial fluid
Transmembrane	XXIII		Limited distribution
Fibril forming	XXIV		Developing cornea and bone
Transmembrane	XXV		Collagenous Alzheimer amyloid plaque component
Beaded filament forming	XXVI		n.d.
Fibril forming	XXVII		Embryonic cartilage, developing dermis
Beaded filament forming	XXVIII		Basement membrane around Schwann cells
Transmembrane	Ectodysplasin A		Ectoderm
Transmembrane	Gliomedin		Myelinating Schwann cells

Collagen type I is the most abundant as well as the best studied and is often viewed as the archetypical collagen. It is the major collagen of bone, tendons, skin, ligaments, cornea, vasculature, and many interstitial connective tissues with very few exceptions such as hyaline cartilage, brain, and vitreous body. Type II occurs mainly in cartilage where it accounts for 80% of the collagen content; it is also found in some other locations such as the vitreous body, the invertebral disk, and during embryonic epithelial–mesenchymal transitions.[7] Type III usually occurs associated with collagen type I, mainly in relatively elastic tissues such as embryonic skin, lung, and blood vessels; type V occurs with type I in bone, cornea, and the interstitial matrix, and is highly expressed during tissue development and wound repair. Type XI occurs with type II in cartilage, while type XXIV and XXVII associate with type I and type II, respectively.[6]

All fibril-forming collagens closely resemble each other. They are composed of three peptide chains called α-chains, forming triple-helical molecules of 300 nm length flanked by the telopeptides, nonhelical sequences about 20 amino acids in length. The larger N- and C-terminal propeptides are removed immediately before fibril formation. Type II and type III each has three identical α1(II) and α1(III) chains, respectively, and type I has two identical α1(I) and one α2(I) chain, while for collagen V and XI all three chains differ. Characteristic of type III is the higher degree of hydroxylation and two cystein residues, which allow this collagen type to rapidly form intramolecular cross-links, something of great advantage during embryogenesis and wound healing.[8]

Type I is dominant in most tissues, but there are a variety of ways to achieve the diversity needed in fibrillar architecture for different tissues and developmental stages. One is through the minor collagens, for which healing of fetal bone is an example. While in mature bone type I is predominant (90%) with small additions of type V, in fracture healing the type III expression rises in the initial phase, forming a scaffold for the migration of osteoprogenitor cells and capillary ingrowth. Only later it is replaced by collagen type I via an intermediate stage of heterotypic I and III fibrils.[8] Such copolymers are the norm in most tissues, with the minor collagens functioning both as initiators of fibril formation and as modulators of fibril morphology. To the latter is attributed the fact that for the collagens V and XI the propeptides can be incompletely removed, which is thought to control fibril assembly, growth, and diameter.[9]

Other regulators of fibril architecture are the so-called small leucine-rich proteoglycans (SLRPs), which have been shown to have a large effect on fibril assembly[10] and are discussed under Section 2.208.2.3.

2.208.2.2. Noncollagenous Glycoproteins

The proteins of this group are quite heterogenous, existing in several variant forms and possessing multiple binding domains capable of interacting with collagen and PGs as well as with the cell surface (Table 2). The binding domains contain specific amino acid sequences that interact with cell-surface receptors and serve as adhesion recognition signals. FN,

Table 2 Noncollagenous glycoproteins and their interactions

Name	*Structure*	*Interactions*	*Occurrence*
Elastin	72 kDa, closely resembles collagen		Elastic tissues
Fibronectin	500 kDa dimer	Collagens (I, II, III), CS, fibrinogen, heparin, α2β1, α3β1, α4β1, α4β7, α5β1, α8β1, αvβ1, αvβ3, αvβ5, αvβ6, αvβ8, αIIbβ3, cell-surface PGs	ECM and cell surface, soluble variant in plasma
Laminin	Heterotrimers in 18 isoforms	Heparin, collagen IV, agrin, α1β1, α2β2, α3β1, α4β1, α5β1 α6β1, α7β1, α9β1, αvβ3, α6β4, syndecans, dystroglycans, perlecan	Basement membranes, epithelial and endothelial tissues
Vitronectin	75 kDa	Heparin, AT-III, PGs, collagens, αvβ3, αvβ5, avβ1, αIIbβ3, urokinase receptor, PAI-1, uPAR	Circulates in blood stream, loose connective tissues, blood vessel walls, lymph nodes
Tenascin (-C, -X, -R, -W)	Multimeric, subunits 190–300 kDa	Heparin, FN, aggrecan, versican, brevican, neurocan, syndecan, glypican, αvβ3, αxβ1, α8β1, α9β1, αvβ6, α2β1, CAM, phosphacan/RPTP ζ/β, annexin II, EGF-R	Connective tissue, dermis, tendons, near kidney, vascular smooth muscle, CNS, lung, skin kidney, bone, muscle
Osteopontin	Phosphoprotein, 264–301 amino acids	Collagen, FN, αvβ1, αvβ3, αvβ5, αvβ6, α5β1, α8β1, α9β1, CD44 variants	Bone, blood vessels, kidney, brain, smooth muscle, immune organs, body fluids
Thrombospondin-1 to -5		PGs, decorin, FN, laminin, collagen (I, II, IX), aggrecan, heparin, HS, DS, CS, matrilin-2, -3, fibrinogen, α5β3, syndecan-1, -3, -4, cell-surface PGs, integrins, perlecan, versican, VEGF	Lung, cartilage, brain, bone, tendon, CNS

laminin, vitronectin (VN), thrombospondin (TSP), and tenascin (TN) are members of this class of ECM proteins.

2.208.2.2.1. Elastin

Although not a collagen, this elastic 72 kDa protein resembles collagen closely, the main difference being that, unlike collagen, it contains only little proline and much lysine. It is the major insoluble protein in elastic tissues, where it contributes to their elasticity and influences cell migration, proliferation, and elastin synthesis.[11]

2.208.2.2.2. Fibronectin

FN is a multifunctional adhesive glycoprotein that plays an important role in tissue repair, in regulating cell attachment and motility, and in embryogenesis. It is a dimeric, disulfide-bonded glycoprotein of 500 kDa with a multimodular structure, comprising repeats of three distinct types of motifs called FN I–III. The protein occurs in the ECM and on the cell surface; the plasma variant does not polymerize into superstructures, but can be integrated into FN fibrils.[12]

The protein interacts with many macromolecules such as collagens, GAGs, and fibrinogen and mediates cell attachment via various sequence domains (RGD, RGDS, LDV, REDV),[13] of which especially the RGD peptide is widely used as a cell adhesion motif. FN is known to bind several types of collagen, with the binding site localized to a 30–40 kDa domain near the N-terminus of each FN chain. FN interacts with the α-chains of collagen I–III through a binding domain approximately two-thirds from the N-terminus of the α-chains, although there may be at least one more binding site of a different affinity along the α1(I) chain.[14]

2.208.2.2.3. Laminin

Laminin is found mainly associated with basement membranes and consists of three disulfide-linked chains that form a cross-shaped structure. There are 18 isoforms, all the products of closely related genes,[15] all of which contain cell adhesion sequences (RGD, PDSGR, YIGSR, IKVAV) and have a high binding affinity for heparin and type IV collagen. Cell adhesion peptides based on laminin sequences that bind α3β1 integrin have been used comparably to the FN-based RGD peptide in matrix engineering.[16]

Laminin also associates with cell-surface receptors, such as through an endothelial growth factor (EGF)-like sequence that becomes available only after degradation and can stimulate cell proliferation and differentiation. Both laminin and FN are reported to promote neurite extension and are thus critical in neural development.[17,18]

2.208.2.2.4. Vitronectin

VN is a multifunctional glycoprotein of 75 kDa that binds to various biological ligands and plays a key role in tissue remodeling by regulating cell adhesion through binding to different types of integrins, mainly via the RGD sequence. VN also regulates blood-system-related protease cascades such as coagulation and fibrinolysis through interaction with heparin and thrombin–antithrombin III complexes. Tissue VN interacts with PGs and collagens, but plasma VN is believed to be in the inactive monomer form that does not bind, requiring activation through urea, heat, or certain ligands like heparin.[19]

2.208.2.2.5. Tenascin, osteopontin, and thrombospondin

TN, OPN, and TSP are glycoproteins that also convey a multitude of functions and might thus be of interest for aECM. Even though no use has been made of them so far, they are shortly mentioned here for this reason.

The TNs are a family of large multimeric, six-armed molecules that are widely expressed: TN-X, -R, and -W, as well as the best described TN-C. They are found during organogenesis and inflammation, in muscle, connective tissue, developing bone, and the nervous system,[20] and contain multiple functional domains including EGF-like and FN III repeats.[21]

OPN is present mainly in mineralized tissues, where it is one of the most abundant noncollagenous proteins. It can bind to collagen and FN, and regulates bone formation and remodeling, the inflammatory response, wound healing, and foreign body response. The protein interacts with the αvβ3 integrin via an RGD sequence and is critical in osteoblast and osteoclast function.[22,23]

The TSPs are a protein family that guides ECM synthesis and is essential for dynamic tissues remodeling, being involved in angiogenesis, matrix assembly, transforming growth factor (TGF) activation, and neurite outgrowth. They bind cell adhesion receptors as well as a multitude of other ECM components: PGs, FN, laminin, matrilin, collagen I, II, and IX, fibrin, aggrecan, heparin, heparan sulfate (HS), dermatan sulfate (DS), and chondroitin sulfate (CS). This may allow them to play a role in forming a molecular bridge between matrix components or components and the cell surface[24] (**Table 2**).

2.208.2.3. Proteoglycans

PGs are molecules composed of a core protein substituted with covalently linked sulfated GAG chains covalently linked to the core protein via serine residues. They can be subdivided into the SLRPs and those PGs of a large molecular weight. These include the hyaluronic acid (HyA)-binding hyalectans, and non-HyA-binding PGs, among which are basement membrane and cell-surface PGs (**Table 3**).

2.208.2.3.1. Small leucine-rich proteoglycans

SLRPs are a large family of proteins characterized by core proteins with leucine-rich repeats (LRR), which are believed to be important for the protein–protein interactions, and at least one GAG side chain.[25] Additional diversity can be achieved by combinations with different GAGs: decorin and biglycan, for instance, are substituted mainly with DS in unmineralized tissues, gaining consecutively more CS as mineralization progresses.[26]

SLRPs are important regulators of various biological processes through their ability to interact with different cell-surface receptors, cytokines, and growth factors (for details see **Section 2.208.3**), while their interaction with the fibril-forming collagens regulates fibril assembly and diameter, something important for the proper assembly of tissues. Loss of decorin results in fused fibrils with irregular contours and an abnormal skin fragility,[27] loss of fibromodulin in thinner tendon fibrils, and loss of lumican in cornea fibrils without diameter control and organization. The interaction is mediated in most cases by the protein core, while the GAG chains maintain

Table 3 Examples for proteoglycans and their interactions

Family	*Name*	*GAG*	*Interactions*
SLRP	Decorin	CS/DS	Collagen, tenascin-X, fibrillin-1, tropoelastin, MAPG-1, EGF-R, IGF-IR, LRP-IR, TGF, PDGF, IGF-I, vWF, TNFα, WISP-I, C1q
	Biglycan	CS/DS	Collagen, tropoelastin, MAPG-1, TLR-2, -4, selectin-L, CD44, C1q, TGF, TNFα, WISP-I, BMP-2, -4
	Fibromodulin	KS	Collagen, C1q, TGF, BMP
	Lumican	KS	Collagen, FasL, CXC-chemokine KC
	Keratocan	KS	Collagen
	Osteoadherin	KS	C1q
	PRELP	KS	Collagen, HS, heparin
	Chondroadherin	KS	C1q
	Tuskushi	n.d.	BMP
Hyalectans	Versican	CS/DS	HyA, collagen I, fibrillin-1, FN, tenascin-R, CD44, P- and L-selectin, EGF-R, β1-integrin, TLR2
	Aggrecan	CS/KS	HyA, HS, heparin, tenascin-R
	Neurocan	CS	HyA, tenascin-R, tenascin-C, N-CAM
	Brevican	CS	HyA, tenascin-R
Basement membrane PGs	Agrin	HS	Laminin, dystroglycan, integrins
	Perlecan	HS	Laminin, collagen IV, FGF
	Collagen XVIII	HS	Basement membrane components
Cell-surface PGs	Syndecans	CS/HS	Collagen, FN, tenascin, laminin, VN, integrins, FGF-2, HGF, VEGF, midkine
	Glypicans	HS	FN, Wnt, TGF, FGF, VEGF, BMP, midkine, IGF
	Betaglycan	CS/HS	TGF, BMP, FGF

interfibrillar space[10] and contribute to matrix integrity by binding other ECM components such as TN-X.[28] Collagen-binding SLRPs include decorin (DS/CS), fibromodulin (KS), lumican (KS), biglycan (CS/DS), keratocan (KS), and osteoglycan (KS), with decorin, biglycan, and lumican being the best characterized. The mechanism of action seems to be an interaction with collagen that leads to coating of the fibril with the PG, as has been shown for decorin. Low decorin concentrations at the fibril tip allow for an increase in length while maintaining a constant fibril diameter. Biglycan interacts with collagen without influencing fibril diameter, and may be involved in organizing assembly of type IV collagen into networks. Both SLRPs may also be involved in elastic fiber biology.[28]

SLRPs bind to a number of growth factors. Decorin, biglycan, asporin, and fibromodulin bind TGF-β, with the decorin–TGF interaction being the best studied. Decorin inactivates TGF-β signaling by forming a TGF–decorin complex and sequestering it into the ECM via binding to collagen. Conversely, this may also enhance TGF activity, as seen during bone formation in remodeling when the TGF is again released. Decorin also binds PDGF and IGF-I, but with a comparatively low affinity, and through its GAG chains it interacts with vWF. Decorin and biglycan are also able to immobilize the proinflammatory cytokine TNFα and interact with WISP-I, while biglycan and fibromodulin can modulate BMP activity.[28]

2.208.2.3.2. HyA-binding PGs (hyalectans)

Among the hyalectans are counted versican, aggrecan, neurocan, and brevican. They consist of three domains: a central one that carries most of the GAGs, flanked by N-terminal domains that bind to HyA and C-terminal domains that interact with lectins.

Versican (CS/DS) is a regulator of cell–matrix interactions through its ability to interact with a large number of ECM and cell proteins (HyA, collagen type I, fibrillin-1, FN, CD44, selectin, integrin β1). Aggrecan (CS/KS) is expressed mainly in cartilage and brain and exists exclusively in the form of HyA/aggrecan aggregates with up to 100 aggrecan molecules, while neurocan (CS) and brevican (CS) occur in the central nervous system.[25]

2.208.2.3.3. Non-HyA-binding PGs

The non-HyA-binding PGs are also often termed heparan sulfate proteoglycans (HSPGs), as they are, unlike the other PGs, often linked to HS. Among these are the PGs that are part of the basement membrane: agrin, perlecan, and collagen XVIII, the last one being considered to be a hybrid collagen–PG. Cell-surface PGs also belong to this group, but these are not part of the ECM, but serve as receptors on the cell surface.

2.208.2.4. Glycosaminoglycans

GAGs are linear polysaccharides able to interact with numerous proteins and modulate their activities. They fall into two classes: (1) sulfated GAGs comprising CS, DS, keratin sulfate, heparin, and HS; and (2) the nonsulfated GAG hyaluronan, which is the only one to occur without a core protein.

GAG chains are made up of repeating disaccharide units consisting mainly of acetylated amino sugars (*N*-acetyl-galactosamine or *N*-acetyl-glucosamine) and uronic acids (D-glucuronic acid or L-iduronic acid) (Table 4).

Table 4 Glycosaminoglycans and their interactions

Name	*Major disaccharide unit*	*Interactions*	*Occurrence*
Heparan sulfate	D-GlcA-β(1→4)-D-GlcNAc-α(1→4)	Laminin, FN, VN, TSP, CD44, P- and L-selectin, PECAM, FGF-R, N-CAM, BMP-R FGFs, HGF, BMP-2, -4, -7, Wnt, TGF-β, interleukines, TNFα, AT-III, EGFs, IGF-II, PDGF, VEGF, GM-CSF, RANTES	Extracellular on cell surface and in basement membrane
Heparin	L-IdoA2S-α(1→4)-D-GlcNS6S-α(1→4)	See heparan sulfate	Intracellular in mast cells
Chondroitin sulfate	D-GlcA-β(1→3)-D-GalNAc4S-β(1→4)	CD44, P- and L-selectin, Chemokines, FGF-2, -10, -16, -18, midkine, pleiotrophin, EGF	Cartilage, tendon, ligament, aorta
Dermatan sulfate	L-IdoA-β(1→3)-D-GalNAc4S-β(1→4)	CD44, P- and L-selectin, FGF-2, FGF-7, HGF/SF	Skin, blood vessels, heart valves
Keratan sulfate	D-Gal-β(1→4)-D-GalNAc6S-β(1→3)		Cornea, cartilage
Hyaluronic acid	D-GlcA-β(1→4)-D-GlcNAc-α(1→4)	Versican, aggrecan, neurocan, brevican, CD44, LYVE-1, HARE, RHAMM	Synovial fluid, vitreous humor, loose connective tissue

L. *FASEB J*. **2006**, *20*, 9–22.

2.208.2.4.1. Hyaluronan

Hyaluronan (HyA) is composed of repeating disaccharides in which *N*-acetylglucosamine and glucuronic acid are combined by β-1,3 and β-1,4 linkages. It is structurally the simplest GAG, as it is neither associated with a core protein nor sulfated, and it is also the largest with a mass up to 10^7 Da, which gives it unique viscoelastic properties.[29] HyA occurs primarily in the ECM and pericellular tissue, with half of the total amount being found in skin. Although it was first assumed to function only as an inert filling molecule in the connective tissue, it is now known that HyA binds to a variety of ECM proteins as well as interacts with several receptors (CD44, receptor for HyA-mediated motility-expressed protein, lymphatic vessel endothelia HyA receptor 1, HyA receptor for endocytosis), so that it may function as a signaling molecule. Nevertheless, the functions of HyA depend mainly on its molecular size: large polymers are space-filling, antiangiogenic, and immunosuppressive, and intermediate sizes (25–50 disaccharides) are inflammatory, immunostimulatory, and highly angiogenic, while still smaller oligosaccharides are antiapoptotic and induce heat shock proteins. Thus, HyA fragments which accumulate during injury may be involved in stimulating the healing response.[25]

2.208.2.4.2. Heparin/HS

Heparin is produced almost exclusively by mast cells, while HS is the most ubiquitous GAG and present on virtually every cell in the body. The differences between the two are quantitative, not qualitative. Both consist of repeating units of glucuronic acid 1,4-linked to glucosamine. Heparin undergoes extensive sulfation and uronic acid epimerization, so that more than 80% of the *N*-acetyl-glucosamine residues are N-deacetylated and N-sulfated, and more than 70% of the glucuronic acid is converted to iduronic acid. HS is similar to heparin in basic design, but with less epimerization to iduronate, lower density of N- and O-sulfation, higher N-acetylation, and greater asymmetry of sulfation and charge density along the polymer.[30]

The interaction of GAGs with proteins involves a variety of mechanisms, such as hydrogen bonds and hydrophobic interactions with the carbohydrate backbone, as well as van der Waals forces and electrostatic interactions, with the sulfation pattern being an important determinator. As the patterns are generated through a non-template-driven process, there is high diversity and tissue specificity. Specific patterns are also associated with various developmental events, such as brain and axon development, as well as angiogenesis. HS is known to interact with a number of proteins such as growth factors, morphogens, ECM molecules, cytokines, and enzymes (see Table 4). Through its associations with the cell membrane, it often plays a role as a coreceptor, binding and presenting solute factors.

2.208.2.4.3. Chondroitin sulfate, dermatan sulfate, and keratan sulfate

These GAGs occur mainly in the ECM. Like HS, they also display distinct sulfation patterns and are able to interact with a variety of proteins. Because of their location in the tissue, they can not only present but also bind and sequester solute factors, building gradients or protecting them from degradation.

CS consists of glucuronic acid and galactosamine [D-GlcA-β(1→3)-D-GalNAc4S-β(1→4)], where the galactosamine can be sulfated in the C4 (chondroitin-4-sulfate, CS A) or the C6 (chondroitin-6-sulfate, CS C) position. DS (also called CS B) consists of iduronic acid and galactosamine [L-IdoA-β(1→3)-D-GalNAc4S-β(1→4)], with galactosamine sulfated in the C4 or C6 and iduronic acid in the C4 position. Keratan sulfates (KS) are based on repeating disaccharides containing galactose [D-Gal-β(1→4)-D-GalNAc6S-β(1→3)].

Chondroitin and DS often exist in the form of hybrid chains that alternate between the two forms, which makes them, together with HS, the structurally most complex species. Like HS, they are biologically active as regulators of growth factors, cytokines, and adhesion molecules through a considerable number of unique oligosaccharide sequences.[31]

CS/DS interact with HS-binding proteins such as FGF and HGF, adhesion molecules, and chemokines, playing important roles in growth factor signaling, morphogenesis, and the development of the central nervous system. In cartilage, their effect is of a structural nature: PGs interact with collagen, and CS side chains provide electrostatic forces, enabling joints to function amid compressive, shear, and tensile forces. Differences in CS sulfation profiles have been observed in arthritic tissues; indeed it has been demonstrated that oversulfated structures of CS such as CS-D, CS-E, and CS-H are involved in various vertebrate tissues and have a strong affinity to heparin-binding growth factors.[32]

2.208.3. Biological Interaction Profiles of aECM and Their Components

2.208.3.1. Direct

All the ECM components described in the previous chapter are able to interact directly with cells. This interaction is conferred by cell adhesion receptors specific to the ECM proteins, and binding of these receptors to their ligands induces signal transduction pathways that in turn influence a wide range of cell and tissue events.[33]

2.208.3.1.1. Cell-surface receptors

Cell-surface receptors are usually transmembraneous proteins that can interact with specific ligands, and the interaction induces the activation of signal transduction pathways in the cell. There are numerous types of cell-surface receptors that can interact with ECM proteins: the membrane-spanning group that includes the PGs syndecan-1 to -4, betaglycan, CD44, neuroglycan C, and RPTG-ζ, as well as the GPI (glycosylphosphatidylinositol)-anchored PGs glypican-1 to -6 and a brevican variant. Syndecan and glypican are the major HSPGs on the cell surface and act as coreceptors, facilitating ligand encounters with signaling receptors via their GAG chains. They are involved in the regulation of various signaling pathways including that of Wnt, FGF, hedgehog, BMP, and IGF, regulating cell proliferation, differentiation, adhesion, and migration.

The largest as well as the best studied group of ECM adhesion receptors is the integrins. Integrins are heterodimeric, transmembrane proteins with 24α- and 18β-units known to date. These can dimerize to 24 different integrins, and they are unique in their bidirectional signaling capacity across the plasma membrane. Of the ECM proteins mentioned in Section 2.208.2, they recognize collagens, FN, laminin, VN, and OPN with a high redundancy in ligand specificity, but the affinities are varied through changes in integrin conformation and clustering, a process known as inside-out signaling.[34,35] For some integrins, interactions with the GAGs, CS, and heparin have also been described.[36,37] All adherent cells express integrins, but the pattern depends on cell type and differentiation state, allowing cells to sense their environment in this way, and making the construction of matrices targeted to specific cell types possible.

Integrin binding induces a wide array of intracellular signal transduction events.[33,34] It not only coordinates cytoskeletal polymerization, allowing integrins to form a physical link to the ECM, but also gives rise to the formation of signal transduction complexes that center around the integrins. These focal adhesion complexes (FACs) include the adhesion receptors, cytoskeletal elements, and a large spectrum of adaptor and signaling proteins (outside-in signaling).[38] The signal transduction pathways activated by integrins are often the same as those utilized by growth factors[34,39] and include influence on the cytoskeleton, serine/threonine phosphorylation, tyrosine phosphorylation, rho GTPase activation, lipid formation, and regulation of proteolytic activity.[38,40]

2.208.3.1.2. Collagen

Receptor-binding sites on collagen can be divided into four different categories: (i) specific motif in the triple-helical areas, (ii) common sequences such as GPO (glycine–proline–hydroxyproline), (iii) cryptic-binding sites that are recognized only after denaturation, and (iv) binding sites in noncollagenous domains. Many collagens seem to have more than one binding site, so that receptor clustering may be of biological significance. The diverse biological functions of collagen receptors include platelet activation, inflammation, angiogenesis, wound healing, proliferation of mesenchymal cells, matrix remodeling (collagen synthesis, matrix metalloproteinase (MMP) expression, collagen endocytosis/phagocytosis), and development (mammary gland, skeleton, periodontal ligament).[5]

Collagen is mainly recognized by integrins α1β1 and α2β1. Although these receptors have opposite effects on many signaling pathways, mesenchymal cells express them simultaneously, indicating that the cellular response may be determined by the dominance of one or the other of these receptors. α10β1 and α11β1 have a narrower tissue distribution, the first seemingly limited to cartilage, while the second is expressed in many mesenchymal tissues during development. The activation state of these collagen receptors can be regulated, which may affect binding specificity to the collagen types.[5]

Many other cell membrane proteins have also been reported to bind collagens. Among them are the discoidin domain receptors 1 and 2 (DDR1 and DDR2), and receptor tyrosine kinases that bind to the intact collagen triple helix in an integrin-independent manner. DDR1 is expressed mostly on epithelial cells and leukocytes, and DDR2 on mesenchymal cells. They control developmental processes, cell adhesion, migration, proliferation, and matrix remodeling.[41] Also mentioned should be syndecans and glypicans, glycoprotein VI that regulates platelet function during thrombosis, the leukocyte-associated immunoglobulin-like receptor-1 (LAIR-1) that is expressed on peripheral blood mononuclear cells, and annexin A5 (annexin V, anchorin II) which is expressed in cartilage and bone where it binds to collagen II and X and may regulate the influx of Ca^{2+} into matrix vesicles, thus playing a role in skeletal development.[5]

2.208.3.1.3. Glycoproteins

2.208.3.1.3.1. Fibronectin

FN is a widely expressed cell adhesion protein influencing cell adhesion, migration, and differentiation. Cells interact with it mainly via its integrin- and heparin-binding sites. The integrin interaction is determined by peptide sequences, with RGD being recognized by α5β1, LDV and REDV by α4β1 and

α4β7, and EDGIHEL by α4β1 and α9β1, while the heparin-binding site interacts primarily with cell-surface PGs.[42]

2.208.3.1.3.2. Laminin

Laminin is recognized by all four syndecans, α-dystroglycan and, depending on the isoform, by the integrins α1β1, α2β1, α3β1, α6β1, α7β1, α9β1, αvβ3, and α6β4,[15] the biological effects of laminin presumably mediated by linking laminin matrices via these receptors to intracellular signaling pathways.

2.208.3.1.3.3. Vitronectin

The main receptors for VN are integrins (αvβ3, αvβ5, avβ1, αIIbβ3) and the urokinase receptor.[43] VN mediates cell adhesion and spreading, cytoskeletal reorganization, intracellular ion transport, lipid metabolism, and gene expression, with protein phosphorylation being one of the earliest events detected in response to binding. This leads to the activation of mitogen-activated protein kinase signal transduction pathways, indicating that the pathways for VN and growth factor signaling may be linked, which may provide a mechanism for the synergistic action of growth factors and ECM proteins. Through the integrin αvβ3, which is involved in angiogenesis, VN may also play an important role in wound healing and tumor progression.[19]

2.208.3.1.3.4. Tenascin, osteopontin, and thrombospondin

Cell-surface receptors for TN include integrins, cell adhesion molecules (CAM) of the immunoglobulin superfamily, phosphacan/RPTP ζ/β, and annexin II. Binding to TN in the developing skeleton may be involved in regulating osteoblast differentiation,[21] as TN-W promotes osteoblast adhesion and inhibits differentiation, while the EGF-like repeats may bind and activate the EGF receptor (EGF-R).[44]

OPN binds via integrins that recognize the RGD motif. In general, OPN promotes cell adhesion, migration, and survival, with αvβ1 and αvβ3 interactions being essential for osteoclast migration and resorption. For smooth muscle cells, it is involved in adhesion and migration, its chemotactic function for these cells being in part mediated by the αvβ3 integrin. αvβ1, αvβ5, and αvβ6 also bind OPN, α5β1, and α9β1 only after a cryptic site on OPN is exposed after cleavage. The hyaluronan CD44 receptors also bind OPN, although for some isoforms this also requires the binding of β1 integrin in an RGD-independent manner. CD44 binding to OPN has been implicated in the migration of macrophages and tumor cells.[22]

The binding of TSPs to PG cell-surface receptors is mainly mediated through their GAG chains. An FN-induced conformational change in TSP-1 promotes the interaction of TSP-1 with α3β1,[24] and proangiogenic effects are mediated by syndecan-4 on endothelial cells. TSP-3 is expressed in osteoblasts and probably also binds to PG cell-surface receptors, affecting bone maturation.

2.208.3.1.4. Proteoglycans

There is little information in the literature on direct binding of PGs to adhesion receptors, as the majority of the interactions seem to be with cell signaling receptors. Versican has been described to bind P- and L-selectin, CD44, EGF-R, integrin β1, and TLR2,[25] and the SLRPs decorin, biglycan, fibromodulin, osteoadherin, and chondroadherine bind C1q, activating the classical complement pathway and leading to an enhanced inflammatory response. Lumican binds and signals via the Fas ligand FasL, enhancing secretion of proinflammatory cytokines and recruitment of macrophages and neutrophils.[28]

SLRPs are also involved in recruitment of immune cells to site of injury, by direct interaction with receptors, or by indirect mechanisms. Decorin stimulates production of MCP-1, a mononuclear cell recruiting chemokine, thereby sustaining the inflammatory state, while biglycan is directly involved in the recruitment of natural killer cells. In combination with VN, decorin can affect the remodeling of the ECM by inducing MMP-1, a scenario where multimeric interactions with integrins may play a role.[28]

2.208.3.1.5. Glycosaminoglycans

The role of HyA in cell motility, adhesion, and proliferation is mediated by cell-surface HyA receptors such as CD44 receptors or RHAMM (receptor for hyaluronan-mediated motility, which also acts as coreceptor modulating PDGF signaling).[45]

CD44 has also been described to recognize sulfated GAGs such as HS and CS, as have been P- and L-selectins. These receptors are expressed by a variety of cells such as neutrophils, endothelial cells, platelets, monocytes, and fibroblasts. Their adhesion to GAGs may play a role in leukocyte invasion, both through direct interactions as well as by binding and presenting chemokines.[46,47]

2.208.3.2. Indirect

The ECM influences biological processes not only by directly interacting with the cells. In addition, there are two major mechanisms which can be considered as indirect, with the dividing line between 'direct' and 'indirect' having been somewhat arbitrarily drawn at the direct interaction with specific receptors as described above. These indirect mechanisms are (i) interaction with growth factor receptors, and (ii) interactions with soluble factors such as growth factors, cytokines, and chemokines, as a large number of such factors can associate with ECM components to form functional units that modulate their biological activity.[48–50]

2.208.3.2.1. Collagens and glycoproteins

The ECM is regarded as a physiological depot for various mitogens. Although the structural proteins such as collagen and the glycoproteins make up the major part of the ECM, and especially collagen is commonly used as a carrier for growth factors such as BMP and TGF, very few specific interactions such as that for certain BMP-2 isoforms binding to collagen have been described.[51]

An indirect interaction according to the definition given above that does occur is the interplay of adhesion receptors with growth factor receptors. Adhesion receptors such as the integrins are able to modulate the function of growth factors,[52] so that the binding of the cell to the ECM influences its ability to respond to soluble mitogens,[53] and differences in matrix composition and consequently integrin-binding pattern can thus influence the activity of growth factors such as EGF, FGF, PDGF, VEGF, TGF-β, and IGF-I.[54–56] Binding of the α2β1 integrin by collagen thus acts synergistically with PDGF on the phosphorylation of the PDGF-receptor (PDGF-R) and the

subsequent ERK-2 activation,[39] while VN influences IGF-I activity via αVβ3 binding. β3 and β1 integrins control angiogenesis, α6β4 cooperates with tyrosine kinase in epithelial cells, and β1 with EGF.[57] The mechanism of these interactions is in most cases an association between integrins and growth factor receptors, such as EGF, bFGF, and PDGF, where both regulate the same receptor tyrosine kinase.[58]

2.208.3.2.2. Proteoglycans

In direct opposition to the situation for collagen and other glycoproteins, PGs interact with a host of different cell-surface receptors, cytokines, and growth factors. Indeed, the PGs, and especially the SLRPs, have been termed matricellular proteins because of their ability to modulate various biological processes,[28] and abundance of certain SLRPs at a specific site may switch on one pathway, whereas their absence is permissive for other pathways,[59] providing a mechanistic explanation for the growth and differentiation-promoting abilities of the ECM.

SLRPs are involved in the triggering of multiple cell responses. Decorin modulates receptor signaling pathways, and influences regulation at certain cell-cycle check points. It affects cell proliferation by binding to EGF-R and inducing dimerization and autophosphorylation of the receptor, which causes a sustained activation level that leads to an activation of the MAPK pathway, Ca^{2+} influx, and subsequent induction of p21, a cyclin-dependent kinase inhibitor. This in turn leads to cell-cycle arrest, and a decorin-induced growth arrest in tumor cells is indeed associated with this pathway.[28]

Decorin also binds to IGF-IR via the N-terminus of the core protein, resulting in phosphorylation, activation, and down-regulation of the receptor, and via the PI3K/Akt pathway leading to the inhibition of apoptosis in endothelial, epithelial, and bone marrow cells. Decorin may even compete with IGF-I for binding to the receptor and thus prevent IGF-I signaling, so that decorin and IGF-IR may cooperate *in vivo*,[59] and VEGF-R2 is another receptor that may be affected by decorin.[28]

Many members of the SLRP family are able to modulate BMP/TGF-β pathways. Decorin, biglycan, asporin, lumican, and fibromodulin all bind TGF-β, with decorin inhibiting TGF action and thus proliferation.[10]

Lumican is similar to decorin in being a negative regulator of cell proliferation, although the underlying mechanisms appear to be different. The infiltration of neutrophils is also regulated by lumican by binding of the core protein to the CXC-chemokine KC and thus establishing a chemokine gradient.[28] It has also been shown to interact with the TLR4 pathway by presenting lipopolysaccharide to CD14, a cell-surface-binding protein required for TLR4 activation.[59]

PDGF-induced proliferation is inhibited by biglycan, but proliferative phases of osteoblast development are associated with biglycan overexpression; perhaps the regulation is cell type specific, either directly via receptors or by contributing to cross talk. There is no biglycan signaling through the EGF-R, but rather Toll-like receptors-2 and -4 have been identified as signaling receptors for biglycan.[28] Biglycan also influences the response to TGF-β, as biglycan-deficient mice develop age-dependent osteopenia due to a decreased ability to make new bone because of a reduced response of bone marrow stromal cells to TGF-β, showing that biglycan is important in controlling skeletal cell differentiation. Biglycan may be important in regulating BMP signaling, too. Osteoblasts lacking biglycan display a defect in differentiation due to reduced BMP-4 binding, followed by lower BMP-4 sensitivity, less BMP-4 signal transduction, and decreased expression of core-binding factor α1, an essential transcription factor for osteoblast activation. Biglycan increases BMP-4 binding to chordin and TSG (twisted gastrulation), improving the complexes' efficiency in inactivating BMP-4.

Tukushi is also involved in BMP signaling, functioning as a BMP antagonist and binding both BMP and chordin. It regulates BMP transcription by directly binding to X-delta-1 and modulating notch signaling, thereby controlling ectodermal pattering and neural crest specification. It also seems to regulate FGF.[59]

Another function of SLRPs is as direct and indirect modulators of inflammation. Biglycan may be involved in the regulation of the inflammatory response by acting as a ligand of immunity receptors TLR4 and TLR2 in macrophages, inducing ERK (extracellular signal-related kinase), p38, and NF-κB, and stimulating expression of inflammatory cytokines TNFα and MIP2 (murine IL-8 analogon). For this activation, intact and soluble biglycan is required, suggesting that both the protein core and GAG side chains are required and that proteolytic release from the ECM is necessary to initiate the proinflammatory function.[59] Collagen XVIII, a hybrid collagen–PG, is also involved in inflammation by regulating the infiltration of inflammatory cells to the endothelium. It may provide a link between the initial rolling of inflammatory cells via L-selectin and the induction of chemokine-independent, integrin-dependent adhesion by enhancing α4β1 integrin binding to VCAM-1.[60]

2.208.3.2.3. Glycosaminoglycans

Although many SLPR functions are determined by the core protein, the GAG chains are at least as relevant, and for a number of growth factors such as BMP, FGF, TGF, and PDGF interactions with GAGs have been described.[61–65] GAGs present the largest diversity among biological macromolecules: They vary in basic saccharide composition, acetylation, and N- and O-sulfation, with respect to their linkage and chain length. A hexasaccharide can thus present 2 million times more variations than a 6-mer of DNA. They are known to interact with hundreds of proteins including proteases, cytokines, adhesion molecules, growth factors, and chemokines.

GAGs fulfill two different functions: they play a critical role in assembling protein–protein complexes such as growth factor–receptor or enzyme–inhibitor aggregates, both on the cell surface and in the ECM, and in this manner are directly involved in initiating cell signaling events. Furthermore, GAGs can potentially immobilize and sequester proteins or present them to the appropriate sites for activation. The positioning of the protein-binding oligosaccharide motif along the GAG chain determines if an active signaling complex is assembled at the cell surface, or an inactive complex is sequestered into the matrix. Such extracellular modulation of biological functions is an emerging paradigm in the postgenomics area,[66] and the chemical heterogeneity and polydispersity of GAG arising from their nontemplate-driven biosynthesis allow them to encode a large amount of information.

2.208.3.2.3.1. Mechanism of GAG–protein binding

The specificity of GAG–protein binding is defined by a number of parameters that are determined by the structural fit between GAG and protein based on the three-dimensional (3D) structure of the GAG. The most important are the ionic interactions of the sulfate and carboxylate groups of the GAG with the basic amino acids of the protein, although van der Waals contacts also play a role. They depend on the number, position, and distribution (O- or N-) of the sulfate groups, the length of the sugar chain,[61,67,68] as well as the 3D structure of the polysaccharide backbone and resultant orientation of the sulfate groups. Typically, tetra- to hexasaccharides are sufficient to bind with high affinity.[66]

GAGs characteristically adopt a linear extended conformation with different helical symmetries for different GAGs. The parameters associated with the different helical structures include bond length, bond angles, and torsion angles of the GAG backbone. Given that bond length and angles are mostly constant, the main parameters are glycosidic torsion angles and the hexapyranose ring conformation of the monosaccharides. Glucosamine and galactosamine adopt a $^4C_1$ (C-chair) conformation, and glucuronic acid favors a $^1C_4$ pyranose pucker. The iduronic acid ring can adopt multiple, equienergetic conformations: $^4C_1$, $^1C_4$, $^2S_0$ (S-skew boat), and $^0S_2$. The orientation and topological arrangement of specific sulfate groups, governed by the rotation about the glycosidic torsion angles and the ring conformation, play a key role in the specificity of GAG–protein interactions. The ability of the iduronic acid to adopt multiple conformations gives additional freedom for IdoA-containing GAG chains to form specific binding motifs.[66]

2.208.3.2.3.2. Physiological significance

On the basis of their importance in cell growth and development, the interaction of GAGs with growth factors is most extensively studied, and the majority of these studies focus on HS, as the HSPGs on the cell surface often work as cofactors for GF receptors. The best characterized interaction is between HS and FGF, both basic FGF-2 and acidic FGF-1. HS plays a critical role in FGF signaling by facilitating the formation of FGF–FGF-R complexes and enhancing/stabilizing FGF oligomerization.

Heparin-derived oligosaccharides contain predominant repeat units of $-[I_{2S}-H_{NS,6S}]_n-$, with n between 2 and 6. The 2-*O*-sulfate of the iduronate and the N-sulfate of the glucosamine are critical modifications that are required for FGF signaling, and while the 6-O-sulfation is critical for FGF-1, it is not completely necessary for FGF-2. As already mentioned, tetra- to hexasaccharides mediate GF binding; however, oligosaccharides or longer are required for bridging dimeric FGF-2 with the receptor to form a ternary signaling complex.[66]

One of the best known activities of GAGs, especially heparin, is the inhibition of coagulation cascade. Heparin prevents coagulation by forming a complex with thrombin and AT-III, a serine protease inhibitor. AT-III recognizes a specific pentasaccharide in heparin ($H_{NAc,6S}$-G-$H_{NS,3S,6S}$-I_{2S}-$H_{NS,6S}$), where a 3-*O*-sulfate group on the glucosamine $H_{NS,3S,6S}$ is absolutely necessary for the specific interaction. Not only sequence but also chain length is important: heparin binding to heparin cofactor II requires a minimal chain length of 13 monosaccharides, and the complete inhibition of thrombin a chain length of 26 monosaccharides.[66]

The specificity of GAG–protein interactions goes beyond the GAG primary sequence. In the case of AT-III, binding induces a conformational change in the protein, and the specificity is precisely defined at the pentasaccharide sequence, where the conformation of IdoA is important. In the case of FGF, there is no conformational change, and there seems to be a significant overlap of sequence specificities for different FGFs. This may be due to the biological interactions involved: the coagulation cascade has to be quickly and tightly regulated, while growth factor interactions require some degeneracy in the GAG sequence to accommodate longer time frames for the signaling events as well as to maintain the graded affinities necessary for generating morphogen gradients.[66] This is of special interest for chemokines, and chemotactic cytokines are a large family of small proteins distinguished from all other cytokines by being the only ones that act on the receptor superfamily of G-protein-coupled receptors. In their case, interaction with GAGs is thought to play a role in the sequestration of chemokines and subsequent presentation to receptors.[69]

Less work than with HS and heparin has been done in the field of CS/DS. CS and DS, like HS, are found on the cell surface and in the ECM. Similar to HS, highly sulfated DS chains have been shown to bind FGF-2 and -7, impacting cell growth and wound repair, and to activate HGF signaling pathways through the c-met receptor. Binding tends to be of a slightly lower affinity, which is reflected in the minimal required length: a tetrasaccharide for HS and a hexasaccharide for DS. Oversulfated variations as for brain CS-PGs with specific sulfation patterns have been implicated in neural adhesion, migration, and neuritogenesis via their interaction with pleiotrophin and midkine, where two mechanisms apply: while cell-surface CS and pleiotropin complexes are involved in signaling, CS in the ECM sequesters this protein instead.[66] CS-E, an oversulfated CS variant, has also been shown to bind several heparin-binding growth factors, including midkine, pleiotropin, heparin-binding EGF (HB-EGF), FGF-16, and FGF-18.[60]

As with HS, CS and DS become soluble after injury and are a major component of wound fluid. Soluble DS activates FGF-2 and FGF-7, the minimum size for activation of FGF-2 being an octasaccharide; 4-O-sulfation is sufficient, and an increase to a 2/4-*O*-disulfide does not appear to increase activity. Hepatocyte growth factor/scatter factor also requires a DS octasaccharide, but with unsulfated IdoA and 4-*O*-sulfated GalNAc.[60]

2.208.3.2.3.3. Inflammation and injury

Recent data show that GAGs initiate and control events associated with inflammation. After injury, GAGs are enzymatically released from the PGs, and these soluble GAGs can be further modified by altering chain length or revealing specific, priorly masked domains, such as a pentasaccharide sequence from syndecan-HS that stimulates FGF-2. Another possible mechanism is the modification of receptor specificity, as for the hyaluronan receptor CD44, which can be modified by HS chain addition to bind FGF-2, VEGF, and HB-EGF, but not chemokines.[60]

The influence on inflammation can be conveyed by affecting the TLR-4 receptor: HyA, C4S, C6S, and HS all have been shown to reduce inflammatory events induced by LPS in this manner. The degrees vary, with C4S and HS being the most effective, followed by C6S, and HyA with a slight effect only.[70] Also, the recruitment of inflammatory cells such as leucocytes is influenced by generating chemokine and cytokine gradients, that is, for IL-2,3,4,5,7,8,10,12, GM-CSF, RANTES, IP-10, MCP-1, and MCP-4. The interaction with IL-8 and HS is especially well studied. The IL-8 is held at the cell surface by HSPGs (syndecan-2 or -1), creating a gradient for inflammatory cell recruitment.[60] Both DS and CS have also been shown to bind several molecules involved in the recruitment of leukocytes, as in the CSPG versican; the CS chain binds L-selectin and P-selectin at the same sites as HS. Binding of CS and DS to selectins is sulfation dependent, and oversulfated CS and DS are able to bind chemokines and inhibit their activity, possibly providing a reservoir.[9]

HyA functions are a special case as they depend mainly on size. HyA recruits leukocytes to sites of inflammation via CD44 interaction, and RHAMM appears to be involved in cellular motility and migration because of its interactions with the cytoskeleton.[9]

2.208.4. Preparation and Structure of aECM

Generating collagen-based scaffolds with noncollagenous components can be accomplished by two main methods. One utilizes the natural self-assembly potential of collagen that allows for an *in vitro* formation of fibrils, the other is on the basis of using insoluble collagen slurres or suspensions. Both can then be used to coat implants or scaffolds, or be freeze-dried and cross-linked into scaffolds with no additional superstructure. Both are discussed in the following, with the focus on the *in vitro* generation of fibrils, as this more controlled approach bears a closer relation to the assembly and resultant structure of the fibrils *in vivo*.

Not taken into account here is the use of gelatin as the denatured form of collagen.

The collagen used in the majority of both cases is extracted from tissues, although in a few instances, recombinant collagen has been utilized.[71] The latter circumvents some issues such as the risk of transmission of infectious agents, but the *in vitro* formation of fibrils from these monomers is often impaired as the posttranslational processing that is crucial for fibril assembly is not comparable to that of tissue-derived collagens.

Although collagen monomers are soluble in dilute acid, most collagen in tissues is enzymatically cross-linked via the telopeptides. Acid extraction yields the non-cross-linked portion with intact telopeptides. Another extraction method uses the protease pepsin, digesting the nonhelical telopeptides and thus breaking the link and giving higher yields. Although removal of the telopeptides reduces antigenicity, it also affects collagen self-assembly. The collagen fraction that is nonenzymatically cross-linked via the helical part is not accessible by either method, but can be used in the already mentioned insoluble slurries.

An often used method, especially for the construction of scaffolds, employs collagen preparations that contain both monomers and insoluble fibrils as extracted from tissues, forming a suspension or slurry, commonly in an acidic buffer. This suspension can be either freeze-dried to form scaffolds or adsorbed to biomaterial surfaces. Noncollagenous components are introduced either by adsorption to preformed fibrils or, if the soluble part is large enough, by coprecipitation in an acidic milieu. Especially, this last method has been used to generate collagen–GAG scaffolds.[72,73] While this results in a matrix consisting of both collagen and GAG, the morphology is that of an amorphous precipitate.

Preparing fibrils *in vitro* using the natural self-assembly potential of collagen allows the generation of a collagen matrix more defined with respect to components and structure, and thus ultimately of more defined properties. Resembling the *in vivo* process, fibrillogenesis can take place in the presence of collagen-binding and noncollagenous components, allowing not only component integration into the matrix but also alterations of collagen organization, controlling both structure and mechanical properties to an extent. The resultant fibril morphology represents a much closer analogy to the situation *in vivo*, for which the retention of the characteristic cross-striation pattern is an indication (**Figure 1**).[74] This may influence the adherent cells, as the supramolecular organization of the collagen matrix is of importance in cellular reactions.[75]

The self-assembly of monomers into fibrils is initiated by raising pH and temperature of the acidic solution into the physiological range. The assembly pattern is determined by the charge pattern on the monomer surface, but the fibril formation itself is an entropy-driven process, where surface-exposed hydrophobic residues are buried within the fibril, thereby increasing the entropy of the solvent. Fibril assembly proceeds via nucleation and growth, and classically shows three phases: an initial lag phase with no change in turbidity, a rapid growth phase, and a plateau region. During the lag phase, small numbers of molecules associate to form metastable nuclei, upon which further molecules accrete during the growth phase. The initial interaction seems to be of a pair of 4D staggered molecules with a short N- and C-terminal overlap, mediated by the telopeptides. Growth in fibril length then occurs via longitudinal and lateral interactions.[76]

In vitro fibrillogenesis was studied by a number of authors, most notably by Williams *et al.*,[77] who determined conditions under which the resultant fibril morphology was optimized, with a clear D-periodic banding pattern (mix on ice 1 mg collagen/ml 5 mM acetic acid with an equal volume of 60 mM TES, 60 mM sodium phosphate, and 270 mM NaCl, pH 7.3, then raise temperature to 30 °C). Most preparations of collagen fibrils are based on modifications of this method. The resulting collagen gel can be used as such, freeze-dried, or homogenized and treated like an insoluble collagen slurry.

The process of fibril formation and the structure of the resultant fibrils are influenced by a large number of parameters: *in vivo*, these include the collagen type or types, the extent of procollagen processing, and presence of noncollagenous components; *in vitro*, there are some additional parameters to be considered such as temperature, pH, and buffer composition.[78,79] In the buffer, pH, phosphate concentration, and ionic strength are deciding parameters. Depending on the pH, early/subfibrils are formed over a comparatively wide range, with low pH possibly stabilizing intermediate states.[80]

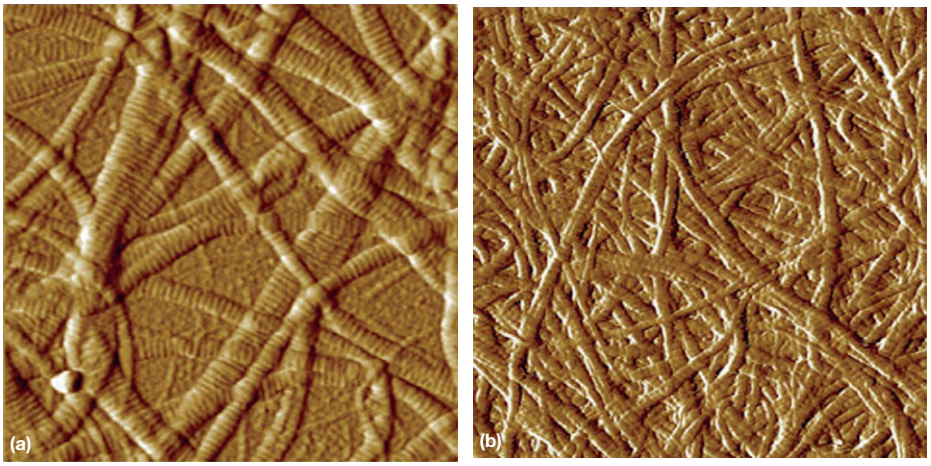

Figure 1 Collagen fibrils adsorbed to Ti6Al4V discs. Fibrils generated with 250 μg ml^{-1} collagen type I (IBFB) at 37 °C; AFM contact mode. (a) collagen buffer B and (b) collagen with 25 μg ml^{-1} decorin buffer B. Represented area 5 × 5 μm. Reproduced from Figure 3 from Bierbaum, S.; Douglas, T.; Hanke, T.; *et al*. *J*. *Biomed*. *Mater*. *Res*. *A* **2006**, *77*, 551–562.

The presence of phosphate is important for producing well-banded fibrils, but increasing phosphate over the optimum results in less and smaller fibrils of a different morphology. This effect is probably on the basis of phosphate binding to collagen; a fibril associated with phosphate may be hindered in the alignment of monomers, as the charge distribution of the monomer is changed, changing the nature of collagen molecular interactions.[81]

Ionic strength also influences the electrostatic interactions of the monomers, but in a way differing from phosphate, as an increase in ionic strength can – in the case of collagen type I – increase the size of the resultant fibrils. This is probably based in part on a facilitation of superfibrillar bundling, again because of changes in electrostatic interactions. Another part may be due to the slower growth rate, as this too gives rise to fibrils of increased diameter,[82] something that can also be achieved by lowering the formation temperature.[76]

The collagen preparation used also has a marked effect on fibrillogenesis. Intact telopeptides as in acid-extracted collagen help to initiate fibrillogenesis, producing long, cylindrical fibrils, while for collagen with degraded telopeptides self-assembly is slower, and the fibrils are slightly thicker and less stable. Selective removal of N-telopeptides results in a so-called D-periodic symmetry (DPS) fibrils, in which molecules assemble in an antiparallel manner, while loss of the D-telopeptides results in relatively short cigar-shaped D-periodic fibrils (**Chapter 2.205, Self-Assembling Biomaterials**; **Chapter 2.207, Extracellular Matrix: Inspired Biomaterials**; **Chapter 2.209, Materials as Artificial Stem Cell Microenvironments**; and **Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration**).[76]

2.208.4.1. Heterotypic Fibrils

One method employed *in vivo* to adapt the ECM to the specific tissue requirements is to modulate the architecture of the type I and type II fibrils by using minor collagens. The same principle can be applied for *in vitro* fibrillogenesis, where the collagens are mixed prior to the initiation of the fibril formation. *In vivo*, collagen type I and III form heterotypic fibrils;[8] *in vitro*, the inclusion of type III in the fibrillogenesis solution results in a decrease in fibril diameter (**Figure 2**). This reduction is probably due to lessening of fibril bundling, with collagen III inhibiting the interfibrillar interaction.[82,83] Type V also regulates the diameter of type I fibrils; in I–V cofibrils, the entire triple-helical domain of collagen V is buried within the fibril and type I molecules are present along the fibril surface, with the N-terminal domains of type V extending outward through the gap zones.[84]

2.208.4.2. Collagen Fibrils with Glycoproteins

Other ECM components such as glycoproteins or PGs can be included in the collagen matrix in the same manner as different collagen types. FN does not influence fibril morphology, but may accelerate assembly, and the amount integrated increased with an increase in ionic strength of the buffer system;[82,85] collagen–laminin gels can seemingly be prepared over a wide range of different ratios (10:1 to 1:1), both with and without the inclusion of other components such as FN and HyA, although no formation conditions and matrix characterization are given.[17,18]

Noncollagenous proteins can also be integrated into a collagen matrix by allowing them to bind to preformed fibrils. Such binding can be modulated by the conditions under which the fibrils were formed: collagen type I fibrils generated in buffers of high ionic strength bind about four times as much FN as fibrils generated in buffers of low ionic strength, reflecting the importance of structural parameters. Another modulating aspect that can be employed is the use of different collagen types: unlike type I, collagen type III binds large amounts of FN under all *in vitro* conditions studied, with heterotypic fibrils displaying intermediate binding profiles depending on the relative amounts of collagen types. This may be based on combination of the larger surface area of type III fibrils, changes in fibrillar architecture, and the fact that *in vivo* type III shows a higher affinity for FN in agreement with its function in the initial stages in wound repair.[82]

Using insoluble collagen instead of fibrils generated *in vitro* is a comparable process, although much less well defined.

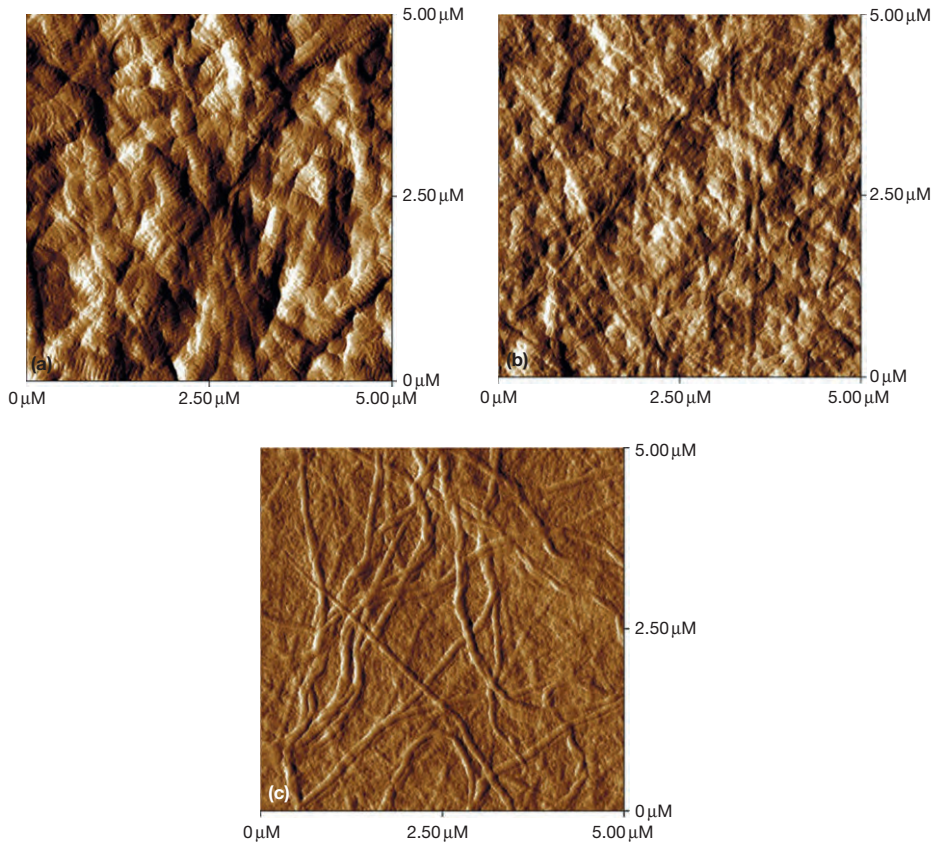

Figure 2 Collagen fibrils adsorbed to Ti6A14V disks. Fibrils generated in buffer B at 37 °C with 500 μg ml^{-1} collagen; AFM image, tapping mode. (a) collagen type I; (b) 50% collagen type I, 50% collagen type III; and (c) collagen type III. Reproduced from Figure 4 from Bierbaum, S.; Beutner, R.; Hanke, T.; Scharnweber, D.; Hempel, U.; Worch, H. *J. Biomed. Mater. Res. A* **2003**, *67*, 421–430.

Elastin/collagen scaffolds have been created in this manner with elastin/collagen ratios between 1:9 and 9:1; the components were mixed in acidic solution, freeze-dried, and EDC cross-linked to increase strength. Elastin and collagen interact with each other, although elastin tends to cluster and form spherical structures attached to collagen fibrils or sheets.[11]

2.208.4.3. Collagen Fibrils with PGs

Of special interest here are the collagen-binding SLRPs such as decorin, biglycan, fibromodulin, lumican, keratocan, and osteoglycin. Both *in vivo* and *in vitro*, decorin, osteoglycin, and fibromodulin interfere with fibril formation, resulting in a delayed assembly and signally reduced fibril diameters. Lumican also results in smaller fibrils, but accelerates fibril formation, while biglycan binds without affecting fibril assembly. In general, PG binding has the added effect of enhancing the thermal stability of collagen.[86] Removal of GAG chains generally does not abolish the described effects, demonstrating that they are due mainly to interactions of the core proteins with collagen, although GAG variations that are specific to tissues or developmental stages can modulate them.[26]

As most PGs inhibit fibril formation, there are limits to the applicable ratios of collagen to PG. In the case of decorin, a decorin/collagen ratio of 1:10 results in a strong decrease both in fibril diameter and the integration of collagen monomers into the fibrils.[74] The probable reason is that decorin binds to collagen closely via the core protein with the GAG chain extending outward,[87] inhibiting both the further association of monomers and the lateral fusion of fibrils. The binding of decorin to the fibrils is higher under conditions of low ionic strength, as they influence the electrostatic interactions of the collagen monomers and thus the resultant fibrils. The protein–protein interaction responsible for the binding of decorin may also be affected, as decorin associates with a polar region of collagen.[87] Still, the nature of the collagen–decorin interaction remains essentially the same as fibrillogenesis and monomer integration is affected similarly.[74]

Other factors influencing PG–collagen interaction are the collagen type, as collagen II binds more decorin and biglycan than type I and III,[88] and collagen preparation.[89]

2.208.4.4. Collagen Fibrils with Modified Proteins and/or Peptides

Instead of naturally occurring ECM components, engineered proteins or parts of proteins down to small peptide sequences may be used in the generation of aECM. This is useful if purification from tissues gives only low yield as it circumvents the question of the purity of the preparation. On the other hand,

using only parts of molecules will exclude a large and possible necessary part of their functions, as the actual principles of ECM tasks are complex and not fully understood yet.

Depending on their modification, these altered proteins can be included in the matrix analogously to naturally occurring ones. Synthetic peptidoglycans consisting of a collagen-binding peptide with an attached DS-chain modulate *in vitro* collagen fibrillogenesis similar to decorin[90] and give rise to D-banded fibrils. The same fibrils could be found if a laminin chain was present during fibrillogenesis, indicating that it did not significantly hinder the self-assembly process. If the fibrils were covalently cross-linked using transglutaminase (TGase), the banding pattern showed a slight shift from 64 and 78 nm to 73 and 94 nm, which can be attributed to changes in the spatial organization of fibrils due to the formation of cross-links within the collagen molecule.[91]

The most commonly used peptides are adhesion motifs for integrins, with RGD being the prime representative of this group. Because of their small size, peptides have to be covalently linked to the matrix to prevent desorption. Using TGase-linked laminin peptides in collagen gels, a peptide gradient could be established, although again there is no further matrix characterization (see **Chapter 4.411, Peptide- and Protein-Modified Surfaces**).[16]

2.208.4.5. Collagen Fibrils with GAGs

One of the most widely used combinations is that of collagen with GAGs, even though it must be considered as the most 'unphysiologic' one as with the exception of HyA, GAGs *in vivo* are usually bound to a core protein. Although no *in vivo* relevance for a GAG–collagen interaction has been described, it is possible that such interactions may occur as bound PGs can be deglycosilated *in situ*.[92]

As described above, the core protein of PGs mediates interactions with collagen, and removal of the GAG makes no significant difference. Removing the protein core and adding only the GAG, on the other hand, gives rise to some interesting results.

GAGs interact with collagens mainly because of their overall negative charge. Their effect on fibrillogenesis is heterogeneous: heparin induces a dose-dependent increase in fibril diameter[93] and gives rise to cigar-shaped fibrils, while addition of CS and HS increases both mean fibril diameters and heterogeneity of diameter distribution, which may be due to a promotion of lateral fusion of fibrils (**Figure 3**). The integration of monomers into fibrils is positively affected by CS below CS/collagen ratios of 1:10,[74] although the reason for this is unclear. Collagen/CS gels also contain larger void spaces, and the viscous gel component (loss modulus) is reduced.[94]

Because of the electrostatic nature of the interaction, ionic strength of the buffer systems has significant effects. In high ionic strength buffers, a characteristic fibrillogenesis curve can be seen over a wide range of GAG concentrations, but under conditions of low ionic strength, the higher GAG concentrations lead to very fast formation of aggregates with a more pronounced effect on fibril morphology. The effect appears to be common in the interaction of collagen and GAG, although the degree seems to vary depending on the collagens and GAGs used,[95] with an increase in sulfation of the GAG leading to a stronger interaction.[96]

Other methods of collagen–GAG matrix generation are precipitation from acidic solution, which has been used for collagen type I[97] and type III[98] with the GAGs CS,[74,98,99] HS,[100] and heparin,[101] or the cross-linking of preformed fibrils in the presence of GAGs.[102] The resultant matrices are cross-linked not only in this case but also as a rule, increasing stability and resistance against degradation.[100] The predominant method utilizes EDC, as glutaraldehyde has raised concerns about cytotoxicity and biocompatibility, with the cross-linking efficiency depending on the molar ratio of EDC to GAG carboxylic groups.[72] Other methods are dehydrothermal cross-linking,[99] where the matrix is heated under vacuum (i.e., 150 °C for 48 h) until the water content falls below 1% and the formation of interchain peptide bonds is possible, or using the enzyme transglutaminase, which cross-links via lysine and glutamine residues, resulting in the formation of ε(γ-glutamyl) lysine isopeptide bond (**Chapter 2.216, Collagen–GAG Materials**).[91]

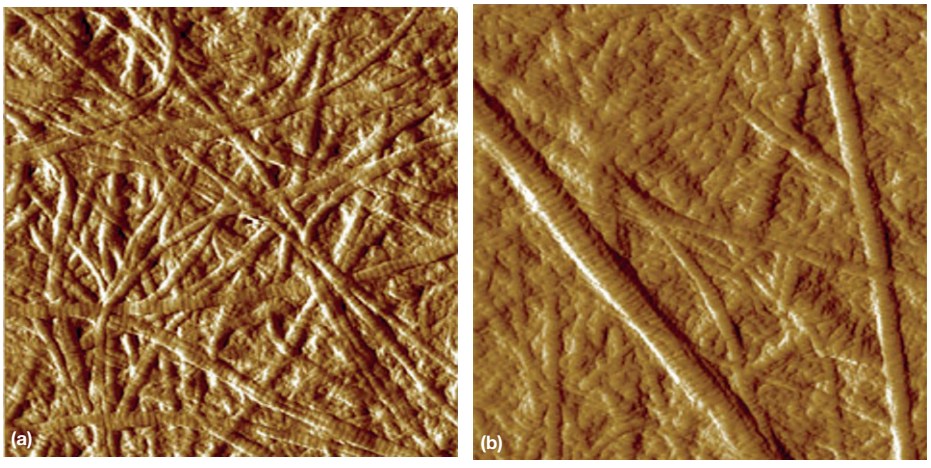

Figure 3 Collagen fibrils adsorbed to Ti6Al4V discs. Fibrils generated with 250 μg ml^{-1} collagen type I (IBFB) at 37 °C; AFM contact mode. (a) collagen buffer A; (b) collagen with 25 μg ml^{-1} chondroitin sulfate buffer A. Represented area 5 × 5 μm. Reproduced from Figure 3 from Bierbaum, S.; Douglas, T.; Hanke, T.; *et al. J. Biomed. Mater. Res. A* **2006**, *77*, 551–562.

2.208.5. Biochemical Characterization of aECM

The morphology of aECMs was described in the previous section. Here, some biochemical characteristics of differently prepared collagen matrices are reviewed, as matrix stability and desorption of components can be an issue. Collagen fibrils are stable under physiological conditions even if not cross-linked, but for noncollagenous components especially in non-cross-linked matrices, the question of stability and release is relevant. Cross-linked matrices, on the other hand, raise the question of bioavailability of their components, and whether their biological functions are still unimpaired. Although both aspects are important in matrix function, the characterization in many cases is only rudimentary and does not take them into account.

Another point that will be dealt with here is the ability of matrices to interact with soluble mediators such as growth factors and cytokines, as this should be impacted by the inclusion of noncollagenous components that possess affinities for such factors.

2.208.5.1. Glycoproteins and PGs

For both glycoprotein and PG-containing matrices, there is little information available. FN appears to be bound to collagen fibrils by two different mechanisms, one being a specific binding of high affinity, engendering only a negligible release of FN under physiologic conditions over 5 days. Any FN in excess of this amount is bound by unspecific adsorption and consequently released within the first 2 h.[82] For decorin that had associated with collagen during fibrillogenesis, only a very small amount desorbed in accordance with the strength of the specific interaction of the PG with collagen (dissociation constant 2.3×10^{-10} M).[103] A measurable desorption occurred only in the first hour, which was larger for conditions under which more decorin had bound to collagen,[74] indicating that here too, unspecific binding may play a role. It seems fair to assume that the mechanisms would be comparable for all collagen-binding proteins.

If higher amounts need to be immobilized, the matrices have to be cross-linked as in the case of collagen–elastin matrices with a ratio of 1:1. Although releasing 60% of the elastin within 24 h, EDC cross-linking practically abolished elastin desorption, after 7 days only 2% had been released. This effect depends on the cross-linking efficiency, which is higher for collagen than for elastin because of more available amine groups. As a result, the efficiency decreases with increasing amounts of elastin, resulting in a slightly higher release.[11]

2.208.5.2. Glycosaminoglycans

The interaction of GAGs with collagen is less specific and of a much lower affinity, for which reason a significant desorption can be detected if the GAG is not cross-linked to the collagen, amounting to a third of the bound amount within the first hour. If GAG is present during fibrillogenesis, the amount that associates with collagen fibrils depends on the GAG, the collagen, and the ionic strength of the buffer. As an example, collagen II binds more CS than collagen type I, and the affinity for different CSs is in the following order: CS C > CS B > CS A. In all cases, this was coupled to a reduction in fibril diameter as opposed to the increase usually seen with collagen type I (**Figure 4**).[104] The differences in affinity are probably based on the differences in CS sulfation, both in pattern and amount. This is supported by the fact that sulfated GAGs are integrated to a much higher degree than unsulfated ones.[94]

If the GAG was cross-linked to preformed fibrils, immobilization depended on available amino groups as well as on concentration of GAG and EDC.[101] The amounts of CS and HS that could be attached in this manner are in the region of 8% (w/w) for CS and 6% (w/w) for HS.[100,102]

Using coprecipitations from acidic solutions of collagen and CS, the immobilized amount was also in the region of 10% GAG in relation to the collagen amount,[99] and cross-linking reduced CS release almost completely; after 28 days in cell culture medium, 30 μg of the original 32 μg could still be found in the scaffolds.[98]

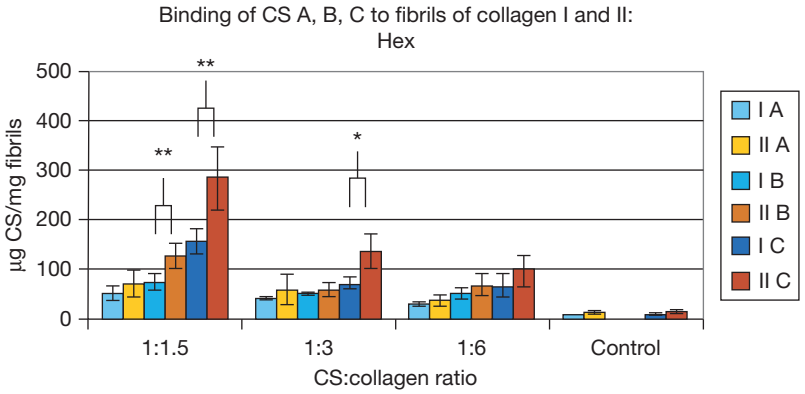

Figure 4 Comparison of amount of CS A–C bound by fibrils of collagen types I and II formed during fibrillogenesis by dimethylmethylene blue (DMMB) assay and hexosamine (hex) assay at differing CS: collagen ratios. A, CS A; B, CS B; C, CS C; I A, collagen I + CS A; I B, collagen I + CS B; I C, collagen I + CS C; II A, collagen II + CS A; II B, collagen II + CS B; II C, collagen II + CS C. All experiments were performed three times. Error bars show standard deviation. Significances: $*p < 0.05$, $**p < 0.01$, $***p < 0.001$. The absence of stars indicates no significant difference. Reproduced from Figure 2 from Douglas, T.; Heinemann, S.; Mietrach, C.; *et al*. *Biomacromolecules* **2007**, *8*, 1085–1092.

Another characteristic of matrices is their mechanical properties. These are not independent of the chemical ones, as not only cross-linking but also composition plays a role. Although for collagen matrices containing laminin, FN, or CS no obvious effects on the mechanical properties could be found,[17,105] this cannot be considered to be a general rule. Using collagen matrices to coat 3D polymeric scaffolds circumvents the problem of changes in the mechanical properties, as this will mainly change the biochemical characteristics.[106]

2.208.5.3. Growth Factor Interactions

An important aspect of aECM is its ability to bind growth factors and cytokines and the possibility to modulate it by adding components that are able to interact with such factors. Some work has been done on collagen scaffolds with no additives, and a certain interaction with growth factors can be observed. TGF-β has been shown to bind slightly faster to collagen fibrils than to uncoated titanium, with a slower release and a stabilizing effect on GF activity, indicating a protective effect of the collagen,[107] and the release of bFGF, HGF, and PDGF-BB is also retarded, most effectively for bFGF.[108] Still, the simple admixture of growth factors to matrices generally leads to a rapid clearance from the implant site because of their unspecific interactions with a low affinity.

Including other ECM components that bind both collagen and growth factors enhances the matrices ability to bind and deliver them, as could be shown for the domain I of perlecan. This domain binds collagen and bears HS and CS chains, and collagen/perlecan fibrils bound significantly more BMP-2 than collagen alone ($112 + 4$ ng vs. $49 + 3$ ng) and sustained a better release characteristic with 7% versus 47% of the initially bound amount after 3 days.[109]

More often, instead of the intact PG, only the GAG chain is used, as GAGs are more easily accessible, with less effect on immune response and inflammation, and have been shown to interact with a large number of growth factors. Collagen–HS matrices prepared by acid precipitation thus bind 1260 ± 207 ng FGF/mg matrix; the same matrices without HS bind only 372 ± 75 ng. Release kinetics were still characterized by an initial burst and following a more gradual release for collagen alone (23 ng followed by 3 ng day^{-1}), while the collagen–CS matrices sustained a more continuous release (13 ng followed by 12 ng day^{-1}).[102] A comparable change in release kinetics could be shown for collagen–heparin matrices;[110] here results suggest that three species populations of VEGF molecules are present in heparinized collagen matrices. The first species is about 15–25% of the total and comprises the nonbound VEGF molecules that are held responsible for the burst release characteristic, while the second group of 10–20% may be nonspecifically adsorbed to the collagen matrix. The third group is bound to the heparin molecule and is assumed to be released with it, and is held responsible for the enhanced angiogenic potential of heparinized collagen.[111] Sulfated GAGs such as heparin have also been shown to enhance the biological activity of BMP by retaining the growth factor in a soluble state (**Chapter 4.416, Growth Factors and Protein-Modified Surfaces and Interfaces**).[112]

2.208.6. Immobilization of aECM

The immobilization process of the aECM is an important aspect in creating surfaces with defined properties. Two basic methods are used: immobilization through adsorption, and through covalent cross-linking. Both have their benefits and their drawbacks. While covalent immobilization gives rise to a stably bound protein surface, it is also a sometimes complicated process, the chemistry of which is not always compatible with more labile molecules. Adsorptive immobilization, on the other hand, is a very simple process that can be conducted at physiological parameters, but the interaction is at least in parts reversible, and may also lead to conformational changes of less stable proteins.

There are a host of methods for the covalent linkage of proteins to surfaces; they vary depending on the surface chemistry and the protein in question. Common to all methods that can be considered as classical covalent linkages is the fact that the linkage is generally formed through reactions with functional groups present on the protein surface. These can be lysine residues, which readily form stable amine bonds with supports bearing active esters, the most common being *N*-hydroxysuccinimide (NHS) esters, a drawback being that NHS is unstable under aqueous conditions. Using protein amine groups is an alternative: they can be coupled with surface aldehydes to produce imines that can be reduced to form a stable secondary amine linkage, or react with epoxides. Cystein residues bearing the thiol group readily undergo conjugate addition with α, β-unsaturated carbonyls like maleimides to form stable thiolether bonds, and acidic residues such as aspartic and glutamic acid can be converted into active esters with a carbodiimide coupling agent (most commonly used is EDC, 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide). These active esters can then react with amine-bearing supports.

With the exception of a few specific cases, conventional immobilization methods suffer from the general disadvantage of generating heterogenous populations of presented proteins because of the random orientation of the immobilized biomolecules, a significant number of which will be inactive. When exposed carboxy- or amino-bearing residues are used, another disadvantage is the coincidental alteration of protein stability, as their charges are important in maintaining proper protein folding; in the case of cystein residues, these are often involved in protein activity. To overcome these limitations, more complex, biologically mediated methods are being developed (the reader is referred to the review of Wong *et al.*[113]).

Covalent collagen immobilization has been performed by grafting of collagen on titanium using low-temperature glow discharge, followed by cross-linking with glutaraldehyde,[114] by deposition on reactive maleic anhydride copolymers that mediate covalent attachment,[115] or by carbodiimide cross-linking using aminopropyl triethoxysilane as coupling agent and the linker molecule *N*, *N*′-disulfosuccinimidyl suberate,[116] to name only a few.

In all cases, cell and animal experiments showed an improved biocompatibility, but the main question in the case of collagen is whether a covalent linkage is indeed necessary,

or if the alternative method of adsorptive immobilization is not sufficient.

Proteins tend to accrue at interfaces between solid and liquid phases; their interactions are determined by protein size, charge, hydrophobicity, and structure, by surface parameters such as roughness, hydrophilicity, and charge, and by the solvent and other solute components present.

Mechanisms which contribute to the adsorption of proteins to a surface are hydrophobic interactions, in which case parts of the protein and the sorbent surface dehydrate, electrostatic interactions, which depend on pH and ionic strength of the solvent, and van der Waals interactions and structural changes in the molecule, which may result in entropy or enthalpy changes. All of these interactions contribute in different parts, with the hydrophobic ones usually discussed to be the most important.[117] Protein adsorption will take place only if the basic criteria of a reduction of the free energy of the system is fulfilled, but because of the number of contributing interactions, no general rules can be established, and adsorption has to be tested for each protein/solvent/sorbent combination.

The kinetics of adsorption can be divided into three stages: a fast and reversible adsorption during the first few minutes, followed by a surface-induced conformational change of the protein that leads to an optimized protein–sorbent interaction, and complete protein denaturation after unlimited adsorption time.[118] The higher the free energy of the adsorption is, the less reversible will the process be. Conformational and orientational changes contribute to the free energy and reduce desorption, but these changes are comparatively slow, for which reason the desorption rate can be described as a function of the contact time. A desorption model that describes the times tending toward zero is a classical Langmuir situation, while the process becoming irreversible for infinitely long times is consistent with most literature data.[119]

For conformationally very stable molecules, there are little to no structural changes, and consequently no contributions to the free energy and no strong adsorptive interactions. Exceptions are large, fibrillar proteins: with their high surface area in relation to their molecular weight, they have a much higher number of potential binding sites than globular proteins of a comparable size, and can interact with the surface via several segments. Although the adsorption free energy of each segment may be small as no structural changes take place to contribute, engagement of many segments will increase the total adsorption free energy until the molecule does not readily desorb anymore.[120] In this case, there is no time dependency and adsorption is irreversible even after short times.

The irreversibility of adsorption refers to situations under buffer; if other molecules are present, the case is different, as the adsorbed proteins can be replaced by competing ones.[119] After longer time periods, only the proteins with the highest affinities will be found on the surface, a phenomenon well known as the Vroman effect.

Collagen fibrils have been successfully immobilized by a purely physisorptive process, with the resultant protein layer being stable against competitive adsorption of serum proteins.[121] The immobilization of the fibrils onto titanium depends to a certain degree on the buffer system used (between 40 and 60 $\mu g\,cm^{-2}$ at the extremes) as well as on the collagen type, but the differences in general tend to be small. For collagen I and III, the mean amount bound was similar despite the much finer type III fibrils. The buffer system used for immobilization had a certain effect, as buffers of high ionic strength tended to reduce immobilization by about 20% with the largest effect for collagen type III. This is probably due to their influence on electrostatic interactions; the increased sensitivity of type III may be on the basis of the higher surface area resulting from the finer fibrils. Heterotypic fibrils were found to take an intermediate position between the homotypic collagen ones, depending on the ratio of the collagen types used.[82] The addition of GAG or PG had no significant effect on the adsorbed collagen amount, the only exception being very thin fibrils as seen for high decorin concentrations.[74] Conclusively it can be said that as long as collagen fibrils can be generated, the adsorption behavior of the aECM will be determined by the collagen part, thus allowing for a stable immobilization by adsorption.

Which immobilization method is best suited obviously depends on the molecules used. For very small molecules such as peptides, the possible contribution of conformational changes is very small, and they do not have many adhesion points, so that adsorptive immobilization is not an option here and a method of covalent immobilization should be selected. For conformationally labile or structurally sensitive proteins, there is in both cases the danger of structural changes that will abolish protein activity. Here a more selective, possibly biologically mediated method is advisable, perhaps including spacers and enzymatic cross-linking, which depends very specifically on the protein in question and the application. Large and structurally extremely stable proteins like collagen fibrils, on the other hand, are optimally suited to adsorptive immobilization, as for them the process is fast, practically irreversible, and not associated with structural changes.

2.208.7. Cell Biological Effects of aECM

In vitro cell studies have addressed a vast number of questions concerning the influence of the ECM on cells, from adhesion and proliferation to signal transduction pathways and differentiation dependent gene and protein expression, using cell lines, tissue-specific primary cells, and stem cells. Consequently, this chapter can only focus on partial aspects, these being mainly studies involving cells relevant for bone, with only a few examples for other tissues.

Cell responses to the biomaterial surface are determined by a number of parameters; using aECM, the main mechanism is expected to be a biochemical one, but the morphological and mechanical aspects also have to be considered. Mechanical issues are of relevance primarily in 3D constructs, as the stiffness of the scaffold is sensed by the cells, and they are known to respond to this stimulus. For 2D coatings, this aspect holds less relevance, but cells also respond to morphological changes of their substrate, a fact that has led to sand-blasting and acid-etching of implant surfaces. As has been described in a previous section, using different components and formation conditions affects the morphology of the fibrils. This may in turn influence cells, but these effects are difficult to differentiate from biochemical ones, as composition and texture of the aECM

depend on each other. Using collagen fibrils as a base material, such effects are probably of secondary importance, as morphological changes of comparable magnitude, though not identical in nature, can be induced by varying the buffer system, and this does not affect cell response; neither does the use of different collagen preparations with obvious differences in fibril morphology.[74] However, the influence of structural changes in the matrix cannot be excluded at this point and may well act in conjunction with the biochemical alterations (**Chapters 2.207, Extracellular Matrix: Inspired Biomaterials** and **2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration**).

2.208.7.1. Collagens

Collagen matrices have long been used as substrates for cell adhesion as either scaffolds or coatings on a variety of materials, and collagen type I fibrils on titanium were shown to promote adhesion of rat calvarial osteoblasts, although not differentiation,[121,122] and to prevent glyoxal-induced apoptosis.[123] Adding other ECM components, it should be possible to extend the influence exerted on the cells.

Variations of the collagen matrix by using different collagen types change mechanical and biochemical properties of the fibrils, influencing cellular responses. An increase in collagen type III in the matrix adsorbed to titanium for instance induced an increased collagen synthesis and a decrease in alkaline phosphatase (ALP) activity and Ca^{2+} deposition in primary osteoblastic cells from rat calvariae, while on collagen type I the situation was reversed (**Figure 5**).[85] This agrees with the fact that during intramembraneous fracture healing, collagen type III appears in the early phase associated with matrix production, and type I on the other hand in a later phase associated with matrix mineralization.[8] Cell morphology differed on gels of collagen I, I/III (a 1:1 mixture of I and III), and III, although this in all probability reflects mainly the changed mechanical properties of the gels, those consisting of type III being less stiff due to the finer fibrils.[85] On hard substrates,

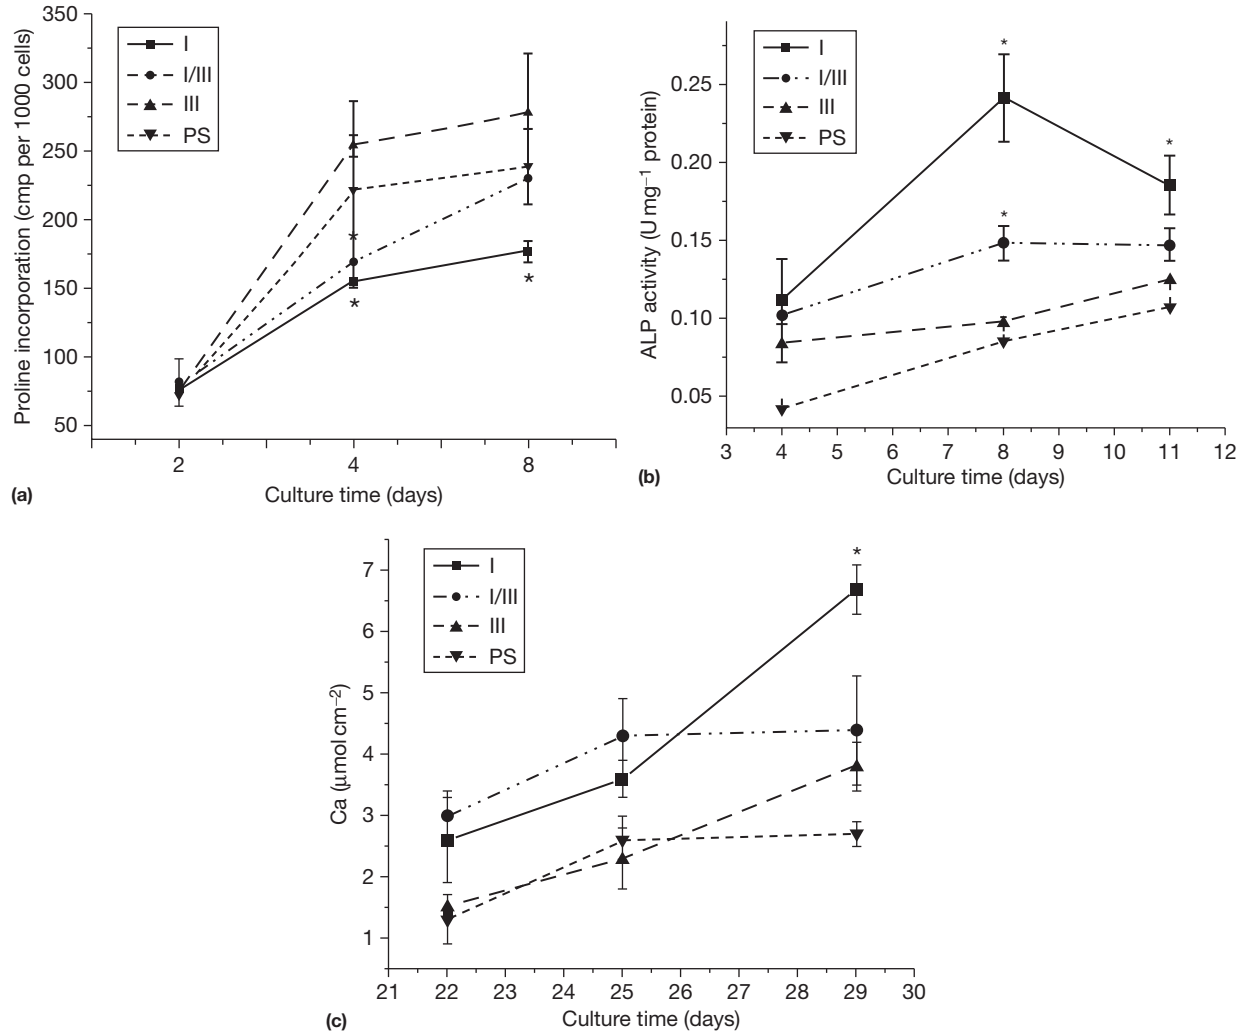

Figure 5 Collagen synthesis (a) alkaline phosphatase enzyme activity (b), and extracellular deposition of calcium (c) in osteoblasts on collagen-coated Ti6A14V disks. Osteoblasts were cultured on Ti6Al4V disks coated with either collagen type I, collagen type I/III cofibrils, or collagen type III with PS as control. At the indicated time points after analyses were performed. Asterisks indicate significant difference ($p < 0.05$) to control. Reproduced from Figures 4, 5, and 6 from Bierbaum, S.; Hempel, U.; Geissler, U.; *et al. J. Biomed. Mater. Res. A* **2003**, *67*, 431–438.

I, III, and V all promote attachment and spreading of fibroblasts, with I and III increasing DNA synthesis more than type V.[124] On soft substrates, on the other hand, collagen I/V coatings impair fibroblast spreading while type I supports it.[125]

The inclusion of growth factors is possible using plain collagen scaffolds, though there will in all probability be no synergistic interactions as the collagen serves only as a passive carrier. TGF-β adsorbed to collagen matrices immobilized on titanium, for instance, induced an increase in collagen synthesis in rat osteoblasts, and reduced mRNA and ALP activity as well as accumulation of Ca^{2+} and phosphate.[107]

2.208.7.2. Glycoproteins and PGs

Further variations include the addition of glycoproteins or PGs into collagenous matrices. The use of glycoproteins in aECM is not common; apart from FN, mainly laminin and, to some extent, elastin have been utilized. Glycoproteins such as FN are recognized by other cellular adhesion receptors rather than collagen, so that including them in the matrix changes the mechanism of cell adhesion. Depending on whether collagen or collagen/FN is used, different integrin receptors are engaged and activated,[85] which in turn can lead to the activation of different signaling pathways and thus ultimately to different cell responses (for details see **Section 2.208.3.1**). FN also interacts with cell-surface HS as part of a mechanism for triggering the signaling process that leads to cell adhesion.[126]

One glycoprotein that has been used in combination with collagen is laminin or laminin-derived peptide, mainly for the positive effect it has on neuronal cell growth. While collagen and HyA have no effect and FN negatively influences neurite growth, laminin has a dose-dependent positive effect, with neurites growing preferentially toward high laminin concentrations. As the gels in this study did not differ much in mechanical properties, the observed effects are on the basis of chemical interactions.[16,17] These interactions may involve α6β1-integrin binding to laminin, as this has been shown to play a role in the expansion and differentiation of human embryonal stem cells (hESC) into neurons.[127] The functions of laminin are not limited to neural cells: for swiss 3T3 fibroblasts, laminin peptides in collagen matrices resulted in a significant increase in cell proliferation,[91] and on human mesenchymal stem cells (hMSC) laminin has been reported to induce an osteogenic phenotype via an ERK-dependent pathway.[128] hMSCs respond similarily to other ECM proteins they adhere to through distinct integrins, although with varying affinities (FN > collagen I > collagen IV > vitronectin > laminin-1). The greatest osteogenic differentiation occurred on VN and collagen I, but almost none on FN.[129] The mechanisms by which collagen and VN support osteogenic differentiation differ: osteogenesis via VN is correlated with enhanced focal adhesion formation, the activation of FAK and paxillin, and the diminished activation of ERK and PI3K pathways. On collagen, hMSC exhibited reduced focal adhesion formation, reduced FAK and paxillin activation, and increased ERK and PI3K activation.[130] This may be on the basis of the fact that cells adhere to collagen mainly via β1-integrins, and to VN via αvβ3 and αvβ5 (**Chapter 2.209, Materials as Artificial Stem Cell Microenvironments**).[131]

Collagen type II, on the other hand, induces and supports chondrogenic over osteogenic differentiation of MSCs; the presence of TGF-β in the matrix enhances this process.[132]

Compared to glycoproteins and even more to GAGs, there are comparatively few studies concerning PGs. Unlike most of the glycoproteins, the largest part of PG influence on cells is probably not conveyed by direct interactions with cell adhesion receptors, but with other cell-surface receptors instead, and through the interactions of PGs with solute factors. Nonetheless, the addition of the PGs decorin and biglycan influences cell adhesion, accelerating and enhancing the formation of focal adhesions in osteoblastic cells.[74,88] Interestingly decorin and biglycan seem to play different roles in rats and humans: they promote the proliferation of humans but not of rat calvarial osteoblasts, collagen synthesis was inhibited by biglycan in rat but not in human osteoblasts, and decorin promoted proliferation slightly in humans but not in rat OB,[89] illustrating that aECM should be adapted carefully to the intended target cells.

Engineered proteins and protein fragments can also be used to modulate cell responses. Artificial peptides based on decorin glycosilated with DS increase the production of elastin, something that would be of interest in the tissue engineering of vascular constructs. The addition of DS without the attached protein core resulted in a decreased elastin production, indicating that presentation of GAG is important.[90]

The addition of growth factors can have different effects depending on the presenting matrices, making synergistic as well as antagonistic effects possible: in the case of adsorbed TGF-β, cell proliferation on collagen was reduced and collagen synthesis enhanced. If biglycan was present in the matrix, the reduction in proliferation was more marked, while decorin enhanced collagen synthesis.[88] Protein fragments can fulfill comparable functions, for example, the perlecan domain I which together with collagen and BMP-2 support chondrogenic differentiation in mouse embryonic mesenchymal cells;[109] peptides cannot be utilized this way, as they usually contain only one functional sequence and are not large enough to sustain additional effects.

2.208.7.3. Glycosaminoglycans

Unlike in the case of PGs, quite a number of studies have been performed using only the GAG part of these molecules, especially in conjunction with collagen. Collagen–GAG composites have been used in a number of applications such as skin, peripheral nerve, muscle, cartilage, and bone, and for the differently composed matrices effects on cytoskeletal organization, and protein expression and differentiation.

As CSs are synthesized by both chondrocytes and bone cells, they have often been used in applications concerning these tissues. In cartilage, CS stimulates PG production, inhibits cartilage cytokine production, and induces apoptosis of articular chondrocytes, while in bones, CS accelerates mineralization process and bone repair. In both tissues, CS has anti-inflammatory effects and inhibits extracellular proteases involved in the metabolism of connective tissues.[133] Matrices containing CS positively influenced adhesion of osteoblastic cells: the formation of focal adhesions was accelerated and enhanced if CS was present. As in case of the PGs, this is

probably not on the basis of specific ligand–receptor interactions, but because of the negatively charged sulfate groups of the GAG which have been shown to improve early cell adhesion.[134,135] The negative charge may accelerate integrin receptor binding via enhanced binding of Ca^{2+}, which has a higher binding affinity compared to monovalent or other divalent cations and is required for the formation of focal adhesions.[136] As about 90% of the cell-surface charges are negative at a physiological pH,[137] Ca^{2+} ions can also mediate cell adhesion by binding to both the negatively charged cell membrane and matrix. Interestingly, this depends on the CS type: in combination with collagen II, CS A and CS B, but not CS C, appeared to stimulate the formation of FACs by osteoblasts, indicating that other aspects may influence cell response over and above the overall charge effect.[104]

Collagen–GAG matrices generally increased proliferation, for example, for chondrocytes on collagen–CS,[97] and for endothelial cells on heparin-containing matrices, an effect that was increased by the addition of VEGF.[101,110]

Protein expression of osteoblastic cells on collagen–GAG matrices was usually slanted toward an osteogenic phenotype. Although calvarial osteoblasts grown on collagen-coated Ti6Al4V already expressed more OPN compared to the uncoated surface,[138] OPN expression was upregulated even more in cells cultured on collagen I–CS, suggesting that interaction with the GAG promotes osteoblastic differentiation.[74] For hMSC, a comparable effect of collagen–CS can be observed, as osteoblastic marker expression and calcium deposition are upregulated even without other differentiation additives.[106,139] Although matrix elasticity, cell shape, and cytoskeletal tension have also been shown to effect linage-specific osteogenic differentiation, many of the soluble growth and adhesive factors involved in osteogenic differentiation require GAG side chains to facilitate their interaction to their cell-surface receptors.[140] BMP has been shown to bind to cell-surface PGs such as perlecan and syndecan via their HS and CS chains; this modulates BMP osteogenic bioactivity by sequestering it at the cell surface where it is unable to bind BMP receptors.[141] GAG chains in the matrix can compete with the cell-surface GAGs for GF binding, thus making a larger part of GFs available. Oversulfated forms of CS have been shown to bind BMP-4 and stimulate osteoblastic differentiation in MC3T3 cells: heparin enhanced only mineralization and ALP activity, whereas CS-E enhanced ALP activity, collagen deposition, and mineralization, and the CS-E-induced mineralization was significantly inhibited by anti-BMP antibodies, demonstrating the interaction of the two factors.[32]

Chondrocytes grown on collagen II–CS scaffolds, on the other hand, show an increased expression of collagen II and PGs and form a denser cartilaginous layer,[97] although CS appears to influence the metabolic activity of chondrocytes seeded in a collagen I–CS matrix in a comparable manner.[142] The optimal ratio of collagen to GAG seems to depend on the cell type and the addressed tissue, and should be optimized in each case.[99,143]

Scaffolds containing HyA tend to behave slightly different, probably because fewer interactions are possible. In collagen–HyA scaffolds, small HyA quantities (2.5% wt) enhanced cell adhesion and growth, while larger ones (over 5% wt) inhibited it,[144] and migration rates of hematopoetic stem cells were reduced.[115] HyA did support chondrogenesis in eMSCs, but this effect was not enhanced by the addition of TGF-β,[145] probably because there was no interaction comparable to the sulfated GAGs possible.

2.208.8. Results from Animal Experiments

Much information exists concerning collagen, both as scaffold and coating for diverse applications in tissue engineering and as carrier for antibiotics and growth factors. Areas of use are in hard tissue, cartilage, and nerve regeneration as well as skin and soft tissue augmentation, and it can be used as lyophilized scaffold or coating of metals or polymers (i.e., silicone, polyurethane, polyethylene terephthalate, polylactic acid); this section will deal mainly with the use of collagen and other ECM molecules as coatings on bone implants. In many cases, for bone applications a mineral phase is included, both with and without organic components such as collagen. As the primary interest of this chapter is the use of aECM made up solely of organic components, such combinations with mineral phases have been specifically excluded here. Nevertheless, it should be kept in mind that they certainly are part of the ECM of bone, and using differently composed organic coatings may have relevance to mineralization processes, both *in vitro* and *in vivo*.

There are two drawbacks to the experiments discussed below. The first is of a general nature: the matrices used in such studies are often characterized only very insufficiently; the components are known, but the structure, the amount bound, or the release behavior is not known, which makes comparison and evaluation of results difficult. The second is more specific to the topic of this chapter: aECM has been defined as consisting of collagen with other ECM components modifying it, but such comparatively complex coatings have only very rarely been used for *in vivo* experiments up to now. For this reason many of the results presented below deal with single component coatings only (**Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration**).

2.208.8.1. Collagens

With very few exceptions, all studies using collagen make use of collagen type I. There are some instances where type II has been utilized, typically for cartilage applications in combination with GAGs,[97] but even here collagen type I has been employed. Type I is of course the most easily available collagen, but using the different types may still be of interest in specific situations. Collagen type III in a goat model appeared to be more effective in less dense bone after 4 and 12 weeks, which may be related to the fact that type III is associated with healing instead of mature bone.[146] This would agree with the fact that after longer time periods (6 months in the mandible of minipigs), collagen I and I/III showed higher bone–implant contact compared to uncoated, sandblasted implants, but no more differences between the collagens could be determined.[147]

Instead of the complete collagen molecule, several studies have used peptides based on the adhesive domains of collagen or, more often, FN. These peptides also convey effects in the *in vitro* studies that are comparable but not identical with those of the whole molecule, as they present only very specific aspects:

titanium coated with GFOGER, a collagen mimetic peptide, selectively promotes α2β1 integrin binding, triggering osteoblastic differentiation, and peri-implant bone regeneration and osseointegration.[148] Using peptides in combination with the larger, 3D molecular networks of ECM proteins is an intriguing aspect, as it allows further modification of aECM functions.

These larger structures of ECM proteins are necessary if growth factors are to be included in the matrix, as peptides cannot interact with them in addition to conveying adhesion. The use of growth factors in tissue regeneration has given rise to the development of a number of carriers, but a significant drawback that remains is that very high amounts of growth factor have to be used to achieve the desired effects. Smaller amounts as can be attained by adsorptively immobilizing, that is, BMP-2 to collagen coatings, often have no significant effect *in vivo*,[149] although cell culture results have been promising. This is certainly an aspect where the inclusion of matrix components that are known to interact with growth factors may be of use in the future.

2.208.8.2. Glycoproteins and PGs

On both glycoproteins and PGs, either alone or in combination with collagen, there is comparatively little *in vivo* data. For collagen and collagen–decorin matrices on acid etched titanium implants in the mandible of minipigs, both were better than uncoated implants, but no significant differences between them could be detected.[150] In experiments in rats, on the other hand, there are interesting results indicating that tissue responses to implants can be modulated by surface treatments using ECM proteins. On porous ePTFE disks implanted into the adipose tissue of rats, an FN coating resulted in an extensive inflammatory response with limited angiogenesis and neovascularization, and collagen IV in significant peri-implant angiogenic response but little neovascularization, while laminin-1 displayed both peri-implant angiogenesis and a coordinate neovascularization of the porous interstices of the biomaterial.[151] It seems that the major effect of FN is to stimulate a cytokine response that enhances monocyte/macrophage recruitment and the differentiation of cells into giant cells, while collagen IV appears as more of an angiostatic factor, supporting the maturation of blood vessels in the peri-implant region but not endothelial cell migration and neovascularization. Laminin, on the other hand, seems to both induce the production of angiogenic factors and support early and late events in the angiogenic process.[151] The mechanisms of these variable responses are still unclear, but they seem to involve the expression of various cytokines and growth factors by cells in the peri-implant region in response to the different matrices.

Laminin is of special interest in nerve cell regeneration: stem cell survival and improvement in cognitive functions in the mouse brain were better for scaffolds containing laminin or laminin peptides.[18] For collagen scaffolds implanted into the spinal cord of rats, a coating of a laminin peptide (YIGSR) enhanced more neurite growth than an FN coating,[152] illustrating that matrix composition affects all types of tissues, and that the most common choices, collagen type I and FN, are not necessarily the best in every case.

Not only the components included in a coating but also their physical presentation can influence cellular response. Collagen–elastin scaffolds that contain solubilized elastin induce angiogenesis and show no calcification in rats, in contrast to scaffolds containing elastin fibrils.[11] Although the mechanism is unclear, this indicates that structural aspects should not be ignored.

As in the case of collagen, peptides instead of the complete molecules can be used. Laminin peptides have already been mentioned, but the most commonly used peptide by far is the RGD sequence derived from FN. RGD and other adhesion peptides, when coated onto titanium, generally gave rise to greater bone–implant contact than uncoated, grid blasted implants,[153] although in comparison to collagen coatings in a goat model, the complete collagen induced more bone apposition than the peptide, indicating that mechanisms over and above adhesion via the integrin receptor targeted by RGD are responsible for tissue response.[146] Combining RGD with collagen, on the other hand, resulted for titanium implants in the dog mandible after 1 month in an enhanced bone–implant contact for collagen grafted with RGD peptide over unmodified collagen or RGD alone. The differences between coatings were no longer apparent after 3 months; interestingly, all coatings still displayed more bone–implant contact and bone volume density than uncoated, machined implants,[154] showing that both short- and long-term responses can be affected differently by the chosen coatings.

The use of an FN fragment such as the α5β1-specific FN fragment FNIII7-10 instead of just the integrin-binding sequence enhanced bone apposition not only over a peptide coating but also over the full-length FN in a rat model.[155] This may, like the use of RGD in combination with collagen, be due to the increased number of binding sites offered by the smaller peptide on the same area.

2.208.8.3. Glycosaminoglycans

Like collagen type I matrices, those consisting of collagen–glycosaminoglycans have been studied in a variety of experiments. Most matrices are cross-linked, which delays resorption and preserves scaffold integrity over a longer time.[100] Whether or not cross-linking is used thus depends on the application and the time that is considered necessary for the scaffold or coating to remain *in situ*. Especially for coatings, this reduces the necessity to cross-link, as the preservation of a 3D, porous structure is not an issue here, and most experiments indicate that the effect of coatings is a comparatively early one.

Among the GAGs, HyA occupies a somewhat separate position. Because of its unsulfated state, there is little interaction with growth factors or other ECM components; the main effect of HyA is via its size (see also **Section 2.208.3**). There are some applications as a dermal substitute, where collagen/HyA membranes were shown to have a good compatibility and low irritability,[144] but in the majority of the cases the sulfated GAGs were used.

Inclusion of GAGs into collagen matrices has a variety of effects, such as influencing the process of inflammation and foreign body response, an observation that has been reported repeatedly. In rats, both CS and HS in combination with collagen aid the generation of new host tissue with only a transient inflammatory response and a reduced foreign body

reaction,[100] and the activity of macrophages was reported to be markedly reduced around collagen–CS coating of titanium.[156]

More specifically, GAGs have been implicated in inducing and promoting angiogenesis, something of paramount importance especially in 3D constructs. Here biomaterials are of interest that can encode matricellular cues which regulate and enhance vascular progression by reproducing the natural interplay existing between matrix, cells, and angiogenic factors. In a rat model, collagen matrices with both HS and heparin showed improved angiogenesis over collagen alone,[100,101] the drawback being that this increase in vascularization was only in the periphery and probably transient.[102] This could be overcome by the addition of growth factors: VEGF further increased the angiogenic potential of collagen–heparin matrices,[101] and bFGF in combination with collagen/HS resulted in scaffolds that remained vascularized throughout the matrix during a 10-week implantation period. In addition, they revealed an intense and prolonged tissue response and considerably promoted the generation of new tissue.[102] The most interesting fact here is that adding bFGF to the collagen matrix had the same transient and peripheral effect as the collagen–HS matrix without the growth factor, indicating that not only does HS directly affect angiogenesis but also that it can work synergistically with bFGF. Including HyA in specific matrix location may be of further interest, as increasing HyA in collagen scaffolds works in a manner opposed to HS and heparin, inhibiting sprouting, and the combination might thus be utilized to direct vessel growth.[157]

In the osseous integration of implants, including GAGs has also led to positive results, although the mechanisms can be expected to be somewhat different. Collagen–CS coatings were consistently found to give higher bone volume and bone-implant contact than collagen alone for titanium implants in the minipig mandible;[158] again these effects were in the early phase and leveled off after 2 months.[150] Interestingly, the extraction torque of collagen–CS implants in the sheep tibia was in the region of hydroxyl apatite coatings (1153 N mm vs. 1088 N mm for collagen–CS) and higher than collagen (900 N mm) despite the fact that after 2 months the differences in bone apposition were no longer significant.[159]

On the cellular level, both for collagen and even more for collagen–CS there was a faster appearance of relevant cell types compared to uncoated, grid blasted implants, and osteoblast activity was increased around both collagen and collagen–CS.[156] This results in a significantly enhanced bone remodeling in the early stages of bone healing, which is reflected in the bone-implant contact after 4 weeks: 89% for collagen–CS, 76% for collagen, and 62% for uncoated implants.[160] In addition, macrophage and osteoclast activity were markedly reduced around collagen–CS coatings in a rat model, which agrees with the observations made in the angiogenic studies.[156] The impact of surface topography and animal model is illustrated by the fact that in the foxhound mandible, for machined and acid etched titanium samples, the bone-implant contact was enhanced by collagen–CS coatings in both cases, but the differences were significant only for the machined surfaces.[161]

GAGs have been described to interact with growth factors; using matrices that include these components to enhance the ability of aECM coatings to bind and deliver growth factors is thus a logical approach. For bone, most of the interest focuses on the BMPs; BMP-2 and BMP-4 are known to induce bone formation when released from carriers such as collagen fleeces *in vivo*. Using the high BMP amounts that are necessary to induce a response (these usually being in the microgram range), collagen–heparin matrices enhance BMP-induced osteoblast differentiation not only *in vitro* but also *in vivo*, the mechanism possibly being the protection of the growth factors from degradation, and an inhibition of BMP antagonists.[162] For lower BMP amounts as could be immobilized on 2D coatings of titanium implants, the situation is a different one. Here, either no BMP effect could be seen,[161] or a detrimental one. In the minipig mandible, the bone-implant contact for collagen–CS was 40%, but for collagen–CS–BMP-4 only 27% (**Figure 6**).[163,164] This indicates that, to utilize the complete range of potential that aECM can offer, still much needs to be learned about how ECM components and soluble factors interact with each other as well as with cells and proteins of the host tissue in the process of healing (**Chapter 5.522, Bone Tissue Engineering: Growth Factors and Cytokines**).

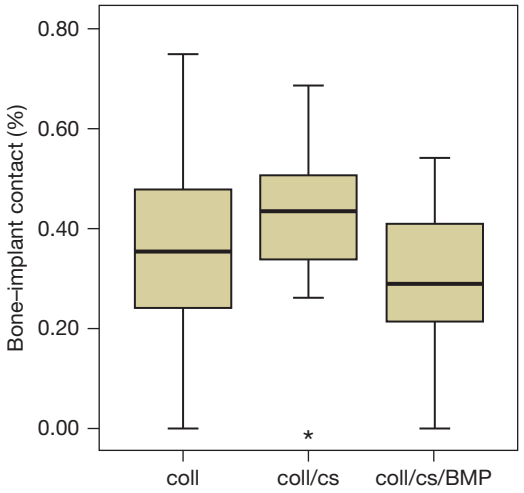

Figure 6 Percentage of implant surface in contact with bone. coll, coating from fibrillar collagen type I; coll/CS, coating from fibrillar collagen type I with chondroitinsulfate associated during fibrillogenesis; coll/CS/BMP4, coating Coll/CS loaded with 400 ng rhBMP4 per implant. 2.208.9. Conclusions and Outlook

Although the matrix has been recognized for a while now as being much more important in determining cell fate than previously thought, much still remains to be done in utilizing the possibilities it offers to construct defined microenvironments that can steer cellular responses. Only few of the components that make up the ECM *in vivo* have been utilized in the construction of aECM up to now; considering how specific the responses of cells and tissues can be, there is still much potential in this respect.

A promising approach is the use of engineered proteins and protein fragments, enhancing specific functionalities over

the naturally occurring levels by repeating the protein domains, or combining them with other functionalities. The ECM proteins themselves constructed in this manner consist of functional domains that occur in different proteins with varying combinations.

Using chemically modified GAGs is a related aspect, as changing the sulfation pattern impacts the interaction of the sugars with other proteins. Modified GAGs can be either sugars that are naturally not sulfated, such as chitosan, dextran, and hyaluronan,[165,166] or oversulfated forms of CS, DS, or HS.[32] It has been shown that such alterations influence the ability to bind growth factors as for HyA, where highly sulfated forms bind more BMP4 than those with low sulfate content.[167] Modified GAGs thus might be either used in GF carriers to immobilize higher amounts of growth factor, or can perhaps even be sufficiently engineered to exploit their ability to act synergistically with soluble factors.

Yet another aspect that has not received much attention is the influence of mechanical cues. Mechanical signals are as important for cells as biochemical ones; one example is the constant remodeling of bone on the basis of the mechanical load. The mechanical information is conveyed to the cells via the ECM, and specifically via the adhesion receptors, some of which also function as mechanoreceptors. Especially the integrins are probably involved in the whole plethora of mechanotransduction phenomenons.[168] Mechanical strain activates signal transduction pathways similar to growth factors;[169] indeed, sometimes mechanical stress activates growth factor receptors even in absence of the soluble ligand.[170] But this depends on the ECM composition: VN has been shown to be involved in the transduction of mechanical signals into the cells, OPN plays a major role in stress-induced bone remodeling,[22] and collagen–CS matrices enhance osteoblastic differentiation in combination with mechanical stress.[171]

Many aspects can thus potentially be addressed by differently composed aECM in healthy organisms and in those compromised by illness. A better understanding of the complex mechanism behind the observed effects of the ECM will be instrumental for significant progress in this field, and the developments in many areas of relevant research such as molecular medicine, cell–matrix interactions, and glycomics, to name only a few, hold much promise for the future.

Glossary

Adult stem cell A stem cell that is derived from an adult tissue. This stem cell is restricted to form the specialized cells of the tissue that it is derived from. These cells are responsible for tissue regeneration throughout life.
Asymmetric cell division Generation of two daughter cells with disparate function from a single stem cell division.
Embryonic stem cell Pluripotent stem cell lines derived from early embryo before formation of the tissue germ layers.
Hydrogel Water-swollen cross-linked polymer network.
Microfabrication Term to describe the fabrication and patterning of structures in the micrometer range. Adapted from the semiconductor industry, these methodologies are increasingly used for bioengineering applications.
Microfluidics Fluidics in micrometers-sized channels that are characterized by a laminar flow regime.
Multipotent Ability to form the types of differentiated cells of an entire tissue. Adult stem cells are considered multipotent.
Niche Stem cell-specific microenvironment regulating behavior of stem cells by niche-specific signaling factors.
Pluripotent Ability to form all types of differentiated cells of an organism, including germ cells. Embryonic stem cells are, for example, pluripotent.
Self-renewal Cell division leading to at least one daughter cell equivalent to the mother stem cell.

Abbreviations

ASC	Adult stem cell
BMP	Bone morphogenetic protein
CAD	Computer-assisted design
CAM	Cell adhesion molecule
DEP	Dielectrophoresis
DLL1	Delta-like 1
DTC	Distal tip cell
ECM	Extracellular matrix
ERK	Extracellular signal-regulated kinase
ESC	Embryonic stem cell
FGF	Fibroblast growth factor
FN	Fibronectin
GAG	Glycosaminoglycan
GSC	Germline stem cell
HSC	Hematopoietic stem cell
iPSC	Enduced pluripotent stem cell
LIF	Leukemia inhibitory factor
MAPK	Mitogen-activated protein kinase
MEF	Mouse embryonic fibroblast
MSC	Mesenchymal stem cells
MuSC	Muscle stem cell
NSC	Neural stem cell
PDFG	Platelet-derived growth factor
PEG	Poly(ethylene glycol)
VEGF	Vascular endothelial growth factor

2.209.1. Introduction

The ability of stem cells to produce more of themselves ('self-renewal') and to give rise to specialized progeny ('differentiation') that makes up a tissue has fueled hope for stem cell-based approaches in regenerative medicine.[1] The key paradigm currently under scrutiny is to implant stem cells or their progeny, possibly in combination with bioactive scaffolds, to the site of a damaged or genetically diseased tissue in order to facilitate regeneration. Alternatively, engineered tissues and organs generated from stem cell sources are sought to be applied in fundamental *in vitro* studies and for the next generation drug screening efforts. However, although significant progress has been made, we are still far away from realizing these appealing concepts, largely because of difficulties to grow stem cells *in vitro* without rapidly losing their characteristic functions. That is to say, pluripotent embryonic stem cells (ESC) or induced pluripotent stem cells (iPSC) can be readily expanded *in vitro*, but are difficult to differentiate in an efficient manner, whereas most adult stem cells types such as hematopoietic stem cells (HSC) or neural stem cells (NSC) can hardly be maintained in culture without loss of their multipotency (Figure 1). It has been hypothesized that the failure of these seemingly simple tasks is caused by the absence of a cell-instructive microenvironment in the currently applied cell culture systems.

In vivo, the delicate balance between stem cell self-renewal and differentiation is governed by tissue-specific niches that display

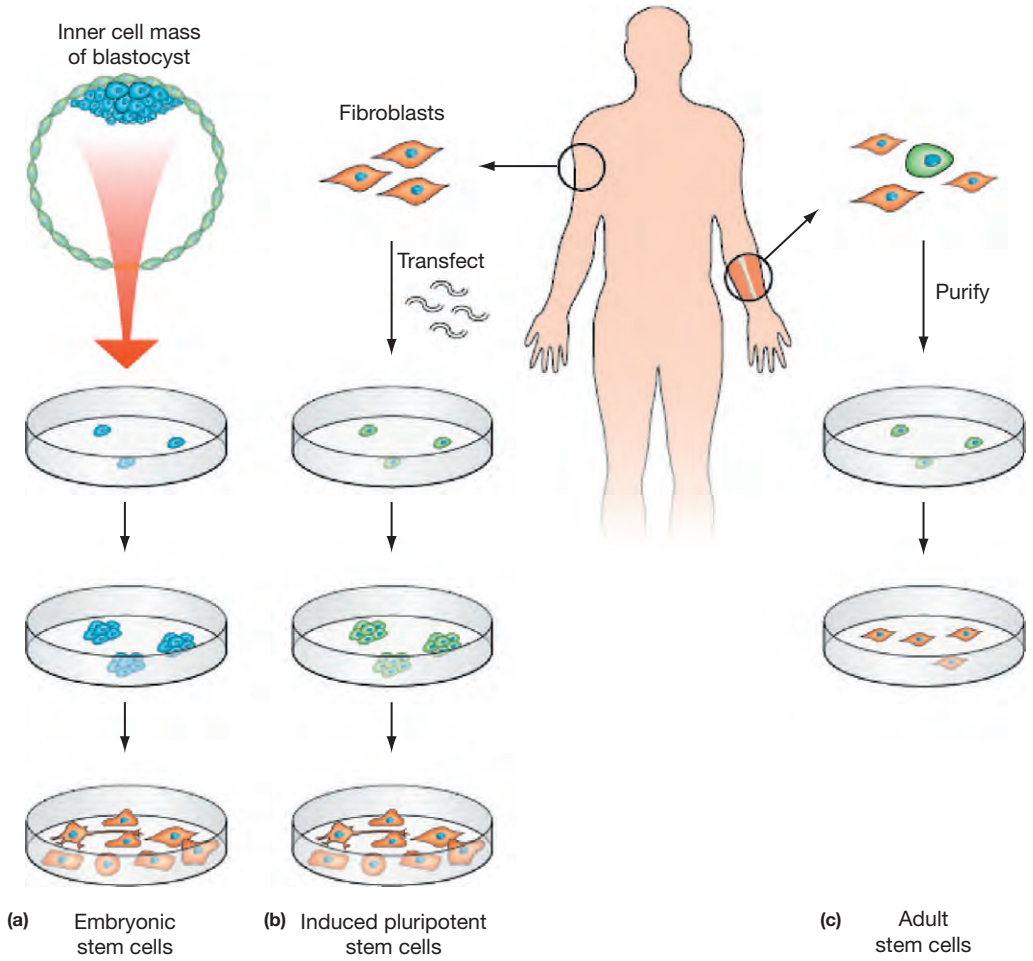

Figure 1 The main stem cell types: embryonic stem cells (ESC), induced pluripotent stem cells (iPSC), and adult stem cells (ASC). (a) ESC are derived from the inner cell mass of the early embryo (blastocyst) and provide a source for pluripotent stem cells that can differentiate into any cell type. (b) iPSC are generated by reprogramming somatic cells such as fibroblasts, with a few essential pluripotency transcription factors such as Oct4 and thus can overcome some ethical issues associated with embryonic stem cells.[2] Both, embryonic and iPSC can be propagated nearly infinitely in culture, which makes them a valuable source for stem cell-based therapy. However, the differentiation of these cells is cumbersome and often results in a heterogeneous mixture of multiple and only partially differentiated cell types, and hence there is a significant risk of tumor formation when transplanted into humans. (c) In contrast, adult stem cells can be found at low frequency in native tissues and hence have to be purified first; they efficiently differentiate into uniquely tissue-specific progenitors, alleviating the risk of tumors. Ironically, this differentiation cannot be halted *in vitro*, given the importance of the tissue-specific microenvironment that host these stem cells. For this reason, it is very difficult to obtain large numbers of these adult stem cells *in vitro* that would be required for clinical and pharmaceutical applications. Adapted from Lutolf, M. P.; Gilbert, P. M.; Blau, H. M. *Nature* **2009**, *462*, 433–441, with permission. © 2009 Nature Publishing Group.

complex, spatially and temporally modular mixtures of cell signaling cues. These signals can either be biochemical in nature, stemming from other cells (niche or support cells), the surrounding cross-linked extracellular matrix (ECM), and soluble biomolecules such as growth factors, or else biophysical, such as the elasticity or three-dimensional (3D) structure of the microenvironment.

The fact that many niches in mammals are poorly accessible and therefore difficult to directly study and manipulate *in vivo*, as well as an increasing awareness of the huge complexity of niches, has evoked the need to reconstruct this system *in vitro* in a much more simplified and better-controlled form. Indeed, important advances in biomaterials engineering have set the stage for the successful development of novel generations of such artificial niches with truly biomimetic functions. In combination with other techniques, such as microfabrication, microfluidics, or novel live-cell imaging modalities, these systems promise to offer novel insights into stem cell biology. This chapter summarizes some of the advances that have been made in the fabrication of artificial stem cell niches. We will focus on *selected* examples and limit our point of view on soft materials and *in vitro* applications, acknowledging that other types of biomaterials are successfully used in this context. For a more comprehensive understanding of the diverse types and applications of biomaterials in stem cell biology and bioengineering, we refer the reader to several reviews.[3–11]

2.209.2. The Adult Stem Cell and Its Niche

Stem cell niches are anatomically distinct, spatially restricted milieus that host and regulate stem cells. The niche concept was first postulated by Schofield on HSCs in the late 1970s.[12] However, experimental support came only 10 years later with the *in vivo* characterization of germline stem cells (GSCs) niches in *Drosophila*, demonstrating that short-range signals from niche cells are essential for stem cell maintenance.[13] Subsequently, mammalian niches were identified in almost all tissues including the skin (in the bulge region of the hair follicle), the brain (in the subventricular zone), bone marrow (on the endosteal surface and near blood vessels), or muscle (beneath the basal lamina of the muscle fiber). Some of these niches have been discussed in detail elsewhere.[14–19]

Although mammalian niches significantly vary in structure and composition, they share common features that are schematically depicted in **Figure 2(a)**. Stem cells in the niche are in close physical contact with niche cells and are either interacting with a basal lamina (e.g., in the muscle) or a highly hydrated, fibrillar network of ECM proteins and sugars (e.g., in bone marrow). By far, the best-studied types of niche signals are *soluble factors*. Niche cells secrete cytokines, growth factors, and developmental morphogen proteins such as Wnt proteins, hedgehog proteins, fibroblast growth factors (FGFs), or bone morphogenetic proteins (BMPs). Many of these proteins are believed to bind to the ECM by electrostatic interactions, in particular via heparan sulfate proteoglycans.[20,21] ECM-immobilization could thus prevent rapid degradation, localize growth factor distribution to the niche, and help establish stable gradients of signaling molecules that could define the size and polarity of a niche.

Another signal type emanating from the niche is the *cross-linked ECM*. Besides keeping stem cells at the right place, the ECM also directly interacts with stem cells which express ECM protein-binding receptors such as integrins. Indeed, most stem cell types express a well-defined set of integrins, and are therefore sensitive to composition of the niche ECM.[22] For example, apart from many other receptors, HSCs express the cell surface glycoprotein CD44 and the two integrins α4 and α5β1 that both bind to osteopontin, a glycoprotein specifically found in the ECM of the bone marrow.[23] The anchoring of stem cells to the ECM via integrins has a dual function. First, adhesion molecules transmit physical forces to the interior of the stem cell by linking the ECM with the cytoskeleton. Through this interaction, cells can sense external forces or mechanical properties of the niche.[24–26] Second, integrins act

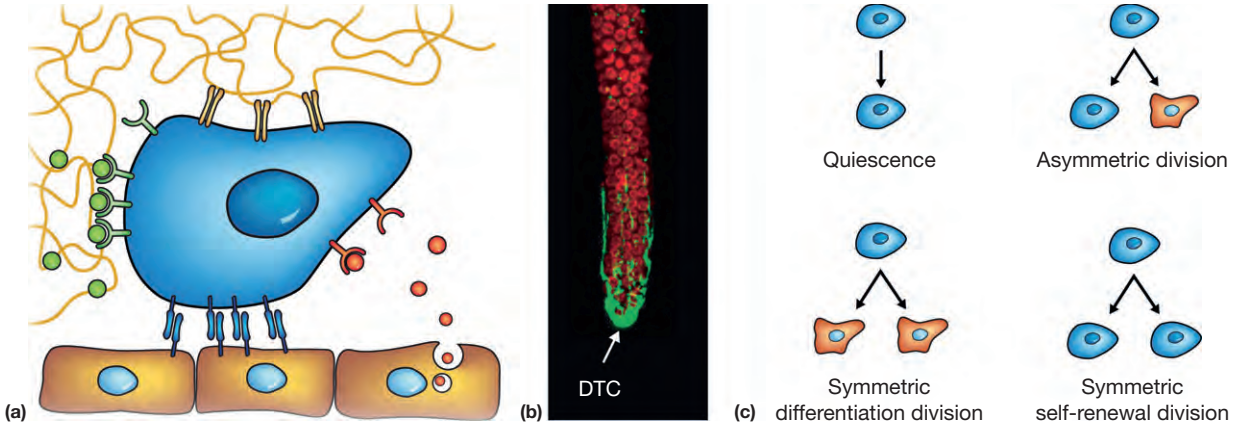

Figure 2 The niche of stem cells and its control of stem cell behavior. (a) *In vivo*, adult stem cells are located in tissue-specific microenvironments with well-defined architecture that protect and regulate stem cells. The niche is composed of extracellular matrix components and other niche (support) cells that present a complex mixture of extrinsic cues. (b) A well-characterized niche of the germline stem cells in the gonad of *Drosophila*, where distal tip cells (DTC, in green) are located at the bottom of an ECM-supported cavity and confine the stem cells through cell adhesion molecules to the niche. Loss of contact with the DTC will induce differentiation of stem cells (in red). (c) Accordingly, in the niche, cells can remain quiescent, proliferate, or differentiate. J.; Kimble, J. *Nature* **2006**, *441*, 1068–1074. © 2006 Nature Publishing Group and 2010 BioTechniques.

as specific ECM protein receptors that upon binding induce intracellular signaling involved in regulating stem cell maintenance. Noteworthy, signals from growth factors and the ECM often synergistically regulate cell behavior, either by proximity effects on the cell membrane or by cross-talk in the downstream signal transduction pathways.[20,27]

A third class of niche cues worth mentioning are direct *cell–cell interactions* via cell adhesion molecules (CAMs) and other transmembrane receptors involved in juxtacrine signaling between adjacent cells. These proteins are either integrated into the cell membrane via transmembrane domains or covalently bound to its lipids and, by providing a very localized signal, prevent migration of stem cells.[22,28] The signaling via cell–cell interactions can be crucial for stem cell regulation as exemplified in the Drosophila gonads (**Figure 2(b)**). There, the niche cells express cadherins that tether the GSCs to the niche. As the niche is small and can host only few stem cells, some daughter cells generated via cell division quickly lose contact with the niche and initiate oogenesis.

Although the behavior of stem cells is not only influenced by the localized cues just described (the activation of HSCs is earlier for example, known to follow circadian rhythms[29]), the complex interplay of niche signals is key to the maintenance of stem cells. Best evidence for this is the loss of stem cell function due to stem cell removal from the niche. Arguably, the prime function of the niche is to retain stem cells in a quiescent state, as adult stem cells *in vivo* are believed to be mostly quiescent.[30] However, the niche presumably also regulates 'fate decisions' that can occur during cell division (**Figure 2(c)**). A self-renewing division of a stem cell can either result in two daughter cells acquiring equal stem cell fates, or in one daughter stem cell and one daughter that has started to undergo the first steps toward differentiation. These self-renewing divisions are either called symmetric (with respect to the potential of the two daughter cells) or asymmetric. Although concrete experimental proof for asymmetric divisions of mammalian adult stem cells is still missing, these divisions are assumed to be induced by an asymmetric distribution of cell-intrinsic, fate--determining proteins (such as Numb or Par proteins[31]), and/or by a polarized distribution of extrinsic cues which expose two equal daughter cells to a different cell-instructive microenvironment. Clearly, these cell fate decisions need to be tightly balanced in response to the physiological demands of a tissue, as insufficient self-renewal would deplete the stem cell pool over time, impairing tissue maintenance and regeneration, and an overproduction of stem cells could lead to cancer.

2.209.3. Naturally Derived ECM Components for *In Vitro* Stem Cell Manipulation

Mammalian ECMs are 3D networks made up of fibrillar proteins (e.g., collagens, fibronectin, elastin, laminin, vitronectin), glycosaminoglycans (GAGs) such as hyaluronan or heparin, and proteoglycans.[23,32] Many of these ECM components are commercially available, either as complex mixtures or as purified proteins, (see **Chapter 2.214, Hyaluronic Acid**; **Chapter 2.215, Collagen: Materials Analysis and Implant Uses**; **Chapter 2.216, Collagen–GAG Materials**; **Chapter 2.217, Fibrin**; and **Chapter 2.220, Extracellular Matrix as Biomimetic Biomaterial: Biological Matrices for Tissue Regeneration**) and have been extensively applied for stem cell culture. For example, Matrigel™, a reconstituted basement membrane hydrogel derived from the ECM-rich Engelbreth–Holm–Swarm sarcoma mainly composed of collagen IV, laminin, and heparan sulfate proteoglycans, is successfully used as substrate for many stem cells including human ESC, which classically rely on feeder layers of irradiated (i.e., nonproliferating) mouse embryonic fibroblasts (MEFs). However, these relatively ill-defined culture conditions are not acceptable for the clinical application of ESC. The application of Matrigel™ or purified laminin (in the case of human ESC) and collagen, gelatin, or fibronectin (in the case of mouse ESC) as substitutes for MEF-based cultures thus represents an important step toward the xeno-free culture of these pluripotent stem cells.[33] This example and a wealth of other studies reporting beneficial effects of adsorbed ECM proteins on directed stem cell differentiation[3,7,34] show that stem cell fate can be controlled *in vitro* by providing essential components of the natural ECM. In comparison to complex coculture conditions, these isolated ECM substrates are also well suited for systematically probing ECM regulation.

2.209.4. Engineered Substrates as Artificial Stem Cell Niches

Although natural ECM components are indispensable *in vitro* tools to further our understanding on how stem cells are regulated by extrinsic cues, the way by which these signals are currently applied in culture is arguably not ideal (see **Chapter 5.508, Scaffold Materials for hES Cell Culture and Differentiation**). In particular, many existing methods lack the possibility to tune the biochemical and biophysical properties of naturally derived ECMs to an extent similar to that observed *in vivo*.

2.209.4.1. Control of Stem Cell Fate by Biomolecule-Functionalized Substrates

Much can be learned on stem cell regulation from studies in which niche proteins are immobilized to biomaterial substrates (see **Chapter 4.411, Peptide- and Protein-Modified Surfaces**) mimicking their tethering to the ECM *in vivo* (**Figure 3(a)**). A logical way to do so is by using heparin, (see **Chapter 4.420, Drug Delivery via Heparin Conjugates**) the natural binding partner of many growth factors in the ECM. Heparin has, for example, been chemically modified in order to covalently incorporate it into a biomaterial scaffold.[35] This affinity-based binding strategy guarantees a good bioactivity and a physiological internalization of the growth factors. However, because affinity-based tethered growth factors are relatively quickly released and the decoration of biomaterials with heparin can be rather complicated and poorly controlled,[36,37] growth factors have been directly conjugated to a biomaterial using chemical linkers. For example, the covalent attachment of fibroblast growth factor 2 (FGF2) to polyamide nanofibers improved its stability in media as efficiently as heparin.[38] Importantly, compared to the soluble form, FGF2-immobilization led to a stronger activation of ERK/MAPK (extracellular signal-regulated kinase/mitogen-activated protein kinase) signaling and an increased proliferation of human ESC. Similar effects were observed in mesenchymal stem cells (MSCs) or

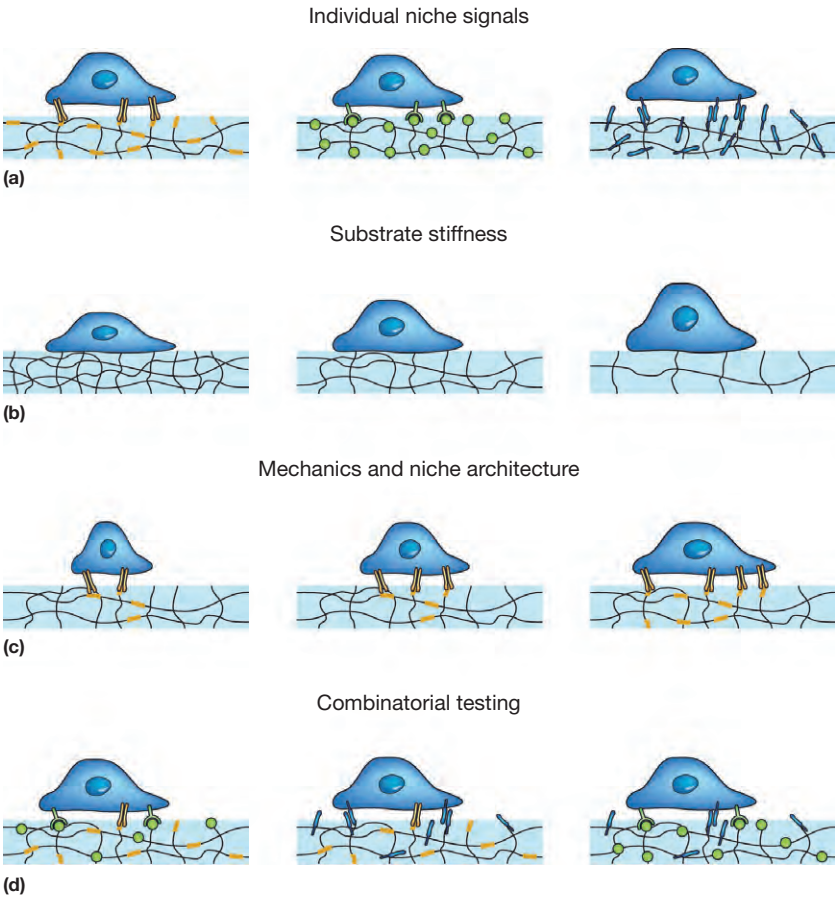

Figure 3 Materials engineering approaches to study stem cell regulation *in vitro*. Advanced biomaterial fabrication techniques enable (a) the decoration of biomaterials with defined biomolecules, such as ECM components, growth factors, or membrane-anchored proteins involved in cell–cell interactions, or (b) the modification of the elastic properties of the cell culture substrate. (c) Micropatterning techniques can be used to recapitulate spatial properties of niches and (d) robotic technology enables the fabrication of combinatorial protein mixtures to systematically screen putative niche signals. primary rat hepatocytes upon immobilization of epidermal growth factor (EGF) to a synthetic matrix[39,40] or in mouse ESC with bound leukemia inhibitory factor (LIF).[41] Importantly, it has recently been shown that many growth factors have strong interactions with nonproteoglycan ECM components. For example, the 12th to 14th type three repeats of fibronectin (FN III12–14) are a strong binding partner of most growth factors from the platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), and FGF families and some growth factors from the transforming growth factor beta (TGF-beta) and neurotrophin families.[42] This strategy was successfully explored to tether growth factors to and release them from fibrin hydrogels and will surely be a powerful means to augment to function of artificial niches.

The immobilization of proteins onto biomaterials can be used not only to recapitulate the tethering of growth factors to the native ECM, but also to mimic cell–cell communication via transmembrane proteins such as cadherins or Notch ligands (**Figure 3(a)**). For example, the immobilization of the Notch ligand Delta-like 1 (DLL1) or Jagged1 resulted in a strong proliferation of human cord-blood $CD133^+$ stem cells[43] or rat esophageal progenitor cells,[44] respectively. In another application, E-cadherin-coated surfaces enabled the retention of ESC pluripotency as was shown by immunostainings and teratoma assays, the gold standard to test the pluripotency of these cells. Concomitantly, ESC proliferated 50% faster on E-cadherin than on gelatin, indicating that cell–cell signals are a rate-limiting step in proliferation and that tethered E-cadherin can even replace the cell–cell signaling within mouse ESC colonies.[45,46]

The beneficial effect of tethered growth factors can probably be explained by a concentration effect, mimicking the aggregation of ligand–receptor complexes on the cell membrane and thus inducing increased signaling.[41] Further, the covalent growth factor immobilization to a surface can inhibit endocytosis of the growth factor and its receptor and consequently could prolong signaling.[27,40] We expect that the ability to precisely modulate the biomolecular properties of a cell culture substrate using smart bioconjugation strategies will be an important tool to further dissect the mechanisms of stem cell regulation and to manipulate stem cell fate in clinical settings.

2.209.4.2. Instructing Stem Cells via Engineered Substrates with Tailor-Made Biophysical Properties

Stem cells in developing and mature tissues are exposed to a wide range of biophysical stimuli, including, for example,

forces that act on cells during gastrulation, muscle movement, or blood flow (see **Chapter 5.504, Effect of Substrate Modulus on Cell Function and Differentiation**). Recent evidence suggests that the mechanical properties of the ECM, which naturally can span over four orders of magnitude, have an instructive role on stem cells independent of biochemical signals[25,47,48] (**Figure 3(b)**). A landmark study showed that the differentiation of human MSCs is strongly influenced by the elasticity of the cell culture substrate.[49] When cultured on soft, collagen I-modified poly(acrylamide) hydrogels in which stiffness was modulated by the concentration of a bisacrylamide cross-linker,[50] MSCs exposed to gels mimicking the elasticity of the brain differentiated into neurons, but acquired primarily a myoblast-like or osteoblast-like phenotype when seeded onto gels with similar mechanical properties as muscle tissues or the bone, respectively. This finding has inspired a wealth of studies in other stem cell systems and has motivated the development and application of engineered hydrogels with mechanical properties that can be independently tuned by the biochemical signals attached to their surface. For example, adhesion peptide-modified interpenetrating polymer networks were fabricated from variable ratios of acrylamide and bisacrylamide monomers having elastic moduli between 10 and 10 000 Pa. Adult NSC grown under differentiation conditions and exposed to these engineered gels were biased toward the neuronal lineage on softer gels (100–500 Pa, near the physiological stiffness of brain tissue) and glial lineage on stiffer gels (1000–10 000 Pa), independent of the cell adhesion ligand concentration.[51]

Not surprisingly, muscle stem cells (MuSCs), termed satellite cells, also respond to matrix elasticity.[52] Poly(ethylene glycol) (PEG) hydrogel substrates formed via Michael-type addition were engineered to recapitulate key biophysical and biochemical MuSC niche features. Unlike MuSCs on rigid plastic dishes ($\sim 10^6$ kPa), MuSCs cultured on laminin-functionalized gels that mimic the elasticity of muscle (12 000 Pa) were shown to self-renew *in vitro* and contribute extensively to regeneration when transplanted into damaged muscles of mice. Thus, the recapitulation of the physiological tissue rigidity in a stem cell culture environment appears to be important in the maintenance of stem cell function in culture, an aspect that will need to be taken into consideration in future stem cell-based therapies as well.

2.209.4.3. Instructing Stem Cells via Engineered Substrates with Controlled Spatial Properties

Apart from the stiffness of the microenvironment, spatial or geometrical inputs might play an important role (**Figure 3(c)**), as stem cells in their niche are also under spatial constraints (**Figure 2(b)**). In combination with biomaterials technologies, micropatterning techniques such as microcontact printing, photolithography, or microfluidics seem particularly well suited to recapitulate spatial niche characteristics, because of their ability to control the display of biomolecular signals *in vitro* at the cellular or even subcellular scale. The application of these techniques ranges from restricting the size of artificial niches and reconstruction of 'polarized' niche mimetics to the generation of gradients of biomolecules.[8,53,54] For instance, the fate of single human MSC grown under mixed adipogenic and osteogenic differentiation conditions was shown to be strongly responsive to the size of microcontact-printed fibronectin patterns.[55] When the cells were allowed to spread on larger patches, they preferentially differentiated into osteoblasts, whereas small features inhibited spreading-induced adipogenesis via a RhoA-dependent mechanism (**Figure 4(a)**). The same approach enabled identification of physical tension as a mechanism regulating MSCs, as well as the colony size-dependent paracrine signaling mechanism in ESC.[56,57] Along similar lines, the nanoscale topography has also been shown to influence stem cell behavior by perturbing the organization of integrins and the cytoskeleton.[58,59]

As stem cell niches are polarized structures with possibly a graded and overlapping distribution of multiple signaling cues, surface engineering efforts have also been dedicated to recapitulate spatial niche complexity. Building on the possibility of microfluidic technology to precisely position tiny amounts of liquids within microchannels, researchers have used microfluidic gradient makers to generate streams with a stepwise distribution or a gradient of adhesion molecules or growth factors.[54,60] Several successful examples of such microfluidic approaches to stem cell biology have been reported, for example the asymmetric stimulation of ESC colonies,[61] or the application of gradients of neurotrophic factors to neural progenitor cells.[62,63] Notably, most gradient systems thus far were applied to soluble rather than ECM-tethered stimuli. These shortcomings have spurred the integration of biomaterials technologies into micropatterning platforms to tether gradients onto substrates. Examples of these endeavors include adsorbed laminin gradients on plastic culture substrates[64] or the photopolymerization of peptide and protein gradients within hydrogels.[65,66] A recent study used PEG-based hydrogels decorated with NeutrAvidin and protein A to capture soluble gradients of biotinylated or Fc-tagged proteins on the gel surface (**Figure 4(b)**). Besides the rapid immobilization, the orthogonal binding scheme permitted to pattern multiple overlapping gradients of any shape on soft gels (**Figure 4(c)**).[67,68]

In summary, biomaterials technology can provide elegant means to precisely control selected biophysical substrate parameters relevant to stem cell biology. A further synergy of material science, microtechnology, and stem cell biology should help to accelerate the identification of new regulatory mechanisms in stem cells *in vitro*.

2.209.4.4. High-Throughput Approaches to Identify Complex Artificial Niche Substrates

As mentioned above, stem cells are influenced by a plethora of different extrinsic signaling cues acting in a spatially and temporally orchestrated manner to control fate. State-of-the-art experimental platforms described above allow modulating just a limited number of these interactions. To overcome this bottleneck in throughput, novel paradigms targeting a more comprehensive, system-level analysis have been conceived (**Figure 3(d)**). For example, robotic spotting technology, conventionally applied to the production of oligonucleotide microarrays, has been adapted to fabricate microarrays of biomaterials or biomolecules (see **Chapter 3.321, Microarrays in Biomaterials Research**). These libraries are arrayed on cell-repellent substrates such that seeded cells cannot migrate

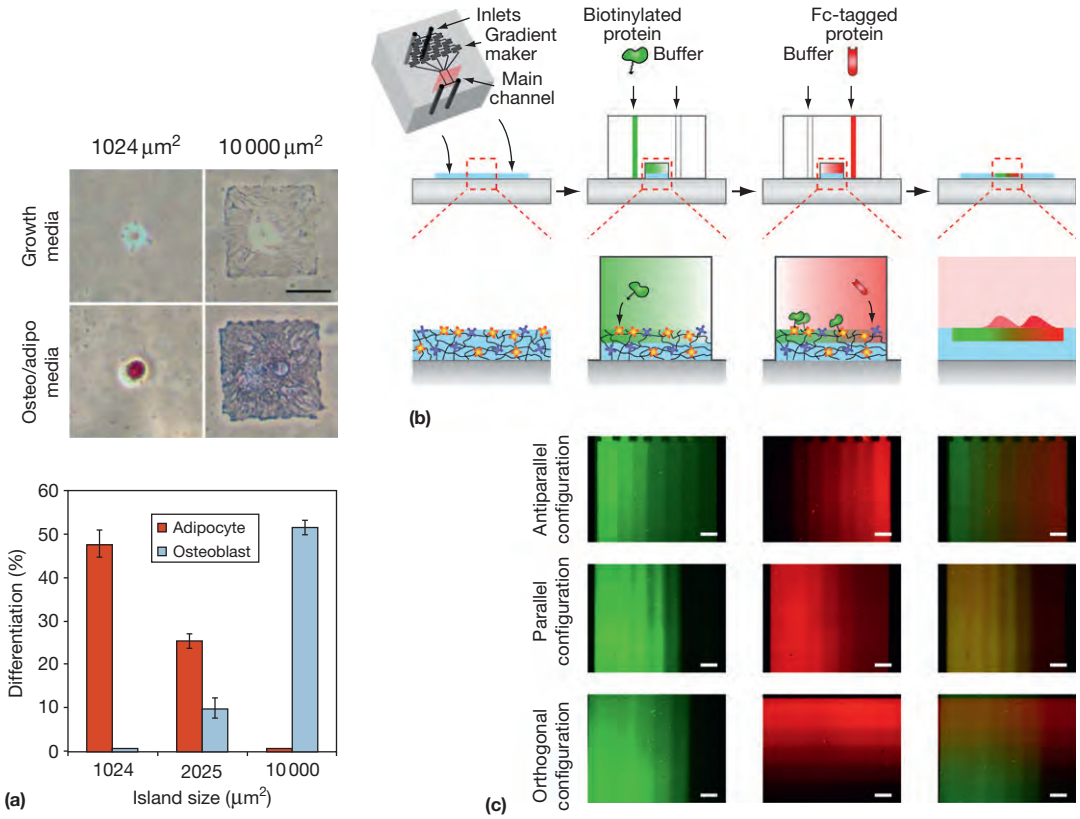

Figure 4 Micropatterning techniques to control the physical properties of the niche. (a) Cell spreading can efficiently be controlled by micropatterning cell adhesive substrates. This approach can confine size or shape of stem cell colonies down to a single-cell resolution. Notably, cell-spreading area can be an effective regulator of the differentiation of MSCs into adipocytes (visualized by a red oil stain) or osteocytes (in blue). (b) Because mixing is limited by diffusion in microfluidics, the merging of two streams, one with a protein and the other without, can yield a graded distribution of the biomolecules across the microchannel. (c) These gradients can be captured on hydrogel surfaces functionalized with capturing groups. Using orthogonal protein-binding systems, overlapping gradients can be produced as occurring during embryonic development. Reprinted with permission from Cosson, S.; Kobel, S. A.; Lutolf, M. P. *Adv. Funct. Mater.* **2009**, *19*, 3411–3419. © 2009 John Wiley and Sons.

between spots and are influenced only by the microenvironment to which they were initially exposed to (Figure 5(a)).

A pioneering study screened 32 combinations of the ECM proteins laminin, fibronectin, and collagen I–IV to induce differentiation of ESC toward an early hepatic fate and for the maintenance of primary rat hepatocytes. Using liver-specific marker genes, these authors observed a more than 100-fold change in gene expression between the least and most efficient protein combination, and identified protein combinations that were active in the regulation of primary hepatocytes and ESC fate.[69] The concept was later extended from ECM proteins to growth factors on arrays with up to hundreds of different microenvironments,[70,71] as well as combination of tethered and soluble regulatory cues.[72] By systematically pairing multiple putative niche signals, these high-throughput strategies allowed, for example, the identification of 'dominant' or 'additive' factors in niche signaling, and the dissection of the effects of growth factors and ECM components (Figure 5(b)).

Intriguingly, the possibility to screen for stem cell-relevant substrates is not restricted to natural niche components, but can be applied to synthetic biomaterials such as polymers. The latter are particularly appealing for the clinical application of stem cells where well-defined, animal product-free culture conditions are required. The robotic fabrication of synthetic polymer arrays, such as those based on acrylate monomers that can be easily polymerized using a light-induced radical initiator,[73] differs only marginally from protein microarrays. A wide range of commercially available monomers with different polarity, chain length, and number of the acrylate groups provides powerful means to diversify the chemical and mechanical properties of the library. Because automated and miniaturized analyses enable the characterization of the chemical and mechanical properties of these arrays in high-throughput, the amount of material can be reduced to a few nanoliters per experiment. The great potential of such a materials microarray approach was demonstrated in the context of maintenance of ECS and iPSC.[73,74] Cell attachment, spreading, and proliferation significantly depended on the chemical and mechanical properties of the substrate and multiple 'hit' polymers were identified that, when coated with human serum or ECM proteins, robustly supported stem cell growth in completely defined media. The ability to characterize the materials properties further allowed the correlation of the frequency of colony formation with the elastic modulus or the wettability of the substrate. For example, polymers with an elastic modulus below 0.2 GPa poorly supported stem cell growth whereas

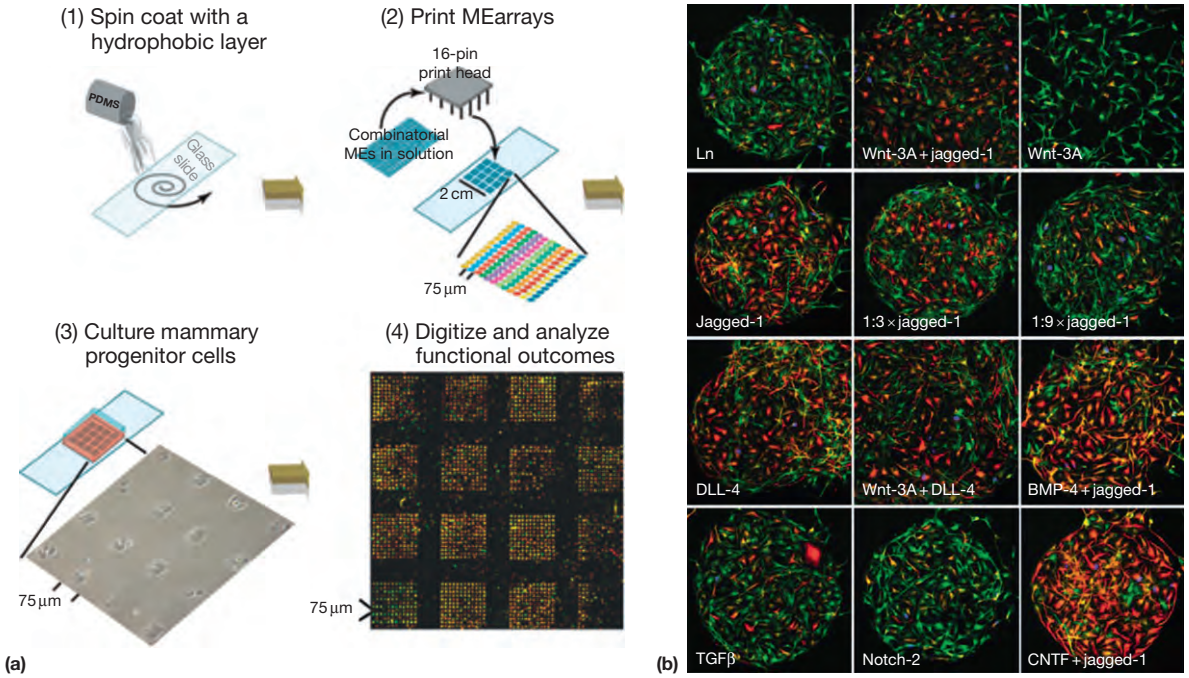

Figure 5 Robotically spotted microarrays for the high-throughput screening of putative niche factors. (a) Protein microarrays are typically fabricated on substrates rendered noncell adhesive with a layer of polydimethylsiloxane (PDMS) or by passivation of glass slides followed by the robotic dispensing of protein mixtures from libraries. The effect of protein combinations on the proliferation and differentiation of stem cells can then be determined by retrospective fate analysis such as immunostaining. softer microenvironments did not significantly increase colony formation efficiency. In addition, a moderate wettability of the surface (contact angle of approximately 70°) was shown to be optimal for stem cell growth over a wide range of elastic moduli, indicating that the contact angle and the elastic properties did not directly correlate.[74] However, despite exciting progress in developing synthetic cell culture substrates by combinatorial chemistry, current biomaterial arrays still rely on a poorly defined coating of spots with proteins such as serum components or fibronectin. Here, the systematic screening of peptide or recombinantly expressed growth factors libraries coupled to materials could be an interesting avenue to move forward.

2.209.5. Topographically Patterned Substrates as Versatile Stem Cell Microenvironments

Most cell culture platforms described above are not amenable to dynamically investigating stem cells at the single-cell level. This could pose a significant problem, as many stem cell populations are highly heterogeneous and information on the behavior of rare stem cells can be masked in bulk cultures. This problem has been solved by the introduction of microwell array cultures for cell biology.[75–82] These modular platforms permit the analysis of a large number of individual, spatially confined cells. They have recently been successfully applied to stem cell biology, on both embryonic and adult stem cells.[77,78,80,81,86–89]

Polymer hydrogel networks such as those formed from PEG are well suited as microwell substrates and offer the advantage to simultaneously and independently assess the effects of biophysical and biochemical properties on stem cell fate at the clonal level, which is often necessary for inherently heterogeneous populations of enriched stem cell populations. Currently available hydrogel cross-linking chemistries and macromolecule architectures can generate a wide range of hydrogels with distinct and reproducible mechanical properties.[90,91] By employing a standard microfabrication technique using PDMS as a replica, it is possible to topographically structure hydrogel arrays to contain thousands of spatially segregated micropatterns such as round microwells with proteins printed specifically at the bottom of each structure.[88] For example, using a hydrogel microwell culture approach in conjunction with time-lapse microscopy, HSC division behavior in response to a panel of soluble and tethered molecules was assessed. Division patterns consistent with depletion (fast symmetric division), asymmetric (asymmetric cell division), and symmetric self-renewal (slow symmetric division) were observed and subsequently assayed *in vivo* with long-term blood reconstitution assays. This study showed that putative niche factors, such as Wnt3a and N-cadherin, could induce HSC self-renewal *in vitro*.[88] Additionally, it corroborates the idea that *in vitro* behaviors can be highly predictive of *in vivo* potential.[87] A similar approach could be applied to any number of stem cell types to identify novel physical and

chemical regulators and the relevant presentation of those molecules to elicit effects on single stem cell self-renewal or differentiation.

2.209.6. Biomaterials Approaches to Emulate Stem Cell Niches in 3D

So far, this chapter has focused on materials as cell culture platforms in which cells are grown on surfaces. This is of course an oversimplification of most native stem cell milieus, as *in vivo* most stem cell types are fully ensheathed within soft and highly hydrated cross-linked 3D networks of proteins and sugars. The exposure to a 2D environment, may – independent of the matrix biochemical features – result in the loss of stem cell functions because of a change in cell shape and polarity imposed by an aberrant substrate. 3D culture systems are believed to overcome this problem and are expected to increase the physiological relevance of artificial stem cell niches. Intriguingly, 3D approaches could allow going beyond the analysis of isolated cells toward a reconstruction and realization of the complexity of multicellular tissue-like constructs.

2.209.6.1. Building a Molecular Toolbox for 3D Artificial Niches

Not surprisingly, because of their inherent biological activity and mild cross-linking conditions, ECM protein-derived hydrogels such as Matrigel™, collagen, or fibrin have been extensively used for 3D stem cell cultures as reviewed elsewhere.[5] However, the biophysical and biochemical properties of these naturally derived matrices cannot be easily tuned and thus it is difficult to create microenvironments for specific stem cell types or to ask questions on the function of specific matrix components. In particular, currently used 3D models do not readily allow modulating matrix properties independently from each other.[92] For example, a change in collagen gel stiffness by increasing or decreasing the precursor content during gelation also alters adhesion ligand density, matrix porosity, degradablility, etc.

These shortcomings have led to the development of entirely synthetic microenvironments offering the intriguing possibility of constructing biophysical and biochemical matrix functionality 'from scratch.' The concept for a generic approach in the creation of such tailor-made 3D matrices is shown in Figure 6.[93] This toolbox concept is built on the mild cross-linking of biofunctional components from an entire array of synthetic building blocks. Proteins or oligopeptides derived from ECM proteins could serve as templates for chemically synthesized or genetically engineered biological building blocks that could be cross-linked via mild reactions using various approaches,[94,95] for example, hydrophilic and completely inert polymers or self-assembling building blocks such as peptides or peptide amphiphiles (see Chapter 2.205, Self-Assembling Biomaterials). Apart from mild reaction conditions for their formation, these 3D artificial niches must fulfill other physiological requirements. For example, dense or highly interconnected polymer scaffolds often suffer from limited nutrient exchange or pose physical constraints impeding cell proliferation, migration, and morphogenesis. To avoid these problems, hydrogel matrix porosity has been engineered in 3D biomaterials such as to allow cell migration.[10] Another approach consists in the design of degradable matrices, which can be achieved either by a chemical mechanism, such as ester hydrolysis, or a cell-controlled mechanism via proteolysis, that is, the incorporation of enzymatically cleavable peptide linkers (see Chapter 1.132, Dynamic Hydrogels). The latter approach is particularly appealing, as the peptide sequences can be engineered to be degradable by selected cell-secreted ECM-remodeling protease (e.g., matrix metalloproteases or plasmin), and thus the 3D matrix degradation becomes entirely controlled by cell-autonomous processes.[93]

The above molecular toolbox concept in synthetic ECM design is currently being exploited to create *in vitro* microenvironments for stem cells to identify the effects of biochemical and biophysical niche components. In an early example, PEG hydrogels were functionalized with adhesion peptide motifs to specifically activate integrins expressed by mouse ESC. In this model system, cells responded to different types and concentrations of adhesion peptides, and a combinatorial stimulation of the integrins $\alpha_5\beta_1$, $\alpha_v\beta_5$, $\alpha_6\beta_1$, and $\alpha_9\beta_1$ was sufficient to maintain ESC pluripotency.[96] By removing individual adhesion peptides, this molecularly well-defined system allow to dissect the influence of specific integrins and their downstream signaling pathways, and thus serves as a good example for this emerging toolbox approach.

2.209.6.2. Toward High-Throughput Screening of 3D Microenvironments

A truly fascinating question in stem cell biology and tissue engineering is just how the numerous signaling components of a stem cell niche could converge to govern cell fate decisions and tissue formation in 3D. This question is difficult to address *in vivo* or by any existing 2D *in vitro* approach, simply because of the complexity of a stem cell niche with the numerous physical, chemical, and mechanical effectors involved. Even if the specific nature of its components were known, testing them systematically would not be possible at the moment. Thus, developing new approaches aimed at high-throughput screening of combinations of 3D microenvironmental variables, in a manner analogous to 2D ECM protein or material microarrays described above, is a major goal.[10] In one of the early examples of this strategy, small-scale screening of cells encapsulated in hydrogels with well-controlled degradation kinetics, type, and concentration of adhesion ligands[97] revealed that MSCs survived and proliferated best in degradable hydrogels with a sufficiently high concentration of adhesion ligands. However, true 3D screening systems need to go beyond this first step of characterizing cell fate, and they also require further miniaturizing of the 3D assay. The latter has been achieved with human MCF7 breast cancer cells that were encapsulated in robotically spotted 20-nl drops of collagen or alginate, similar to 'classical' microarrays.[98] However, although the cells survived the spotting process and could be used for 3D drug testing applications, the spotting of cells is still challenging compared to spotting of biomaterials, because nanoliter samples with encapsulated cells are very sensitive to evaporation. Another challenge is the analysis of cellular responses such as self-renewal and differentiation in 3D, for which one focal plane in microscopic readouts is not sufficient and confocality is required.

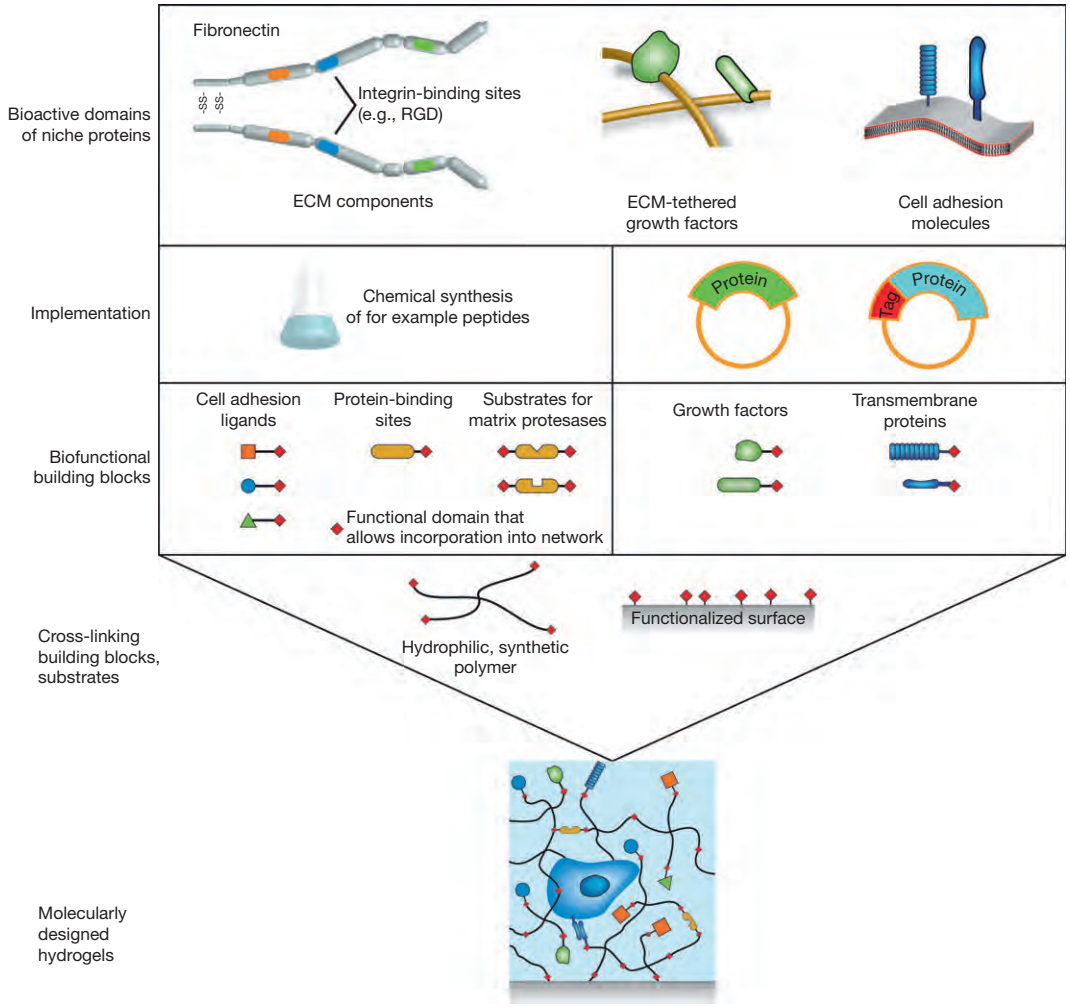

Figure 6 Design strategies for the fabrication of 3D matrices that can recapitulate key components of stem cell niches. Niche proteins or even single domains or peptide sequences thereof are fabricated as bioactive building blocks using chemical means or by recombinant protein expression. These building blocks ideally comprise cell adhesion ligands, proteins, or protein-binding sites such as heparin, and cleavage sites for matrix metalloproteases or other proteases. Synthetic hydrogels can be fabricated by cross-linking these building blocks into 3D hydrogels networks for stem cell culture. The modularity of this approach permits to molecularly engineer the properties of a desired cell culture substrate. Adapted from Lutolf, M. P.; Hubbell, J. A. *Nat. Biotechnol.* **2005**, *23*, 47–55, with permission. © 2006 Nature Publishing Group.

2.209.6.3. 3D-Micropatterning of Artificial Stem Cell Niches and Cells

Another formidable challenge in 3D stem cell culture is the recapitulation of the spatial architecture of niches, as randomly dispersed cells and biomolecules in a 3D matrix do not serve as a good model of native niches with their intricate spatial organization, even in tissues such as the skin or the intestine where stem cells grow on a sheet-like basal lamina providing crucial positional information on the stem cells.[14,16,17] Thus, there is an unmet need for tools to pattern artificial stem cell niches in 3D. The ideal approach should combine the construction of 3D hydrogel matrices with methods to precisely position multiple cell types and biomolecules with a high spatial resolution inside hydrogels (Figure 7).[10,99] This is currently not possible, but encouraging progress is being made.

For example, patterning approaches for biomolecular gradients have been adapted to 3D hydrogels integrated in microfluidic devices.[100,101] In one example, soluble protein gradients were established from microfluidics channels inside of a cell-laden alginate hydrogel, allowing to expose the cells to well-defined gradients of soluble molecules.[100] As proteins can be readily tethered to gel networks, it should be possible to combine tethered and soluble gradients of protein morphogens to mimic the exposure of cells to both ECM-bound and soluble biomolecule gradients, in order to more closely recreate a stem cell niche in 3D.

A powerful alternative to microfluidic technology for 3D hydrogel patterning is the light-controlled patterning of photoreactive moieties within synthetic gels. Using standard confocal laser scanning or two-photon microscopy, researchers have shown that virtually any 3D pattern can be generated in a

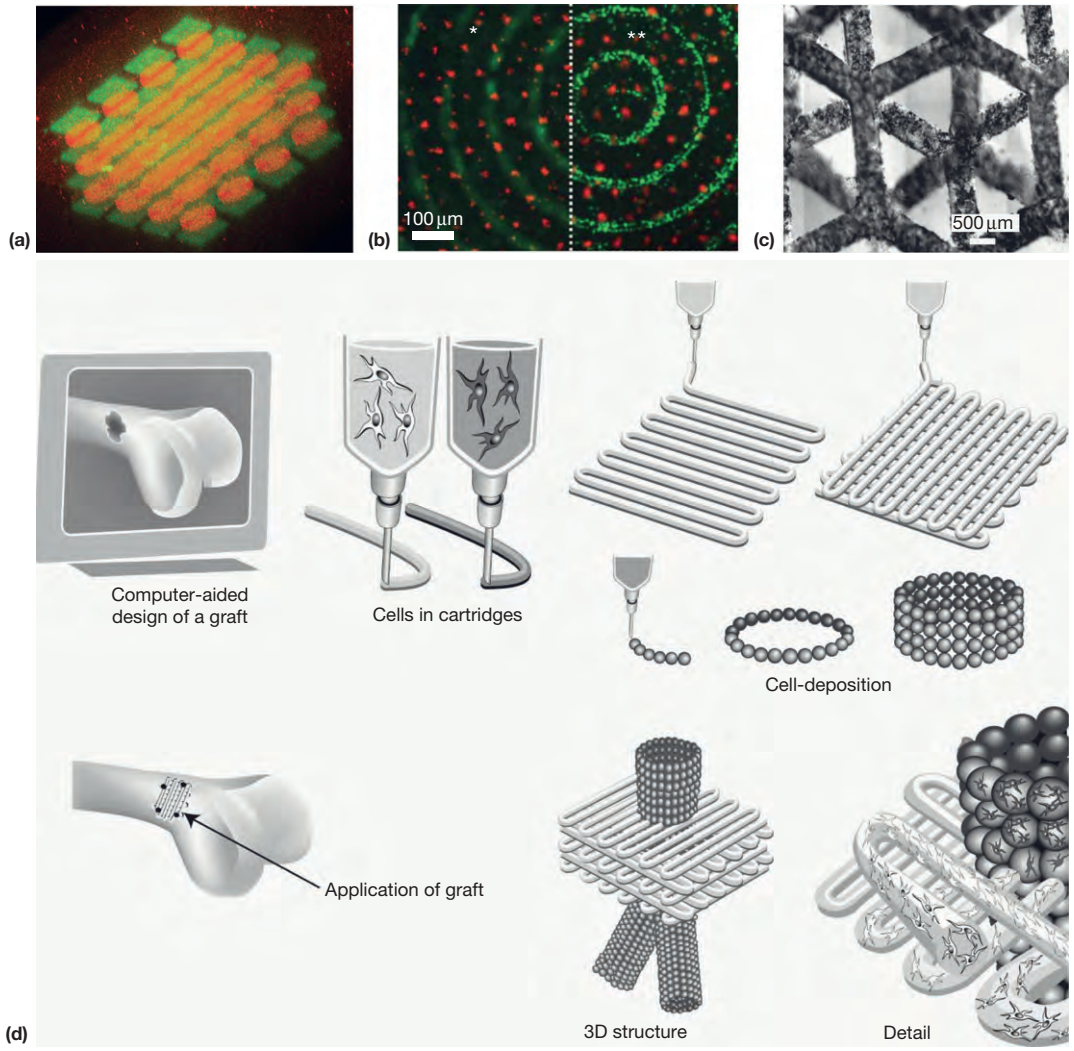

Figure 7 Promises and challenges of 3D micropatterning. Current biocompatible 3D patterning methods allow (a) the patterning of biomolecules with photolabile chemistries (reproduced from Wosnick, J. H.; Shoichet, M. S. *Chem. Mater.* **2008**, *20*, 55–60, with permission. © 2008 American Chemical Society), (b) the patterning of cells for example by using dielectrophoresis (reproduced from Albrecht, D. R.; Underhill, G. H.; Wassermann, T. B.; Sah, R. L.; Bhatia, S. N. *Nat. Methods* **2006**, *3*, 369–375, with permission. © 2006 Nature Publishing Group), or (c) the definition of complex 3D structures via photolithography (reproduced from Liu Tsang, V.; Chen, A. A.; Cho, L. M.; *et al. FASEB J.* **2007**, *21*, 790–801, with permission. © 2007 Federation of American Societies for Experimental Biology). (d) Bioprinting, the dispensing of miniature biological samples using ink-jet technology to assemble complex 3D tissue mimetics, could provide a valuable alternative in the future (reproduced from Fedorovich, N. E.; Alblas, J.; De Wijn, J. R.; Hennink, W. E.; Verbout, A. J.; Dhert, W. J. A. *Tissue Eng.* **2007**, *13*, 1905–1925. © 2007 Mary Ann Liebert, Inc.).

rapid-prototyping-like manner and with a very high spatial resolution (Figure 7(a)).[83,102,103] In addition, these systems permit to dynamically change the properties of a hydrogel, as photolabile groups can be cleaved within hydrogels, in the presence of cells and at any desired time point during an experiment. Accordingly, human MSCs were shown to respond to locally induced changes in matrix stiffness or availability of adhesion ligands. By cleaving a photolabile RGDS peptide, the change of the microenvironment of MSCs could be dynamically modulated and chondrogenic differentiation induced.[103]

The patterning of cells in 3D has also been achieved. For example, microfluidics was used to sandwich cells between two layers of hydrogel[104] or to create multiple hydrogel streams within microfluidic channels.[105,106] An alternative approach is the patterning of cells in hydrogels using dielectrophoresis (DEP) (Figure 7(b)). Cell handling and patterning via DEP is based on the fact that cells migrate when placed in nonhomogeneous electrical field. In combination with photopolymerization, DEP was used to construct gels with precisely 3D-patterned cells.[84,107] A caveat here could be the potential toxicity of some DEP buffers and the heat generated during DEP patterning, which would limit the use of this technique to relatively robust cells.[107,108]

2.209.6.4. Toward Constructing Tissue Models

3D hydrogel patterning has also been applied to fabricate artificial tissue models. For example, micromolding of collagen gels allows a precise control of the initial geometry of multicellular epithelial cell aggregates that have

morphogenetic potential.[109] These constructs can be induced to undergo a geometry-dependent epithelial-to-mesenchymal transition, occurring preferentially at the corner of the tissue mimetic. Using multilayered photolithography, another group fabricated artificial hepatic tissues that mimicked the 3D anatomy of the liver. The obtained mesh-like structure of the construct enhanced the performance of seeded cells, presumably by facilitating the perfusion and the nutrient exchange (**Figure 7 (c)**).[85] These are exciting advances, but the layer-by-layer assembly of hydrogel structures and cells is relatively complicated and has limited spatial resolution, problems that could potentially be overcome by the application of printing technologies of cells and soft biomaterials. Emerging 'bioprinting' approaches envision the application of custom-designed inkjet printers to deposit picoliter droplets of biomaterials precursors, containing cells and regulatory cues, into 3D constructs with high spatial resolution. Using computer-assisted designs (CAD) software, any type of cellular and materials architecture could in theory be assembled. Bioprinting is fast, as droplets can be printed at a frequency of several thousands of droplets per second, and allows to fabricate relatively large constructs (**Figure 7(d)**).[99,110] Although this technique has already been applied to a wide range of cell types and biomaterials,[110] only a few applications of bioprinting in stem cell biology have been reported.[111] One difficulty has been the lack of a 'bioink,' a hydrogel precursor which can rapidly polymerize and has cell-instructive characteristics to foster morphogenesis.[110] However, if these hurdles can be overcome, the *de novo* construction of complex artificial niches and tissue models with precisely patterned stem cells and their microenvironments should become possible.

2.209.7. Conclusions

The application of biomaterial engineering to stem cell biology offers many tantalizing possibilities to manipulate stem cell fate *in vitro* or *in vivo*. The rate at which biomaterial approaches are being applied to address questions in stem cell biology assures new insights into the mechanistic regulation of stem cell fate. In particular, much can be learned from studies using artificial niches that allow expansion of functional adult stem cells such as HSC as well as more efficient differentiation of ESC and iPSC toward specific lineages. However, although a plethora of ingenious biomaterial platforms to deconstruct the influence of stem cell niche biophysical and biochemical properties have been developed already, their application to direct stem cell fate remains in its infancy. True collaborative efforts between cell biologists and material scientists, as well as a new generation of bioengineers with in-depth training in both engineering and biological disciplines, are critical to move stem cell biology one step closer to the clinic.

Glossary

Angiogenesis The physiological process by which blood vessels are formed.

Apoptosis The process by which cells die in response to a variety of stimuli in a controlled, regulated fashion, and is often referred to as programmed cell death.

Cytokine A signaling molecule, such as a protein or peptide, which is secreted by immune cells to regulate the activity of other biological cells.

Differentiation The process by which a biological cell alters its size, shape, membrane potential, metabolic activity, and gene expression in response to signals to become a more specialized cell.

Hematoma A collection of blood within a body tissue in response to injury of a blood vessel.

Hematopoietic stem cell An unspecialized cell from the blood or bone marrow that can renew itself and differentiate to a variety of specialized cells.

Mesenchyme Mesenchyme is loose reticular connective tissue which is derived from all three germ layers and located within the embryo.

Morphogenesis A biological process that causes a tissue or organ to develop its shape by controlling the spatial distribution of cells during embryonic development.

Morphology The form or shape of an organism (i.e., cell, tissue, organ).

Osteogenesis The term used for the biological process by which osteoblasts produce bone tissue.

Abbreviations

BMD	Bone mineral density
BMU	Basic multicellular unit
ECM	Extracellular matrix
MSCs	Mesenchymal stem cells
NCPs	Noncollagenous proteins
OPG	Osteoprotegerin
OVX	Ovariectomized
PTH	Parathyroid hormone
RANK	Receptor for activation of nuclear factor kappa B
RANKL	Receptor for activation of nuclear factor kappa B ligand
μCT	Micro-computed tomography

2.210.1. Introduction

The skeletal system gives the body its structure, provides support for the heart and lungs, protects internal organs, such as the brain, kidneys, and uterus, and facilitates movement by acting as a system of kinematic links to which muscles can attach. Bone tissue is the primary structural element that forms the skeletal system. It is an exceptional material that is lightweight to allow efficient movement but also exhibits excellent strength and stiffness. This unique mechanical behavior is imparted by a composite material of organic proteins and mineral crystals, which are intricately organized on many scales to create the material properties that allow bone to serve these functions under the variety of loading conditions experienced during everyday activities.[1] Furthermore, healthy bone is a living, growing, dynamic material that has the capacity to renew itself, and adapt its architecture, so that it can maintain strength and continue to serve its functions throughout life. This adaptive behavior is facilitated by specialized biological cells from bone surfaces and marrow that continuously digest aged or damaged bone and reform new bone tissue in its place. During normal physiology, bone cells can also repair fractures that occur. Each of these characteristics is fundamental to the normal physiological function of bone tissue and is discussed in detail subsequently.

2.210.2. Bone Composition

Bone tissue is a porous composite material, consisting of a mineral phase and an organic phase. The organic phase comprises approximately 35% of the total mass of bone, of which 90% is a collagen matrix and the remainder is composed of other noncollagenous proteins (NCPs), water lipids, and cells. The mineral phase of bone is composed mainly of calcium and phosphorus in the form of hydroxyapatite crystals and accounts for approximately 25% of the total bone volume and 50% of the bone mass. The structure and mechanical behavior of bone is determined by the quantity and mechanical integrity of each of these phases, the structural organization of the different phases, and the physical interaction between them.

2.210.2.1. Collagen

Collagen is a ubiquitous constitutive protein that forms the fundamental matrix upon which all connective tissues are assembled. Its primary function is to provide structural integrity and shape to biological tissues. The tropocollagen molecule is the basic structural unit of collagen and comprises three polypeptide strands (α-chains), which are twisted together into a right-handed coiled coil known as a triple helix (Figure 1(d)). In bone tissue, tropocollagen molecules are synthesized by osteoblast cells during the initial phase of bone formation (Section 2.210.3). The formation of tropocollagen initiates when the polypeptide chains are produced by the nucleus of osteoblast cells (Figure 1(a)). Next, these chains are modified in the endoplasmic reticulum of the osteoblast when enzymes (proteases) break the peptide bonds between amino acid side chains (proline and lysine) of the polypeptide. This process is known as proteolytic cleavage (Figure 1(b)). These chains are

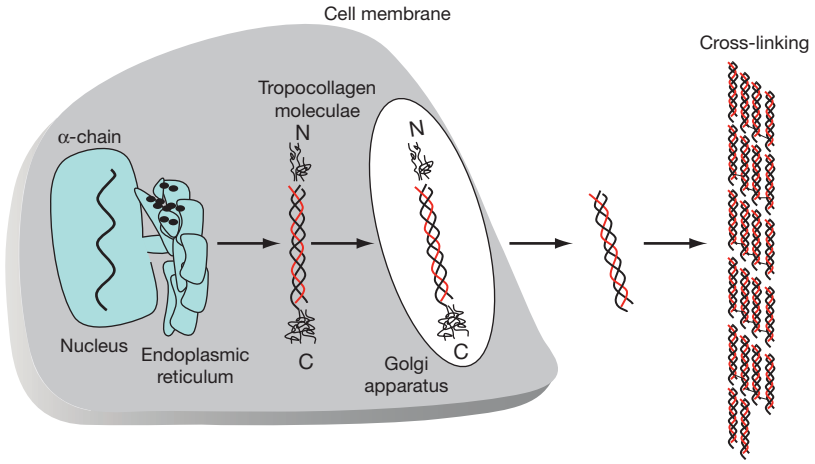

Figure 1 Intracellular synthesis and assembly of type I collagen in the osteoblast (a–c) and extracellular formation of collagen fibrils (d–e).

assembled into a triple-helix tropocollagen structure that is stabilized by hydrogen bonds. Within the space at the center of the triple helix, there is a repeating amino acid sequence consisting of glycine molecules and amino acids (e.g., proline and hydroxyproline). This process produces triple-helical collagen molecules that are approximately 1.5 nm in diameter and 300 nm long and have short nonhelical regions called telopeptides at each end, known as amino (N) and carboxyl (C) telopeptides, which facilitate later assembly into fibrils. The tropocollagen molecules are processed and packaged in the Golgi apparatus (**Figure 1(c)**) and then secreted to the extracellular matrix (ECM) in the form of soluble precursors called procollagens (**Figure 1(d)**). During secretion, the propeptides are removed by procollagen N and C proteinases, and this triggers these molecules to aggregate together extracellularly and assemble to form collagen fibrils (**Figure 1(e)**). Intermolecular cross-links are formed between the nonhelical domains and the helical domain of adjacent collagen molecules. These molecules are staggered from each other at a space of approximately 67 nm in fibrillar collagen.[2] The newly formed collagen fibers are stabilized by the formation of covalent cross-links between neighboring collagen molecules. Immature ketomine and aldimine cross-links are first formed, which contribute to the later formation of mature pyridinium or pyrrole cross-links. Together, these cross-links result in fibril formation, and these fibrils act as a scaffold for bone minerals and provide strength[3,4] and are responsible for the postyield behavior of bone tissue.[5]

There are more than 27 forms of collagen in biological tissues and each type is distinguished by roman numerals (e.g., Types I, II, III, V, and XI). The differences between each form of collagen lies in the manner in which the tropocollagen molecules and fibrils are arranged. Depending on the collagen type, the triple helix can be homotrimeric, that is, comprising three identical α-chains (e.g., type III collagen), or heterotrimeric, whereby at least one of the polypeptides is not identical to the others (e.g., type I collagen). The collagen in bone is primarily type I collagen ($[\alpha1(I)]_2\alpha2(I)$), which comprises 95% of the collagen content and 80% of the total proteins present in bone,[6] but types III, IV, and VI are also present.[7,8] In contrast to ligament and tendon, where fibrils are arranged in parallel bundles, the collagen fibrils in bone are arranged concentrically into packages known as lamellae (**Section 2.210.4.1**). Collagen fibers within the same lamella are parallel to one another (**Figure 2(a)**), whereas collagen fibers in adjacent lamellae may be oriented at an angle of up to 90° relative to each other (**Figure 2(b)**). It is through the intricate arrangement of collagen molecules at the nanoscale and fibrils at the microscale that collagen provides tensile strength, elasticity, and toughness (capacity to absorb energy) to bone.[9] Collagen forms the basis of immature bone tissue (osteoid) and acts as a template upon which proteins and mineral crystal are deposited[10] and are interspersed in the spaces between molecules and between adjacent fibrils (**Figure 3(a)**).

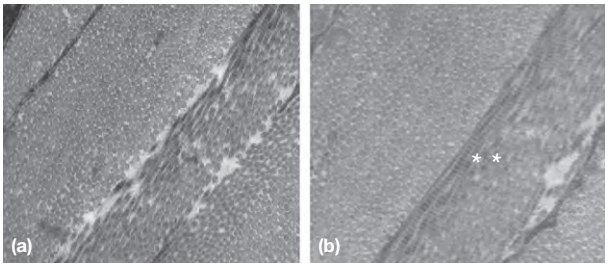

Figure 2 Transmission electron imaging of collagen fibrils in bone tissue: (a) collagen fibrils are oriented parallel to each other and (b) collagen fibrils in adjacent lamellae are oriented at an angle to each other (** indicates interface between lamellae).

2.210.2.2. Mineral

The mineral component of mature bone tissue consists of small crystals of impure hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$) that are bound within and between the collagen fibrils in an ordered manner. This mineral is produced by osteoblast cells on the calcification front after the organic matrix is deposited, when calcium and phosphate ions bind in the presence of NCPs. These cells also regulate the binding of circulating calcium and phosphorus to the ECM. Over time, the size of the mineral particles increases slowly (secondary mineralization) so that within 5–10 days the matrix is 70% mineralized. Complete mineralization at any site takes between 3 and

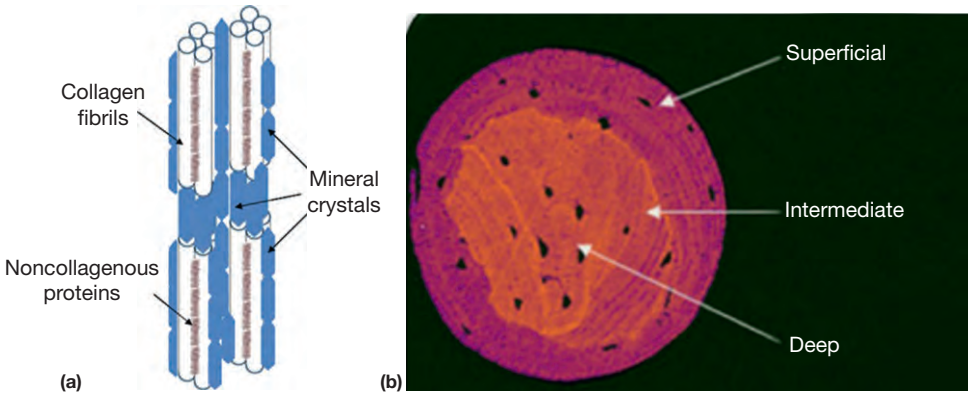

Figure 3 (a) Distribution of mineral and noncollagenous proteins within and between collagen fibrils and (b) color-enhanced image depicting variation in tissue mineral content with age; mineral content is lower in the superficial region.

5 months,[11] and mineralization of the entire skeleton does not occur for years. The mineral crystals are located within and between the spaces between collagen fibrils (**Figure 3(a)**) and are approximately 0.5 μm in length and have a thickness of 0.03 μm. The distribution and growth of these minerals, as well as their orientation, is governed by the structure and spatial limitations of the underlying collagen matrix,[12] which interacts with the mineral crystals.[13] Some proteins can inhibit crystal formation by binding to specific surfaces, blocking potential nucleation sites and thereby decrease crystal length.[14] Changes in local ionic concentration can also influence the rate of mineral deposition.[15] Together, these events regulate the formation of inorganic mineral crystals at distinct sites within bone tissue, which are aligned in the same orientation as the collagen fibrils.[11] The osteoid seam is a thin layer of unmineralized organic matrix that remains at the interface between newly formed osteoid and mineralized bone prior to mineralization of newly formed matrix.

The degree of bone tissue mineralization is vital for mechanical integrity of the skeleton, its load-bearing strength, and its stiffness.[1] The quantity of bone mineral varies considerably from different skeletal regions, within an individual, and from person to person; in particular sex, race and age-dependent differences have been reported.[16,17] The overall mineral content of bone tissue increases with age by an average of 5–10%,[18] but after 60 years of age, it has been shown to decrease again in males and females.[19] Such changes alter the stiffness and strength of bone tissue.[20] At high mineral contents, bone tissue becomes brittle and allows cracks to propagate easily, leading to a reduction in toughness and impact strength.[1,19] Genetic disorders that lead to defects in the underlying collagen structure can result in an altered mineral composition (**Section 2.210.7**).

2.210.2.3. Noncollagenous Proteins

There are many NCPs in the ECM of bone and these comprise approximately 10% of the entire bone by mass. The most prominent proteins are osteocalcin, osteopontin, alkaline phosphatase, fibronectin, bone sialoprotein, osteoprotegerin (OPG), osteonectin, and thrombospondin. These proteins fulfill numerous functions, including organizing the collagenous matrix, mediating cell attachment, regulating the rate of growth, and regulating the stability of the mineral phase crystals,[21] as is outlined in detail subsequently.

Osteocalcin, also known as bone gla protein (BGP), constitutes 20–25% of noncollagen bone protein and is ubiquitous in bone tissue. It is produced by osteoblast cells and binds to the calcium of hydroxyapatite to regulate the growth of mineral crystals in bone.[22] In particular, it is believed to be able to slow down the growth of HA crystals and thereby act as a mineralization inhibitor.[23] Other studies propose that osteopontin may act as a signal to osteoclast precursors to begin differentiating into mature osteoclasts and initiate the process of bone resorption.[23–25]

Osteopontin is a phosphorylated protein that is found in abundance in cement lines, in the spaces between mineralized collagen fibrils, and along the canalicular wall.[26–29] It mediates cell attachment by binding cell surface integrin receptors. Therefore, it is believed that osteopontin acts as a regulator of osteoclast activity during bone resorption.[25] It is able to influence cell dynamics, and it is proposed that it may also promote adhesion between opposing surfaces at cement lines in bone.[27] Furthermore, it has been proposed that osteopontin might facilitate osteocyte mechanical sensing[30,31] by binding the ECM to an integrin receptor ($\alpha_v\beta_3$) that is present along osteocyte cell processes.[30] In the absence of osteopontin, the response of bone to underloading is altered.[31] Osteopontin also plays an important role in the formation of new blood vessels (angiogenesis) and prevents apatite formation and growth because of its high affinity for apatite crystals.[14]

Thrombospondin is a protein that is synthesized by osteoblasts[32] during the early stages of bone formation and as such is ubiquitous in unmineralized osteoid.[25] Bone sialoprotein is a member of the small integrin-binding ligand, N-linked glycoproteins family (SIBLING proteins) that is produced by osteoblasts at a late stage of maturation. The protein codistributes with osteopontin and accumulates in cement lines and interfibrillar collagen spaces.[28] Fibronectin is an ECM glycoprotein that is relatively abundant in bone tissue. Thrombospondin, bone sialoprotein, and fibronectin – all mediate binding of osteoblasts to the collagen, mineral, and other proteoglycans in bone tissue.[22] Bone sialoprotein is also believed to act to promote the mineralization process,[25] whereas fibronectin regulates the differentiation of osteoblasts.[33]

Alkaline phosphatase is an enzyme glycoprotein that is produced by osteoblasts during the early stages of bone formation. It functions to remove phosphate groups (hydrolyze) from mineral deposition inhibitor proteins[34] and thereby provides an initial attachment site for mineral nucleation along the collagen fibrils and is vital for increasing local phosphate concentration.[15]

OPG, also known as osteoclastogenesis inhibitory factor (OCIF), is a cytokine that is a member of the tumor necrosis factor (TNF) receptor superfamily.[35,36] It is believed to play a role in inhibiting the formation of mature osteoclasts by blocking the binding of receptor for activation of nuclear factor kappa B ligand (RANKL) to RANK.[37] Therefore, the primary role of OPG is to act as a regulator of osteoclastic bone resorption.[36]

Osteonectin is the most abundant NCP in mineralized bone matrix. It contains calcium-binding domains and plays a role in regulating the bone mineralization process.[22] It also binds varyingly to collagen, and it has been shown to play roles in regulating the cell cycle, cell–matrix interactions, and cell morphology.[25]

It has long been established that many proteins regulate matrix organization by acting as mineral crystal nucleation sites that bind mineral crystals to the collagen matrix.[38–41] The proteoglycans have a high negative fixed charge density and readily bind to Ca^{2+} ions. They are also known to play an important role in facilitating cell attachment[42] and thereby regulate cellular activity and maintenance of the collagen–mineral interface. They are believed to be responsible for regulating the mechanical properties of the collagen–mineral interface between modulating the formation of bonds between collagen and mineral.[21] Recent studies now suggest that NCPs form tough bonds between the mineralized fibers[42,43] and that these bonds have molecular self-healing abilities.[44,45] Interestingly, *in vitro* studies have shown that these bonds may have both energy dissipation[42] and energy storage capabilities.[42,43] There are substantial local variations in the content and

distribution of bone proteins,[28] and it has been proposed that such compositional differences may influence cell dynamics and remodeling.[46] Therefore, collectively, the NCPs in the bone are important for regulating the mechanical strength of the bone by several different means.

2.210.2.4. Bone Cells

Bone tissue is made and maintained by cells of the osteogenic and phagocytic lineage. There are five main types of bone cells in bone tissue osteoprogenitors, osteoblasts, osteocytes, osteoclasts, and bone-lining cells, each of which are crucial for bone growth, healing, and remodeling. Osteoprogenitors, osteoblasts, and osteocytes are responsible for the production of bone matrix and mineral, whereas osteoclasts and bone-lining cells are fundamental for the maintenance of this tissue throughout life. Each cell type has a different internal structure, they interact varyingly with their external matrix, and these differences play a large role in dictating the different physiological functions of these bone cells and more importantly, the unique behavior of the bone as a material.

2.210.2.4.1. Mesenchymal stem cells and osteoprogenitors

Mesenchymal stem cells (MSCs) are unspecialized multipotent cells that have the potential to mature into various cell types. MCSs are present in the primary cells of the embryo (germ layers) and are responsible for early skeletal development, but they also persist in mature adult bones where they are found in the periosteum, endosteum, and bone marrow (**Figure 4(a)**). The MSC has a basic cell morphology characterized by a small cell body, comprising a large, round nucleus with a prominent nucleolus that is surrounded by finely dispersed chromatin particles, a Golgi apparatus, a rough endoplasmic reticulum, mitochondria, and polyribosomes. Within the cytoplasm, there is a three-dimensional (3D) network of proteins known as the cytoskeleton, which consists of microtubules, intermediate filaments, and actin filaments that extend across the entire cytoplasm and are oriented in parallel.[47] The cytoskeleton dictates the morphology and shape of cells, and MSCs extend their cytoplasm into the surrounding matrix in which they reside by means of cell processes. At the beginning of the bone formation process (osteogenesis), MSCs proliferate to form a dense nodule of cells and differentiate to become osteochondral progenitors (osteoprogenitors) under the influence of growth factors, cytokines, and physical stimuli. Osteoprogenitors are cells that have committed to differentiating along the osteochondral lineage, and from this stage onward, they only have the ability to differentiate into chondrogenic (cartilage) or osteogenic (bone) cells. Morphologically, osteoprogenitors have large cell bodies, with more Golgi apparatus and rough endoplasmic reticulum than MSCs and do not have cell processes. The question whether or not they ultimately become chondroblast or osteoblast cells is dependent on the presence of growth factors and the surrounding physical environment. Bone morphogenetic proteins (BMPs), fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), and transforming growth factor beta (TGF-β) are believed to promote the division of osteoprogenitors and increase differentiation along the osteogenic lineage to become osteoblasts.

2.210.2.4.2. Osteoblasts and bone-lining cells

Osteoblasts are the bone cells that are primarily responsible for synthesizing bone matrix proteins and minerals during early bone formation in the embryo, but also control bone formation and mineralization throughout life. They are found in areas of high metabolism where new bone formation is occurring. They have differentiated from either osteoprogenitors in the mesenchyme of the embryo or osteoprogenitors near bone surfaces in mature bone to become cuboidal, columnar cells that have a large Golgi apparatus, a rough endoplasmic reticulum, and a central nucleus[50] (see **Figure 4(a)** and **4(b)**). During embryonic bone formation, osteoblasts secrete collagen and NCPs that act as a template for the bone, but also produce minerals and regulate the precipitation and binding of minerals from the blood to the newly formed osteoid to facilitate the formation of a mature mineralized bone tissue and regulate the flux of ions into the extracellular environment during mineralization. Osteoblasts also function throughout life to produce new bone that is required to replace aged or damaged bone (**Section 2.210.6.2**) or repair bone fractures (**Section 2.210.6.3**). The formation period typically persists for about 100–150 days.[49] Osteoblasts express a range of genetic markers and synthesize various proteins, including type I

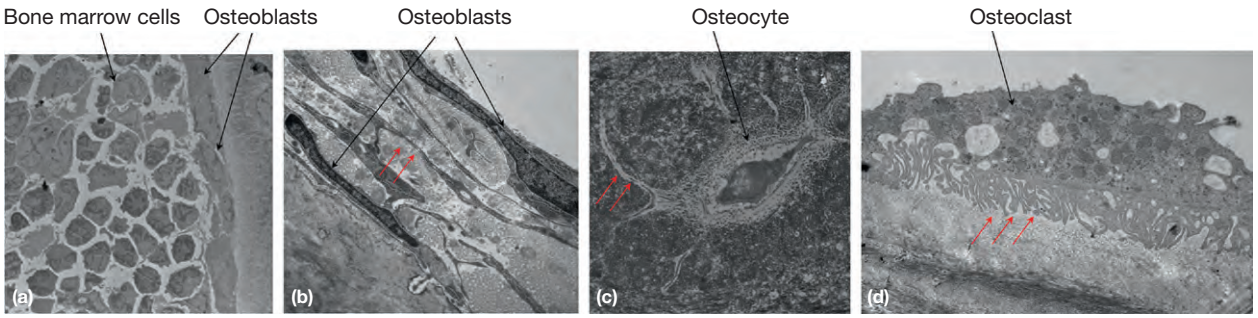

Figure 4 Transmission electron microscopy images of bone cells: (a) bone marrow cells containing blood cells, platelets, and progenitor cells and osteoblasts lining the bone surface; (b) osteoblasts on the surface become embedded in newly formed osteoid and develop cytoplasmic cell processes (↑↑) as they differentiate into osteocytes; (c) osteocyte embedded in bone cells with cytoplasmic cell processes encased in bone canaliculi (↑↑); and (d) osteoclast cells with ruffled border (↑↑↑) and multiple nuclei.

collagen, bone sialoprotein, macrophage colony-stimulating factor (M-CSF), RUNX2, alkaline phosphate, osteocalcin, osteopontin, and osteonectin. The mode of differentiation, recruitment, and inhibition of osteoblasts is controlled by numerous hormonal and growth factors,[48] including vitamin D, estrogen, and parathyroid hormone (PTH). Estrogens and PTH can increase the number of osteoblasts, which subsequently increases collagen production. Vitamin D also plays a part in the mineralization of bone matrix, and a lack of vitamin D results in osteomalacia (impaired mineralization). Osteoblasts have the ability to communicate with neighboring cells and osteocytes via gap junctions, and they secrete factors that activate osteoclasts (RANK ligand).

After osteoblasts have produced newly formed osteoid, a certain amount of the cells become encased in this matrix and differentiate to become osteocytes distributed throughout the bone matrix. Those that are not embedded remain on the new bone surface as quiescent osteoblasts, known as bone-lining cells, or undergo apoptosis (programmed cell death). Bone-lining cells have similar morphology to that of osteoblasts and serve to regulate the movement of calcium and phosphate into and out of the bone and provide access for osteoclasts during bone resorption.

2.210.2.4.3. Osteocytes

Osteocytes are the most mature and abundant cells in bone tissue and are formed when some osteoblasts become embedded in their secreted osteoid and begin to extend cytoplasmic cell processes to interconnect with each other (**Figure 4(b)**). During this time, the cells begin to differentiate into osteocytes and alter their morphology, their anabolic activity, and lose much of the organelle of osteoblasts. Mature osteocytes reside in a fluid-filled space in the ECM known as a lacuna and have a large nucleus, very little cytoplasm, and extend many elongated processes into their ECM (**Figure 4(c)**) to facilitate communication with other embedded osteocytes, bone-lining cells, and osteoblasts. These cell processes reside in fluid-filled channels known as canaliculi, which radiate from the osteocyte lacunae to the osteonic (haversian) canal to provide passageways for nutrient supply through the impermeable matrix.[11] The cell body and processes are surrounded by a glycocalyx,[50] and the cell processes are attached to the ECM by means of punctate integrin-based attachments.[30] The cells are distributed throughout the ECM at a spacing of approximately 1600 mm^2.

Osteocytes play an important role in controlling the extracellular concentration of calcium and phosphate in bone tissue over time, by means of a process known as secondary mineralization whereby they control the growth in the crystal size of mineral.[51–53] Some studies also suggest that osteocytes might be capable of controlling calcium release from the bone tissue to the blood in a process known as osteocyte osteolysis, although this theory remains contentious.[54] It is also believed that osteocytes play an integral role in sensing mechanical signals and transducing these into biochemical signals to osteoclasts and osteoblasts to alter bone mass.[55–57] Their ubiquitous spatial distribution throughout the bone and their extensive communication network is ideal to facilitate intercellular communication. It is by this mechanism that they communicate the requirements for adaptation of the skeleton under altered mechanical demands or repair due to damage. Osteocytes also have the ability to sense changes in interstitial fluid and the levels of hormones that circulate in it[58] and stabilize bone mineral by maintaining an appropriate local ionic environment.[11] It has been shown that osteocytes secrete large amounts of factors known to stimulate osteoclast resorption (M-CSF, RANKL) along their cell processes.[59] The activity of the cells is governed by estrogen, PTH, glucocorticoids, vitamin D, calcitonin, and prostaglandin.[60]

2.210.2.4.4. Osteoclasts

Osteoclasts are derived from precursor stem cells of the macrophage lineage, known as bone marrow stromal cells or monocytes, which reside in the hematopoietic bone marrow.[50] The primary function of the osteoclast is to digest aged, damaged, or disused bone during the physiological processes of modeling and remodeling. This process is known as bone resorption and begins when bone-lining cells degrade unmineralized osteoid and increase expression of growth factors to recruit preosteoclasts from the bone marrow. Under the influence of cytokine and growth factors, the monocytes fuse and differentiate to form mature active osteoclasts that have multiple nuclei and a large cytoplasm (**Figure 4(d)**) that has many vesicles and vacuoles.[61] The mature osteoclast attaches to bone surface via integrin-based attachment proteins, which involves binding of the integrin $\alpha_v\beta_3$ to vitronectin, to form a specialized cell membrane known as the ruffled border (**Figure 4(d)**). This membrane seals off the resorption site of the underlying matrix, and it is through this membrane that hydrogen ions and enzymes are secreted to acidify and dissolve the calcium and phosphate minerals in the matrix and thereby facilitate bone resorption. The function of the ruffled border is to maximize the surface through which hydrogen ions are released. The digested material is absorbed into small vesicles and these are released into the extracellular fluid as waste products. After resorption, osteoclasts undergo apoptosis.

Osteoclast differentiation and function is controlled primarily by three factors: M-CSF, RANKL, and OPG. M-CSF is produced by osteoblasts and is required for survival and differentiation of osteoclast precursors. RANK is a receptor that is present on the surface of osteoclast precursor cells. RANKL is expressed on the surface of osteoblasts and lining cells and binds to RANK, which leads to the differentiation and maturation of the osteoclast precursor into mature multinucleated osteoclasts. OPG is made by osteoblasts and blocks both osteoblasts formation and bone resorption. Osteoclast recruitment and differentiation is also governed by hormonal and growth factors[48] including estrogen, vitamin D, and PTH. Estrogen's effect on osteoclasts is inhibitory; estrogen activates osteoclast receptors to decrease formation of mature osteoclasts[62] and increases osteoclast apoptosis.[63] Vitamin D and PTH can increase the recruitment and activity of osteoclasts, stimulating bone resorption and resulting in an increase in blood calcium levels. Other growth factors and cytokines also regulate osteoclast activity: TNF-α, the interleukin cytokines (IL-1, IL-6, IL-7), TGF-β, vascular endothelial growth factor (VEGF), PDGF, and FGF.[64–66] As a result, the osteoclast resorption process is sensitive to hormonal status and drug treatments.

2.210.3. Bone Formation

During embryonic development, bone formation occurs by two distinct mechanisms; either endochondral ossification or intramembranous ossification. Bone formation also persists throughout life to alter the geometry of bones and provide larger bones that are sufficient to withstand changes in mechanical loading (modeling), or to replace aged or damaged bone (remodeling) or fill fracture gaps (Section 2.210.6). Bone formation is typically a two-step process whereby an organic matrix (osteoid/cartilage template) is initially laid down by osteoblasts, and then mineral crystals are precipitated and grow slowly over time to produce the composite material.

2.210.3.1. Endochondral Ossification

Endochondral ossification is the process by which bone tissue is formed in early fetal development. It begins when MSCs start to produce a cartilage template of long bones, such as the femur and the tibia, upon which bone morphogenesis occurs.[67] The process initiates when MSC cells differentiate to become chondroblast cells (Figure 5(a)) and form a membrane around the template known as the perichondrium. This template grows in length (interstitial growth) and thickness (appositional growth) when the chondroblasts proliferate or more chondroblasts are recruited from the perichondrium (Figure 5(b)). Together, these cells secrete an ECM comprised mainly of collagen and proteoglycans. Over time, these chondroblasts differentiate to become chondrocytes and begin to secrete alkaline phosphatase, which is an enzyme that acts as a nucleator for deposition of minerals on the template. They also secrete growth factors to promote the invasion of blood vessels into the perichondrium, which is known as vascularization. This process forms the outer membrane of the bone, which is primarily a dense irregular connective tissue known as the periosteum (Figure 5(c)). The periosteum is an important source for undifferentiated osteoprogenitor cells.[68] It is divided into an outer fibrous layer, which is a source for fibroblasts, and an inner osteogenic layer, which is a source for osteoprogenitor cells that develop into osteoblasts. The periosteum also provides sites for attachment for ligaments, tendons, and muscles. This process begins in the middle of the template, which is known as the primary center of ossification (Figure 5(c)). During mineralization, the chondrocytes undergo apoptosis and the cavities that remain are invaded by blood vessels from the perichondrium. These blood vessels are a source for hemopoietic cells that form the bone marrow and osteoprogenitor cells, which differentiate to become osteoblast cells and secrete bone proteins and minerals. Endothelial cells (ECs) on the lining of blood vessels produce essential growth factors that control the recruitment, proliferation, and differentiation of osteoblasts.[69] Therefore, vascularization is an essential requirement for bone formation.[68,70] A number of other factors regulate the formation of blood vessels, including oxygen tension, mechanical loading, nutrients, and growth factors.[71] Osteoclasts are also recruited during this time to remodel the template and form a cavity for bone marrow (medullary cavity), and together, these events provide the first bone tissue during fetal development. At birth, a secondary ossification center appears in the epiphyses of long bones, which is vascularized and forms a cartilage layer known as the growth plate (Figure 5(d)).

The formation and growth of bones is ongoing throughout childhood and is regulated by the epiphyseal or growth plate (Figure 5(d)), which continues to produce new cartilage, which is replaced by bone, and thereby facilitates lengthening of bones. In adults, lengthening of bones stops and the growth plate fuses and is replaced by bone, known as the epiphyseal line. Bones can continue to grow in diameter around the diaphysis by deposition of bone by osteoblasts beneath the periosteum, and simultaneously osteoclasts on the interior surface (endosteum) resorb bone to maintain a lightweight structure. The coordinated process of endochondral ossification is essential to the development and growth of long bones of the body, but also regulates fracture repair, as is discussed in Section 2.210.6.3.
