such as remembering to perform a task ("prospective memory"), finding misplaced objects (which may reflect attention or organizational skills rather than memory per se), and remembering recent events or newly acquired information ("episodic memory"). Even when the concern is narrowed down to episodic memory, it is important to distinguish between a range of underlying memory-related tasks or processes, including difficulties with initial learning or encoding information or difficulties efficiently retrieving information, and actual loss of the memory trace. Results from standardized memory tests are invaluable in making such distinctions. For instance, if a patient shows poor performance on initial learning or recall trials of a test, but after a delay, he or she is still able to recall most of whatever amount of information he or she learned, then his or her deficit is likely one of learning or encoding rather than forgetting. Comparison of cued recall, performance on a recognition format, or both to free recall permits identification of patients with inefficient retrieval rather than actual forgetting. These types of distinctions are key in the differential diagnostic process. Rapid forgetting, that is, the inability to retain recently learned information, is relatively uncommon with normal aging and even in patients with depression but is quite common among patients with cortical dementias. One would not diagnose a patient based on his or her performance on an isolated test score (most healthy adults will manifest one or more impaired range scores on some measure when given a large test battery), but the presence of rapid forgetting would be an important piece of evidence more consistent with the presence of cortical dementia than with normal aging or depression.

Even when a patient's diagnosis is known, neuropsychological assessment can be valuable in the documentation of the trajectory and rate of cognitive change. For instance, there is considerable variability between patients with neurodegenerative conditions in terms of the rate of cognitive decline. Repeated evaluation with a targeted battery can be useful in determining how fast a particular person is likely to reach a point requiring a more structured or intensive level of care. Conversely, for a patient who has experienced a stroke or other acute brain trauma, repeated neuropsychological testing can be useful in documenting the rate, trajectory, and degree of recovery of cognitive functioning.

Neuropsychological evaluation in geriatric mental health care can also be useful in treatment plans involving the remediation of deficits in everyday functioning. For example, it may be known that a particular patient's "forgetfulness" is causing difficulties in everyday functioning (such as missed appointments, unpaid bills, etc.). In such instances, a key goal of neuropsychological evaluation is to identify areas of spared cognitive functioning, in addition to documenting the type and degree of any cognitive deficits. With such information, the specific cognitive processes underlying any apparent deficits in independent functioning can

be identified, and information about spared abilities can be used to arrange the environment in a way that maximally draws upon the individual's strengths and reduces the potential deleterious functional effects of impaired abilities.

ASSESSMENT DOMAINS AND COMMONLY USED MEASURES

The length and extent of cognitive testing performed by a neuropsychologist frequently varies depending upon the nature of the presenting problem and the general context or purpose of the evaluation. Some cognitive screening procedures require 30 minutes or less. However, a comprehensive neuropsychological evaluation generally requires several hours to complete. The latter type of testing is particularly valuable in identifying cognitive strengths and weaknesses across a range of more specific neurocognitive abilities. Some of the common constructs evaluated as well as examples of tests frequently used to assess these constructs are described below.

Cognitive Screening

The majority of brief cognitive screening measures were designed specifically to stage severity of Alzheimer disease or other dementias so may be insensitive to other functionally relevant forms of cognitive impairment and tend to be less helpful in identifying areas of clear cognitive strengths.

One of the most widely used dementia screening measure is the Folstein Mini-Mental State Examination (MMSE). The MMSE has a potential range of 0 to 30, with scores below 24 generally considered "impaired." Advantages of the MMSE include ease of administration and scoring; it typically takes less than 10 minutes to complete, can be reliably administered and scored by trained clinic staff, and can be tolerated even by very low functioning patients. Also, it is so widely used that most clinicians have a tangible sense of how scores at a given range are likely to correspond with actual functioning. MMSE scores can thus serve as a useful means of quickly communicating the severity of a patient's overall deficits. Disadvantages of the MMSE include its sensitivity to education (highly educated patients with mild Alzheimer disease may perform very well on the MMSE, whereas healthy individuals with low education may earn scores in the "impaired" range) and its relative insensitivity to mild cognitive deficits and deficits associated with noncortical dementias. One caveat, although not always appreciated by users, is that the MMSE is a copyrighted test that requires purchase for legal use.

Another brief screening instrument for cognitive performance is the Montreal Cognitive Assessment (MoCA). Similar to the MMSE, the MoCA is brief (less than 10 minutes), easy to administer and score, and yields

total scores ranging from 0 to 30, with lower scores representing worse cognitive impairment. It was originally designed to screen for Mild Cognitive Impairment (MCI), rather than cortical dementia per se, and thus may be more sensitive to subtle impairments in the nondemented range of functioning. Another advantage of the MoCA includes availability in multiple languages in addition to English. The copyright holder permits use free of charge and without written permission for noncommercial clinical and educational use, and with written permission in many other applications (see MoCA website for current details: http://www.mocatest.org/permission.asp).

The Mattis Dementia Rating Scale-Second Edition (DRS-2) is another widely used scale of dementia screening; it generates a total score (maximum possible points = 144), indicating overall cognitive functioning, as well as five subscale scores, that is, Attention, Initiation/Perseveration, Construction, Conceptualization, and Memory, and takes from 15 to 20 minutes (for a cognitively intact individual) to approximately 25 to 30 minutes (for an impaired individual) to administer. Like the MMSE, it is prone to age and education effects, but available age- and education-corrected norms facilitate interpretation of DRS-2 scores. The DRS-2 is sensitive to mild dementia, although the ideal "cut-off" score seems to vary slightly among studies; one cross-validated study applied a cut-off of 129 of 144 and yielded a 98 percent sensitivity and 97 percent specificity while distinguishing patients with Alzheimer disease from healthy comparison subjects. Overall DRS-2 scores as well as subscale scores have been shown to be good predictors of functional outcome (basic and instrumental activities of daily living) among patients with Alzheimer disease. The cognitive subscale of the Alzheimer's Disease Assessment Scale (ADAS-Cog) is another widely used screen for cognition among those with Alzheimer disease.

An intermediate option between a brief screening instrument and a lengthy comprehensive neuropsychological battery is to use an instrument such as the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS). The RBANS takes approximately 30 minutes to administer and assesses a number of domains of interest. Computerized cognitive screens, such as the MicroCog, were developed to reduce time and administration burden and are also available for use.

A screening measure is useful for a quick and cursory evaluation of cognitive functioning, but is limited in the extent to which it can assess the breadth and depth of neuropsychological abilities. A comprehensive neuropsychological test battery is the best way to measure more nuanced aspects of cognition across multiple domains of functioning.

Crystallized Knowledge

Crystallized knowledge refers to information and facts typically learned in

formal school settings. Tests that measure crystallized knowledge include the Wechsler Adult Intelligence Scale-4th Edition (WAIS-IV) Vocabulary subtest, in which the examinee is asked to define a common word, the WAIS-IV Information subtest, in which the examinee is asked to answer "common knowledge" questions, and the Wide Range Achievement Test-4th Edition Reading subtest that measures one's ability to recognize or read isolated words. Crystallized knowledge tends to be resistant to most forms of neurocognitive injury and tends to be relatively stable (or even improve) over the life span; word reading and vocabulary scores are therefore, often used, together with educational history, to estimate levels of premorbid cognitive functioning.

Receptive and Expressive Language

Deficits in language functions may reflect specific or localized lesions (such as a stroke in the left frontal lobe) or diffuse neuropathology such as that occurs with Alzheimer disease. Common receptive language measures include such tasks as reading comprehension or comprehension of increasingly complex aurally presented instructions, such as measured by the Token Test or the Complex Ideational subtest from the Boston Diagnostic Aphasia Examination. The Boston Naming Test may be the most widely used measure of expressive language functions in assessments of adults and is particularly useful with patients reporting word finding difficulties. The task involves presenting the examinee with line drawings of objects one at a time and asking him or her to identify each one in succession. If the examinee cannot identify the item within 20 seconds, then he or she is given a cue to see if that aids responding. Confrontational naming is often one of the first abilities to deteriorate in patients with cortical dementia, such as in early Alzheimer disease. Patients with subcortical dementias may have difficulty retrieving the names of the objects, but they tend to do better with cueing.

Another widely used set of tasks that are sometimes categorized under expressive language are the letter and category fluency (word generation) tasks. For instance, in the "FAS" test, the examinee is given three 1-minute trials to name as many words as he or she can think of that begin with the letters "F," "A," and then "S," respectively. Category fluency involves having the examinee rapidly name words from a given category, such as types of animals. Because word knowledge tends to be organized by meaning (semantics) rather than by the initial letters, healthy individuals generally find the category fluency task considerably easier than the letter fluency task. However, with some neurodegenerative conditions, such as Alzheimer disease, the semantic links begin to deteriorate, so the typical advantage of category fluency over letter fluency performance no longer exists. This is another example of how considering the pattern of performance across tasks can be useful in the differential diagnostic process.

Attention and Vigilance

The construct of attention comprises a range of specific functions that include consciousness (attentional, arousal, and temporal orientation), simple attention (the ability to repeat recently presented stimuli, most commonly, strings of digits), selective attention (distinguishing target stimuli or information from irrelevant stimuli), sustained attention (ability to stay mentally "on track"), and vigilance (the ability to wait/look out for a particular stimulus or event over time). Some aspects of working memory, best described as a "mental workbench," also fall under the larger domain of attention (with the more complex aspects constituting executive functions). This function of working memory allows for a limited amount of information to be actively held for short periods of time for further processing and requires active rehearsal or allocation of attentional resources for it to be retained; a classic example is the holding of a telephone number in one's working memory so long as is needed to dial the telephone, and the number may be retained via active rehearsal over the delay period.

Attentional functions are among the first to be affected by a variety of neurological and psychiatric conditions. Attentional decline may therefore be readily observed in older clinical populations. Alterations in consciousness are common in elderly patients with delirium, for example, which in turn may be caused by multiple etiologies (e.g., substance use, prescription medication, urinary tract infections). Other aspects of attention may be moderately to severely impaired in patients with dementia, especially subcortical dementias such as those associated with Parkinson disease. DLB is also associated with impairments in both consciousness and arousal and simple and sustained attention. Mild to moderate impairments in attention are present among patients with Alzheimer disease, but they tend to be able to perform basic attention tasks fairly well even in more advanced stages of the disease. Fluctuating attention, especially within a single attention-oriented task, is often associated with geriatric depression or anxiety.

Orientation and simple attentional tasks are included in the MMSE, MoCA, and DRS-2. The MMSE and MoCA include the serial 7s subtraction task, while the DRS-2 includes some cancellation tasks. A common measure of simple attention and working memory is the WAIS-IV Digit Span subtest, in which the examinee is asked to repeat strings of digits of increasing length and is then asked to repeat strings of digits in reverse order. Cancellation tasks are common measures of sustained attention or vigilance; for example, in the Digit Vigilance Test from the expanded Halstead–Reitan Battery (HRB), the examinee is asked to rapidly identify and cross out every time a target number appears in a much larger array of numbers. The various versions of the Continuous Performance Test (CPT),

such as the "identical pairs" version, in which the examinee is shown a series of numbers rapidly flashed on a computer screen and is required to make a response after any number is shown twice in a row, is also an example of such a task.

Learning and Memory

Memory complaints are prevalent among older individuals, and there is consistent evidence that some aspects of memory, specifically, episodic declarative memory, deteriorate with advanced age. The function of an objective memory evaluation is to determine whether memory decline is above and beyond age-appropriate memory decline. Therefore, normative data on standardized memory tests become even more important to accurately interpret the target person's test results. Also, given that memory components of episodic memory tests are typically preceded by learning new material (e.g., word lists, stories, geometric designs), it is also important to rule out the possibility of a learning disorder (which may have remained previously undiagnosed or undetected among older patients). The presence of a learning disorder is determined by performances on achievement tests (e.g., reading, spelling, simple arithmetic) and the individual's educational or occupational history (repetition of a grade, difficulties in school, special education programs, extra tutoring, and behavioral problems in school being common red flags). If a learning disorder exists, then memory test results must be interpreted with caution, and education-corrected norms will give skewed results.

Referral questions for neuropsychological evaluation among geriatric patients typically include a request for "memory assessment," often because it is the primary cognitive complaint of patients, their caregivers, or both. There are several reasons why older individuals may experience impairment in episodic learning and memory, such as dementia, depression, anxiety, and even physical conditions, such as pain. Procedural memory (e.g., driving a car, making dinner) tends to fade at a slower rate and may only be seen in moderate to severe stages of dementia. Finally, autobiographical memory tends to remain intact for the most part, except in patients with very advanced stages of dementia.

Neuropsychological evaluation typically includes measures of simple registration (e.g., asking the patient to repeat three or five words, as in the MMSE and MoCA, respectively) and both auditory and visual episodic learning and memory. Tests of episodic learning and memory typically begin with a series of learning trials followed by short and long delay recall trials. The time between the learning and delay trials is filled with unrelated tasks (typically, another neuropsychological test or "distraction stimuli") so that the patient cannot rehearse the test stimuli. Delayed recall trials may include free recall, cued recall, recognition paradigms, or a combination of these. Cued recall and recognition trials help identify retrieval versus

encoding deficits; in the former, the information is encoded but can only be retrieved with help (e.g., cues or recognition), and in the latter, the information is never encoded in the first place (so neither cues nor recognition will help).

The most commonly used tests of auditory learning and memory include the Hopkins Verbal Learning Test-Revised, Rey Auditory Verbal Learning Test, and the California Verbal Learning Test-2nd Edition (CVLT-II), all of which are list-learning tasks, and Logical Memory (from the Wechsler Memory Scale-4th Edition [WMS-IV]) or the Story Memory Test in which the stimuli are stories or short passages. Visual learning is often measured with the Brief Visuospatial Memory Test-Revised, Visual Reproductions (from the WMS-IV), and the Rey–Osterrieth Complex Figure Test. These tests require the examinee to learn and remember geometric figures by copying them or via immediate recall, recalling them by drawing as many figures as possible from memory. These tests therefore also have a visuoconstructional element in addition to a visual memory component. The Visual Reproduction test also has recognition components.

Two classic distinctions made between memory test score profiles among older individuals are those of cortical versus subcortical dementia and dementia versus late-life depression. Cortical profiles of list-learning tasks, such as the CVLT-II, seen most often among patients with Alzheimer disease, include a flat learning slope across the learning trials, rapid forgetting (i.e., little to no words in short and long delayed recall), high recency effect (i.e., most words recalled from the last third of the list), high number of intrusions (i.e., words not on the list, similar to confabulations seen in informal assessments of patients with Alzheimer disease), high number of repetitions, and no benefit from cueing or recognition formats. Patients with subcortical dementias, such as Parkinson disease, also have flat learning slopes and difficulty recalling any words during free recall trials, but are unlikely to have intrusions or repetitions and do better with cues or on the recognition trial. The performance of patients with depression is marked by overall slowness of responding and a lower output of words during free recall. They will almost never have intrusions or repetitions, and they tend to recall words from all over the list. They tend to do significantly better with cueing and recognition, often achieving scores within the normal range for their age.

Visuospatial Cognition

The assessment of visuospatial cognition or perceptual organizational skills is an important component of both screening and comprehensive neuropsychological evaluations. Broadly, these functions consist of perceptual ability (the ability to discern forms or patterns), visuospatial judgment (the location of objects in space), and constructional ability (the

manipulation of objects in three-dimensional space). Intact visual acuity is an obvious precondition to all subdomains of visuospatial cognition, and adequate use of hands is necessary for the constructional tasks. Visual field defects and hemiparesis can also cause impairments in visuospatial cognition. Some of the most common neurological conditions affecting visuospatial cognition among older adults are vascular incidents (lesions causing contralateral hemispatial neglect), Balint syndrome (associated with bilateral lesions in the posterior parietal cortex), and dementias caused by Lewy body, Parkinson, and Huntington disease. Patients with Alzheimer disease also have impairments in visual cognition, but they are less severe compared with those among individuals with other dementias. Incipient Alzheimer disease is associated with difficulties with constructional ability, but other visuospatial abilities may only get severely impaired in advanced stages of the disease.

Visuospatial abilities are commonly measured with subtests of the WAIS-IV such as Picture Completion, in which the examinee must identify the important missing element in a series of pictured scenes, and Matrix Reasoning, a visual reasoning task wherein the examinee must identify the missing element in a matrix by discerning the rule underlying the relationship between each of the several subparts. The Hooper Visual Organization Test is another widely used measure, wherein the examinee is shown pictures of objects that have been cut and randomly arranged in pieces; he or she must mentally rotate the various pieces and put them together, and then name the object. Constructional skills are measured by graphomotor tasks, such as the Rey–Osterrieth Complex Figure Test, in which the examinee is presented with a complex geometric figure, which he or she must copy (the order in which the figure is copied is noted by the examiner), or, most commonly, the Block Design subtest (from the WAIS-IV), in which the examinee is required to rapidly match a two-dimensional design by combining three-dimensional red-and-white blocks.

Executive Functions and Working Memory

There is wide consensus among neuropsychologists that intact executive functions are central to optimal daily functioning; yet, the precise definition of the construct remains elusive. The term, “executive functions” is used to describe an array of subdomains, including abstraction and concept formation, planning, response inhibition, cognitive flexibility, and some aspects of working memory. The products of all these executive functions typically involve novel problem solving, initiating and maintaining goal-directed behavior, or disengaging from such behaviors when appropriate to the goals or in response to environmental cues. Executive functions were also previously called “frontal cortical functions” because they were thought to be mediated by the frontal cortex. However, there is now overwhelming evidence that these functions are not limited to

the frontal cortex but that they involve several frontal–subcortical circuits as well. Therefore, lesions in frontal as well as subcortical brain structures can disrupt any of the executive functions.

People with Alzheimer disease often show signs of executive dysfunction even in early stages of the disease. People with frontotemporal dementia and those with any of the several forms of subcortical dementias (such as those due to Parkinson disease) have significant impairments in cognitive flexibility, abstract thinking and conceptualization, and fluency. Executive functions may also be more sensitive to low or inconsistent effort; therefore, patients with depression may do poorly on some or all executive functioning measures.

The Wisconsin Card Sorting Test (WCST) is the most commonly used measure of executive functioning, specifically, concept formation and cognitive flexibility. The task involves asking the examinee to discern an unspoken rule that defines correct versus incorrect matches and also requires the examinee to change strategies when appropriate. The Booklet Category Test, another popular test of conceptualization and abstract thinking, similarly requires the examinee to discern the pattern or rule underlying the sequence in a sequence of presented stimuli, but that rule may change over various subsections.

The Delis–Kaplan Executive Function System (D-KEFS) is a battery of nine executive functioning tests and has normative data for adults up to 89 years. The D-KEFS includes the Trail Making Test, Verbal Fluency Test, Design Fluency Test, Sorting, Tower Test, Color–Word Interference, the Word–Context Test, the Proverb Test, and Twenty Questions. These tests, some of them modified from popular, existing tests (e.g., the Trail Making Test is modified from the Trail Making Test, Parts A and B, a.k.a., the Partington Pathways Test), measure a broad range of executive functions and are useful to include in a comprehensive battery for use with older adults.

Mental Processing Speed/Psychomotor Speed

The term “mental processing speed” (or information processing speed) refers to the speed with which one thinks and executes a task. As the tasks used to assess this construct generally include a motor response component, it is also commonly labeled “psychomotor speed,” reflecting the fact that test performance is determined not only by the speed with which one thinks, but also by the integration of those thoughts with the motor response. Whether construed as psychomotor speed or pure mental processing speed, tests in this domain tend to be among the most sensitive to virtually any form of neurocognitive injury or dysfunction, including that caused by psychiatric conditions such as depression. Indeed, the steady, if gradual, stowing of processing and psychomotor speed is the most ubiquitous and consistent change seen with normal aging, beginning at

least by the early part of the fourth decade of life. When examining an elderly patient for possible presence of pathological motor disorders, it is important to consider his or her psychomotor speed relative to that expected from an age-comparable normative sample.

The Digit Symbol (a.k.a., "Coding") test is a prototypical example of processing/psychomotor speed tests, and is among the most widely used tests to assess this domain. The Digit Symbol test consists of a stimulus key with the numbers 1 through 9, each paired with a unique geometric figure. Beneath this stimulus key is a large matrix of numbers with spaces below each number. The patient's task is to rapidly fill in the symbol paired with each number. The stimuli used for this task have appeared in largely unaltered form since the early 1900s; the stimuli used in the Army Mental Test battery during World War I are almost identical to those used in the adult versions of Wechsler intelligence test batteries, up through the 1997 edition of the Wechsler Adult Intelligence Scale (WAIS-III). The Digit Symbol subtest stimuli were substantially redesigned for the WAIS-IV, published in 2008, but there is little reason to expect that the modifications will alter the sensitivity of the task to age-related or other psychomotor slowing.

Another widely used measure of psychomotor speed is the Trail Making Test Part A (originally published as Partington Pathways Test in the 1930s), which requires the patient to connect a series of circled numbers in order as fast as possible, and measures scanning, visuospatial sequencing, and motor speed. The D-KEFS includes a number of interesting modifications of the Trail Making Test, including a Motor Speed subtest that may prove helpful in distinguishing pure motor slowing from slow mental processing.

OTHER ASPECTS OF COMPREHENSIVE NEUROPSYCHOLOGICAL EVALUATION

Assessment of Mood and Anxiety

Emotional functioning is extremely important to monitor as part of any assessment with older adults. Depression is often undetected among older adults, although increasing awareness of the frequency of psychiatric problems in this population has led to more routine assessments of depression, anxiety, and suicidality in psychiatric, neurological, and general medical treatment settings. Two useful and quick measures of depression are the Geriatric Depression Scale and the Beck Depression Inventory-2nd Edition (BDI-II). The former is particularly helpful for use with older patients and is validated for use with patients with Alzheimer disease. Occasionally, if the patient has been able to tolerate a lengthy neuropsychological battery and may have potential emotional problems, he or she may be given the Minnesota Multiphasic Personality Inventory-2nd Edition (MMPI-II). The MMPI can give a detailed profile of the patient's emotional functioning as well further highlight targets for intervention.

Activities of Daily Living/Everyday Functioning

It has been common practice in neurology and psychiatry to informally assess older patients' basic and instrumental activities of daily living (ADLs and instrumental ADLs [IADLs], respectively). Basic ADLs include personal functions such as feeding oneself, showering, dressing, and using the toilet, among other things. Intake interviews as part of neuropsychological assessments tend to focus more on evaluating IADLs, such as cooking, driving, managing finances, and so forth (i.e., skills that are more complex than basic ADLs, yet necessary for independent everyday functioning).

ISSUES IN THE ASSESSMENT OF OLDER ADULTS

Sensory Impairment

Hearing impairments tend to be fairly common among older adults in general and can considerably impede verbally administered neuropsychological tests (e.g., the CVLT-II). The potential examinee's hearing should be at least informally assessed to determine whether it is adequate for the verbal neuropsychological tests. If hearing is deemed too impaired, he or she can still be assessed with largely visual tests (assuming they have adequate visual acuity). Visual acuity may be informally assessed, for example, using the Rosenbaum Pocket Screener. Visually impaired patients can be assessed with a variety of tests, including all of the verbal memory tests, some attention tests, all of the verbal D-KEFS tests, and the Tactual Performance Test, which is a measure of visuospatial functioning.

Interpretation of Test Results in the Context of Normal Aging

Normal aging is itself associated with some changes in cognitive functioning, including improvements (at least during the first seven decades of life) in crystallized verbal knowledge, and slowing of mental processing speed, psychomotor speed, and subtle declines in some aspects of memory and executive functions. A key advantage of the standardized testing emphasized in neuropsychological assessment over other neurobehavioral examinations is that it ascertains that the interpretation of an examinee's responses is not based solely on the absolute level or content of responses (or pathognomonic signs) but also in reference to the level of performance expected from a neurologically healthy individual. The latter is determined by comparing the examinee's test scores to demographically appropriate norms. The most widely used neuropsychological tests have normative data that are developed and collected using standardized administration and scoring procedures.

LISA T. EYLER, PH.D., AND ZVINKA Z. ZLATAR, PH.D.

INTRODUCTION

The brain, long recognized as the site of pathology in mental illness, has

only recently become accessible for study in the living human. Modern neuroimaging techniques now permit detailed measurement of the brain's size, shape, and function. These methods provide a window into the disordered organ in mental illness and therefore provide important clues about the pathological processes that cause these disorders. In addition, neuroimaging techniques have the potential to improve the ability to diagnose and treat some of the most complex and disabling brain disorders.

In geriatric mental illness, the advantages of neuroimaging are even greater because they allow one to observe directly how the brain's aging processes might combine with disease processes. Neuroimaging methods have been used widely to examine changes in brain structure and function associated with normal aging and diseases of aging such as dementia. These findings provide a basis for examining the effect of aging on mental illness and for understanding new onset psychiatric disorders in late life. Furthermore, neuroimaging studies have provided some of the growing evidence suggesting that mental disorders may involve a process of accelerated aging.

Theoretically, there are several ways that neural processes related to aging and mental illness could combine. Out of many theoretical possibilities, there is empirical support for several scenarios. One possibility is that aging processes and mental illness produce additive effects, even when they involve similar brain systems. In this case, an older patient would have different brain findings compared to a younger patient, but the differences would parallel those seen in normal aging. For instance, brain volume in a certain region that is abnormally small in young patients with the disorder might further shrink with age, but at the same rate as seen in healthy individuals. An alternative scenario is that the effects of age and mental illness on the brain may involve similar neural systems, and these influences may interact with each other. The synergistic nature of this interaction could take several forms. One possibility is that aging processes could trigger new onset of a disorder in late life, perhaps among individuals with a genetic or environmental liability. A second possibility is that aging might alter the brain profile observed in younger individuals beyond that predicted by the effects of aging alone. For example, if functional brain response during a cognitive challenge is influenced by age and the mental disorder in an interactive fashion, a steeper decline in levels of activation with age among patients than among healthy individuals may be observed.

Most studies of the brain in geriatric psychiatry have so far sampled from two main populations: (1) elderly patients with a typical age of onset earlier in life (which, in this chapter, is referred to as early-onset elderly, or EOE) or (2) elderly patients with new onset of a disorder late in life (late-onset elderly, or LOE). In general, studies of EOE compare these individuals to healthy individuals with similar ages, or, more rarely, include

a comparison to younger patients with a comparable age of onset. Studies of LOE frequently compare findings to a group of age-comparable healthy participants and may include a group of EOE of comparable age. A fully factorial design crossing age of onset and current age, and including young and old healthy individuals is rarely used, even though it is ideally suited to disentangle the effects of age from the age of onset and to examine the nature of how age and illness interact. Longitudinal studies, perhaps the gold standard for examining age-related changes, are very rare in neuroimaging studies of geriatric mental illness, but can provide important insights into the trajectory of mental illness across the adult life span.

OVERVIEW OF NEUROIMAGING TECHNIQUES

Modern neuroimaging techniques can be divided into two primary categories: (1) those that measure the size and shape of tissues and structures within the brain, known as structural neuroimaging, and (2) those that measure the activity of the brain, known as functional neuroimaging.

Structural Neuroimaging

Structural neuroimaging uses techniques such as computed tomography (CT) and magnetic resonance imaging (MRI) to create images of different tissue types within the brain, namely gray matter, white matter, and cerebral spinal fluid. MRI is the preferred structural neuroimaging technique for research and clinical uses in mental illness because it lacks ionizing radiation, can easily be repeated, and generally provides good spatial detail and a sharp division between tissue types (see Fig. 57.2f–1). The digital images collected using MRI can be manipulated, either through use of mathematical algorithms or human experts, in order to measure quantities such as volume of substructures or tissue types, number and size of certain abnormal occurrences such as white matter lesions, and cortical surface area and thickness. In addition, detailed information about the shape of three-dimensional structures and cortical folding patterns can be extracted from these images and mathematically compared between individuals using the latest computerized techniques. Measurement of the organization, integrity, and connectivity of the brain's myelinated fiber tracts can also be achieved using diffusion tensor imaging (DTI), which is a form of MRI that is sensitive to the constrained and directional diffusion of water molecules in white matter tracts. Finally, the degree of local neuronal integrity can be inferred through the measurement of chemical compounds such as *N*-acetyl aspartate using a variant of MRI called magnetic resonance spectroscopy (MRS).

FIGURE 57.2f–1. High-resolution T_1-weighted magnetic resonance image of brain structure showing six axial slices at the level of the lateral ventricles.

Although MRI-based structural imaging provides a wealth of quantitative data about the static properties of the living brain, there are several limitations that should be kept in mind when evaluating its use in the study of geriatric mental illness. In addition to practical constraints due to the expense and lack of portability of the instrument, safety issues associated with MRI exclude a proportion of patients, particularly older ones, who may have pacemakers or metal in soft tissue. Furthermore, scanning is difficult for those who cannot comfortably lie still for long periods of time (a more frequent concern in the elderly), those who are very obese (which may preferentially exclude some mentally ill patients for whom weight gain is a side effect of medication), and those who have claustrophobia (an anxiety that may be more common among mentally ill patients). These difficulties may reduce the generalizability of research findings due to a biased sample and may also limit the usefulness of MRI as a clinical tool for some patient groups. Also, image quality and reliability is severely reduced in MRI by participant movement during the scan. To the extent that certain groups may have greater trouble staying still (due, e.g., to motoric side effects of medication), this too can lead to a biased sample at the time of data analysis. A final caveat regarding MRI structural measures is that, like all assessments, they are subject to potential problems with measurement error, reliability, and validity. Variability

between and within individuals across multiple measurements can occur due to mechanical fluctuations in the hardware and due to variability in processing of the data including that introduced by the use of human experts. In the case of validity, measurements based on MRI images, which are, after all, only pictures of the brain, may or may not have systematic biases relative to measurements of the brain itself. Studies comparing features of postmortem brain dissections with measurements based on MRI images of the same specimens are underway to help address this issue.

Functional Neuroimaging

In contrast to the static measures provided by structural neuroimaging, several techniques are now available that attempt to measure the dynamic function of the brain. In some cases, activity is measured during a cognitively unstructured resting state; in other cases, the brain's response to a sensory, cognitive or emotional challenge is assessed. Positron emission tomography (PET), functional magnetic resonance imaging (fMRI; see Fig. 57.2f–2), electroencephalography (EEG), and magnetoencephalography (MEG) are the most frequently used techniques to examine the brain in action; each has its strengths and weaknesses. PET scanning uses radiolabeled compounds to measure blood flow, cerebral metabolism, or receptor occupancy. PET measures of blood flow have the advantage of permitting quantification of absolute levels of regional perfusion, and measures of cerebral glucose metabolism and receptor occupancy are only available using PET technology. More recently, PET techniques have been used to measure in vivo brain beta-amyloid deposition, the hallmark neuropathology of Alzheimer disease, which previously could only be achieved postmortem. Disadvantages of PET relative to other functional neuroimaging measures include poorer spatial resolution compared to MRI-based measures, coarser temporal resolution, limits on the ability to repeat scans due to concerns about exposure to radioactive compounds, and less availability for research and clinical use because of the need to synthesize the necessary agents on site.

Functional MRI uses endogenous sources of contrast to create images of blood oxygenation and blood flow. The most common signal measured by fMRI is blood oxygen level dependent (BOLD), which takes advantage of the fact that more oxygen is delivered to the vessels surrounding active neurons than is consumed by them, creating a surplus of oxygenated hemoglobin in the local area. Oxygenated hemoglobin is less disruptive to the MRI signal than deoxygenated hemoglobin, so the BOLD signal is relatively greater in active regions. The BOLD signal can be used to determine changes in blood oxygenation at the whole brain or regional levels, and it can be measured at rest or during a specific task (cognitive, affective, motor, etc.). Data obtained by measuring the BOLD signal can be analyzed in different ways to answer distinct questions. For example, group

differences (age, disease state, etc.) and within person change in the location and shape of the BOLD signal in response to different tasks can be measured, which can help to elucidate whether age or disease states manifest in differential brain activity patterns. Brain activity changes can also be measured over time in the same individuals, or before and after a particular intervention to assess whether or not the intervention changed brain activation patterns, and purportedly, neural activity. Since the brain is a network of interconnected and spatially distributed regions, it is also important to study how connectivity between different regions and within brain networks may be affected by age or disease states. Functional connectivity analyses apply the BOLD signal to study temporal connectivity patterns between different brain regions and networks to investigate how these connections may be affected by age or disease states. Correlations of the BOLD signal between regions can be measured either during a cognitive challenge task or during rest. Data from resting state fMRI scans have recently been used to identify reliable large-scale networks of correlated BOLD signal and to examine patterns and properties of these networks. Another MRI-based functional technique, called arterial spin labeling (ASL), can be used to quantify the amount of blood flowing into an area by measuring the inflow of an applied magnetic "tag." Both of these methods have millimeter spatial resolution, temporal resolution on the order of seconds, and have the advantage of being able to measure brain structure in the same scanning session as the functional images. A disadvantage of BOLD fMRI relative to ASL is that it does not measure an absolute quantity, so activation must always be compared between an experimental condition and some baseline condition. The most appropriate choice for a baseline comparator has been widely debated. As MRI-based techniques, the same caveats mentioned above for structural scans also apply to BOLD and ASL, with an even greater concern about the effect of participant movement, especially movement that is coordinated with the cognitive activity of interest. In addition, fMRI images are susceptible to unique artifacts that make visualization of particular areas of the brain, such as the orbitofrontal cortex, more challenging. Finally, both PET and fMRI are blood-based measures, so differences between groups might reflect vascular rather than neuronal deficits, although measuring baseline cerebral blood flow using ASL can help to disambiguate group brain activation differences by better characterizing the vascular contributions to the BOLD signal.

FIGURE 57.2f–2. Processed image of areas of significant blood oxygen level–dependent (BOLD) response as measured by functional magnetic resonance imaging. Brightest contrast within dark areas indicate those areas where change in the BOLD signal over time was most highly correlated with the behavioral paradigm presented, and these activation clusters are superimposed onto a three-dimensional rendering of the cortical surface based on a high-resolution magnetic resonance scan.

In contrast, EEG and MEG both measure the electrical activity of the brain using detectors at the surface of the scalp. The temporal resolution is, therefore, on the order of milliseconds, similar to the timing of neuronal processes. The spatial resolution, however, is generally coarser than MRI-based measures and localization of deep brain sources is especially problematic, although mathematical source localization techniques have recently improved the ability to pinpoint the origin of the electrical and magnetic signals within the brain.

LATE-LIFE DEPRESSION

Course and Features in Late Life

Unipolar depression often has a recurring course; so many individuals with onset early in life continue to suffer from the disorder into old age. In addition, a proportion of individuals will manifest depression for the first time in late life. The combined prevalence of EOE and LOE patients with depression varies tremendously and it ranges from ~1 to 35 percent in

community-dwelling samples, with major depression in ~1.8 percent and minor depression in ~9.8 percent of the community-dwelling population. The prevalence of major depression is higher in nursing home settings (12 to 14 percent). In general, the core symptoms of late-life depression (LLD) are similar to those seen in younger patients and include emotional distress, somatic complaints, and cognitive impairment. Cognitive deficits are more prominent among elderly patients with depression compared to younger depressed individuals, particularly in the realm of executive function. LOE with depression may have more pronounced cognitive deficits than EOE patients and there appears to be a stronger association between depression and dementia among LOE patients.

Features of LLD that contrast with depression earlier in life include greater variability in treatment response, high medical comorbidity, increased nonsuicidal mortality, and less reported family history of depression. Some of these features may be particularly linked to late-onset depression. LOE patients with depression suffer from less psychiatric comorbidity and have fewer relatives with depression, but have even greater rates of medical comorbidity compared to EOE patients. The distinction between late- and early-onset depression is complicated, however, by the fact that chronic, subclinical depression symptoms may have existed, or mild mood episodes may have occurred earlier in life, without proper diagnosis or treatment among some LOE patients. Thus, some LOE with depression may be more properly classified as EOE with a milder initial course, although there are also clear cases of first onset of mood problems late in life.

Structural Neuroimaging

Compared to age-matched healthy individuals, patients with LLD have smaller brain volumes of several cortical regions, including prefrontal and orbitofrontal cortex and anterior cingulate, and of subcortical regions including the basal ganglia, hippocampus, and amygdala. In addition, LLD is characterized by cerebrovascular disease with white and gray matter hyperintensities, particularly in subcortical structures and frontal projections. The integrity of frontal and temporal white matter connections as measured by DTI also appears to be reduced in geriatric depressed patients, implicating a possible frontostriatal disconnection syndrome. Finally, at least one study using MRS has revealed disruptions of the neurochemical properties of the frontal white matter in geriatric depressed patients.

Hippocampal volume reductions may be particularly pronounced among LOE with depression, and a recent study that compared surface characteristics of hippocampal shape between age-matched EOE and LOE patients showed more pronounced deformations in several hippocampal subregions among LOE compared to EOE patients. Furthermore, a recent

study that followed LOE- and EOE-depressed patients over 4 years found that EOE had greater severity of depressive symptoms, while LOE was associated with more severe cognitive and neurological changes, and with accelerated rate of hippocampal volume loss compared to EOE. EOE-depressive symptoms have also been associated with greater disturbance in cortical thickness compared to LOE. White matter hyperintensities are also strongly linked to late onset of depression: a recent meta-analysis found an odds ratio greater than 4 for these abnormalities in LOE versus EOE with depression as well as greater severity among LOE than EOE. White matter abnormalities have also been linked to worse functional outcomes and mobility measures in depressed older adults compared to those never depressed.

The direction of causality of the associations between LLD and these structural abnormalities is not yet clear. Smaller cortical and subcortical volumes may be predisposing factors for depression (since they are also seen in younger adult samples), but there is also a suggestion that stress hormones associated with depressive episodes may cause volume loss. The association between smaller hippocampal volume and longer duration of illness is consistent with the latter interpretation, while the recent finding that hippocampal atrophy was associated with higher subsequent depressive symptoms and with shorter-term symptom exacerbation in women followed for over a 10-year period is suggestive of the former. In terms of white matter damage, the established link between stroke and late-onset depression has led to the conclusion that at least some LLD is vascular in origin. However, it also may be the case that history of depression predisposes to cardiovascular problems and that the observed white matter lesions are a result of the disorder rather than the cause. Several ongoing longitudinal studies should help to disentangle these possibilities. In at least one of these, initial results suggest that presence of white matter hyperintensities independently predicts depressive symptoms 1 year later.

Given the observed cerebrovascular pathology and increased risk of dementia in those with LLD, especially in those with LOE depression, recent studies have begun to investigate the association between LLD, cognitive decline, and brain structure as a predictor of conversion to dementia. Studies comparing four groups of individuals (cognitively normal, LLD, amnestic mild cognitive impairment [aMCI], and comorbid LLD and aMCI) have found increased white matter vulnerability in the comorbid group, suggesting that white matter disruptions may be a marker of disease severity. A similar study found that gray matter volumes were associated with mood-regulating circuit structures in LLD, while associations with regions subserving multicognitive domain functions were found in those with aMCI only. The group with comorbid LLD and aMCI showed gray matter atrophy in widespread regions implicated in early

Alzheimer disease, such as the dorsal anterior cingulate cortex, the medial-temporal lobe, and prefrontal cortices.

The relationship of structural brain abnormalities to treatment response in LLD also has been examined. The results, unfortunately, have been mixed. Some studies find that increased white matter hyperintensities and volume deficits are associated with poor short-term response to antidepressants, but others have found no such association. Importantly, since studies have found gender differences in the underlying neural substrates of LLD, such as higher white matter disease as a consequence of depressed mood only in men, future studies should take into account gender differences when attempting to parcel out the contribution of structural and functional neural deficits to LLD diagnostic features and disease course.

Functional Neuroimaging

In LLD, disruptions in metabolism, functional activity, and network connectivity have been identified. Hypometabolism and hypoperfusion have been observed compared to age-matched healthy individuals. A recent PET study of individuals from age 20 to 79 found a significant negative relationship between age and glucose metabolism in the rostral and dorsal anterior cingulate cortex that was not observed in a similarly aged healthy comparison group. This negative relationship with age was most pronounced in a subgroup of patients with a higher degree of illness severity; there was no such correlation among first-episode patients. Studies during cognitive tasks have revealed underactivation of the dorsal anterior cingulate and hippocampus during a verbal fluency task, decreased prefrontal and increased caudate activation during sequence learning, and decreased temporolimbic response during episodic memory among individuals with LLD compared to age-matched healthy volunteers. A role for illness duration and severity is also suggested in at least one cognitive challenge study that found anterior cingulate hypoactivation only in the LLD subgroup that had suffered multiple episodes. Potential functional brain differences between depressed LOE and EOE have not yet been examined.

Several studies have examined the neurophysiology of LLD. When measuring brain stem auditory–evoked responses using EEG, the wave V latency (linked to functioning of the pons) was found to be longer among patients than comparison participants, particularly those with comorbid vascular disease. The latency of P300 response has also been found to be increased in elderly depressed patients. More recent studies have examined evoked potentials during a go/no-go paradigm and found greater responses during inhibitory trials on waveforms thought to reflect anterior cingulate cortex conflict monitoring. As of late, many studies have attempted to combine imaging modalities in an effort to better understand the neural

changes associated with health and disease. One such study combined EEG and MRI modalities and found changes in electrophysiological markers of cerebral arousal and information processing in LLD, some of which were related to white matter hyperintensities. Another multimodal imaging study found elevated glucose metabolism with corresponding atrophy in frontal and posterior regions using PET and MRI in a small sample of older adults with depression, supporting a possible compensatory metabolic response resulting from structural atrophy in these regions.

Disruptions in several major brain neurocircuits important for cognitive and emotional functioning have been identified in LLD using several imaging modalities (resting state fMRI, structural MRI, DTI, EEG, MEG). A recent review of the literature indicated that individuals with LLD exhibit dysfunction in the default mode network (medial prefrontal cortex, posterior cingulate, precuneus, and medial temporal lobe), the cognitive control network (dorsolateral prefrontal cortex, dorsal anterior cingulate, and posterior parietal cortex), the affective/frontolimbic network (amygdala, subgenual anterior cingulate, hypothalamus, orbitofrontal cortex, and nucleus accumbens), and corticostriatal networks (connections between frontal cortical regions and the basal ganglia and thalami). Above and beyond alterations in discrete network systems, abnormal function in whole-brain network topographical properties have been identified in LLD using newer methods such as graph theory. Graph theory–based techniques can estimate network efficiency (integration) and resilience (ability to maintain its structural and functional integrity when challenged) and recent studies using this technique have found reduced global efficiency, network strength, and network resilience in LLD. Furthermore, white matter disease burden may mediate these network alterations in LLD.

The role of cognitive impairment and risk for dementia in LLD has been further explored in recent studies. One such study followed people with depression for 2 years and found that those with persistent cognitive impairment at follow-up had decreased baseline activity in dorsal anterior cingulate, hippocampus, inferior-frontal cortex, and insula compared with noncognitively impaired depressed patients. Similarly, resting state functional connectivity analyses were used to measure hippocampal frontal connectivity similarities and differences in LLD and aMCI. While aMCI was associated with overall diminished connectivity, LLD was associated to increases and decreases in connectivity in cortical and subcortical structures involved in mood regulation. Interactive effects of LLD and aMCI were found in frontal regions associated with emotion processing and cognitive functioning, where LLD and aMCI showed diminished hippocampal connections whereas the comorbid group exhibited enhanced connectivity.

Given the variability in treatment response in geriatric depression and

concerns about poor prognosis in this age group, there has been considerable interest in using functional neuroimaging to understand and improve treatment response. For example, a large body of work has used PET methodology to examine neurotransmitter binding. Among patients with midlife depression, however, only modest differences in binding of transporters or receptors for serotonin and dopamine compared to healthy individuals have been observed. Other studies have used metabolic or electroencephalographic imaging in the context of treatment studies to examine change with treatment. Geriatric patients treated with sleep deprivation and paroxetine showed a decrease in metabolism in the anterior cingulate cortex that was correlated with symptom improvement. A more recent study administered citalopram for a period of 8 weeks to older adults with LLD compared to a control group while evaluating changes in glucose metabolism over a 2-year follow-up. Compared to the control group, patients in the treatment group had higher glucose metabolism in the anterior cingulate and insula, with most patients being remitted at follow-up. Furthermore, both groups showed decreased metabolism in posterior association cortices implicated in dementia, which were more extensive than the decreases in brain volume. Even though the latter study included a very small sample, investigations such as this one can help to elucidate the underlying mechanisms of treatment response in LLD.

Summary and Clinical Implications

Structural MRI and DTI have consistently revealed white matter abnormalities in patients with LLD, although this is not the case for all studies. The current evidence associating cerebrovascular and cardiovascular disease with LLD is sufficiently strong that a cerebrovascular workup should be considered, especially when late-onset, elderly, depressed patients present in the clinic. Recent studies have identified that comorbid MCI and depression is associated with more frontal, parietal, and temporal white matter atrophy compared to those without depression over a 2-year period. Similarly, in individuals with MCI and depression, higher beta-amyloid pathology was found in those with LOE compared to EOE, while higher beta-amyloid load was found in comorbid MCI and depression compared to depressed individuals without cognitive impairment. Given the increased conversion rates from MCI to dementia in older adults with depressive symptoms, abnormal hippocampal volume or shape, increased cerebrovascular disease burden, and metabolic changes in areas associated with dementia presenting in concert with memory impairment among elderly patients with late-onset depression may be prognostic signs of cognitive decline. The care of such patients should include routine assessments of cognitive functioning and behavioral interventions, such as increasing engagement in exercise and

other cognitive and social activities, to preserve brain health and boost cognitive function. As with depression in young adulthood, depression in the elderly is associated with impaired glucose metabolism and abnormal brain activation and network connectivity patterns. The prognostic value of abnormal metabolic findings and brain activation patterns as predictors of treatment outcome remains to be determined, although some progress has been made through short-term longitudinal studies. The current literature, however, indicates that abnormal findings in subdivisions of the anterior cingulate might be as useful in predicting outcome and monitoring treatment response in LLD as they are in predicting treatment response in younger depressed patients.

LATE-LIFE BIPOLAR DISORDER

Course and Features in Late Life

In contrast to the growing body of evidence regarding late-life unipolar depression, less is known about the course of bipolar disorder in late life. Although some authors have suggested that symptoms of bipolar disorder may eventually "burn out," longitudinal studies show a recurrent and chronic course into old age. Epidemiological studies find a low community prevalence of bipolar illness in older individuals (between 0.1 and 0.5 percent), but among geriatric psychiatry visits, 8 to 10 percent of cases have bipolar disorder diagnoses and nearly 25 percent of bipolar disorder patients are over the age of 60. Approximately 6 to 8 percent of patients over age 60 have first experienced symptoms of bipolar disorder in late life. Clinically, these late-onset cases appear broadly similar to those with more typical onset in their early 20s. In general, older patients with bipolar disorder are more likely to be women, have lower substance abuse comorbidity, high physical illness comorbidity, and low perceived social support. Although manic symptoms may be less severe in older patients, hospital stays are longer suggesting slower resolution of symptoms. Older patients are more likely than younger ones to take valproate rather than lithium, although treatment guidelines specific to older patients are lacking.

A small number of recent studies have examined cognitive performance among elderly, nonsymptomatic individuals with bipolar disorder. Older bipolar patients performed worse compared to age-comparable healthy individuals on broad measures of cognition, and, when tested with comprehensive neuropsychological batteries, had deficits in multiple domains, including those linked to the function of prefrontal cortex such as working memory, attention, and problem solving. Whereas in younger samples, cognitive deficits of bipolar patients tend to be intermediate between those of patients with schizophrenia and those of healthy individuals, one study found that older patients with bipolar disorder were

as impaired as schizophrenia patients in most domains, including abilities like attention/working memory and reasoning/problem solving. This raises the question of whether cognitive performance may worsen with age among patients with bipolar disorder and whether the degree of worsening is greater than expected due to the effects of age alone. Two studies have addressed this question in a cross-sectional design. When groups of younger and older bipolar patients were compared, the older group had greater cognitive impairment, and the degree of deficit compared to unipolar patients and spouse controls was greater among the older group than among the younger group. Longitudinal studies of cognitive changes in bipolar disorder are difficult to conduct and interpret due to changes in mood state that increase within-subject variability. Manic patients over the age of 60 showed steeper cognitive decline than a comparison group, but several other studies in which mood state was required to be the same at baseline and follow-up showed no evidence of more rapid cognitive changes. Future work is needed to understand which patients might be at risk for cognitive declines and how variability of mood state contributes.

Structural Neuroimaging

Despite a growing interest in cognitive performance in geriatric bipolar disorder, structural brain abnormalities associated with bipolar disorder in late life have not been extensively studied. The few studies comparing elderly bipolar patients to age-equivalent healthy individuals have shown structural abnormalities, including more frontal white matter hyperintensities, smaller right caudate volume, greater hippocampal volume, and reduced fractional anisotropy (FA) in the corpus callosum. Some studies of predominantly young to middle-aged adult patients have examined the relationship of age to structural abnormalities and generally found more abnormality with older age, although other studies found no association. Neuronal integrity of the right lenticular nucleus as assessed by MRS was also negatively related to age in one study. Two cross-sectional studies directly compared the age correlation between patients and comparison subjects. One found that bipolar patients had a much larger negative correlation between age and total gray matter volume than healthy individuals. The other found that patients and healthy controls had a similar slope of age-related change in dopamine D_2-receptor occupancy. Evidence from longitudinal studies is mixed: one found that gray matter in hippocampus, fusiform gyrus, and cerebellum declined more over 4 years among bipolar patients than among healthy individuals, but another showed no change over 2 years. No changes in white matter volume were observed over 4 years in patients whose age at first assessment averaged 40 years, and DTI measures of FA showed a similar pattern of change over 2 years in bipolar patients compared to a matched group. The mixed

neuroimaging findings emphasize the heterogeneity among bipolar patients in terms of age-related change. Much more work is needed to understand the role that other age-related factors such as duration of illness, medication history, substance abuse history, and medication comorbidity may play in observed age-related decrements. It will be particularly important to conceptualize bipolar disorder in late life as a multisystem disorder and account for the complex interplay of immunity, inflammation, blood sugar regulation, and cardiovascular function. Each of these is likely to have independent and interacting effects on the brain and therefore influence the course of neurocognitive aging in late-life bipolar disorder.

Onset of bipolar disorder in late life also has been associated with structural brain abnormalities. LOE (onset >45 years) patients were found to have decreased caudate volume relative to age-matched healthy controls and decreased brain volume relative to an EOE group, and another study found that LOE patients had bilateral-temporal sulcal and cortical sulcal atrophy compared to normal, age-matched individuals. Other studies examined white matter hyperintensities and silent cerebral infarctions and found them to be more prevalent among LOE compared to EOE bipolar patients. Consistent with this, among a group of elderly patients with mania and a wide range of ages of onset, later age of onset was related to greater frontal white matter hyperintensities. A negative relationship of age of onset to neuronal integrity (as assessed by the *N*-acetyl aspartate to creatine ratio measured by MRS) of the right lenticular nucleus has also been observed.

Functional Neuroimaging

A growing body of evidence suggests that young to middle-aged patients with bipolar disorder have abnormalities of resting blood flow and metabolism, and altered electrical and blood-based brain response to both cognitive and emotional challenges. These dysfunctions are apparent during episodes of mania and depression but also during periods of euthymic mood. Unfortunately, the authors are not aware of any functional neuroimaging studies that have specifically studied older patients with bipolar disorder or examined a late-onset group of patients. Clearly, this is an important area for future exploration, as functional imaging studies in geriatric psychiatry could help to improve diagnostic specificity, explore mechanisms of treatment response, and understand the interaction of age and age of onset with disease-related pathophysiology.

Summary and Clinical Implications

Fewer studies have examined brain structure and function among elderly patients with bipolar disorder compared with studies of late-life unipolar

depression. The studies that have been completed suggest greater involvement of the basal ganglia in late-onset bipolar disorder compared with late-onset unipolar depression. White matter abnormalities can be observed in both late-life bipolar disorder and unipolar depression, reducing their usefulness in the differential diagnosis of the two conditions. Even fewer studies have examined abnormal brain activity or metabolism in elderly bipolar disorder. The research that has been completed in young and middle-aged individuals shows that abnormal brain metabolism can be observed even in euthymic states.

LATE-LIFE SCHIZOPHRENIA

Course and Features in Late Life

Schizophrenia symptoms typically occur for the first time in late adolescence and the course of the disorder is then generally fluctuating but unremitting into old age, although some proportion of individuals can experience true remission. Thus, there are many elderly individuals who have been suffering from schizophrenia most of their life and are still symptomatic. In addition, new onset of schizophrenic symptoms can occur in middle age, and these individuals have a very similar clinical picture to early-onset cases, albeit slightly less severe. For instance, LOE with schizophrenia onset in middle age have similar levels of positive symptoms, functional impairment, and family history of psychosis, but fewer negative symptoms, lower average doses of antipsychotic medication compared to EOE patients, and somewhat better adjustment in young adulthood. A final group of elderly patients with psychosis have onset after age 60 and have been termed very–late-onset schizophrenia-like psychosis. These individuals are more predominantly female, have lower rates of thought disorder and negative symptoms, have a lower genetic load for schizophrenia, and are more susceptible to antipsychotic side effects, suggesting that they may suffer from a qualitatively different disorder.

Cognitively, LOE patients with onset in middle age have deficient neuropsychological function relative to healthy individuals and display a pattern that resembles that of EOE patients, except that the deficits of LOE patients in learning and abstraction are less severe than those seen in EOE patients. Widespread cognitive deficits also are observed in LOE patients with onset after age 60. There is some debate about whether cognitive performance declines with age among EOE patients with schizophrenia more rapidly than would be expected based on age alone. Studies of EOE elderly who have been institutionalized suggest that a subgroup of patients with very poor outcome shows a steep decline in cognitive function late in life that mimics a dementia. In contrast, EOE outpatients living in the community were found to have declines in neuropsychological performance that did not differ from those of age-comparable healthy individuals.

Structural Neuroimaging

Structural brain abnormalities such as ventricular enlargement, reduced hippocampal size, and reduced whole-brain volume are present in first-episode patients with schizophrenia, and some findings (especially ventricular enlargement) appear to worsen over time, both near the time of onset and in more chronic patients. In one study, some patients followed for 10 years after their first episode had continual ventricular enlargement at a significantly faster rate than that observed in healthy individuals. Progression may be particularly common within the subgroup of EOE patients with very poor outcome and steep cognitive declines in old age. These patients have larger ventricles than both healthy individuals and better outcome patients, show progressive increase in ventricle size, have a more posterior distribution of gray and white matter volume deficits, and evidence more severe and widespread deficits in white matter organization as measured by FA based on DTI. Unfortunately, few of the longitudinal studies in chronic patients have included a healthy comparison group, so it is unknown whether the rate of change later in life is more precipitous than that seen in healthy aging. LOE with schizophrenia also show structural deficits relative to age-matched healthy individuals, although at least one study has suggested that the volume of the thalamus is greater in LOE than EOE. Other studies show that LOE schizophrenia patients have more white matter hyperintensities than those with typical-onset schizophrenia. Some studies have also reported more signs of white matter abnormality and focal cerebrovascular findings among patients with very–late-onset schizophrenia-like psychosis, but other investigations that carefully ruled out organic pathologies have not. One study found greater cerebellar atrophy among very–late-onset schizophrenia-like psychosis patients compared to EOE with schizophrenia.

Functional Neuroimaging

Several functional neuroimaging studies using PET and fMRI have compared the brain function of EOE patients with schizophrenia to age-matched comparison groups and found abnormalities similar to those seen in younger patients, including hypofunction of frontal cortex and abnormal hippocampal activation. Additional PET studies have directly examined age-related change in brain functioning within schizophrenia; although most of the studies were cross-sectional, the samples were generally small and mostly middle aged, and brain function was measured predominantly at rest (see Table 57.2f–1). In general, the reviewed cross-sectional studies have found evidence for negative correlations of hemispheric and regional brain blood flow and metabolism with age, and those that included a control group showed steeper negative slopes among patients in some regions including frontal and temporal cortex and the caudate. In contrast,

one study found regions with more positive age-related slopes among patients, and the only longitudinal study observed no change in degree of hypofrontality across 18 years. Also, it is important to note that the largest study to date, while finding a negative correlation between age and mean hemispheric blood flow, also observed a strong relationship of duration of illness to hypofrontality. In a follow-up study, the same authors found that the relationship of duration of illness to anterior–posterior blood flow ratio persisted despite controlling for and statistically covarying age in the analysis. In a recent investigation, correlations of age with functional brain response to a verbal learning task as measured by fMRI were examined in both patients with schizophrenia and healthy individuals. The authors did not find significant negative correlations with age among the schizophrenia patients; patients specifically failed to show normal positive age correlations in regions associated with the "default mode" (a network of brain regions that is more active during passive baseline conditions than during active experimental tasks).

LOE patients with schizophrenia have been found to have deficits in brain function relative to healthy individuals that are similar to those seen in separate studies of younger patients with schizophrenia and EOE patients. Specifically, deficient blood flow in frontal and temporal regions has been consistently observed in LOE with schizophrenia, and elevated D_2-dopamine receptors in LOE has also been found. The only direct comparison of brain function in LOE compared to EOE patients with schizophrenia found reduced blood flow in temporal cortex among the LOE individuals.

The electrophysiology of late-life schizophrenia also has been examined. EEG abnormalities, such as decreased amplitude of the P300-orienting response, have been observed in young individuals with schizophrenia and in EOE with schizophrenia compared to healthy individuals. The latency of the P300 response has also been found to relate positively to age among patients with schizophrenia. Since P300 latency and amplitude become more abnormal in healthy aging, it is not clear whether the age-related changes in schizophrenia are greater than expected. The mismatch negativity component, in contrast, does not seem to be impaired in first-episode younger patients, whereas deficits are commonly found in more chronic and older patients with schizophrenia. Longitudinal studies will be needed to confirm that these differences reflect steeper age-related decreases among the schizophrenia group rather than cohort effects. Interestingly, general EEG and P300 deficits have not been found among LOE with schizophrenia, although an increased latency of the N400 semantic incongruity response was observed in LOE patients but not EOE patients compared to controls in one small study.

Summary and Clinical Implications

Like young patients with schizophrenia, ventricular enlargement and reduced hippocampal volume have been observed when brain images of older patients with schizophrenia are compared with age-matched, healthy individuals. Cortical thinning of the posterior third of the superior temporal gyrus on gray matter parcellated images, another consistent imaging finding in younger patients with schizophrenia, has not been systematically investigated in older patients. Similar patterns of abnormal resting cerebral metabolism and blood flow have been observed in younger and older patients with schizophrenia. Whether the pattern of regional brain abnormality for resting blood flow and metabolism differs in some subtle manner between younger and older patients with schizophrenia awaits an appropriately powered study comparing these two groups. Despite the interesting fMRI data showing a complex pattern of increased and decreased brain activation among patients with schizophrenia, little research using cognitive challenge tasks to study brain activation in older patients has been reported. Findings from current P300 and N400 studies of late-onset schizophrenia patients suggest that differences in functional brain activation of early- and late-onset patients might exist. In contrast to growing interest in the use of functional and structural brain imaging to predict and measure treatment response in geriatric mood disorders, these techniques have not been widely applied in the study of psychosis in the elderly.

LIMITATIONS OF EXISTING LITERATURE

There are several limitations of the existing literature that make it difficult to draw firm conclusions about the neural systems involved in late-life mental illness. First, as mentioned in the beginning of the chapter, in order to begin to disentangle the effects of aging and illness, a cross-sectional design should compare three groups of patients (early-onset young, early-onset old, and late-onset old) to two groups of healthy individuals (young and old). Although few studies have compared early- and late-onset older adults to each other, none of the reviewed studies contained all of these groups, so, for many of the neuroimaging findings, it is difficult to know if the magnitude of age-related change is greater than expected due to normal aging and also whether the effects are different depending on age of onset. This is especially important for studies investigating late-life depression and cognitive impairment, which have not studied the effects of age of onset with regards to longitudinal conversion to dementia. Ideally, longitudinal studies would follow early- and late-onset patients over many years to identify treatment response and monitor the associations between

depressive and cognitive symptoms. Some such studies are underway in the realm of unipolar depression, but are also needed for other disorders. Second, as can be seen from the above review, many of the neuroimaging abnormalities (e.g., reduced frontal volume, white matter hyperintensities, hypofunction of the prefrontal cortex) are common to multiple psychiatric disorders. Direct comparisons between groups of elderly patients with different disorders are rare, although at least one study did find differences between the structural abnormalities of late-life mood disorders compared to late-life psychotic disorders. Further work is needed to determine the specificity of late-life neuroimaging findings to particular disorders. A third limitation of the existing literature is that very little is known about neural systems in late-life anxiety disorders or geriatric patients with personality disorders. These gaps will need to be filled in order to fully understand the pathophysiology of late-life mental illness.

FUTURE DIRECTIONS

In addition to addressing the limitations above, future neuroimaging studies in geriatric mental illness will benefit from combining multiple imaging technologies. For example, to better elucidate the functional systems that are involved in late-life mental illness, results from metabolic and blood flow imaging techniques can be combined with mapping of white matter tracts using DTI. Similarly, combining the spatial resolution of fMRI with the temporal resolution of EEG or MEG is likely to yield sensitive measures of pathology. More work is also needed to investigate the functional and structural connectivity of brain networks associated with geriatric psychiatric disorders and how disruptions in these networks predict treatment outcomes and comorbidities or functional impairments. The future is also likely to bring an increased emphasis in the use of functional neuroimaging to examine predictors and mechanisms of treatment response. It is likely that metabolic, blood flow, blood oxygenation, and neurochemical imaging all will be brought to bear in these types of studies, which ultimately promise to help address difficulties in treating geriatric patients. One day, it may be possible to use neuroimaging measures to aid in diagnosis and guide treatment decisions, although much work is needed to establish the validity and reliability of such techniques before they can be put to clinical use. Studies that combine imaging information with genetic testing are becoming more common, and could also be useful to help bring individualized medicine to geriatric psychiatry. Neuroimaging techniques are powerful tools that have already provided important clues in the search for knowledge about etiology, course, and treatment of late-life mental disorders. In the coming years, advances in these techniques and their use in combination with each other and with genetic technologies will lead to even greater advances to the benefit of the growing numbers of elderly mentally ill.

57.2g Genetics of Late-Life Neurodegenerative Disorders

SEETHALAKSHMI RAMANATHAN, M.B.B.S., D.P.M., AND STEPHEN J. GLATT, PH.D.

Genetic studies of any complex condition, including late-life neurodegenerative disorders, attempt to identify the elemental biologic underpinnings of these disorders to facilitate their early identification, early intervention, and ultimately, prevention. In addition, the identification of genes that influence the development and/or progression of these illnesses may foster medicinal chemistry applications that target faulty DNA sequences or the altered RNA transcripts or proteins produced by such genes. Such discoveries could usher in the long-awaited era of "personalized or precision medicine" in which the treatment of any given

late-life neurodegenerative disorder can be tailored to individual patients based on their genetic and biologic background.

The search for genes influencing late-life neurodegenerative disorders falls under the broader umbrella of genetic epidemiology, which has been defined as a science that deals with etiology, distribution, and control of disease in groups of relatives and with inherited causes of disease in populations. Genetic epidemiologists examine the distribution of illness within families with the goal of finding genetic and environmental causes of illness. Genetic epidemiologic research on a particular disorder such as Alzheimer disease (AD) tends to follow a series of questions in a logical progression. This sequence proceeds as follows: First, we ask, "Is the phenotype familial?" or "Does it run in families?" which can be established by family studies. Second, "What is the relative magnitude of genetic and environmental contributions to the phenotype?" which can be established by twin studies. Third, "How is the phenotype transmitted from generation to generation?" which can be addressed by segregation analyses. Fourth, "If genes mediate this transmission, where are they located?" a question that may be answered by linkage studies. Fifth, "What are the specific genes and variants in those genes that influence risk for the phenotype?" which can be addressed by association studies, including genome-wide association studies (GWASs). Finally, "How do the specific genes functionally cause the illness?" which is addressed by mechanistic studies looking into gene and protein expression and further functional assays. These are difficult questions to answer for any trait, but particularly so for phenotypes as complex as late-life neurodegenerative disorders, which can often be confused or misconstrued with other medical, psychiatric, or substance use disorders. Fortunately, the wide variety, specificity, and power of available methods have allowed genetic researchers to begin to find meaningful answers to some of these questions for each late-life neurodegenerative disorder.

GENETIC METHODS AND PRINCIPLES

Family Studies

The first question that must be asked and answered when attempting to delineate the genetic and environmental components of a complex late-life neurodegenerative disorder is, "Does the phenotype run in families?" or, "Is this phenotype familial?" This question can be answered through the use of family studies. The basic design of the family study begins with the ascertainment of a group of subjects who are affected by the disorder (cases) and a comparable group of comparison subjects who do not have the disorder. Next, the biologic relatives of these index subjects, or "probands" are ascertained and evaluated for the presence of the illness, or in some cases, subthreshold forms of the illness. The rate of the disorder or

associated "spectrum conditions" among family members of affected probands is then compared to the rate of the disorder among family members of comparison probands to determine the familial risk or relative risk. If a late-life neurodegenerative disorder has a genetic etiology, then biologic relatives of cases should have a higher likelihood than relatives of comparison subjects of carrying the gene or genes that influenced illness in their relative, and thus they should be at greater risk for the illness themselves. In addition, the risk to relatives of cases should be correlated with their degree of relationship to the proband, or the amount of genes they share in common. First-degree relatives such as parents, siblings, and children, share 50 percent of their genes, on average, with the proband. Thus, first-degree relatives of cases should be at greater risk for the disorder than second-degree relatives (grandparents, uncles, aunts, nephews, nieces, and half-siblings), who share only 25 percent of their genes with the proband.

Twin Studies

Once a disorder has been established as familial, it becomes necessary to determine if that pattern is attributable to the inheritance of genes or to shared familial and other environmental factors. It is also important to quantify the contribution that genes make relative to that made by environmental factors, as this may encourage or discourage future molecular genetic studies; it may also influence the decisions made by individuals seeking genetic counseling and the usefulness of family information in identifying high-risk individuals to target for early intervention and prevention protocols. These questions can be answered by twin studies. In twin study designs, the ratio of concordant:discordant MZ twin pairs is compared to the ratio of concordant:discordant DZ twin pairs. If the concordance for a late-life neurodegenerative disorder is higher among MZ twin pairs than DZ twin pairs, this is a good indication that there is a genetic contribution to the disorder; if MZ and DZ twin pairs have approximately equal concordance rates, environmental factors are more strongly implicated. Concordance rates among twin pairs are then used to estimate the "heritability" of a disorder. Heritability refers to the ratio of genetic to phenotypic variances, or the proportion of variance in risk for a late-life neurodegenerative disorder that is accounted for by variability in genetic factors. A heritability of 1.0 (or 100 percent) indicates that all variability in the phenotype is due to genetic factors alone. In contrast, a heritability of zero attributes all phenotypic variation to environmental factors.

Segregation Analyses

Once twin and/or adoption studies demonstrate that the familial

transmission of a disorder is due, at least in part, to genetic factors, it becomes necessary to identify the manner in which those genetic factors exert their influence. The mode of transmission of a late-life neurodegenerative disorder through multiple affected families can be modeled statistically through the use of segregation analysis. Segregation analysis is a flexible procedure that can test various known and hypothesized modes of genetic transmission; the familiar mendelian model of single-gene transmission of a trait is only one of the many transmission mechanisms that can be tested. Mendelian diseases have recognizable inheritance patterns (autosomal dominant, autosomal recessive, and X-linked) and generally are caused by mutations in a single gene within a particular family. In contrast to Mendelian diseases, complex diseases display no clear inheritance pattern. Complex diseases are multifactorial in their etiology and are caused by an interacting web of genetic and environmental risk factors. The genetic risk factors for such complex diseases are generally referred to as *risk* or *susceptibility genes*, in which genetic variants that are common in the population act to increase risk of developing the disease. Unlike mutations in mendelian genes, susceptibility genes are neither necessary nor sufficient to cause disease.

Linkage Studies

Knowing that genetic factors are involved in the etiology of a late-life neurodegenerative disorder—and to what degree and in what manner—is essential for designing optimal molecular genetic studies to reveal the chromosomal location of the responsible risk genes. To identify regions of chromosomes that have a high likelihood of harboring risk genes for (especially mendelian forms of) late-life neurodegenerative disorders, linkage analysis is a highly appropriate strategy. Families are ascertained for linkage analysis through a proband affected with the disorder of interest. Each individual in the family is then genotyped as a series of DNA markers (not necessarily in genes) spaced evenly throughout the genome, and the cosegregation of these DNA markers with the illness is tracked in each pedigree. Evidence for cosegregation at each marker locus is summed across pedigrees to derive an index of the likelihood of the obtained patterns of marker-phenotype cosegregation given the sampled pedigree structures.

Association Studies

Once regions of certain chromosomes have been implicated from linkage analysis as harboring a risk gene for a disorder, the next step is to identify what specific gene is segregating through families to give rise to that linkage signal. A gene can be selected for such an analysis subsequent to linkage analysis as a means to follow up on evidence for increased genetic

similarity at a locus among affected individuals in a family (i.e., a "positional candidate gene" approach). Alternatively, specific genes can be examined in the absence of linkage information if there is some compelling physiologic reason to suspect that the gene influences risk for a given disorder (i.e., a "functional candidate gene" approach). For example, dopamine-system genes, such as receptors and transporters, are commonly examined as functional candidates for Parkinson disease (PD), based on the neural structures involved in its pathology and treatment. In contrast to linkage analysis, which uses random DNA markers as proxies for nearby risk genes, genetic association analysis is an appropriate method for determining if a particular gene variant has a direct effect on risk for an illness, or is in very tight linkage disequilibrium (LD) with such a gene.

Genome-Wide Association Studies

In the last few years, the completion of the human genome project and advancements in the genotyping of single nucleotide polymorphisms (SNPs) laid the foundation for a more broad examination of the human genome: GWASs. GWASs, as the name suggests, examine the entire genome for causal associations with specific traits. This broad approach accords GWAS more flexibility in exploring complex diseases, including late-onset Alzheimer disease (LOAD). GWAS techniques examine numerous markers distributed throughout the genome in order to understand the contribution to disease of various types of SNPs, including LD-based markers that are highly correlated with the causal allele, markers for missense mutations associated with mendelian diseases, and convenience-based markers that are chosen based on logistical conveniences such as cost.

Clearly such a broad examination has advantages as well as disadvantages. One advantage that GWAS has over other methods is its unbiased nature; however, the examination of the entire genome requires large samples to establish relationships with adequate power. Another unfortunate constraint of most current genome-wide association methods is that, unlike candidate genes which are often typed on functional polymorphisms, the DNA markers included in GWASs are often intergenic or otherwise do not constitute any recognized functional motifs. Researchers have been following and attempting to replicate the extensive list of SNPs identified by GWASs, and are now concluding that while these early "hits" are useful in understanding the pathology of various diseases, the added benefit of continued GWAS analysis is diminishing. This has led to forays into newer areas such as pooling summary statistics from multiple GWASs by meta-analysis, pooling individual data from independent GWASs by mega-analysis, and examining functional outcomes associated with implicated loci, including their identification as expression quantitative trait loci (eQTL), or their impact on protein interaction

networks.

Transcriptomics

Individual candidate-gene studies and GWASs have opened up a new catalog of risk genes, triggering new research into functional aspects of genes, including their potential as biomarkers. Transcriptomics, or gene expression analysis, measures the mRNA levels of all known human genes in a given sample simultaneously. In addition to mRNAs, transcriptomics also aims to understand noncoding RNAs and small RNAs, transcriptional structure of genes, splicing patterns, and other posttranscriptional modifications. These transcripts, whose expression is regulated by both genetic (i.e., DNA sequence) and environmental (i.e., chemical or biologic inputs transduced onto the genome *via* epigenetics) factors have both a trait-like quality and a state-like quality, and thus may better fulfill the definition of a biomarker than the DNA sequence variation alone (which, of course, is static and cannot reflect the state of disease or health as it changes through development). This search for biomarkers is not without its limitations, including bias (due to potential sample contamination), overfitting of statistical models due to overparameterization, and lack of statistical power. Nonetheless, transcriptomic studies have been particularly useful in identifying biomarkers that can predict various disorders.

MAJOR OR MILD NEUROCOGNITIVE DISORDER DUE TO ALZHEIMER DISEASE

AD is a progressive neurodegenerative disorder characterized by an insidious onset and progressive loss of memory and other cognitive functions. AD is the most common form of dementia in older adults. Two broad subtypes of ADs have been identified: an early-onset subtype, defined as occurring before age 65 years, accounts for no more than 5 percent of cases, and a late-onset subtype, defined as occurring on or after age 65 years, accounts for 95 percent or more of cases.

Early-onset AD has been characterized as a familial, autosomal-dominant genetic disease with causative mutations in several genes. Early family studies of early-onset AD revealed linkage to a locus on chromosome 21q, which was later identified as the gene for amyloid precursor protein (*APP*) which encodes the beta amyloid protein found in amyloid plaques. However, since linkage to chromosome 21 was not found in most families with early-onset AD, other potential loci were investigated. This led to the discovery of other gene mutations in presenilin 1 (*PSEN1*) on chromosome 14 and in presenilin 2 (*PSEN2*), based on homology to *PSEN1*, on chromosome 1. The net effect of the mutations in these genes is overproduction of the more pathogenic form of beta amyloid; that is, more beta amyloid 42 relative to beta amyloid 40.

The less complicated genetic nature of early-onset AD paved the way for a greater understanding of the genetically complex LOAD, which is sporadic or familial with no clear segregation patterns in families. AD has been estimated to be 60 to 80 percent heritable with influence from nonshared environmental factors. Thus far, *APOE* is the only gene that has been reproducibly and consistently identified as a risk for the disease, with just a single copy of *APOE ε4* allele increasing the risk of AD by approximately 300 percent. Recent studies have also identified that *APOE* affects age of developing dementia in a gene-dosage dependent manner. On the other hand, the *APOE ε2* allele has been shown to reduce risk for AD relative to the *ε3* allele. *APOE ε4*, however, does not account fully for the genetic variance in AD. Effects have been noted for no less than 40 candidate loci in LOAD; however, the effects of each variant are minimal. Some of these genes include the ones implicated in early-onset AD (*APP*, *PSEN1,* and *PSEN2*) and other tauopathies such as frontotemporal dementia, progranulin (*GRN*), and microtubule-associated protein tau (*MAPT*). A rare mutation in the triggering receptor expressed on myeloid cells (*TREM2*) was recently identified as a risk factor that can triple one's risk of developing AD, providing support to the role of neuroinflammation in AD. Among the variants, an arginine-to-histidine substitution at amino acid 47 (R47H) had the strongest association with AD, having an effect size similar to *APOE ε4*. Some of the others include bridging integrator 1 (*BIN1*), clusterin (*CLU*), complement component [3b/4b] receptor 1 (*CR1*), phosphatidylinositol-binding clathrin assembly protein (*PICALM*), siglec-3 (*CD33*), GRB2-associated binding protein 2 (*GAB2*). A meta-analysis of GWASs of clinicopathologic AD using data from 4,914 brain autopsies confirmed the association of *ABCA7*, *BIN1*, *CASS4*, *MEF2C*, and *PICALM* with neurofibrillary tangles and neuritic plaques, both of which are involved in the pathology of AD. Another recent meta-analysis of GWASs identified 20 genes that were statistically significantly involved. When these loci were explored in a pathway study, four functional modules became evident including ubiquination, endocytosis, immunity, and cholesterol metabolism. In addition to the role of the immune system in AD, genes involved in the insulin-like growth factor (ILG) and genes regulating the cholinergic and glutamate receptors have also been implicated in AD. Studies examining the role of genes in the behavioral and psychological symptoms associated with AD have implicated a number of genes including serotonergic genes (serotonin receptor [*HTTLPR*] and transporter [*SCL6*]), dopaminergic receptor and metabolic genes (dopamine receptor [*DRD1* and *DRD3*] and catechol-*O*-methyl transferase [*COMT*] genes), and nicotinic genes in psychotic symptoms.

Most transcriptomic studies in AD have focused on areas that demonstrate increased amyloid accumulation or the medial temporal region. Broadly, studies have noted dysfunction of genes that mediate two

broad biologic processes: calcium channel signaling and neuroinflammation. These have also been identified in peripheral blood-based markers, including blood mononuclear cells and leukocytes. Gene expression studies of the entorhinal cortex and hippocampus have identified mitochondrial dysfunction in AD.

MAJOR OR MILD NEUROCOGNITIVE DISORDER DUE TO PARKINSON DISEASE

PD is a neurodegenerative disease characterized clinically by a progressively worsening movement disorder and dementia in 20 to 30 percent of cases late in the course of disease. Similar to AD, PD largely follows a complex pattern of inheritance with only 5 to 10 percent aggregating in families and showing an autosomal-dominant or recessive inheritance. It is therefore not surprising that early family studies failed to find much support for a familial aggregation of the disorder, causing many to suspect that the etiology of PD was largely (if not exclusively) driven by environmental factors. However, later studies ultimately supported a genetic contribution to the etiology of the disorder. The largest family study has been the Mayo Clinic study, which established that biologic relatives of a patient with PD are at an approximately 70 percent elevated risk of themselves developing the disorder as compared to relatives of unaffected individuals. It appears that genes may only (or more strongly) contribute to the risk for early-onset PD (less than 66 years of age). Relatives of such early-onset PD patients are at a 2.6-fold increased risk of developing PD as compared to relatives of patients with onset of PD later than 66 years, who were not at an increased risk for the disorder. Segregation analyses further suggest that early-onset PD may be driven by an autosomal-recessive mechanism.

Late-onset PD (like AD), on the other hand, has a more complex etiology involving environmental factors and not excluding some major genes of additive or recessive effects. Linkage studies of PD have identified certain distinct loci as possibly harboring risk genes for the disorder in chromosomes 1, 2, 4, 5, and X. Numerous functional candidate genes have also been reliably implicated in the etiology of PD by association analysis. GWASs have further added to this list by identifying unsuspected candidate genes for PD, as well as other late-life neurodegenerative disorders. Genes encoding alpha-synuclein (*SNCA*, which accumulates in Lewy bodies), *MAPT* (which is a constituent of tangles in AD), and leucine-rich repeat kinase 2 (*LRRK2*) have also been repeatedly associated with PD. A recent meta-analysis of GWASs found that together *MAPT* and *SNCA* contribute to up to 25.6 percent of the population attributable risk for PD. Mutations in parkin (*Park2*), *PTEN-induced kinase 1* (PINK1) and *oncogene DJ1* have been associated with autosomal recessive parkinsonism, which is early onset and responsive to DOPA. However, considering the significant clinical role of the dopaminergic system in PD, other dopaminergic system

candidate genes, such as *DRD1* and *DRD2* which code for dopamine receptors, are not similarly implicated. Similarly, genes involved in other neurodegenerative disorders such as APOE have not been implicated. Another meta-analysis of genome-wide association data of 13,708 cases with PD and 9,522 comparison subjects identified 26 loci, six of which were novel candidate genes (*SIPA 1L2, INPP5F, MIR4697, GCH1, VPS13C*, and *DDRGK1*). The genes at these 26 risk loci meditate diverse biologic processes, but collectively they are enriched with genes that bind nucleotides, and genes that are involved in dopamine biosynthesis. Similar to GWAS in AD, these new findings are triggering new studies aimed at understanding the various functional aspects of the implicated genes. Transcriptomic studies involving substantia nigra pars compacta (SNpc) tissues have noted altered expression of genes involved in dopamine neurotransmission, mitochondrial function, protein degradation, and synapse dynamics.

MAJOR OR MILD NEUROCOGNITIVE DISORDER WITH LEWY BODIES (DEMENTIA WITH LEWY BODIES)

Dementia with Lewy bodies (DLB) is characterized by cognitive decline, parkinsonian signs and symptoms, fluctuations in cognition and attention, and visual hallucinations. Individuals with DLB can also have REM sleep disturbance, repeated falls, autonomic dysfunction, and a heightened sensitivity to neuroleptics. Based on the distribution and density of Lewy bodies, DLB can be categorized into three types: the brainstem-predominant type, the limbic (transitional) type, and the neocortical type (also known as diffuse Lewy body disease [DLBD]).

DLB has a great deal of clinical overlap with both AD and PD. DLB differs from AD in that the onset of hallucinations is much earlier in DLB. Similar to PD, individuals with DLB demonstrate parkinsonian signs; however, these motor manifestations are markedly more in PD as compared to DLB. DLB has been found to be largely sporadic and has been noted to be complex in nature, resulting from genetic and environmental interactions. Considering this sporadic nature, most genetic studies of DLB have been limited to family studies. Family studies have noted that DLB can be autosomal dominant or recessive. Reflecting the overlap in clinical signs, DLB shares a considerable genetic overlap with AD and PD. For example, the *APOE4*, synuclein genes (*SNCA* and *SNCB*) and *PSEN1* genes have been found to be risk factors in DLB.

MAJOR OR MILD FRONTOTEMPORAL NEUROCOGNITIVE DISORDER (PICK DISEASE AND OTHER FRONTOTEMPORAL DEMENTIAS)

Pick disease, or frontotemporal lobar degeneration, is a progressive dementia characterized clinically by prominent behavioral and language deficits and neuropathologic signs including atrophy in the frontal and

temporal lobes, *tau*-containing intraneuronal inclusion bodies (Pick bodies), and ballooned neurons. There are several clinical syndromes of frontotemporal lobar degeneration including frontotemporal dementia, semantic dementia, and progressive nonfluent aphasia. Other related neurodegenerative diseases with similar clinical features and *tau* neuropathology include corticobasal ganglionic degeneration, progressive supranuclear palsy, and motor neuron disease. Collectively, these neurodegenerative diseases are commonly referred to as "tauopathies."

Frontotemporal dementia has rarely if at all been evaluated within the context of family, twin, or segregation studies; thus, it is difficult to estimate the familial risk, heritability, and mode of inheritance of this group of disorders. However, within the context of several linkage studies, it has been shown that frontotemporal dementia may be inherited in an autosomal-dominant manner with age-dependent penetrance (i.e., risk increases with age). One of the most routinely identified loci linked to frontotemporal dementia has been chromosome 17q21. Approximately10 to 20 percent of familial cases are accounted for by mutations in the *MAPT* and *GRN* genes, which are located in this region. In addition to these, *C9ORF72*, genetically linked to chromosome 9p, has been recently identified as having a mutation that may singly account for the most number of cases (11.7 percent) of familial FTD. The association with 9p has been found by at least two GWASs, thus giving credence to the importance of 9p in FTD. While *MAPT* is associated with an increased deposition of phosphorylated tau, *GRN* and *C9ORF72* have been associated with deposition of the transactive response DNA binding protein of 43 kDa (*TDP-43*). GWAS has also identified associations with immune system processes and possibly lysosomal and autophagy pathways in FTD through 6p21.3, encompassing the *HLA* locus (immune system), and 11q14, encompassing *RAB38/CTSC* (transcripts of which are related to lysosomal biology).

MAJOR OR MILD VASCULAR NEUROCOGNITIVE DISORDER (VASCULAR DEMENTIA)

Vascular dementia (VaD) is the second most common form of dementia in older adults. VaD is caused by the effects of cerebrovascular disease and events (i.e., "stroke") that initiate a cascade leading to CNS damage and, ultimately, a dementia syndrome in some individuals. Evidence for the role of genetic factors in VaD (other than familial VaD) has largely been limited.

While familial forms of VaD are uncommon (accounting for less than 10 percent of cases of VaD), cerebral autosomal-dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL) and hereditary cerebral hemorrhage with amyloidosis-Dutch type (HCHWA-D) are among the better studied genetic syndromes of cerebrovascular disease and dementia. CADASIL is a syndrome of subcortical small vessel disease with

lacunar strokes, migraine, and dementia. Discovery of linkage to chromosome 19q12 in two unrelated families and, subsequently, mutations in the *NOTCH3* gene explain the cause of most cases of CADASIL. *NOTCH3* is expressed in vascular smooth muscle cells and is important in cell proliferation and differentiation. FCAA, or familial cerebral amyloid angiopathy, is another heritable form of VaD, which is characterized by the deposition of amyloid on the vessel walls. A number of distinct forms of FCAA have been identified. Hereditary cerebral hemorrhage with amyloidosis-Dutch type, HCHWA-D, is an autosomal-dominant syndrome primarily of hemorrhagic strokes and dementia. Since extensive deposits of beta amyloid protein in brain vasculature had been found in HCHWA-D, linkage to the *APP* gene was tested for and was found in two unrelated families with HCHWA-D. A point mutation in the *APP* gene was found in two patients, providing evidence that *APP* gene mutations can cause HCHWA-D. Italian and Flemish types of HCHWA also are caused by point mutations in the *APP* gene and exhibit autosomal-dominant transmission. The Icelandic type of HCHWA, also with autosomal-dominant transmission, is caused by point mutation in the cysteine protease inhibitor cystatin C gene, while the British type of FCAA has been associated with mutations in the *ITM2B* gene (also called *BRI2*).

The genetic underpinnings of most cases of VaD however remain largely undetermined. This deficiency stems largely from the heterogeneity of the illness. VaD and AD frequently occur together as "mixed dementia." *APOE* gene variants are known to affect risk for cerebrovascular disease, and presenilins have been shown to interact with *NOTCH3*—suggesting mechanistic overlap if not the possibility of additional genetic overlap between AD and VaD, which may be driving the comorbidity. Studies examining candidate genes have noted inconsistent associations with genes coding for proteins involved in lipid metabolism, inflammation, and the renin–angiotensin system. A complex disease such as VaD warrants exploration into epistatic interactions. Studies have identified that epistatic interactions may act as a stronger risk factor for VaD. For example, the combined genotype of tumor necrosis factor (*TNF*α T-1031C) and heat shock 70-kDa protein 1A (*HSP70-1* A-110C) showed a much stronger odds ratio as compared to the individual genotypes. Similar synergistic relationships have been noted between transforming growth factor beta 1 (*TGF-β1*) and angiotensinogen (*AGT*) genes, and between family with sequence similarity 134 member B (*FAM134B* [rs10041159]) and tumor necrosis factor receptor superfamily member 19 (*TNFRSF19* [rs9317882]). A recent GWAS also noted an association with a variant near the androgen receptor (*AR*) gene on the X chromosome. While the mechanistic role of this association is unclear, this finding replicates past reports of associations with CAG repeat lengths on AR and VaD.

MAJOR OR MILD NEUROCOGNITIVE DISORDER DUE TO PRION DISEASE (CREUTZFELDT–JAKOB DISEASE AND OTHER TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES)

Creutzfeldt–Jakob disease (CJD) is one of several neurodegenerative diseases, characterized by progressive dementia and ataxia, called *transmissible spongiform encephalopathies* (TSEs). TSEs are rare diseases that include CJD, kuru, Gerstmann–Sträussler syndrome, and fatal familial insomnia. The sporadic form of CJD is the most common TSE, with one to two incident cases per million people worldwide. The TSEs are unique in that they are inherited, sporadic, or acquired by infection. An abnormal isoform of the prion protein has been implicated as the causal agent in the TSEs. The prion protein exists in one of two states: PrP^{C}, for the normal cellular form of the protein, and PrP^{SC}, for the abnormal isoform isolated from the brains of individuals with TSE. The genetic epidemiologic study of this class of late-life neurodegenerative disorders has largely bypassed behavioral genetic approaches such as family and twin studies; thus, it has never been firmly established that these disorders have a familial or genetic basis. Data from Finland showed that 6 of 30 cases observed nationwide from 1975 to 1984 were familial cases, and all belonged to the same extended kindred. Further evaluation of this pedigree identified autosomal-dominant transmission of an early-onset long-duration form of the illness.

Despite the dearth of behavioral genetic data on CJD and related disorder in general, molecular genetic methods have been used often in the study of these disorders, largely due to their ease of application. Much of the focus of earlier studies had been on the *PRNP* gene, which encodes the prion precursor protein. In fact, most of the affected individuals in the Finnish family described above also carried a nonsynonymous mutation in codon 178 of *PRNP*, whereas none of 10 healthy controls carried the same variant. Since then *PRNP* (specifically an amino-acid polymorphism at codon 129 coding for methionine or valine) has been confirmed in a number of studies as a reliable risk factor for both variant or vCJD and sporadic or sCJD. Over the last 5 years, a number of other risk genes have been identified, although *PRNP* still remains the strongest universal factor. Variations in associations have been noted across populations for sCJD; SNPs at the *ZBTB38–RASA2* locus (a zinc finger transcriptional activator that binds methylated DNA) have been associated with CJD in UK populations, while an SNP in the *CHN2* gene has been found to be associated with vCJD in German population. Some of the other associations include myotubularin-related protein 7 gene (*MTMR7)* and neuronal PAS (per-ARNT-sim) domain-containing protein 2 gene (*NPAS2*), which have been identified to increase risk independently, and β-site APP cleaving enzyme 1 (*BACE1)* influence the risk of sCJD by interacting with PRNP gene.

MILD NEUROCOGNITIVE DISORDER

The DSM-5 introduced a new category of neurocognitive disorder—mild neurocognitive disorder (or mNCD). The introduction of mNCD in DSM-5 will likely help formalize a uniform definition which, in turn can help further our understanding of factors that drive progression to dementia. mNCD essentially refers to cognitive impairment, the severity of which does not amount to dementia. mNCD can be characterized based on the pathology into different subtypes. Two of the most popular subtypes include mNCD secondary to AD and mNCD secondary to vascular processes. As the titles indicate, the underlying pathogenic and genetic mechanisms are similar to the major neurocognitive disorders. Understanding the genetics of mNCD becomes critical for purposes of early intervention and prevention and also furthering personalized medicine. Thus far, most of this research has been limited to individuals with the amnestic type of mNCD and progression to AD. Thus, it is natural that most studies have focused on *APOE*. While individual studies produced varying results (likely driven by ancestral differences in genetic background and allele frequencies), a recent meta-analysis revealed that *APOE4* was associated with an increased relative risk (2.09) of conversion to AD. Similarly, studies have noted that the *ACT* and *CHRNA7* genes may modify risk of progression to dementia, with the former increasing risk and the latter being protective.

FUTURE DIRECTIONS

Over the last decade, significant strides have been made in understanding the genetics of late-life neurodegenerative disorders. Despite the initial successes, association studies remain plagued by limitations, including their propensity to produce false-positive results and their limited breadth in terms of identifying causal variants rather than markers. Regarding the former, genes identified as associated with a late-life neurodegenerative disorder in an initial study often overestimate the true effect size and subsequently fall victim to the winner's curse, wherein the same magnitude of an effect cannot be replicated. Regarding the latter, association methods have traditionally focused on one or, at most, a handful of genes at once, whereas linkage analysis constitutes a genome-wide survey of (relatively) unselected markers. Unfortunately, the prior probability of selecting the right candidate gene (out of ~25,000 human genes) and the right polymorphism (out of more than 11,000,000 in the human genome) for analysis is understandably remote. Most candidate genes for late-life neurodegenerative disorders have been targeted based on their expression within systems widely implicated in the disorder (e.g., amyloid plaques in AD and functional candidate genes in the dopamine neurotransmitter systems in PD). This approach has been critical in clarifying the nature of

dysfunction within these recognized candidate pathways; however, it has not been optimal for identifying additional novel risk factors outside of these systems. GWASs have attempted to fill some of these deficits. The result has been the elucidation of a more complex profile of gene involvement. The discovery of the complexity led to the identification of newer and advanced methods including imputation, which relies on the knowledge that certain gene sequences are usually coinherited. GWAS often identifies a large number of loci, some of which are noncoding. This has led to the identification of expression quantitative trait loci (eQTLs). eQTLs are regions in the genome that regulate nearby genes. In their attempts to integrate functionality with observations, researchers are also beginning to look into one of the limitations of GWASs—the tendency to filter out "near-misses." Preliminary work in this area has led to the identification of an "inflammatory subtype" of PD, which may have a greater involvement of genes associated with the immune system.

The multifactorial polygenic etiologies and heterogeneity of late-life neurodegenerative disorders have proved to be a huge challenge in the discovery of their underlying genetic bases. The multifactorial polygenic nature of these diseases dictates that the "signals" obtained in linkage and association studies will be numerous and of very low intensity, while the heterogeneity of these disorders increases the "noise" against which these already faint signals must be detected. Some of the most effective ways of combating these complexities are through the maximization of power, both by increasing sample size and by studying homogeneous groups of affected individuals. To identify the numerous genes with small effects on risk for late-life neurodegenerative disorders, various data-pooling strategies, such as combination of study-level data by meta-analysis or direct combination of primary data by mega-analysis, can be particularly effective. However, to overcome the obstacles introduced by heterogeneity, delineating and studying smaller more homogeneous subgroups of affected individuals may have the greatest beneficial effects on power. When used in tandem, the practices of pooling and splitting will yield maximal power for genetic studies, and hasten the discovery of the full compendium of risk genes for each heritable late-life neurodegenerative disorder.

Along the same lines, researchers are beginning to explore other approaches such as epigenomics, which has led to the study of DNA methylation and microRNA expression. As an example, in DLB, studies have noted an epigenetic regulation of the *SNCA* gene. The p.A53T mutation in *SNCA* can cause an overall imbalance in allelic expression by epigenetically silencing the mutant gene. Other promising avenues for elucidating risk genes include the analysis of gene–gene interactions as well as the aggregation of risk genes into polygenic scores which in aggregate account for a larger proportion of variance in susceptibility than any single variant in isolation. As an example, a genetic risk score, based on

ABCA7, *BIN1*, *CD2AP*, *CLU*, *CR1*, *MS4A4E*, *MS4A6A*, and *PICALM*, was noted to predict the rate of progression (a twofold increase in rate) to AD from mNCD. But, perhaps, one of the most interesting shifts in paradigm is the recommendation to examine neurodegenerative disorders from the bottom-up, that is, identifying common biologic pathways in neurodegenerative disorders that become individualized, leading to the unique clinical and pathologic characteristics. Recent GWASs have emphasized the biologic pathways that have subserved shared mechanisms between AD and PD such as apoptosis, autophagy, mitochondrial dysfunction, ubiquitin–proteosome system, oxidative DNA damage, inflammation, lipid metabolism, and vascular changes.

CLINICAL IMPLICATIONS

Since the first draft of the human genome was produced in 2001, scientists have touted the promise of genetic analysis for identifying risk factors for common diseases and the development of personalized (or, more recently, "precision") medicine. Yet, the vast potential of genetic studies to change the clinical practice of psychiatry is just beginning to be tapped. Recently, commercial genetic tests for (especially mendelian forms of) late-life neurodegenerative disorders have become available to individuals with a strong family history of illness (e.g., *APP*, *PSEN1*, and *PSEN2* for AD, *MAPT* for frontotemporal dementia and Pick disease, *PRNP* for CJD, and *PARK*s *1,2,6,7*, and *8* for PD). However, individuals in the general population cannot be tested for the possession of particular genotypes to determine their cumulative risk of developing a particular disorder. Similarly, over the past decade, progress has been made in understanding the factors that contribute to conversion to AD. However, despite these advances, the leads that have been generated from molecular genetic studies are simply not yet understood well enough.

Once genetic risk factors for these conditions become established and widely recognized, they can serve many purposes for early intervention and prevention efforts. For example, understanding risk factors involved in conversion to dementia could speed the initiation of appropriate treatments, which consequently may promote better prognoses through early intervention efforts. Needless to say, the most ideal situation would be preventing the development of cognitive impairment and perhaps, identification of individuals at high risk of developing cognitive impairment through the development of biomarkers will be useful. The operationalization of the definition of early cognitive impairment will clearly advance the investigation into early identification and prevention. Advances in the area of transcriptomics have also been encouraging researchers in their attempts to develop personalized interventions in terms of biomarker tests, including both diagnostic and prognostic tests, as well as understanding the functional biologic consequences of possessing

certain risk-conferring genetic variants. All of this information may someday be harnessed to identify the earliest biologic changes associated with a trajectory toward a late-life neurodegenerative disorder, and this in turn may help identify specific molecular targets around which the next wave of pharmacotherapies can be designed. Furthermore, the delineation of numerous, distinct etiologies for what are now considered unitary disorders (e.g., PD) may allow, in the future, for these disorders to become recognized as distinct and treated as such (e.g., *PARK1*-positive PD, *PARK2*-positive PD, etc.). Recent successes in identifying specific risk genes for these disorders have been encouraging. Replicating and refining these results, and translating them into meaningful clinical applications, signals exciting times ahead for research on the genetics of late-life neurodegenerative disorders.

ACKNOWLEDGMENTS

The authors would like to thank Matthew Weinerth and Totadri Dhimal for assistance in summarizing recent GWASs.

▲ 57.3 Psychiatric Disorders of Late Life

57.3a Assessment of Functioning

DAVID J. MOORE, PH.D., AND PARIYA L. FAZELI, PH.D.

INTRODUCTION

Older adults are the fastest growing segment of the population in the United States. By 2030, the number of Americans aged 65 and older will more than double to 72.1 million; roughly 1 in 5 Americans will be over 65. Given that older persons represent such a large part of the American population, it is increasingly important that clinicians and researchers in the field of psychiatry be prepared to work with and care for older adults. Older adults, like any other segment of the population, will require care for physical and mental health problems, and they may be at increased risk for impairment in both of these areas. Decline in everyday functioning may be associated with mental and physical health problems. Clinicians are increasingly asked to make decisions regarding patients' capacity to live independently, as well as to determine capacity to conduct other daily tasks such as managing health care and finances. This chapter defines and reviews domains of everyday functioning and discusses factors (e.g., neurocognitive impairment) that are likely to interfere with daily functioning in older adults. Additionally, this chapter discusses various assessment methods and specific clinical populations, and we make recommendations for future instrument development. The authors hope that this chapter will serve as a resource for clinicians and spur additional needed research on everyday functioning difficulties among older adults.

WHAT IS EVERYDAY FUNCTIONING?

Before discussing the various assessment modalities and other factors related to everyday functioning, a few terms must be defined. Quite simply, *everyday functioning* refers to all of the activities in which people engage in their daily lives. By this definition, *everyday functioning* is different for every person. The nature of one's daily activities and behaviors depends on numerous factors including culture, socioeconomic status, and the presence or absence of medical or psychiatric conditions. Despite the wide range of possible daily activities, certain basic behaviors are nearly universal. They range from basic *Activities of Daily Living (ADLs)* such as eating and grooming to more complex behaviors, often termed *Instrumental Activities of Daily Living (IADLs)*, such as managing finances and medications. Some scientists would confine assessment of functioning to physical behaviors, but we take a broader view. For instance,

the authors believe that social skills and quality of life (QoL), neither of which is based on physical ability, fit nicely under the umbrella of everyday functioning.

Even though many useful everyday functioning instruments exist, so far researchers have failed to reach a consensus on the instrument or instruments that would represent the "gold standard." Several factors may have contributed to this. First, the assessment of everyday functioning in older adults is important to a wide variety of disciplines, such as geriatrics, gerontology, occupational therapy, psychiatry, psychology, nursing, general practice, neurology, and psychiatry, each of which has its own particular focus. This diversity of focus is apparent in the literature as well. Because of the multitude of disciplines conducting research on this topic, different terms are often used when referring to very similar constructs. As a result, no unified search term for "everyday functioning" is available in library reference databases (e.g., MeSH) in contrast to such terms as "neuropsychology" or "cognition." The most widely used terms for everyday functioning are *ADL*, which refers to very basic skills needed to survive, and *IADL*, which covers higher-order tasks that represent a level of independence that may or may not be present among individuals with intact ADLs. These terms are discussed and defined in more detail below.

Many individuals experience declines in their ability to perform everyday tasks as they age. Some of these declines may be considered normal, whereas other impairments may result from a disease process. Declines in daily functioning can result from numerous factors including physical, medical, cognitive, and psychiatric factors. Daily functioning ability is so important that it is included as a diagnostic criterion in the determination of many psychiatric and cognitive disorders. For instance, a diagnosis of major neurocognitive disorder due to *Alzheimer Disease* (AD) according to the fifth edition of *Diagnostic and Statistical Manual for Mental Disorders* (DSM-5) requires cognitive deficits that "interfere with independence of everyday activities." Due to its typically late onset, many individuals who are diagnosed with AD are no longer working. The specific means used to determine "independence of everyday activities" are typically left to the discretion of the clinician making the diagnosis. Along these same lines, a diagnosis of mild neurocognitive disorder due to AD—thought to be a transition between normal cognitive functioning and dementia—requires that "cognitive deficits do not interfere with the capacity of independence in everyday activities." Again, the methods for determining whether daily living skills are intact are left to the clinician, although recent standardized methods for assessing everyday functioning in mild neurocognitive disorder have been employed.

DOMAINS OF EVERYDAY FUNCTIONING ASSESSMENT

Daily functioning tasks lie on a continuum that ranges from tasks that are

necessary to function independently (e.g., ability to get oneself to the toilet and use it) to tasks that are optional but common (e.g., driving a vehicle in the United States). Tasks falling in between these extremes, such as managing one's finances, are not critical to living independently, but inability to perform them requires strong environmental or personal supports such as a structured living facility or a committed family member or caregiver. Although we prefer not to classify daily functioning skills by category, several terms are used in the literature. These terms should be familiar to clinicians so that they are able to effectively communicate with other members of a multidisciplinary clinical team.

Activities of Daily Living

As discussed previously, some basic daily functions seem to cut across cultures. Termed ADLs, these are personal care behaviors and basic physical skills necessary in daily life. They include walking, grooming, bathing, and dressing.

Some ADLs are more physically based than others (Table 57.3a–1). They are sometimes simply referred to as physical functions. The assessment of physical functioning is often left to physiatrists, physical therapists, rehabilitation specialists, and general practice physicians. Often, these practitioners will use the *Functional Independence Measure* (FIM) (later described in the Clinician Rating of Everyday Functioning section) or a similar measure to describe the level of physical dependence. Perhaps the most basic form of everyday functioning assessment is determining whether an older individual has the physical capabilities to perform basic motor tasks. Motor-based assessments such as timed gait and grip strength may provide additional information in this area. For example, the Timed Up and Go Test (TUG) tests the time it takes to rise from an arm chair, walk 3 m, turn, walk back, and sit down, and has been shown to be well correlated with scores on scales of balance, gait speeds, and ADL, and is predictive of falls. Another measure of physical functions is the Short Physical Performance Battery (SPPB), which evaluates balance, gait, strength, and endurance by examining ability to stand with the feet together in side-by-side, semi-tandem, and tandem positions; time to walk 8 ft; and time to rise from a chair and sit back down 5 times. This test has been reported to predict mortality, disability, and nursing home admissions.

Table 57.3a–1.
Typical Everyday Functioning Domains by Activities of Daily Living (ADL), Instrumental Activities of Daily Living (IADL), and Others

ADLs	IADLs	Beyond IADLs
Physically based ADLs	Financial management	Social Functioning

Transferring
- ► Chair, bed, wheelchair
- ► Toilet
- ► Tub/shower

Walking
- ► Given distance
- ► Climbing stairs
- ► Uneven surfaces

Quality of Life
Multi-tasking

Other ADLs are required for autonomous functioning at home (e.g., grooming, bathing, dressing). Persons incapable of conducting these basic activities require significant assistance and are likely to live in a structured setting (e.g., nursing home) or receiving assistance in completing these tasks from a full-time caregiver. A list of common ADLs can be found in Table 57.3a–1.

Instrumental Activities of Daily Living

Assessments of IADL were developed to assess certain higher-level abilities that are required for autonomous functioning within society. Examples of IADLs include managing medications, balancing a checkbook, and preparing a meal (Table 57.3a–1). Assessments of IADLs are targeted at older persons who live independently and have little problem with basic ADLs but may need some assistance with higher-order tasks. Most assessments of everyday functioning either focus on ADLs or IADLs, and assessment approaches are discussed below.

Beyond IADLs

There are several abilities that go beyond IADLs but can nevertheless be important for higher levels of daily functioning. These include social functioning, QoL, and driving. Furthermore, everyday functioning abilities do not exist in isolation. Thus, a discussion of multi-tasking and what it might mean for everyday functioning in specific cases is also pertinent here.

Social Functioning. Ability to function socially can be important for many aspects of an older adult's life. For instance, social skills are essential to maintaining friendships and remaining actively engaged with other

persons. Social skills are also critical in many everyday situations such as articulating an error on a recent bill or discussing health care choices with a physician. Assessments of social skills may be particularly important in conditions known to impact these abilities, including dementia and schizophrenia.

Driving. Many older adults continue to drive in later life. Although they typically drive fewer miles per year than do younger drivers, they are at greater risk for accidents than all other age groups with the exception of teenagers. Risk for accidents seems to increase most noticeably after age 75. After adjusting for miles driven per year, those over age 75 have the greatest number of fatal crashes of any group.

Given that older adults are at significant risk for driving-related accidents and even death, it is important for clinicians to understand what factors put these individuals at risk so that they can appropriately intervene. Equally important is to avoid stigmatizing older adults who are still capable of safe driving. Decisions regarding the advisability of continued driving can be difficult, since driving often gives older persons a sense of independence and allows them to maintain meaningful social relationships that may be otherwise hampered. The final decision regarding continued driving typically rests with each state's Department of Motor Vehicles (DMV). While many states have adopted special provisions for older drivers, such as no mail renewal after a certain age, very few states require individuals to take an exam or a road test once a certain age is reached. Some states require clinicians to report patients diagnosed with dementia to the DMV (e.g., California). The DMV then evaluates the driver to determine if he or she may retain driving privileges.

Neuropsychological abilities play a large role in determining whether persons of any age should be allowed to continue driving; however, given that dementia is more prevalent in older adults, it is especially important in this population. Some cognitive domains appear to be more strongly associated with impaired driving performance. They include memory, executive functioning, and processing speed. Some evidence exists that cognitive training may help improve processing speed among older adults.

Interactions may exist between driving ability and medication use. Studies have shown that persons over 65 exposed to psychoactive medications, particularly cyclic antidepressants, have a significantly increased rate of involvement in motor vehicle collisions. Furthermore, depression, which is common among older adults can contribute to decreased responsiveness and poor concentration and lead to an increased risk for driving accidents.

Quality of Life. QoL, while not in itself a functional ability, is perhaps the most important factor contributing to successful daily functioning.

Certainly, improved QoL is an assumed treatment goal with any medical or psychological intervention. QoL can be viewed from two perspectives. The global perspective considers all aspects of a person's life; these assessments are typically both subjective and multidimensional. Alternatively, health-related QoL (HRQoL) focuses exclusively on the effects of health, illness, and treatment. HRQoL can be assessed generically or with reference to a specific disease. The most commonly used generic HRQoL instrument is the 36-Item Short-Form Health Survey. Although several HRQoL instruments are used with older adults, the authors are unaware of any specifically designed for this population. Physical functioning is often a part of HRQoL questionnaires and may unknowingly bias these instruments against older adults. A sampling of QoL and HRQoL instruments is shown in Table 57.3a–2. By nature, these instruments are primarily self-report, although some collateral-report measures are available. In 2011, an expert panel of the National Institute on Aging recommended that older adults, particularly those with multiple chronic conditions, complete a brief but comprehensive (i.e., assesses physical symptoms and mental health symptoms) composite screening measure such as the SF-8/SF-36 or the Patient Reported Outcomes Measurement Information System 29-item Health Profile (PROMIS-29). This recommendation was made to identify domains where additional follow-up measures may be warranted (e.g., depression, daily functioning).

Multi-Tasking. One problem for virtually all assessments of everyday functioning is that they are conducted in isolation; that is, each domain of functioning is assessed separately. It is known, however, that "multi-tasking" is the norm in most people's lives, and that parts of many everyday tasks are embedded within the performance of other tasks. For example, few people preparing to cook pasta will drop all other activities simply to sit and wait for the water to boil before placing the pasta in the water. Rather, most higher-functioning individuals will engage in some other behavior such as preparing some other part of the meal, calling a friend, or watering the plants. Attention typically shifts away from one daily task to another and must be reoriented in order for the original task to be completed. Few instruments, if any, have succeeded in capturing the multi-tasking nature of daily functioning. The few that have been developed are mentioned in the performance-based assessment section.

FACTORS INFLUENCING EVERYDAY FUNCTIONING

Given the complexity of most everyday functioning tasks, many factors may significantly affect performance. These include, but are not limited to, cognition, mood, physical health, culture and ethnicity, and the physical environment. Research on the relative impact of each of these factors is fairly limited, and each factor has shown varying levels of influence. A discussion of each of these factors and the evidence supporting its role in everyday functioning difficulties is provided below.

Cognition and Everyday Functioning

Of all the factors pertinent to daily functioning, the strongest evidence exists for cognitive impairment as a significant contributor to decline in many everyday functioning abilities. However, this literature discussing the relationship between cognition and everyday functioning is not as well developed and complete as one might expect. A recent comprehensive review of the cognitive correlates of functional status found that (1) the proportion of variance accounted for by cognition was modest, (2) some cognition domains had a stronger relationship to functional status than others, (3) cognitive impairments in executive control may be particularly strong correlates of impaired medical and financial decision-making, and (4) global cognitive screening instruments may be relatively strong predictors of functional status. As a rule, neuropsychological tests have undergone a more rigorous test development process, than have everyday functioning assessments, and consequently their reliability and validity are better established.

Many of the early researchers on functional abilities (e.g., Lawton, Brody) hypothesized that daily functioning skills would be lost in the opposite order from that in which they were acquired. Indeed, more complex daily tasks seem to be more susceptible to cognitive impairments than are basic tasks.

The role of neurocognitive impairment for daily functioning in older adults is not the same for all disorders. For instance, some individuals may have cognitive difficulties that have long affected their daily functioning (e.g., an older person with schizophrenia), whereas others may have experienced recent and sudden changes (e.g., an older person who recently suffered a stroke). Moreover, the profiles of neuropsychological impairment vary greatly among the disorders found in older adults, and these distinct cognitive profiles may lead to different declines in daily functioning abilities. For instance, memory impairments offer a unique set of difficulties for everyday functioning as compared to motor impairments. A person with declarative memory impairment may have difficulty remembering to take his medications, whereas a person with motor difficulties may remember to take his medications but have difficulty opening the pill bottle.

Mood and Everyday Functioning

Depressed mood and other psychiatric difficulties appear to contribute less to everyday functioning impairment than do cognitive difficulties. Obviously, persons who are severely depressed or experiencing florid psychotic symptoms may experience significant impairment of daily functioning; however, persons who are only mildly to moderately impacted by psychiatric symptoms appear to suffer less resultant functional disability than do persons with comparable impairments in cognition. This issue is discussed further in the "Clinical Populations and Everyday Functioning" section.

Physical Disability and Everyday Functioning

Persons who experience physical disability typically have relatively intact daily functioning with the appropriate assistive devices and compensatory strategies. For example, persons recently confined to a wheelchair may need special accommodations installed in their dwellings. On the whole, however, compensating for physical disability is usually easier than compensating for cognitive difficulties. Several methods for assessing physical functioning are found in the "Assessment of Everyday Functioning" section.

Culture and Ethnicity in Everyday Functioning

Ethnicity and culture can play a substantial role in the types of everyday activities in which people engage as well as in the support that they receive in accomplishing those activities. Certainly individualistic cultures differ from collectivist cultures in the amount of support that each offers. For example, Latinos and many Asian cultures have, comparatively speaking, a collectivist approach to functional impairment in family members.

Households are frequently multigenerational, encompassing parents, grandparents, and other older relatives as well as the householders and their children. Hence, families in these cultures often provide greater support to older family members in carrying out daily tasks than do persons from families with individualistic cultural background (e.g., Caucasian Americans). Latino and Asian families, by virtue of their family-oriented support system, may be less likely to seek treatment for an older family member who is experiencing decline and may prefer to handle the matter within the family. Another consideration is the shame associated in some cultures (e.g., Japanese Americans) with acknowledging mental health difficulties in oneself or a family member. In such cases, persons may try to convey mental or cognitive difficulties by presenting with physical complaints (e.g., referring to a decline in cognitive abilities as a headache).

Given such cultural considerations, using everyday functioning assessment instruments designed primarily for English-speaking, Caucasian persons with individuals of other cultural backgrounds or who do not speak English as a first language can be problematic. Persons from different cultures may perform poorly on assessments of a daily functioning task for cultural reasons unrelated to functional capacity. For example, in one study, Black and Latino subjects over 55 years of age who had recently been prescribed an antidepressant attributed intentional nonadherence to concern about side effects and stigma; they also attributed less importance to antidepressants than other medications. In some cases, everyday functioning instruments have been translated and culturally modified for use with other, non–English-speaking populations, for example, Chinese elders as shown in Table 57.3a–3; however, there is clearly a need for additional translations, adaptations, and culturally appropriate modifications.

Environment and Everyday Functioning

An older person's physical environment also can negatively affect everyday functioning abilities. Persons with limited financial resources are often living in physical environments that exacerbate their everyday functioning difficulties. For instance, persons with limited ability to climb stairs may live in apartments on upper floors of buildings without elevators, or they may not be able to afford to have bars installed over the toilet to assist with transferring. Likewise, a person of lower socioeconomic status (SES) may not to be able to afford to hire a health care assistant (e.g., for help with managing medications).

Table 57.3a–3.
Multidomain Performance-Based Batteries of Everyday Functioning

Battery Name	Brief Description	Site	Scoring	Admin. Time (Min.)	Notes
Dementia (Primarily Alzheimer Disease–AD, some dementia NOS)					
Activities of Daily Living Situational Test (AST) (Skurla, 1988)	4 subscales; 38 individual items. Item examples include making instant coffee, and finding and calling a phone number.	Clinic	Items scored from 0–4. Total score ranges from 0–152.	15–20 min.	
Cognitive Performance Test (CPT) (Burns, 1994)	6 tasks; ratings of specific behaviors are used to place individuals into 1 of 6 levels of disability. Task examples include getting dressed, and preparing a piece of toast.	Clinic	Tasks scored from 1–6. Total score ranges from 6–33.	45 min.	Requires t and spe equipm Availabl specific subpop (Elderly Israelis and wit Dement
Direct Assessment of Functional Abilities (DAFA) (Karagiozis, 1998)	10 domains; Designed to measure Pfeffer Functional Activities Questionnaire (PFAQ) IADL items. Examples include writing a check and making a sandwich.	Clinic	Items are scored from 0–3.	45–90 min.	The DAFA been translat adapted use witl Kong Ch Elders.
Direct Assessment of Functional Status (DAFS) (Loewenstein, 1989)	7 subscales; 53 individual items. Item examples include balancing checkbook and writing out a check.	Clinic	Items scored from 0–2. Total score ranges from 0–106.	25–40 min.	DAFS has a been us with otl geriatri samples older schizop patients

Functional Performance Measure (FPM) (Carswell, 1995)	3 subscales; 8 subsections; total of 40 items. Participants are videotaped doing tasks and then the videotapes are rated. Item examples include washing and drying hands, and putting on and taking off sweater.	Clinic	Each sub-section scored from 0–50. Total score ranges from 0–400.	<20 min.	
Refined ADL Assessment Scale (RADL) (Tappen, 1994)	5 domains; 14 individual items. Item examples include washing hands and brushing teeth.	Clinic	Tasks are broken into component parts and scored from 1–6.	5–60 min. for eating subtask Total >90 min.	
Structured Assessment of Independent Living Skills (SAILS) (Mahurin, 1991)	10 domains; 50 individual items. Item examples include zipping a jacket, and using a key.	Clinic	Items scored from 0–3. Total score ranges from 0–150. Both time and accuracy contribute to the score.	60 min.	An abbrev version SAILS is availabl Eating a money subscal validate older M America
Texas Functional Living Scale (TFLS) (Cullum, 2001)	5 subscales; 21 individual items. Item examples include making change, and remembering to take medications.	Clinic	Items scored from 0–5. Total score ranges from 0–52.	15–20 min.	
Bay Area Functional Performance Evaluation (BaFPE) (Houston,	2 general domains; 5 tasks in the first domain, 7 items in the second. Item	Clinic	Rated from 1–4.	>45 min.	This inforr is basec the revi BaFPE.

1989)	examples include filling out a bank deposit slip and drawing a person.				
Older Psychiatric Patients (Primarily schizophrenia, some mixed psychiatric groups)					
Kohlman Evaluation of Living Skills (KELS) (Thomson, 1992)	5 subscales; 17 areas assessed. Item examples include budgeting money, and recognition of dangerous situations.	Clinic	Item scores range from 0–1; ½ points are possible.	20–30 min.	Test sold b publish KELS is a combin of self-r NP, and perform based t
Performance Assessment of Self-Care Skills (PASS) (Rogers, 1984; Holm, 1999)	In the home version, participants are observed conducting various tasks primarily with their own tools and props. Example items include sweeping and mailing bills.	Home	Most recent version is scored on a 4-point ordinal scale ranging from 0–3. Higher scores indicate better performance.	>90 min.	Contains b physica and IAD section
UCSD Performance-based Skills Assessment (UPSA) (Patterson, 2001)	5 subscales; item examples include shopping for items in mock grocery store and planning a recreational activity.	Clinic	Each subscale transformed to 0–20 score. Total score ranges from 0–100.	30 min.	
Mixed (Psychiatric and Dementia)					
Independent Living Scales (ILS) (Loeb, 1996)	7 subscales; 68 individual items. Example items include how to use a telephone book, and writing a check.	Clinic	Items scored from 0–2.	45 min.	Test sold b publish Combin of NP a perform based t ILS has used wi schizop patient

					older ac
Occupational Therapy Evaluation of Performance and Support (OTEPS) (Nadler, 1993)	4 domains; 42 individual items. Item examples include making a sandwich and identifying medication dosage from a bottle.	Clinic	Items scored from 0–2. Total score ranges from 0–84.	Not provided	Also know OTAPS.
Performance Test of Activities of Daily Living (PADL) (Kuriansky, 1976)	16 individual tasks; item examples include lifting food onto spoon and to mouth, combing hair, and drinking from cup.	Clinic	Scored 0 (completes task with minimal assistance) to 1 (unable to complete on own).	Not provided	
St. George Hospital Memory Disorders Clinic Occupational Therapy Assessment Scale (OTAS) (Fairbrother, 1997)	8 domains; 30 individual items. Example items include using a telephone book, and offering correct money in a simulated shopping activity.	Home	Items scored from 0–3. Total score ranges from 0–90. Score is based on time and the number of prompts.	30–40 min.	
Older Healthy Individuals Activities of Daily Living Test (ADL-T) (Warren, 1989)	4 tasks; item examples include boiling an egg and writing a check.	Home and Clinic	Scores ranged from 0–16.	>90 min.	
Day out Task (DOT; Schmitter-Edgecombe et al., 2012)	8 subtasks; laboratory apartment; participants told to imagine they are planning for a day out (beginning with meeting a friend at	Laboratory	Accuracy of subtasks (i.e., complete/efficient; complete/inefficient; incomplete/inaccurate; never attempted), overall task accuracy, and task sequencing.	No specific time, but average completion times between 10–14 min.	Used in M healthy adult cc

	museum at 10 AM and later traveling to friends house for dinner), the 8 tasks must be completed to prepare for the day; participants are told to multitask.				
Everyday Problems Test (EPT) (Willis, 1993)	7 domains; 84 individual items. Participants are shown printed material of everyday items. Examples include ordering merchandise from a catalog and determining amount to pay from phone bill.	Clinic	Scoring available in published test.	<60 min.	Test sold b publish There is al Everyda Problen for Cog Challen Elderly (EPCCE)
Observed Tasks of Daily Living (OTDL) (Diehl, 1995)	3 domains; 31 individual items (21 useable items). Example items include baking a cake in a microwave oven and loading a pill reminder.	Home	Scoring available from author.	90 min.	

Note: Tests preceded by a < or a > indicate approximation of administration time based on the text provided. Readers are encouraged to examine the literature for additional studies pertinent to their clinical or research question that may apply their candidate measures.

ASSESSMENT OF EVERYDAY FUNCTIONING

Standardized assessment instruments and procedures have been developed to evaluate everyday functioning. Functional assessments typically aim to determine the level of ability or disability in a given domain of daily functioning. Depending on the individual being evaluated, an assessment may focus on basic ADLs (e.g., bathing or grooming), physically-based ADLs like mobility (e.g., ability to walk without assistance), or IADLs (e.g., cooking, financial management). Table 57.3a–1 shows some of the domains typically assessed.

Some assessments focus on capacity (what the person can do), while others focus on performance (what the person actually does). Glass describes three "tenses" of functioning: (1) a *hypothetical* tense representing the capacity of the person, (2) an *experimental* tense defined as what the person is capable of doing, and (3) *enacted* tense which represents what the patient actually does. Furthermore, Glass describes common errors in classifying older adults' functional status. The first occurs when persons provide a low self-report of functioning but actually function at a higher level; these persons are "overachievers," and their reports as compared to behavior represent a discrepancy between the hypothetical and the enacted tense. The opposite situation also occurs: some persons report high functioning but engage in few activities that would qualify for that designation. These persons can be termed "underachievers" and also show a discrepancy between the hypothetical and the enacted tense.

When interpreting functional assessment data, the clinician or researcher must take into account whether the person being assessed has ever done a given task before. For example, performing a financial assessment with a person who has never managed her own finances has little to no meaning.

There are many reasons for conducting a functional assessment. In many cases, functional assessments are used to get a "snapshot" of an individual's current level of functioning. Functional assessments are rarely done as part of routine care; rather, they are often conducted following some acute event (e.g., stroke) or referral complaint (e.g., patient is having difficulty managing medications). An evaluation in this context serves as a baseline for future evaluations and, ideally, would be sensitive to improvement or worsening of abilities over time. Functional strengths and weaknesses can be identified, and interventions can aim to improve areas of disability and utilize areas of intact functioning to compensate for deficits. In the optimal situation, improvements would be observed following a treatment intervention to improve the targeted area of functional impairment. It is important to place particular emphasis on those abilities that are critical for functioning within a given environment. For instance, medication management may not be important for an individual living in a structured living facility that administers medications,

but bathing, grooming, and ability to transfer remain important. In this way, a functional assessment can be used as a tool for discharge planning and estimating the level of functional assistance that a particular individual may need.

Often a person receiving a functional assessment has significant pre-existing cognitive or physical disability, but persons with more subtle difficulties may be even more appropriate candidates for a functional assessment. For example, a person with AD is likely to have many functional impairments, and decisions regarding housing placement and the level of care may have been determined prior to the administration of a functional assessment. On the other hand, a person who is having mild cognitive difficulties, and who evidenced impairments on tests of arithmetic and memory, may be a perfect candidate for a financial capacity assessment if he or she is still managing personal finances. The authors argue that functional assessments should be used at earlier stages of clinical care to facilitate gradual life changes (e.g., enlisting a family member to help with finances), rather than wait for a radical upheaval of all aspects of daily life at once.

Everyday functioning assessments are not just for individual-level clinical purposes. These assessments can be used with representative samples of clinical populations to draw general demographic conclusions. For instance, research using the Social Skills Performance Assessment (SSPA) has shown that older schizophrenia patients have difficulties with social skills. As a result, Cognitive-Behavioral Social Skills Training was developed and has targeted these problems among persons with schizophrenia and improved the functioning of this group.

There are several different methods for assessing everyday functioning. The most common are clinical interview, self- or collateral report, clinician ratings of behavior, laboratory performance-based measures, and direct observation. Several reviews in the literature provide additional information about the everyday functioning assessment instruments designed for older adults.

Each assessment method has inherent strengths and weaknesses (Table 57.3a–4). For example, some types of instruments are easily administered, but may not be reliable (e.g., self-report), whereas others may provide more reliable data but are not feasible to administer routinely (e.g., direct observation). Choosing the type of functional assessment to use is largely driven by the referral question, available resources, and the person's particular needs. In the sections below, common functional assessment methods are reviewed, and some of the instruments frequently used with each type are discussed.

Clinical Interview of Everyday Functioning

Time is often at a premium when psychiatrists and other physicians

conduct clinical interviews. Despite this, a detailed clinical review of a patient's daily functioning can be extremely helpful in establishing current levels of functioning as well as for treatment planning. Understandably, a thorough assessment of everyday functioning cannot be conducted at every clinical visit; however, psychiatrists can make referrals to other disciplines (e.g., physical and occupational therapy, clinical psychology, neuropsychology) that may be able to spend more time both conducting a clinical interview as well as other assessment modalities described below.

Certain elements are essential to a thorough clinical interview designed to assess a person's daily functioning. First, it is important to get a sense of the persons' daily activities. Open-ended questions such as, "Can you describe a typical day for me?" are often helpful. This puts the onus on the patient to elaborate his or her daily activities. Queries should be made about difficulties with ADLs and IADLs. All assessments should include questions about other important domains such as social functioning, driving, and safety. Table 57.3a–5 lists some of the critical elements of an everyday functioning interview. Similarly, follow-up questions pertinent to any daily functioning domain of concern should be phrased in ways that give the patient the opportunity to elaborate any possible concerns or difficulties. It is sometime helpful to disarm patients by saying things like, "All persons have difficulties managing their medications. Can you tell me about the last time that you had difficulties managing yours?"

It is also important to elicit patients' histories with particular daily tasks. For instance, older men may have little experience cooking and preparing meals, while older women may have little experience managing finances. If a patient has recently lost a significant other or a support system that used to perform a particular task, poor performance may not represent a decline in daily functioning ability, but rather a lack of experience. Some assessment performances, however, may represent declines, and it is useful to pose questions such as the following: Was the onset of these difficulties gradual or sudden? Has there been continued decline? Was the decline associated with any other recent change (e.g., medical problem, change in medications)?

Table 57.3a–4.
Strengths and Weaknesses of Various Functional Assessment Modalities

	Cost	Ease of Use	Reliability	Validity	Predictive
Self-report	Inexpensive	Easy	High	Weak	Weak
Collateral report	Inexpensive	Easy	Questionable	Questionable	Questionable
Clinician-rating	Moderate	Moderate	Moderate	Moderate	Moderate
Performance-based	Moderate	Moderate	High	Strong	High
Direct	Expensive	Difficult	High	Strong	High

Table 57.3a–5.
Topics to Cover in Clinical Interview of Everyday Functioning

For All Older Adults

- Current daily activities?
- Difficulties with:
  - Physical demands (e.g., climbing stairs, walking)
  - ADLs (e.g., bathing, dressing, feeding)?
  - IADLs (e.g., cooking, medication/financial management, driving)?
  - Social skills?
  - Safety (e.g., two-story house in frail person)?
  - Decision making?

Additional questions for persons with difficulties

- Experience with daily activities of difficulty?
- Onset (e.g., gradual/discrete)?
- Progression (e.g., continue to decline)?
- Decline associated with critical event (medical, change in medication, grief)?
- Availability, reliability, commitment of support declines in daily functioning?
- Concrete plan for dealing with daily functioning difficulties?

Among patients exhibiting daily functioning difficulties, it is important to find out whether they have support for daily tasks. Clinicians should assess the availability, commitment, and feasibility of the proposed support system. Where possible, clinicians should get consent from the patient to follow up with the identified support person or network to determine if the person or people identified are truly capable of providing support in performing daily tasks.

Self-Report of Everyday Functioning

Self-report is the most widely used modality for assessing problems with daily functioning. Self-reports are limited by the knowledge and objectivity of the respondent. Although self-report is subject to inaccuracies, particularly overestimation of functional abilities, it has several advantages including cost effectiveness, ease of administration, and portability. Furthermore, in persons without significant psychopathology (e.g., depression, personality disorders) or health problems (e.g., chronic pain, fatigue), self-endorsement of functional difficulties is generally held to equate to actual difficulties; however, the opposite does not always prove to be true. That is, persons often fail to report, or minimize, difficulties that they may be having. Among older persons with mild neuropsychological impairment or dementia, self-reports of functional status may have little to no utility. Even among older individuals without cognitive problems, overestimation of abilities is common.

Another disadvantage of most self-report measures is that they are not

particularly sensitive to change over time. Individuals tend to hold fairly constant views of themselves regardless of recent personal events and tend not to report changes in daily functioning abilities until they become drastic. Self-report measures appear to elicit more accurate data and correlate more robustly with performance-based measures when queries are specific and pertinent to the individual's difficulties (e.g., about stair climbing) rather than abstract (e.g., about mobility in general).

Self-report data concerning functional abilities can be collected in several different ways, including structured, semi-structured, or unstructured interviews. Interviews allow clinicians to hear, in the patient's own words, the difficulties that he or she is having. Clinicians can then ask follow-up questions that help specify the particular difficulty or difficulties. This is the approach most commonly used by general practitioners. Where indicated, problem areas can be addressed with more formal assessments.

Another way of assessing functional status is through the use of standardized self-report questionnaires. These instruments vary in their levels of reported reliability and validity. The outcome is generally a score that represents the level of functional impairment. Some of the most widely used instruments of self-reported daily functioning are the Katz ADL scale, the Lawton–Brody IADL scale, and the Patient's Assessment of Own Functioning Inventory (PAOFI). Additional self-report assessment instruments are listed in Table 57.3a–6.

Katz ADL Index. The Katz ADL Index uses a 3-point Likert-type scale to assess ability to bathe, dress, toilet, transfer, feed oneself, and maintain bowel and bladder continence. It was designed for use primarily with older hospitalized patients who function at lower levels, and hence it is unlikely to identify functioning difficulties among most community-dwelling outpatients. Another limitation is the scale's hierarchical structure. Functional difficulties are assumed to accrue in this order: bathing, dressing, toileting, transferring, continence, and feeding. Research has shown that alternative hierarchies of functions may apply equally as well.

Lawton–Brody Instrumental Activities of Daily Living. The Lawton–Brody IADL scale is another structured questionnaire that focuses on higher-level domains needed for independent functioning at home and in the community. The scale covers eight domains: telephone use, shopping, food preparation, housekeeping, laundry, transportation, medication management, and financial management. This scale is often used in conjunction with the Katz scale to provide indicators of both basic ADLs and IADLs. Although the questionnaire is often used in self-report mode, the clinician or caregiver can also complete it.

Table 57.3a–6.

Self-Report Measures of Everyday Functioning

Self-Report measures of Functional Status
Lawton–Brody IADL
Katz ADL
Functional Status Questionnaire
Health Assessment Questionnaire
World Health Organization Questionnaire
Short-Form Health Survey (SF-36)
Sickness Impact Profile (SIP)
Functional Disability Index Score (FDIS)
Older American Resources and Services (OARS)
Patients Assessment of Own Functioning Inventory (PAOFI)
Rapid Disability Rating Scale–2 (RDRS-2)
Questionnaire on Clinical and Preclinical Disability (QCPD)
Unmet Needs Indices (UNI)
Identification of Seniors at Risk (ISR)
Instrumental Activities of Daily Living Compensation (IADL-C) Scale
Everyday Competence Questionnaire (ECQ)

Patient's Assessment of Own Functioning Inventory. Another self-report instrument of everyday functioning is the PAOFI. The PAOFI is a 41-item questionnaire that is widely used in conjunction with neuropsychological testing. Respondents report the frequency with which they have had difficulties with memory, language and communication, manual dexterity, sense-perception, higher-level cognitive and intellectual functions, and work and recreation. The main focus is on cognitive symptoms, and the scale is often used in conjunction with ADL and IADL questionnaires such as those described above.

Collateral Report of Everyday Functioning

Reports from caregivers, family members, or other persons who are close to the individual with everyday functioning difficulties can be extremely valuable. In situations where the collateral reporter knows the patient well, is capable of providing an accurate report, and is able to maintain objectivity, collateral reports can be one of the best ways of gathering information regarding a patient's functional status. Accurate collateral reporters provide the same types of information as a self-report assessment, but they do so from the perspective of a direct observer. Unlike clinical direct observers, collateral reporters are typically part of the individual's daily routine, which obviates some of the problems common to traditional direct observation (see below). Unfortunately, collateral reports also have limitations. Close family members or friends may have reasons for distorting their reports. For example, they may minimize the level of functional disability in an effort to protect the patient from unpleasant but

inevitable transitions, or they may overemphasize the level of impairment in order to obtain medical or psychosocial assistance for the patient more quickly. The collateral reporters may also have cognitive or psychiatric impairments of their own that limit their ability to render accurate judgments. Finally, in many cases, older patients are socially isolated such that a knowledgeable informant is unavailable. Where collateral reports are available, the clinician must decide how likely they are to be accurate. Many of the self-report measures listed in Table 57.3a–6 also have collateral-report versions. Additionally, the Physical Self-Maintenance Scale (PSMS) was specifically designed for use by a person with significant knowledge of the skills of the patient, and the Specific Levels of Functioning (SLOF) was designed for caretakers (detailed below).

Specific Levels of Functioning. Another measure is the SLOF, which is a 43-item caretaker report of a patient's behavior and functioning in the following domains: physical functioning (e.g., vision, hearing), personal care (e.g., toileting, eating, grooming), interpersonal relationships (e.g., initiating, accepting, and maintaining social contacts; effectively communicating), social acceptability (e.g., verbal and physical abuse, repetitive behaviors), activities (e.g., shopping, using telephone, paying bills, use of leisure time, use of public transportation), and work skills (e.g., employable skills, level of supervision, punctuality). The SLOF rates the amount of assistance that the patient requires to perform real-world tasks (personal care, activities), and it rates levels of physical functioning and the frequency of certain behaviors (interpersonal relationships, social acceptability, work skills). An important aspect of collateral reports such as the SLOF is how well the caretaker or informant knows the patient. Performance-based measures of everyday functioning discussed below have been shown to predict real-world outcomes as determined by the SLOF.

Clinician Rating of Everyday Functioning

Another common functional assessment approach is the clinician rating. Such an assessment is typically conducted in a clinic or hospital and can be administered by a physician, nurse, occupational or physical therapist, or a specifically trained rater. In contrast to self- or collateral reports, the clinician rating has the advantage that the clinician is generally familiar with specific daily functioning difficulties and the particular behaviors that may put individuals at risk for poor daily functioning. Many clinician-rated instruments have reported good interrater reliability, although it is likely that experienced clinicians will produce more accurate ratings and classifications. These instruments can measure both actual behavior and capacity. For instance, some clinician instruments measure what they see patients actually doing and others ask patients to conduct a given behavior

(capacity). A disadvantage of clinician ratings is that they are typically conducted outside of the patient's habitual environment (i.e., clinic or hospital) rather than in the patient's home or some other everyday setting. Therefore, they may not generalize to the patient's everyday setting (particularly if the patient still lives independently).

Barthel Index. One of the most widely used clinician-rated scales is the Barthel Index. To complete this and other, similar instruments (Table 57.3a–5), the clinician rates several different ADLs on a Likert-type scale that ranges from dependent to independent. The Barthel Index assesses more basic functions such as feeding, bathing, grooming, dressing, bowel movements, bladder control, toilet use, transfers from bed to chair and back, mobility, and stair use. Items on the index mostly range from 0 to 10 (some from 0 to 5) and have behavioral anchors for midpoints (e.g., for the transfers item, a rating of 5 indicates major help from one or two people). The Barthel Index and the Katz ADL (which assesses bathing, dressing, toileting, transfers, continence, and feeding) are most appropriate for individuals who have significant physical or cognitive impairments.

Functional Independence Measure. The FIM is a clinician-rated assessment that is widely used within rehabilitation settings for the determination of functional dependence/independence. It is important to note that the FIM rates observed performance, not capacity; this limits the measure's usefulness to inpatient or other settings where the clinician has frequent observation of the patient. Each of the FIM's 18 items is rated on a 7-point Likert-like scale that ranges from total dependence to functional independence. The scale requires trained raters (with at least 80 percent accuracy), and certification is provided for a fee by the Uniform Data System for Medical Rehabilitation (UDS). The FIM features both a motor and a cognitive component. The items covered are listed in Table 57.3a–7.

The Functional Assessment Measure (FAM) was created to supplement the FIM and includes 12 items related to cognitive, behavioral, communication, and community functioning. These items are also listed in Table 57.3a–7. The FIM + FAM comprises a total of 30 items and is often used to evaluate change over the course of an inpatient stay. Both the FIM and the FAM were designed primarily for persons with brain injury, but they are also widely used in other settings that provide treatment for older adults.

Performance-Based Measures of Everyday Functioning

Performance-based measures of everyday functioning use role play and mock settings to simulate traditional everyday functioning tasks. These tasks are administered under consistent conditions and use standardized instructions. For instance, rather than ask a patient or a collateral

informant about the patient's cooking skills and safety (which is limited by the insight, candor, and objectivity of the patient or the informant) or observe the patient at home and watch him or her prepare a meal (which may be too time- or labor-intensive), a performance-based measure will have the patient prepare a meal using a mock kitchen based in a laboratory or hospital. Performance-based measures assess capacity or what a person "can do," and represent the enacted tense of the Glass (1998) model, under standardized, optimal conditions rather than in the patient's habitual environment. This distinction is important because in some disorders, what impairs performance is not a lack of capacity, but rather a failure to translate functional capacity into self-initiated functional performance.

Table 57.3a–7.
Everyday Functioning Skills Assessed by the Functional Independence Measure and the Functional Assessment Measure

FIM	FAM
Eating	Swallowing
Grooming	Car transfer
Bathing	Community access
Dressing upper body	Reading
Dressing lower body	Writing
Toileting	Speech intelligibility
Bladder management	Emotional status
Bowel management	Adjustment to limitations
Bed, chair, wheelchair transfer	Employability
Toilet transfer	Orientation
Tub and shower transfer	Attention
Walking/wheelchair locomotion Stairs	Safety judgment
Comprehension	
Expression	
Social interaction	
Problem solving	
Memory	

It should be noted that the distinction between clinician ratings and performance-based measures of functioning is fundamental. Performance-based measures typically use a mock setting and are scored similarly to a neuropsychological test, with little ambiguity in criteria. By contrast, clinician ratings occur in less-standardized settings (hospital or clinic), are generally geared toward more basic ADLs, and typically require a more experienced or highly trained rater to score appropriately.

A variety of performance-based measures have appeared over the past 30 years in discipline-specific journals (e.g., occupational therapy, clinical and educational psychology, psychiatry, neurology). The authors conducted a review of these measures. Table 57.3a–8, adapted from the authors' review, shows the functional domains assessed by commonly used

performance-based measures. The authors present measures that assess multiple domains as well as some that focus on a specific domain. Tables 57.3a–3 and 57.3a–9 briefly describe these measures and provide information on scoring and approximate assessment times (more details in Moore DJ et al., 2007). In addition to these tables, which primarily show assessments of traditional ADLs and IADLs, Table 57.3a–10 shows some common performance-based measures of physical functioning and simple motor skills. As there is no specific gold standard measure, a broad representation is presented in the tables.

Performance-based measures of everyday functioning, like all assessment tools, have strengths and weaknesses. The strengths are many. Foremost are the standardized methods of administration, which leave little ambiguity in the scoring. As a result, inter-examiner reliability tends to be high. Additionally, these assessments focus on real-life skills in a safe setting (e.g., cooking tasks can be controlled) and are face valid. Furthermore, they do not rely on the patient's insight, or ability to answer questions on a self-report questionnaire which might be influenced by education or reading level, and they do not depend on the knowledge or objectivity of a collateral or proxy reporter. These instruments are good targets for intervention studies designed to improve everyday functioning and have been implemented in this role (e.g., the UCSD Performance-based Skills Assessment, UPSA). The UPSA is a real-world outcome measure for the Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS) trial, which is designed to assess the effectiveness of antipsychotic medications in improving cognition. The consensus appears to be that performance-based measures have more strengths than weaknesses and offer benefits over other assessment approaches that make them useful for clinical treatment studies.

However, performance-based measures do have weaknesses. One is that the test environment is contrived (e.g., it is not the patient's own kitchen, but a mock one). This decreases the patient's ability to follow behavioral scripts or schemas that allow him or her to successfully complete a task at home but not elsewhere. Performance-based assessments may achieve high reliability at the cost of validity. Perhaps the greatest weakness of performance-based measures of functional capacity, however, is that they measure capacity, not actual performance. For instance, a person may very well have the capacity to complete the task, but may not have the initiative or supportive environment in order to complete the task on his or her own. Finally, most of the current performance-based measures are designed to only assess one given functional domain at a time, whereas in daily life a person is often completing many functional tasks simultaneously.

While there are far more single-domain performance-based tests and/or multiple-domain tests that test each separately, there have been some multi-tasking tests developed. For example, a novel performance-

based multi-tasking assessment, which involves balancing the demands of four everyday tasks (i.e., financial management, cooking, medication management, and telephone communication) has been used in the HIV population and shown convergence with both neuropsychological performance as well as self-reported everyday functioning. For the aging population there is also the Day Out Task (DOT), which is a laboratory-based multi-tasking qualitative assessment using an automated smart home apartment. In this task participants must complete an interweaved set of activities needed to prepare for a day out. In addition to assessing everyday functioning and multi-tasking in elderly populations, this test was also designed to help researchers develop smart home adaptive technology interventions to help older adults age in place and live independently for longer.

Virtual Reality Performance-Based Measures of Everyday Functioning

While virtual reality (VR)-based assessment has been used to assess driving ability, there are several VR, performance-based everyday functioning assessments that have been developed recently that show promise for geriatric everyday functioning assessment. Moreover, many of these take into account multi-tasking. These VR tasks that assess multi-tasking aspects of everyday functioning may be particularly sensitive to executive dysfunction accompanying age-related neurodegenerative disorders involving frontal pathology (e.g., planning, task switching).

The VR multiple errands test (VMET) was adapted from a non–VR version of the MET, due to the need for a more feasible approach to assess multi-tasking and executive abilities in the context of everyday functioning. Several versions have been established, but in general participants complete a set of diverse subtasks within a simulated shopping mall and/or office environment, and include a planning component, tapping into the role of metacognition and metacognitive strategies in everyday task performance.

Table 57.3a–9. Single Domain Performance-Based Batteries of Everyday Functioning

Test	Test Description	Site	Scoring	Admin Time (Min.)	Other
Dementia (Primarily Alzheimer Disease—AD, some dementia NOS)					
Beck Dressing Performance Scale (BDPS) (Beck, 1988)	In most recent version, participant is rated on 42 discrete component steps of dressing for males and 45 steps for females (e.g., button shirt).	Home	Participants are scored on a scale from 0–7 with 7 indicating maximal assistance and 0 representing no assistance.	<30 min.	
Financial Capacity Index (FCI) (Marson, 2000)	6 domains; 14 individual tasks of financial ability. Domains range from basic monetary skills to financial judgment.	Clinic	Cutoff scores place individuals into levels of capacity.	30–50 min.	Modified version (FCI-8) assesses 8 domains and has 19 tasks.
Kitchen Task Assessment (KTA) (Baum, 1993)	Rate the participants' ability to cook pudding from provided directions. 6 components are assessed. Components scored include performance of all steps, and judgment and safety.	Clinic	The level of support from the tester is scored from 0–3.	<30 min.	
Psychiatric Patients (Primarily schizophrenia, some mixed psychiatric groups)					
Medication	Asks participant to	Clinic	Comprehensive		

Management Ability Assessment (MMAA) (Patterson, 2002)	walk through 4 fictitious medication regimens.		manual available upon request.		
Individual medication points vary. Total score ranges from 0–25.	15 min.	Older Schizophrenia Patients			
Mixed (Psychiatric and Dementia)					
Time and Change Test (T&C) (Froehlich, 1998)	Tests participant's ability to tell time and make change.	Clinic	Screen for dementia or not based on cut scores.	2 min.	
Older Healthy Individuals					
Drug Regimen Unassisted Grading Scale (DRUGS) (Edelberg, 1999)	Patient is asked to perform each of four medication-related tasks: identification, access, dosage, and timing. Participants used their own medications.	Clinic	Participant given a score of able (1) or unable (0) for each task for each medication.	>20 min.	
Functional Ability to Take Medications (FATM) (Meyer, 1989)[a]	Patient is presented with 6 specific medication-related tasks (e.g., opening a pill bottle).	Clinic	Items are scored as either yes or no.	<10 min.	Instrument was later slightly modified.

Note: Tests preceded by a < or a > indicate approximation of administration time based on the text provided. Readers are encouraged to examine the literature for additional studies pertinent to their clinical or research question that may apply their candidate measures.

Another measure is the Multi-tasking in the City Test (MCT), an errand-running (e.g., shopping, attending appointments, etc.) task that takes place in a virtual city. Similar to the VMET, the MCT measures multi-tasking and executive abilities in an everyday setting and requires participants to create a plan before they begin. Unlike the VMET test, tasks must be performed with little explicit rule constraints because the goal of this test was to explore whether and how often subjects participate in behavior that is

clearly not goal-directed when there is no explicit instruction or "rules" directing against such behaviors

Table 57.3a–10.
Performance-Based Tests of Physical Functioning

Physical Performance Test (PPT)
Established Populations for Epidemiologic Studies of the Elderly (EPESE)
Timed Manual Performance Test (TMP)

Table 57.3a–11provides a list and description of several recently developed VR assessments. Although many of these tests were not necessarily designed for older adult populations, they may prove useful in healthy and pathological aging. The advantages of VR-based assessments are: (1) increased safety, (2) improved standardization and objectivity in terms of stimulus delivery, measurement/scoring, and error reduction, (3) ability to detect subtle deficits, and (4) portability which makes them ideal for clinical settings and has potential for remote delivery. Many of these tasks are new and are therefore still in the development and validation stages; however, they do show promise for geriatric assessment in future research and practice (Table 57.3a–11lists the populations that have been used in to-date). It is important for these VR assessments that participants and patients are given a change to familiarize themselves with the computerized interface, especially when they have no prior computer experience.

Table 57.3a–11.
Virtual Reality (VR) Performance-Based Everyday Functioning Assessments

Test	Test Description	Scoring	Admin Time (Min.)	Populations Used In To Date	O
Nonimmersive Virtual Coffee Task (NI-VCT; Allain et al., 2014)	14 steps; virtual environment simulates kitchen; patients must make a cup of coffee; requires multiple cognitive processes: serial ordering of several steps (open the drawer, etc.), object selection (coffee filter, etc.), and technical manipulations (coffee machine) to complete goal.	5 outcomes: Total completion time; percentage of task steps completed with or without error (range 0–100%); total number of errors (e.g., omissions, commissions).	15 min. for instructions and training. No time limit, but in Allain et al., 2014 it took AD patients ~11 min. and healthy elderly controls ~6 min.	AD patients and healthy older adult controls	A

Virtual Errands Test (VET; McGeorge et al., 2001); also called Virtual Multiple Errands Test (V-MET)	12 errands (in McGeorge version); diverse subtasks (e.g., collecting a book, meeting a colleague) within simulated environment; includes a planning component, which taps into the role of metacognitive strategies in everyday tasks. McGeorge version more vocationally oriented and contains work-related errands, while other versions of the task include shopping-related errands.	Planning; total number of errands completed.	Unlimited planning time; 20 min. for test.	Healthy adult controls; brain damage patients; Parkinson disease.	A
Multi-tasking in the City Test (MCT; Jovanovski et al., 2012)	8 tasks; virtual environment has several stores (e.g., drug store, post office); specific task requirements/errands listed on screen, along with errands completed, amount of money in wallet, and clock displaying time; designed to be open-ended with few explicit rules (i.e., complete as many errands as possible in 15 min.).	Planning; completion time; number of tasks completed; qualitative errors (i.e., task failures, task repetitions, inefficiencies).	Unlimited time for planning; 3 min. for instructions and 15 min. for test.	Stroke; TBI; Healthy young adult controls; not used in aging yet.	
Virtual Reality Functional Capacity Assessment (VRFCAT; Ruse et al., 2014)	4 scenarios (i.e., navigating a kitchen, getting on a bus to go to a grocery store, finding/purchasing food in a grocery store, and returning home on a bus); 12 objectives; three factors identified in development: Reasoning and Problem Solving, Speed of Processing, and Working Memory.	Completion time for each objective; accuracy/errors for each objective.	Not specified; time limits for each task; for healthy controls range across 12 objectives was ~25–120 sec., for schizophrenia was ~25–225 sec.)	Healthy adult controls and schizophrenia (developed for schizophrenia and other CNS disorders; studies are underway)	

VRMMA (Virtual Reality Apartment Medication Management Assessment Kurtz et al., 2002)	3 types of pills must be "taken"; exploration phase then actual "test" phase. In ''testing'' phase, participant told several seconds into task a post-it note would appear telling them which medications to take and when to take them (e.g., ''Remember to take: 2 yellow, 4 red, and 1 blue pill in 15 min.'' and to use all items in apartment that were explored during the practice phase; virtual apartment consists of a living room, bedroom, bathroom, and kitchen.)	Dependent measures include: quantitative errors; qualitative errors; time discrepancy; total distance traveled; clock checks; reminder note checks.	If an attempt to take medications not initiated by 18 min., notice appears saying ''time has expired, please go take your medication now.'' If 23 min. elapses and participant still has not taken medication, the program terminates.	Schizophrenia and healthy adult controls.	D

Direct Observation of Everyday Functioning

Some measures employ direct observation, which may be more valid than subjective reports. Direct observation has typically been used in inpatient settings where clinicians can easily record behaviors. Although many consider direct observation to be the "gold standard" of functional assessments, it is in fact more of a theoretical technique than a practical tool. That is, the most accurate representation of functional ability would consist of observing someone in her natural environment as she conducts her daily tasks without knowledge that she is being observed. In most cases, direct observation of this type is unethical and unrealistic. Even where the patient's consent has been obtained for direct observation, it is labor intensive and provides data only about the behaviors engaged in during the observation period. Furthermore, a person who knows he is being observed will frequently alter his behavior, sometimes radically.

CLINICAL POPULATIONS AND EVERYDAY FUNCTIONING

The following text discusses selected domains of everyday functioning that are of concern among specific clinical populations of older adults or that have received substantial research (e.g., functional impairments in older persons with schizophrenia). This list of clinical populations is in no way exhaustive, but it gives a sense of the ways in which functional impairment can differ from group to group.

Normal Aging

Cognitive declines associated with normal aging seldom reach a level sufficient to impact daily functioning. Among older persons without dementia or some other condition known to affect cognition, the neuropsychological domains that show the greatest decline with aging are processing speed and psychomotor speed. Declines in these domains are unlikely to significantly influence basic ADLs such as grooming, bathing, or using a telephone. Normal declines in these domains may, however, have some effect on speeded IADLs such as driving. Driving relies heavily on intact processing and psychomotor speed, and as discussed above, driving is a domain that warrants particular attention from clinicians when assessing older adults.

Dementias and Neurological Conditions

The cognitive profiles of individuals with dementia can be quite varied. AD, the most common of the dementias, often produces difficulties with memory (particularly with delayed recall) as well as language difficulties (e.g., anomia). Difficulties with memory can lead to problems with many IADLs such as financial and medication management. Tasks such as cooking and meal preparation are highly dependent on the order in which they are conducted, and a person with memory impairment may forget a critical step or unknowingly repeat a task. See the following case study (Mrs. Smith) for an example of a thorough assessment of neuropsychological, mood, and daily functioning in a patient suspected of having AD.

DEMOGRAPHICS

Mrs. Smith is a 71-year-old, right-handed, Caucasian woman.

EDUCATIONAL AND VOCATIONAL HISTORY

The patient completed 14 years of education. After completing 2 years of college she accepted a position as a secretary in a law office and remained in that position until she retired at the age of 55.

BEHAVIORAL OBSERVATIONS

The patient was alert and oriented to day of the week, year, and city, but was incorrect by 2 days on the exact date. She knew the month and she could name the president, governor, mayor, and the name of the building she was in. The patient was pleasant to work with. Her mood was positive and her affect was congruent with her mood. She mentioned that her children were worried about her memory lately, particularly her daughter. She interacted with the examiner in an appropriate manner. She took a few breaks to stretch her legs. Her frustration tolerance was good. She showed very good attention and low distractibility. Gross visual acuity with glasses was intact and her hearing was adequate. She was able to understand test instructions with minimal repetition. Overall, the patient seemed to put forth good effort on all of the tests. The results are considered to be a valid estimate of her current cognitive and everyday functioning.

GENERAL COGNITIVE FUNCTIONING

Mattis DRS-2 out of a total possible score of 144:		
Total Raw Score:	127	Scaled score: 6
Attention Raw Score:	36	Scaled score: 11
Initiation/Perseveration Raw Score:	37	Scaled score: 11
Construction Raw Score:	6	Scaled score: 10
Conceptualization Raw Score:	32	Scaled score: 7
Memory Raw Score:	16	Scaled score: 2

VISUOSPATIAL FUNCTIONING

Performance on the Clock Drawing Test was normal, at the 50th percentile, consistent with her performance on the DRS construction score.

PSYCHOMOTOR SPEED

Trail Making Test Part A and Trail making Test Part B were severely impaired, at the <1st percentile.

EVERYDAY FUNCTIONING ASSESSMENT

The patient was administered several measures of everyday functioning. Specifically, the patient was administered portions of the performance-based Independent Living Scale (ILS): Managing Money; the self-report Minimum Data Set (MDS) questionnaire that queries on the frequency that one needs help on and difficulty experienced when performing 20 IADLs; the SPPB; and an on-road driving assessment. On the ILS: Managing Money her performance fell within the mildly impaired range when compared to matched peers. For example, the patient inaccurately calculated how much change she should get back if she purchased something for $1.19 and gave the clerk $5.00 (her answer was $4.79). When presented with mock check materials and specific directions for completing the check, she correctly filed out all of the check, except writing the wrong date. She was able to calculate the balance in her checking account. On the self-report MDS, she reported that she only needs help "some of the time" with cooking, and experienced no difficulty with any of the activities. On the SPPB the patient scored 8 points total of 12 possible points, indicating relatively intact physical functioning: 3 out of 4 points on the balance tests (missed 1 point on holding the tandem stand for less than 10 seconds); 2 out of 4 points on the gait speed tests; and 3 out of 4 points on the chair stands. Finally, on the on-road drive, the patient's discrete maneuvers were rated unsatisfactory within the majority of 8 domains evaluated but fully intact in the remaining domains.

CORROBORATING REPORT FROM MRS. SMITH'S DAUGHTER

The patient's daughter stated that her mother developed memory problems over the last 12 months. She stated that Mrs. Smith is able to remember to take her daily medications with no issues, but has trouble remembering appointments and birthdays. Her daughter also reports that Mrs. Smith does require some assistance with managing finances and does not drive alone. Her daughter mentions that since Mrs. Smith has started being more diligent about using a pocket calendar to keep track of events and appointments, her memory functioning is better.

MOOD ASSESSMENT

On the Center for Epidemiologic Studies Depression Scale (CES-D) (a self-report measure of depressive symptomatology), the patient endorsed two items, indicating that she was not experiencing significant clinical depressive symptoms.

SUMMARY AND CONCLUSIONS

Results of the current evaluation indicate that the patient's overall level of cognitive functioning was overall in the moderately impaired range for her age (DRS-2 Total score = 127); however, her memory and executive functioning were severely impaired, fitting the profile of amnestic Mild Cognitive Impairment (MCI) due to AD. The patient is overall independent in most IADLs, however her memory impairments are having at least a mild effect on some domains, such as managing finances and keeping track of appointments, which is consistent with her daughter's reporting. The etiology of her cognitive deficits is unknown, however vascular disease does not appear to be a primary contributor, as she has no medical

comorbidities, vascular or otherwise (e.g., no depressive symptomology). It was recommended that she receive assistance with her complex financial and medical decisions. She could continue to manage her own medication administration with some supervision and aid (e.g., weekly pill organizer). Her driving, while not impaired at this stage, should be closely monitored. She was advised to not drive alone and only drive in familiar areas that are proximally closer to her home. Finally, her family was cautioned that the observed difficulties may continue progress and plans should be made now for this possibility.

Dementias and Neurological Conditions (Continued)

The use of memory aids such as calendars, electronic reminders, and checklists may help patients to circumvent their problems for a brief period; however, as dementia progresses, cognitive difficulties tend to worsen and compensatory strategies may fail. Many persons in later stages of AD become completely dependent in all their ADLs. Persons in early stages of AD can appear to have few daily functioning difficulties. They may be particularly capable of maintaining appropriate over-learned social interactions (e.g., introducing themselves to a new person); however, if pressed for details about newly obtained information, they may have difficulty recalling.

Other neurodegenerative conditions can present interesting challenges for everyday functioning assessments. For example, persons with Lewy Body Dementia can have profound impairments of visuospatial skills. They are likely to have great difficulty with higher-order tasks dependent on intact visuospatial functioning such as driving, whereas they may have less difficulty with social skills. Persons with Parkinson disease may have a slightly different set of daily functioning difficulties. Parkinson disease causes particular difficulties with initiation of motor movements and more generally with motor skills. Initiation problems may hinder a person from starting activities that they are cognitively capable of planning and executing. Difficulties with fine motor skills may prevent the accomplishment of basic tasks like opening medication bottles.

Psychiatric Conditions

Older persons suffer from the same types of psychiatric conditions as younger persons, although in some cases (e.g., depression), incidence may increase in older adulthood. Accordingly, assessment instruments need to be designed to capture daily functioning difficulties in persons with a serious mental illness. This group manifests particular deficits that may be important to evaluate. The following text reviews the difficulties with everyday functioning among these individuals as well as some of the instruments used to assess those difficulties.

Depression. Some of the most consistent evidence linking depression to neuropsychological dysfunction comes from studies of older people, in whom disturbances in executive function can be prominent and these

impairments may relate to everyday functioning difficulties. Given that depression is common in older age, and that cognitive problems can increase among older adults, this is a particularly important concern. Some investigators have suggested that impaired cognition may be limited to patients experiencing somatic symptoms of depression. Other studies have suggested that cognitive problems are not necessarily more common with increasing age bands, but rather that "premature" aging may occur in certain cognitive domains (e.g., nonverbal memory, word generation, and certain frontal lobe skills). Given that difficulties with daily functioning can be more common among older adults, the presence of depression can exacerbate these difficulties.

Particularly among older individuals, the presence of depressive symptoms is associated with a decline in performance of ADLs. Thirty to 60 percent of individuals who have been hospitalized for depression experience a drop in their ability to perform ADLs, including bathing, dressing, toileting, transferring, and eating. One study of 572 recently hospitalized older individuals found that persons with more depressive symptoms were significantly more likely to be dependent on others to help them perform ADLs as compared to individuals with no or few depressive symptoms. This finding was also true for IADLs, which include taking medicine, handling finances, transportation, and using the telephone. Elderly patients increased their risk of being hospitalized by failing to comply with prescribed medication regimens. Other studies have confirmed that depressive symptoms are strongly associated with poor functional performance, and depression scores for older individuals were significantly higher for those who reported experiencing ADL decline. Among community-based samples of older adults, neuropsychological impairment and depression appear to be two of the strongest predictors of daily functioning problems, even when controlling for baseline cognitive function, alcohol consumption, and chronic health conditions. Unintentional nonadherence to psychotropic medications has been shown to be associated with greater cognitive impairment.

Among adults with a primary major depressive episode and severe depressive symptoms (mean Beck Depression Inventory = 34.3 [SD = 11.0]) cognitive impairment was strongly associated with impairment in IADLs (e.g., medication taking and finance handling), whereas more severe depressive symptomatology and older age were strongly associated with impairments in basic ADLs. However, patients' satisfaction in role functioning and relationships improved with age.

Schizophrenia. Daily functioning difficulties are common among persons with schizophrenia. As a result, there are several performance-based instruments to capture everyday functioning difficulties common among older persons with schizophrenia that have been developed. These

instruments include the UPSA, including newer computerized versions; the Medication Management Adherence Assessment (MMAA); and the SSPA. Performance on these everyday functioning measures is strongly correlated with global neuropsychological functioning. A recent study showed that processing speed, episodic memory, and executive functions were associated with general everyday functioning (UPSA scores), whereas working and episodic memory and verbal fluency were associated most strongly with social skills (SSPA scores). These results suggest that neuropsychological abilities and social skills have differential effects on general everyday functioning skills. Consistently, neuropsychological impairment has been shown to be a stronger correlate of functional status than psychiatric symptoms among persons with schizophrenia. Negative symptoms of schizophrenia (e.g., flat affect) tend to be correlated with neuropsychological impairment; however, positive symptoms are rarely associated with neuropsychological or daily functioning impairments.

Recent research indicates that scores on the UPSA are associated with "real-world" outcomes, thereby making the UPSA a potentially useful tool to aid in clinical decision making. For example, a recent study found that UPSA scores of 75 or above were predictive of patients' ability to reside independently (e.g., alone in a home or apartment). In this same study, the UPSA was significantly better at predicting residential independence than the Mattis Dementia Rating Scale (DRS), a commonly used instrument that assesses global cognitive functioning. In another study, higher scores on the UPSA were associated with greater involvement in community responsibilities, such as working for pay, engaging in volunteer work, and attending school, among Hispanic/Latino patients with psychosis. In contrast, the DRS was not significantly associated with greater engagement in community responsibilities. These two studies may suggest that performance-based assessments of daily functioning are more proximal to community functioning than is global cognitive functioning.

Recently Hospitalized Older Individuals

Unfortunately, many older persons never receive an assessment of their everyday functioning abilities until they are hospitalized. Because information about how the person was functioning prior to hospitalization may be sparse, it is often difficult to determine how much change in daily functioning resulted from the hospital stay and related events. The hospitalization may result directly from a recent decline in functional abilities or from some unrelated cause (e.g., a need for hip replacement or coronary bypass surgery). Regardless of the reason, ADLs among elderly patients are more likely to deteriorate and less likely to improve after hospitalization. Specifically, it has been shown that 30 to 60 percent of older individuals who have had a recent hospital stay acquire at least one new dependency in daily functioning. A recent study showed that the

variables most often associated with functional decline among older patients who have been hospitalized are age, lower current ADL or IADL abilities, worse cognitive functioning, lower preadmission IADL, depression, and length of hospital stay. Few screening instruments have been developed to measure the risk of functional decline among elderly individuals who have been recently hospitalized; however, a recent review of the literature identified three useful screening instruments: Hospital Admission Risk Profile (HARP), Identification of Seniors at Risk (ISAR), and Care Complexity Prediction Instrument (COMPRI).

Persons Living with HIV

Neurocognitive impairment commonly occurs in HIV infection, particularly among older individuals living with HIV. Neurocognitive problems may stem from the disease itself, HIV medication side effects, comorbidities associated with HIV (e.g., stroke, diabetes) or a combination of factors. The severity of the HIV-associated neurocognitive disorders (HAND) varies from asymptomatic forms that do not interfere with daily functioning to more moderate and severe forms that interfere moderately or significantly with everyday functioning. Specifically, neurocognitive impairment in HIV has been associated with driving, medication management abilities, and other IADLs. Many of the daily functioning assessments used with older HIV-infected persons, such as UPSA and Lawton & Brody ADL Scale, were originally developed in non–HIV-infected populations. While translating these assessments to the older HIV-positive population may be appropriate in terms of measuring functioning, the etiology of the everyday functioning impairment should be considered in the context of the unique risk factors in this heterogeneous population.

DEMOGRAPHICS

Mr. Anderson is a 62-year-old, right-handed, African-American male.

EDUCATIONAL AND VOCATIONAL HISTORY

The patient completed 13 years of education and received his high school diploma. He denied having any problems learning to read or write and never skipped or repeated a grade. He worked as a cook in a restaurant for approximately 30 years.

BEHAVIORAL OBSERVATIONS

The patient was alert and oriented to day of the week, date, year, and city. The patient was diagnosed with major depressive disorder in his early 20s and was diagnosed with HIV infection at age 50. He has been worried for some time that he may have some neurocognitive difficulties. He complains of slowed ability to process information, difficulty learning new strategies, and difficulty planning and initiating new activities. During the assessment the patient was apathetic and appeared somewhat lethargic, but was pleasant and cooperative. Gross visual acuity and hearing were intact. Overall, the patient seemed to put forth very good effort on all of the tests. The results are considered to be a valid estimate of his current cognitive and everyday functioning.

GENERAL COGNITIVE FUNCTIONING

The patient was administered a comprehensive neuropsychological test battery. Using T-scores

adjusted for age, education, sex, and ethnicity, Mr. Anderson was found to be impaired in the domains of learning and executive functioning. His performance was within normal limits on verbal functioning, speed of information processing, recall, motor, and attention/working memory. His global neuropsychological performance is mildly impaired (impairment ≥2 domains).

EVERYDAY FUNCTIONING ASSESSMENT

The patient was administered the UCSD Performance-based Skills Assessment (UPSA), which assesses overall ability to manage everyday functional tasks including ability to plan and organize events, manage finances, communicate with others, arrange for transportation needs, and conduct household chores. Overall, his performance fell within the moderately impaired range (overall score = 63). His UPSA score suggests some reduced capacity in maintaining his independent living situation.

CORROBORATING REPORT FROM MR. ANDERSON'S THERAPIST

The patient's therapist stated that the patient has experienced some mild difficulty performing day-to-day tasks including managing his own medications and finances. Specifically, the therapist stated that on occasion the patient has reported that he sometimes has difficulty in organizing and managing his medications. The therapist has increasingly become concerned with the patients neurocognitive and daily functioning difficulties. The therapist indicated that these neurocognitive and functional impairments have been stable over the past several years and do not appear to be worsening.

MOOD ASSESSMENT

The patient scored 11 on the Hamilton Depression scale, which is indicative of mild symptoms of depression. The patient denied suicidal ideation.

SUMMARY AND CONCLUSIONS

Results of the current evaluation indicate that the patient's overall level of cognitive functioning was mildly impaired as compared to other individuals of his demographic background. The patient also demonstrated moderate impairments on a measure of everyday functional abilities (UPSA). The patient's therapist corroborated many of the patient's daily functioning difficulties. These test results suggest mild to moderate impairments in cognitive and everyday functioning. The longitudinal course of these impairments has been stable. That is, cognitive and everyday functional abilities appear to have remained stable over the past several years, which is again consistent with published literature on this topic. Based on his current level of cognitive functioning and deficits in functional skills, the patient was recommended to seek additional assistance in instrumental activities in daily living activities. It was also recommended that the patient receive functional skills training classes, which may help improve his ability to perform essential everyday skills (e.g., mange finances, communicate with others). Particularly important is his ability to self-administer his medications. Providers should consider additional training in managing medications as well as methods to reduce errors in administering medications (e.g., blister packs, electronic reminders, pill organizers).

RECOMMENDATIONS FOR FUTURE INSTRUMENT DEVELOPMENT

Assessments of daily functioning continue to evolve. Below, the authors offer recommendations for future development.

Everyday functioning is multi-faceted; however, most assessment instruments are designed to test a given domain in isolation. For instance, the MMAA assesses medication management abilities independent of other abilities. Medication management in "real life" occurs over a much longer time span and is intertwined with other daily tasks. The ideal assessment of daily functions would test multiple domains of functioning concurrently.

Some multi-tasking tests of this nature have been developed, but additional assessments of this type are clearly warranted.

Another desirable component of future assessment instruments is that they be adaptive. That is, instruments should have the flexibility to adjust to the level of mastery of a particular individual. If an item was too difficult, the individual could be tested with easier items, or vice-versa. A great deal of research has been done on adaptive testing, particularly with computer-administered, standardized achievement tests. Hopefully this technology can be applied to the assessment of functional capacity.

VR technology may offer a way of creating more realistic mock environments in which multiple aspects of functioning could be tested. Assessments could even be designed to recreate a patient's unique habitual environment, and many assessments have already been developed and are currently being tested. Some argue that older adults are too resistant to digital technologies for such technologies to be useful with this population, but the degree of resistance may be exaggerated. Furthermore, performing VR tasks may not require high levels of technical knowledge. These techniques may be useful both for assessments and for interventions. These technologies have already been implemented for the treatment of certain disorders (e.g., PTSD).

Very few functional-assessment instruments provide demographically adjusted normative data, with the most important variable being age. This constitutes a significant limitation as compared to other types of assessment, such as neuropsychological tests, for which the assessor typically has an indication of where a given score falls on a continuum. Ideally, all functional assessments would have normative information. In the absence of normative data, an evaluator who is more experienced is likely to have a better sense of what a given score means in the context of other objectively gathered data. The authors understand that normative studies are not easily funded; however, the authors believe that future studies of this type should be a research priority.

In addition to demographically corrected normative data, there are significant advantages to the co-norming of different assessment modalities together. If evidence could be obtained of how certain instruments work with one another, then better insight into a given patient's true difficulties would be available. For example, if a self-report, collateral report, and a performance-based measure were concurrently administered to a large sample of older adults with varying diagnoses and ages, the results might help us to understand the distinct strengths and weaknesses of the various assessment modalities. It might be found that persons who score below a given level of self- and collateral-reported functioning would derive no benefit from receiving a performance-based assessment. On the other hand, in persons who report a relatively intact level of functioning there might still be difficulties on performance-based assessments due to

inaccuracies in self- or collateral report. The combinations are many, but ideally it would be helpful to know how the most widely used instruments worked together.

Finally, the discussion of norming and co-norming is moot if the instruments in question have no validity for predicting actual functioning. Predictive validity is difficult to obtain without a widely recognized gold standard of assessment for everyday functioning abilities; however, the authors believe that using a multi-modal assessment strategy allows for an accurate representation of daily functioning. Until reliable and valid instruments with strong predictive validity are established, there will be difficulty in establishing the true usefulness of everyday functioning assessments.

SUMMARY

Older adults are at significant risk for difficulties with everyday functioning. These difficulties can range from impairments on basic behaviors critical for independent functioning, such as toileting to optional daily tasks, such as driving. Several factors may influence daily functioning, and cognitive impairment appears to be a strong predictor of daily functioning difficulties. Numerous everyday functioning assessment methodologies are available and include clinical interview, self- and collateral report, clinician ratings, performance-based measures, and direct observation. Performance-based measures may offer significant advantages such as improved reliability and a better estimate of functional capacity as compared to other assessment approaches such as self-report. More research is clearly needed to develop quick, reliable and valid assessments of everyday functioning for older adults; the field is currently burgeoning, and improved assessments will continue to be developed in the near future.

ACKNOWLEDGMENT

The authors would like to thank Virginia Wadley, Ph.D. for contributing to one of the case presentations in this chapter, and Thomas L. Patterson, Ph.D. for contributing to a prior version of this chapter.

57.3b Psychiatric Problems in the Medically Ill Geriatric Patient

ANNA BORISOVSKAYA, M.D., BETH ANN LABARDI, M.D., MATTHEW ALAN SCHREIBER, M.D., PH.D., AND MARCELLA PASCUALY, M.D.

Since the beginning of the 20th century, a dramatic increase in life expectancy has produced an aged population of unprecedented size and longevity. According to demographic forecasts, one out of five people will be over the age of 65 in the year 2060, up from one in seven in 2012. In the United States, a 65 year old will typically remain independent until he or she reaches the age of 75, and will live an additional 6.5 years once he or she becomes dependent on others.

People over the age of 65 account for twice the average number of prescription drugs, one and a half times the number of physician contacts, and three times the number of hospital-bed days. Overall, the aging population accounts for more than one-third of the total personal health expenditures in the United States. Among the top 5 percent of highest health care spenders who collectively make up one-half of total spending, adults over age 65 account for 40 percent.

Over half of the population that is 65 and older report having at least one chronic disability, and a third report having a chronic condition that is severe enough to limit their activities. For the psychiatrist, medical comorbidity and disabilities, which aggregate with age, are the most

important factors distinguishing older patients from their younger counterparts.

Some of the most common disorders in the aged population include degenerative arthritis and cardiovascular disorders, mainly hypertension and heart disease. In addition, geriatric syndromes such as falls, vision and hearing loss, urinary incontinence, and impaired cognition disproportionately impact health care costs and quality of life. One recent study found that about 65 percent of adults over age 65 have two or more chronic diseases, and this increases to 82 percent in individuals over the age of 85.

Estimates of the prevalence of psychiatric disorders among the medically ill and disabled elderly vary widely across clinical settings, and reliable data on comorbidities are still sparse. For example, 30 percent of older adults in primary care have at least one active psychiatric diagnosis: 10 to 15 percent have clinically significant depressive syndromes such as major depression, dysthymia, or minor depression; 5 to 10 percent have dementia; and 2 to 5 percent have alcohol abuse or dependence or psychoses. The lowest prevalence rates for psychiatric symptoms and disorders are found among medically healthy persons living independently in the community, and prevalence increases with severity of medical illnesses and extent of functional dependency (Fig. 57.3b–1). The relationship between functional health and psychiatric comorbidity has been most clearly established for depression, but emerging data suggest similar trends for anxiety disorders, sleep disorders, and psychoses. In addition to impairing day-to-day functioning and quality of life, depression in medically ill older adults has been associated with decreased self-care and adherence to treatment regimens for chronic medical conditions, worse medical outcomes, increased health care costs, and mortality from suicide and medical causes.

The profound changes in the demographics of chronic disease have resulted in an increased need for psychiatric care of patients with comorbid medical and mental disorders. New models of practice, based on effective collaboration between psychiatrists and primary care providers or medical specialists, are required to address the needs of older patients. Clinical care of psychiatrically disturbed medical patients poses several special challenges for the psychiatrist. Clinical syndromes may vary in presentation from the classical disorders for which treatment guidelines are well established to situations where common disorders such as depression and anxiety are masked by medical comorbidities and functional disability, in place of overt expression of emotional symptoms. Thus, one needs a working familiarity with the common medical and functional problems of the elderly, and a full range of skills in psychotherapeutic and somatic treatment modalities. In spite of these inherent challenges, most psychiatrically disturbed older persons can be substantially helped when

approached within a systematic framework.

FIGURE 57.3b–1. Prevalence of depression in older adults.

APPROACH TO THE PATIENT

Mastery of a few central concepts helps integrate the range of clinical data essential in the successful evaluation and management of psychiatrically disturbed, medically ill geriatric patients (Table 57.3b–1). The adaptive reserve of all vital organs, including the brain, tends to decline with aging, even in the absence of manifesting disease. This loss of physiological resilience is generally detectable in clinical settings only after a sudden or severe deterioration in the face of acute illness or psychosocial stress. Age-related loss of adaptive reserve underlies the downward spiral and multiple organ failures often seen in sick elderly. It is responsible for the narrowed margin of safety observed for many drugs, changes in the presentation of disease, and increase in morbidity of medical and psychiatric disorders. For example, acute myocardial infarction in an octogenarian may present as painless delirium, while a mild chronic anxiety disorder may become fulminant panic in a patient with rectal bleeding who, ultimately, may not have a serious medical problem. Such complex patterns of causation are typical of psychiatric symptoms in the very old and in persons with *multimorbidity*—the most common chronic medical condition—used to define the presence of several comorbid medical conditions. Sometimes causal factors emerge clearly only after a successful intervention, or not at all.

A 78-year-old man with bipolar disorder since age 40 became manic while residing in a nursing home. His situation had been complicated by chronic alcoholism and mild dementia. He had no history of renal disease, and his serum creatinine was normal. After an initial period of manic grandiosity, when he was often seen near a local tavern, he soon deteriorated to crawling on his hands and knees, growling and barking like a dog, and striking out at all who approached him. His lithium level was 1.2 mEq/L with a maintenance dose of 750 mg/day. After reduction in lithium dose to achieve a level of 0.6 mEq/L, the temporary addition of low-dose olanzapine, and close attention to adequate fluid intake and preventing access to alcohol, both the manic syndrome and the superimposed delirium cleared within 3 weeks without the need for psychiatric hospitalization.

Medical causes should be considered whenever an elderly patient develops a new psychiatric symptom or disorder. When psychotropic medications are used, clinicians are advised to carefully watch for the emergence of side effects, allow sufficient time for medications to reach effective plasma and receptor site concentrations, and seek optimal therapeutic outcomes. Particularly with newer-generation psychotropic medications, the differences between "geriatric" and "adult" doses are minimal; careful titration of medications from a low dose to a usual adult dose may be necessary to achieve the desired therapeutic benefit. Close collaboration with other clinicians and caregivers is essential for maximal safety and effectiveness at every stage of treatment. The greatest overall therapeutic gain, at the smallest cost in treatment-related adverse events, is usually achieved by combining psychotherapeutic, social, environmental, and somatic interventions. A rehabilitation model that specifies progress toward attainment of specific goals in stepwise increments is a useful way to frame the ongoing process of care that is often most appropriate for chronically ill older adults.

Table 57.3b–1.
Key Concepts in Psychiatric Care of the Medically Ill Elderly

Decreased organ reserve alters response to illness, treatment, and social stressors.
Comorbid medical illness affects presentation and treatment of psychopathology.
Nondrug treatments are preferable when effective.
Combining treatment modalities optimizes gains.
Comfort, function, and safety are the major goals of treatment.
Coordinated care is better care.
Family and caregivers are essential to patients' recovery and must be involved in the treatment.

An 83-year-old woman with long-standing diabetes and ischemic and hypertensive cardiovascular disease had become bedfast over several years in a nursing home. Two months before psychiatric consultation was requested, she developed a psychotic illness characterized by delusions of being beaten during the night, aggressive outbursts, and pervasive despondency, which led to disruptive nocturnal phone calls to her daughter and to the local fire station. Initial clinical assessment disclosed a moderately severe dementia in a personable but angry and frightened woman, eager for relief. Collateral history confirmed progressive cognitive deterioration over the course of her chronic medical illness, on a background of long-standing dysthymia. Trials of several antipsychotic and antidepressant medications had exacerbated her symptoms. A review of her medications showed that 4 of the 12 drugs she was taking on a regular basis were not essential for her medical management. A head computed tomography (CT) scan showed mild cerebral cortical atrophy, moderate periventricular white matter hyperintensities, and numerous lacunar infarcts. The onset of her psychosis was eventually associated with the initiation of aggressive treatment of arterial leg ulcers, including round-the-clock debridement dressings, oral antibiotics, and narcotic analgesics. Control of her diabetes had deteriorated, and her insulin dose had been increased. Nursing staff members had provided excellent physical care, but were resentful of her racist attitudes and physical aggressiveness, which exacerbated her loneliness and paranoia. Her treatment plan was as follows: discontinuation of night-time debridements (allowing elimination of narcotics for pain), simplification of her drug regimen, preventing nocturnal hypoglycemia, installation of a night light in her room, problem-solving discussions with staff, weekly psychotherapy, and

wheelchair walks, which represented her first opportunity to go outdoors for months. Her distressed phone calls ended soon after. Her mood, sleep, and interactions with staff improved gradually, and her delusions and racist remarks disappeared. Foci of psychotherapy were discovery of traumas she experienced in Cossack Russia, psychoeducation about her delirium, and discussions of her desire to die rather than live in a deteriorated state. She developed a firm therapeutic alliance and regained the dignified and compassionate manner that characterized her response to adversity in the past.

PSYCHIATRIC SYNDROMES IN MEDICALLY ILL PATIENTS

General Principles

Systemic medical illness can mimic or cause almost any psychiatric syndrome, often through more than one pathophysiological mechanism. They can also coexist with psychiatric illnesses that were present prior to the onset of such medical problems. The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) further simplified the classification of psychiatric disorders due to medical diseases, dividing them into cognitive disorders, psychotic disorders, depressive and bipolar disorders, anxiety disorders, obsessive-compulsive disorders, catatonic disorders, and personality changes. Changes from DSM-IV-TR include addition of obsessive compulsive and related disorders due to another medical condition, removal of amnestic disorder and sleep disorder due to a medical condition, and specifying depressive or bipolar illness due to another medical condition. Distinguishing a "medical" psychiatric syndrome from a primary psychiatric disorder is often difficult. Clues to the secondary nature of a psychiatric syndrome include partial expression, first onset in old age or a change in clinical features with recurrence of an earlier-onset disorder, lack of family history, a recent change in health or medical treatment, and concurrent cognitive processing deficits that point to impaired brain function.

Psychiatric disorders not caused directly by the effects of a medical illness interact with chronic medical conditions in complex ways. This is best understood for depression in the setting of chronic disease: Depression can amplify somatic symptoms, leading to excess functional impairment and overestimation of disease severity; it decreases motivation and brings about despair about the efficacy of treatment, leading to poor treatment adherence, poor self-care, and finally, poor outcomes. In such cases, consideration should be given to the newly introduced diagnosis in DSM-5, *Psychological Factors Affecting Other Medical Conditions*, denoting psychological or behavioral factors that affect a medical condition adversely. Comorbid medical illness, in turn, can delay or prevent recognition and treatment of psychiatric disorders that might be readily treated in primary care.

Medications as a Cause of Psychiatric Symptoms

Most drugs, in sufficient doses, can affect central nervous system function in a vulnerable host. Drugs affecting the brain, either as their primary site of therapeutic action (e.g., all psychotropic drugs, narcotic analgesics, anti-Parkinson agents, and many antihypertensive agents) or as a secondary site not essential to their therapeutic effect (e.g., digitalis [Lanoxin], cimetidine [Tagamet], glucocorticoids, and nonsteroidal anti-inflammatory agents, such as aspirin and indomethacin), can cause psychiatric symptoms in medically ill elderly patients. As an example, corticosteroids used for the treatment of inflammatory states such as rheumatoid arthritis may lead to depression, while thyroid replacement and even antidepressants can cause anxiety.

Clues to a possible drug-induced psychiatric syndrome include presence of associated systemic or neurological signs and symptoms, such as recent loss of appetite, reduced sense of well-being, blurred vision, slurred speech, dizziness, gait instability, or somnolence. A patient's complaint of being drugged, while occasionally delusional, should always raise suspicion of drug toxicity.

Identifying a drug as the primary cause of a change in mental state can be accomplished in several ways. Some drugs produce classical symptoms in overdose, such as nausea and distorted color vision in digitalis overdose, or tinnitus and dizziness with aspirin. In other instances, a neuropsychiatric syndrome results from pathophysiological mechanisms common to a number of drugs with very different primary indications but similar pharmacological properties. An example is the central anticholinergic syndrome, characterized in its most extreme form by tachycardia, pupillary dilation, visual hallucinations, and delirium in patients receiving medications with known affinity for muscarinic receptors, such as tricyclic antidepressants (TCAs), but also caused by pharmacodynamic interactions of a vulnerable brain with multiple drugs, each having weak individual antimuscarinic actions.

Blood levels often don't help in determination of whether a medication is causing a neuropsychiatric problem, except for the relatively few drugs readily measured in serum or plasma and for which therapeutic ranges are well established. However, medication toxicity may occur in older adults without elevated plasma levels, and improvement when a suspect drug is decreased or discontinued is the most crucial test of its role in pathogenesis.

An 87-year-old woman came to a psychiatrist with a mild depression associated with a recent cross-country move and hepatic cirrhosis of unknown etiology with mild renal insufficiency. Treatment was initiated with fluoxetine 20 mg/day and supportive psychotherapy. Over the ensuing 9 months, she was hospitalized several times with intractable vomiting for which no cause was found. When she again presented with the same picture and, now, ascites and severe demoralization, a fluoxetine level was obtained. The combined concentration of fluoxetine + norfluoxetine was within the expected range at 138 ng/mL (normal range 100 to 930 ng/mL). Discontinuation of fluoxetine eliminated the nausea, vomiting, and demoralization within a

week.

Drug and Disease Interactions

Psychiatric symptoms arising from the interactive effects of medications and underlying disease may be severe enough to lead to psychiatric hospitalization. In a series of nearly 16,000 consecutive adult psychiatric admissions, about 1 percent was attributable to adverse drug reactions. Elderly patients were most often affected, particularly those with neurological disease or those receiving multiple medications. Nearly 30 percent of elderly persons develop delirium after hospitalization for acute medical illness. Particularly at risk are those with cognitive impairment at the time of admission, the very old (>80 years), patients with fractures or symptomatic infection, and those receiving neuroleptics or narcotics. Early detection of mental disorders due to drug–disease interactions depends on familiarity with the common medical illnesses of older people, their potential impact on brain function, and the pharmacological properties of drugs used in medical management and their special potential for interactive effects. Table 57.3b–2 shows examples of some drug–drug and drug–disease interactions that may be encountered in clinical practice.

Differential Diagnosis

Differential diagnosis of psychiatric syndromes in the medically ill older patient begins with a mental status examination that incorporates a careful assessment of several cognitive dimensions, including attention and orientation (both impaired in delirium), memory and learning, and executive control function, the ability to understand, organize, and carry out goal-directed cognitive and motor sequences. Thorough collateral information and an evaluation of the patient's past and current medical conditions, emphasizing disease of vital organs and painful conditions are essential. A complete medication history and a focused physical examination are important, including at a minimum a review of vital signs and a screening neurological examination to check for abnormal gait or movements, focal areas of weakness, or abnormal deep tendon reflexes. The judicious use of appropriate laboratory tests may clarify the possibilities in complex situations (Table 57.3b–3). Finally, the gathered data can be synthesized into a list of possible differential diagnoses and probable causes. For example, in a patient with blood pressure in the low-normal range, pitting ankle edema, apathy, weakness, and depressed mood, who has been taking a high-potency diuretic for many years, an electrocardiogram (ECG) and echocardiogram may be needed to determine whether CHF or the diuretic is the most salient contributor to the depressive syndrome, whether it is safe to try discontinuing the diuretic, and what special precautions are required in prescribing an antidepressant.

In doubtful cases, where the differential diagnosis includes a primary psychiatric disorder not caused by physical effects of illness, the electroencephalogram (EEG) may be helpful. The EEG in patients with psychiatric syndromes due to metabolic, toxic, or circulatory causes typically shows diffuse slowing, although it cannot implicate specific diseases or drugs, and the interpretation may be confounded when an underlying dementing illness is present. An increase in dominant frequency accompanying recovery lends weight to the formulation.

Table 57.3b–2.
Examples of Drug–Drug/Drug–Disease Interactions in the Elderly

Drug	Indication	Adverse Effect
Cimetidine	Gastroesophageal reflux	Delirium Elevated drug levels (e.g., TCAs, benzodiazepines, neuroleptics, propranolol, theophylline)
Metoclopramide	Gastroparesis	Parkinsonism, inappropriate prescription of levodopa
TCAs	Depression, anxiety, insomnia, chronic pain	Confusion Constipation Tachycardia, cardiac conduction defect, hypotension Altered effect of antihypertensive agents (↑ effect of diuretics, ↓ effect of α_2 agonists, e.g., clonidine)
SSRIs	Depression, anxiety, obsessive-compulsive symptoms	Apathy Insomnia Restlessness, agitation, extrapyramidal symptoms, akathisia Central bradycardia ↑ Potential for diverse drug–drug interactions Destabilization of Coumadin dosing Gastrointestinal distress, diarrhea
NSAIDs	Arthritis	Cognitive impairment ↑ Serum lithium levels ↑ Blood pressure, ↓ hypertension control
Neuroleptics/atypical antipsychotics	Dementia with psychosis	Death ↑ Cognitive impairment Extrapyramidal symptoms Falls Aspiration pneumonia
Ginkgo biloba	Impaired memory, arterial insufficiency	↓ Clotting time Restlessness (high doses)
Glucocorticoids	Inflammation, COPD	Depression, mania, psychosis, cognitive impairment (especially at high doses), insomnia

COPD, chronic obstructive pulmonary disease; NSAIDs, nonsteroidal anti-inflammatory drugs; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

When a drug is believed to cause or contribute to a psychiatric disorder, all drugs should be sorted into those with a high potential for causing psychiatric symptoms (such as anticholinergic and sedating drugs), those clearly required for the management of serious medical disease, and those that may be modified or stopped on a trial basis. Familiarity with drug side effects, with interactions, and with the pathways for their elimination may assist in the detection of otherwise occult medication toxicity syndromes. Close adherence to the "rule of maximal simplification" of medication regimens can produce clinical improvement in up to half of all psychiatrically disturbed medically ill older persons.

A 73-year-old man with severe chronic obstructive lung disease (COPD) came for the treatment of anxiety with insomnia and severe daytime fatigue. He had been treated with fluoxetine for several years after initial psychiatric evaluation, to which clonazepam had been added by his pulmonologist in doses up to 2 mg/day, without relief. Shortness of breath and activity-induced panic attacks were his most pervasive complaints. Physical examination and imaging disclosed hypertension (190/120), persistent tachycardia, and signs of emphysema but no indication of CHF. A walk with oximetry led to oxygen desaturation from 93 to 83 percent after 3 minutes. His medication list included two antihypertensive agents, only one of which he took, since the other was a diuretic that prevented him from leaving home unless assured of constant proximity to a bathroom. He was also on three scheduled inhaled medications and albuterol when needed (prn). It turned out that he was using his prn albuterol at least 12 times daily, but his technique was ineffective in achieving drug deposition in smaller airways. Pulmonary function tests showed no improvement with bronchodilator therapy. Diagnoses of activity-dependent oxygen debt and albuterol toxicity were made, manifested by treatment-resistant anxiety and hypertension, tachycardia likely to endanger his heart if uncorrected, and severe exercise intolerance. Reduction in albuterol use to four times daily, addition of a second antihypertensive drug without diuretic activity, and prescription of continuous oxygen therapy with judicious oral morphine significantly improved his shortness of breath and activity tolerance, and reduced his blood pressure and tachycardia to safer levels.

Elderly patients who present with previously undiagnosed cognitive impairment warrant aggressive assessment. The most prevalent dementia syndrome among geriatric patients is Alzheimer disease, dementia with Lewy bodies a close second. Other common causes of cognitive impairment in older patients include vascular dementia, frontotemporal dementia, dementia due to Parkinson disease, Korsakoff syndrome, and potentially reversible cognitive impairment (if caused, e.g., by depression, drugs, B_{12} deficiency, and others). (See chapter on Dementias for additional discussion.) A meta-analysis of rates of reversible dementia found 9 percent of cases had a partially or completely reversible etiology, but that a total of only 0.6 percent of cases actually reversed with appropriate clinical management. These figures likely reflect general improvements in geriatric medical care.

Table 57.3b–3.
Practical Evaluation of Psychiatrically Disturbed Medically Ill Older Patients

Establish rapport quickly.

Define the reason for the consultation or visit.

Learn and use a few rapid screening instruments:

- ► Cognition—e.g., Mini-Cog
- ► Depression—e.g., Patient Health Questionnaire-9 (PHQ-9)
- ► Neuropsychiatric symptoms—e.g., Neuropsychiatric Inventory (short version)
- ► Functional ability—e.g., Functional Activities Assessment

Expect more than one psychiatric diagnosis (e.g., delirium plus chronic depression).

Make a complete problem list:

- ► Medical
- ► Psychiatric
- ► Social
- ► Functional

Identify all drugs in current use:

- ► Prescription drugs
- ► Over-the-counter medications
- ► Vitamins, minerals, botanicals, and "natural" remedies
- ► Alcohol and tobacco
- ► Include those used infrequently
- ► Ask patients or caregivers to bring all medications from home in a paper bag for your inspection

Interview capable collateral sources:

- ► Family or other primary caregivers
- ► Primary physician
- ► Staff of residential facilities

For acute exacerbations of chronic problems, ask "why now?"

If problem unexplained, search for:

- ► Undiagnosed medical illness
- ► Drug effect or interaction
- ► Occult injury
- ► Undetected social problem (abandonment, abuse)

Conduct a screening physical examination: vital signs, gait, neurological signs.

Obtain appropriate corroborating laboratory studies; consider broad-spectrum tests to screen for suspected disease, e.g., complete blood count, blood glucose, serum electrolytes, blood urea nitrogen and creatinine, liver enzymes, thyroid-stimulating hormone and free thyroxine, vitamin B_{12} and folate, syphilis serology if indicated, urinalysis, electrocardiogram, chest radiograph, electroencephalography for delirium, erythrocyte sedimentation rate for occult systemic disorders, hip radiographs for a delirious patient who will not walk, neuroimaging (head computed tomography for screening, or magnetic resonance imaging when microvascular disease is a possibility; single photon emission computed tomography for more precise diagnosis).

Completing an evaluation of a patient with dementia often requires two or more visits, particularly for frail elderly patients, as well as a thorough collateral history gathering. Medical illness can interfere with the adequate diagnosis of dementias, or unnecessarily delay antidementia pharmacotherapy. Also often overlooked in the management of demented, medically ill patients is the opportunity to improve cognition by eliminating medications with mild but cumulative central nervous system effects that worsen both cognition and function.

Approach to Treatment: Overall Recommendations

When treating an older adult with medical comorbidities, some overarching principles are worth calling to mind. Where appropriate, involve family and other supports. Knowing the extent, strength, and reliability of a patient's social support system affects treatment planning, and can aid in predicting what additional resources may be needed and how likely a given treatment is to be successful. Likewise, economic status can shape treatment and its delivery, especially in older adults managing multiple medical conditions, medications, Medicare copays, and hospital bills. The living environment should be safe and adequately accessible to needed medical resources, and should be addressed directly in a multidisciplinary treatment plan if it is not. Do not neglect the patient's preferences in treatment, but continually assess for medical decision-making capacity.

Always consider medical illnesses and treatments as potential causes of or exacerbating factors of the symptoms one is addressing, and work collaboratively with other health care professionals involved in the care of an elderly patient with psychiatric and medical comorbidity. See the end of this chapter for more discussion on the collaborative models of care.

It is wise to consider available nonpharmacological options for treatment of a given condition first, and weigh their potential appropriateness prior to turning to pharmacological strategies. These options could involve a variety of interventions from individual therapy modalities to structured activity and physical exercise, and improved caregiver communication.

Prescribing medications in the elderly poses a particular challenge, for reasons such as polypharmacy, pharmacokinetic (e.g., increased drug volume, decreased renal and hepatic clearance) and pharmacodynamic (e.g., increased sensitivity to certain classes of drugs) changes that occur with aging, overall reduced functional reserve that limits compensatory homeostatic mechanisms, and underlying medical and neurological diseases that impact drug metabolism and tolerance, variables that should be viewed as a constantly evolving process requiring close continued attention.

Polypharmacy is a significant concern in this population. A survey of community dwelling older adults (between the ages of 57 and 85 years) reported that 5 or more prescriptions were used by 29 percent of the overall group surveyed and this number increased to 36 percent in the group aged 75 to 85 years. In addition, almost half of the prescription users also took an over-the-counter medication on a regular basis. Herbals and dietary supplements use are also on the rise in the elderly. The Beers Criteria is a useful guide to assess inappropriate drug prescribing in the elderly due to ineffectiveness or high risk of adverse events.

These are the general guidelines that the authors recommend when prescribing medications for an elderly patient:

- Keep goals of care and patient's current health and cognitive status in mind.
- Before adding a medication, carefully review the current regimen, simplify the dosing schedule, and discontinue any unnecessary medications. Consider the cost of medications.
- Change one medication at a time, as much as possible.
- Be patient and use a slow pace of titration.
- Focus on potential drug–drug interactions and keep anticholinergic load to a minimum.
- Be equally concerned about overprescribing and underprescribing.
- Educate the patient and caregivers about side effects and expected improvements.
- Periodically review effectiveness, need for dose adjustment, or continued use. Standardized scales are invaluable feedback devices.
- Be vigilant of treatment adherence.
- Do not neglect cognition, as it may be a target of treatment and a factor complicating treatment of medical and psychiatric conditions.

PSYCHIATRIC SYMPTOMS ASSOCIATED WITH SPECIFIC MEDICAL DISORDERS

Vascular Disease

Vascular disease is being increasingly recognized as a cause of late-onset psychopathology as well as a factor exacerbating pre-existing disorders such as recurrent major depression, bipolar disorder, and Alzheimer disease. Ischemic and hemorrhagic strokes cause a variety of disturbances of behavior and emotionality related both to effects of the lesions on brain function and to psychological problems in adaptation to disability. Depression is often comorbid with vascular disease, occurring in roughly one-third to a half of all patients following an acute cerebrovascular accident. Though it has long been thought that lesions in the anterior left hemisphere are particularly predisposed to depression, this has more recently been disputed. The most recent review of available evidence indicates that right hemisphere lesions correlate with depression in the acute stroke recovery period, but that lesion location is otherwise not predictive in this regard. Persistence of milder depressive syndromes after the acute phase has been associated with factors related to functional impairment, including cognitive deficits, weak social supports, and inadequate living environment. The link between mood and vascular health is notable for its converse relationship: depression is an independent risk factor for stroke.

The importance of cerebrovascular disease in psychiatry extends well

beyond poststroke depression. The vascular depression hypothesis supposes that cerebrovascular disease may be etiologically related to geriatric depressive syndromes. The clinical presentation of this entity is characterized by cognitive deficits, psychomotor retardation, lack of insight, and disability disproportional to depression severity, as well as a suboptimal response to antidepressants. The most common neuropsychiatric outcomes of cerebrovascular disease are depression, anxiety, fatigue, and apathy. Less common but equally distressing are emotional lability, personality changes, psychosis, and mania. There is often no clear relation to location of the brain lesion, and management is challenging given lack of evidence base.

Cerebrovascular disease can cause psychomotor slowing, impaired executive function, and significant functional dependency even in the absence of depression. Associated clinical features include encoding-based memory deficits and impaired gait and urinary control. Neuroimaging studies, especially those using magnetic resonance imaging, typically demonstrate ischemic changes in subcortical and deep white matter and/or lacunar infarcts in the thalamus, the basal ganglia, and sometimes the upper brainstem. Interference with the function of frontal-subcortical circuits appears to be a common underlying anatomical feature of lesions that cause depression and executive dysfunction, and can be seen as a partial disconnection syndrome. Many patients with subcortical vascular disease have minimal or no discernible mood change, showing instead only cognitive, motivational, and neurological signs (often quite subtle). A diagnosis of vascular neurocognitive disorder may be appropriate in such cases, but minor depression may also be diagnosed when apathy and disengagement are functionally impairing. Vascular brain diseases can be caused by intrinsic disease of small and/or large vessels supplying the brain, due to atherosclerotic narrowing, occlusive plaque emboli, medial (muscular) hypertrophy, vascular amyloidosis, and cardiogenic causes. Among the latter, several pathogenic mechanisms are recognized: recurrent or severe hypotensive episodes and arrhythmias, CHF, and complications in patients after coronary artery bypass grafting. A third of older adults who undergo such a procedure develop permanent cognitive impairment, the causes of which are still debated. All physicians caring for such patients, including psychiatrists, need to be alert to the potential to improve long-term outcomes with aggressive management of vascular risk factors.

In fact, prevention of further vascular insults should be a key component in the psychiatric treatment plan of patients suspected of having vascular psychopathology. Relevant measures include fasting lipids, homocysteine, vitamin B_{12}, and folate levels; a careful history and ECG to identify cardiac arrhythmias or, if already recognized, coordination of care and education of other physicians about the possible cognitive consequences, monitoring serial blood pressure measurements to identify

hypertension and hypotensive episodes. Appropriate therapeutic steps can be taken after identification of patient's particular risks, such as prescription of folate/vitamin B_6/vitamin B_{12} combinations, antihypertensives, antithrombotic agents, or lipid-lowering drugs. Depression related either to an acute cerebrovascular accident or to cerebrovascular disease is responsive to pharmacological treatment with antidepressants, but a ceiling effect short of full recovery is likely and may call for adjunctive therapies, particularly stimulants such as methylphenidate or amphetamines, and psychosocial measures to provide activity structure and supportive or problem-solving psychotherapy. Antidepressants are also worth considering for their preventative role. Treatment of nondepressed stroke survivors with selective serotonin reuptake inhibitors (SSRIs) has been shown to significantly lower the incidence of poststroke depression, and has now been incorporated into standard practices. When the executive dysfunction or gait impairment is significant, extra caution is needed in choosing psychotropic medications. A broad treatment strategy is needed for optimal results: securing structure and support to compensate for defective executive function; supervised exercise to improve and maintain gait and balance; and management of frequently associated urinary incontinence.

Heart disease is a well-recognized cause of depression and anxiety. Medical and psychological factors both play a part, and a bidirectional causal relationship exists. Depression is an independent risk factor for coronary heart disease and myocardial infarction, and untreated or inadequately treated major depression is associated with adverse outcomes in individuals with known coronary disease. Effective psychiatric treatment often requires both psychotherapeutic and pharmacological modalities. SSRIs are usually the drugs of choice. They may cause bradycardia, by a central medullary mechanism, but lack primary cardiotoxicity, and are considered safe and effective in most patients with heart disease. Patients who fail to respond to SSRIs and don't have cardiac conduction defects or CHF can generally be safely treated with other antidepressants such as bupropion, mirtazapine, duloxetine, or venlafaxine. While electroconvulsive therapy is an undisputed myocardial stressor and should be avoided in the acute post–myocardial infarction period, treatment can be given without major complications if anesthesia and treatment are carefully individualized.

A 72-year-old man had a history of recurrent major depression since early adulthood as well as coronary heart disease. Depressive episodes were seasonal and consisted of low mood, anergia, amotivation, and increased appetite. With treatment with an SSRI and seasonal phototherapy, he suffered no major episodes in a 3-year period of relative stability. In January, he suffered a cardiac arrest, and had a prolonged course of cardiopulmonary resuscitation complicated by a difficult intubation in the field. During the hospitalization that followed, he was diagnosed with a diffuse anoxic brain injury, primarily affecting the subcortical watershed areas of the right

hemisphere greater than the left. After his acute rehabilitation, he was left with residual left-sided weakness and new psychiatric complaints. He described his mood as "blah," couldn't find anything that interested him, and had profound psychomotor retardation, exceeding his physical limitations. He expressed worry about becoming like his father who had had Alzheimer disease. His wife took over management of his medication and finances, and he wasn't allowed to drive. He reported that his previously effective antidepressant medication was no longer helping. In consultation with his cardiologist, low-dose methylphenidate was added to his medication regimen. Six weeks later, his affect was brighter, his speech and movements were less labored, and he had been able to dabble in his old hobby of collecting military memorabilia.

Parkinson's, Alzheimer's, and Other Neurological Diseases

Depression occurs with disproportionate frequency in Parkinson disease, affecting up to half of all patients. This depression is believed to be caused, in large part, by the neurodegenerative process itself; its presence is associated with evidence of damage to noradrenergic and serotonergic systems, and is thought to identify a group of Parkinson patients with a more rapid course of disease. Nevertheless, antidepressant drugs or other treatments can be effective. Venlafaxine (Effexor) and pramipexole (Mirapex) have been found to be clinically useful; the latter especially so for targeting motor symptoms concomitantly. Though evidence is lacking for use of specific SSRIs, they are commonly used and relatively safe. TCAs may be effective, but are less commonly used due to concerns about adverse effects in older patients. Selegiline (Deprenyl), an anti-Parkinson agent that selectively inhibits monoamine oxidase B, may be a useful addition to treatment of depression in Parkinson's. Cognitive-behavioral therapy (CBT) has also proven effective. Hallucinations are both a feature of later-stage Parkinson disease and consequence of anti-Parkinson drugs, and may respond to lowering the doses of these medications. If that is not feasible, atypical antipsychotic drugs with less impact on nigrostriatal dopaminergic pathways can be helpful. Clozapine (Clozaril) and quetiapine (Seroquel) are the most extensively studied, and though clozapine is consistently efficacious, quetiapine is usually prescribed first because of the risk of agranulocytosis and the requirement for frequent blood monitoring with clozapine. Use of ziprasidone (Geodon) is supported by limited but promising evidence. Motor deterioration outweighing impact on psychosis has been observed with olanzapine (Zyprexa), risperidone (Risperdal), and aripiprazole (Abilify). The majority of depressed Parkinson patients also have cognitive deficits, which may occur as an independent neurocognitive disorder unrelated to depression. Major neurocognitive disorder due to Parkinson disease commonly affects learning and memory, initiative, planning, and capacity for independent functioning, in excess of the constraints imposed by the motor disability alone. These cognitive deficits tend to persist after successful treatment of any mood disorder, and are not substantially improved by anti-Parkinson agents. The currently available evidence supports the use of cholinesterase inhibitors in these patients,

with a positive impact on global assessment, cognitive function, hallucinations, behavioral disturbance, and activities of daily living rating scales. The rivastigmine (Exelon) transdermal patch is better tolerated than oral formulations, though exacerbation of tremor remains a concern. Response to memantine (Namenda) in this disorder has been disappointing.

In Alzheimer disease, depression affects up to one-third of patients, especially in milder stages, and may be the major presenting problem. In recent years, the cumulative evidence is found to be insufficient to support the use of antidepressants in this population; they also lead to increased rates of adverse events, including falls. Trials of antidepressants may be best reserved for those with moderate or severe depression, and risks and benefits should always be carefully weighed. Apathy and other neuropsychiatric manifestations of major neurocognitive disorder due to Alzheimer disease may be modestly improved by cholinesterase inhibitors. With the progression of dementia, classical presentations of depression become less frequent, while agitation, psychosis, and aggressive behavior with or without dysphoria become more common. Mixed behavioral syndromes are the rule in middle- and later-stage dementia. Assaultive or threatening behavior demands thorough medical and socio-environmental assessment to identify precipitating and promoting factors, but pharmacological interventions are often required. Second-generation antipsychotics are commonly used off-label in these cases, a controversial practice due to the black box labeling by the Food and Drug Administration (FDA). Recent reviews conclude that use of these agents confers modest benefits for short-term treatment of aggression and psychosis as well as a small but significant benefit on caregiver burden. This is offset, however, by the substantial risk of serious adverse events, including a 1.5 to 1.8 times increased mortality risk. Trials of valproate for these dementia-related behaviors have been disappointing. Existing evidence for use of SSRIs in this condition is promising but limited.

A 90-year-old male Holocaust survivor with major neurocognitive disorder due to Alzheimer disease was brought to a psychiatrist with increased tearfulness and speaking about the loss of his family in concentration camp settings. His family reported that this was a change for him, and that he had not previously focused so much on these troubling memories. They also reported that the television in the home was often left on to a channel covering World War II and other historical topics, at the caregiver's preference. The family was instructed to ensure different programming was on television, and as a result, the caregiver spent more time interacting with the patient. His mood improved. A year later, the man returned, now with aggressive behaviors of grabbing and yelling out, especially around toileting. The patient was assessed for any physical cause of discomfort, but none could be found. The caregiver received additional information on communicating with individuals with Alzheimer disease, and providing distractions and rewards around these difficult times. The patient's behavior improved only minimally with these interventions, and a low dose of quetiapine was started. The behaviors improved, and the psychiatrist was able to gradually taper off the medication after 3 months.

Posttraumatic and postanoxic encephalopathies, hydrocephalus, central nervous system tumors and infections, multisystem atrophy, Shy–Drager syndrome, Huntington disease, demyelinating diseases such as multiple sclerosis, idiopathic inflammatory diseases such as systemic lupus erythematosus and temporal arteritis, and occupational neurodegeneration such as chronic organic solvent encephalopathy may all be associated with depressive, manic, delirious, and psychotic syndromes. For depressions in patients with these disorders, antidepressant trials are generally warranted, though drug intolerance may be problematic and require the use of innovative and combination treatment strategies. The management of other psychiatric complications is less well established.

Chronic Respiratory, Metabolic, and Endocrine Disorders

COPD is the most prevalent of the chronic respiratory diseases of the second half of life. Cigarette smoking and, in the developing world, exposure to biomass fuels, are significant risk factors. COPD is strongly associated with depression, anxiety, and, in advanced cases, a special form of panic disorder precipitated by exertion. Over 40 percent of patients with COPD suffer from depressive symptoms. Smoking is a shared risk factor in depression and COPD and the rates of depression are even higher in COPD patients who are actively smoking. Untreated depression in COPD worsens overall outcomes with more COPD exacerbations per year, contributes to persistent smoking, and has been associated with increased risk of death, poorer social functioning, increased physical disability, poor adherence to treatment, and health care overutilization.

Psychological complications are common, and include feelings of hopelessness and helplessness that contribute to impaired treatment and rehabilitation adherence, anxiety-related dyspnea and secondary panic symptoms fostering further inactivity, fear of sudden death by asphyxiation, intense self-blame in patients whose illness is related to smoking and social isolation due to shame, low mood, and lack of motivation. For milder dysphoric states not meeting criteria for a depressive diagnosis, a multidisciplinary rehabilitation and counseling approach improves mood in many patients. In such cases, the efficacy of antidepressants in COPD has not been demonstrated either for alleviation of depression or improvement of dyspnea. However, available evidence suggests that, in patients with syndromal depression and absence of left ventricular disease or hypercapnia, antidepressant pharmacotherapy is beneficial for depression, anxiety, and somatic symptoms. A risk and benefit analysis regarding the use of antidepressants needs to be considered in each patient. Comprehensive nonpharmacological interventions for anxious depressed patients with COPD provide individualized education about the disease, its management, and adherence to recommended treatment, teach patients to modify their symptoms with

appropriate techniques such as breathing retraining, and offer supervised physical training. The use of behavioral activation, CBT and collaborative care approaches should also be considered. Patients with pulmonary disability and those who require home oxygen therapy may benefit from self-help groups. Patients with lung cancer may develop psychiatric complications similar to those occurring in COPD; in addition, paraneoplastic psychiatric syndromes with psychotic, cognitive, and/or affective symptoms have been reported.

Deterioration in pulmonary or cardiopulmonary status in patients with COPD can lead to acute and chronic encephalopathies, to sustained hypoxemia and hypercapnia, or to the central nervous system effects of drugs used in management (oral or inhaled bronchodilators, high-dose prednisone, cough or dyspnea suppressants, or benzodiazepines). Psychotic states may occur, usually related to acute impairment of brain function by severe exacerbation of illness. Prior to the establishment of guidelines for oxygen therapy in COPD, neurocognitive impairment was thought to be quite widespread, but recent studies questioned the prevalence of cognitive disorders due to COPD prior to severe and end-stage disease.

Chronic renal and hepatic disease can lead to well-known delirium states due to their detrimental effects on nutrition, metabolism, clearance of toxic metabolites, and drug disposition. In addition to these transient alterations of mental function, the prevalence of other psychiatric disorders in these conditions approximates those for chronic disease in general. Pharmacological treatment considerations include evaluating the effects of disease on effective half-life and plasma drug levels and adjusting prescribing accordingly. More specifically in renal disease, chronic hemodialysis has been associated with neurocognitive decline, but improvements in this area have occurred since aluminum was eliminated from dialysate. There is also substantial comorbidity with depression. For patients with end-stage renal disease, suicide risk appears to be less elevated than previously thought. However, complex end-of-life issues associated with dialysis termination remain a clinically challenging issue where nephrologists, palliative care specialists, and psychiatrists can work closely together with patients. With hepatic disease, an area of notable concern is the effect of hepatitis C and its treatment which is associated with depressive states.

Diabetes is implicated in both depression and cognitive impairment. Depression rates are at least twice those of the general population and can be associated with poorly controlled hyperglycemia, lessened adherence to medications and reduced self-care, all of which can contribute to increased diabetic complications and elevated mortality rates. In short-term studies, treatment for depression improves both glucose control and quality of life. In epidemiological studies, diabetes (in its more common type 2 form in particular) has been found to be associated with dementia, which is

exacerbated by the associated increased rates of comorbid cardiac and vascular disease. However, the pathogenesis of this neurocognitive risk is not yet understood. It is believed that the adverse effects of diabetes on cognition can be modified by optimal glucose control, with longitudinal studies in this area continuing.

Hormonal changes are useful to consider in clinical assessment in the medically ill geriatric population. For example, even subtle thyroid abnormalities can play a role in mimicking or worsening psychiatric syndromes. Another area of interest and continuing investigation relates to changes in sex hormone levels which can be deranged with illness and evolve substantially with age. There is suggestive evidence that sex hormone dynamics can have effects on both general well-being and the presentation of depression and related symptoms.

Chronic Pain and Musculoskeletal Disorders

In older patients, the prevalence of chronic pain ranges between 36 and 80 percent, depending on the setting. Patients suffering from pain often restrict activity to prevent further deterioration and to avoid exacerbation of pain, which leads to deconditioning, isolation, and worsening disability. Over half of older adults with depressive disorders have chronic pain, with depression more likely to be present in patients with multisite pain and higher pain intensity and frequency. Older patients who have both chronic pain and depression are more likely to experience insomnia and suicidal ideation; they have a higher level of impairment and poorer quality of life.

The causes of chronic pain in older adults include musculoskeletal disorders, neuropathies, and pain related to cancer, with musculoskeletal disorders being the predominant cause. These include fractures, osteoarthritis, rheumatoid arthritis, microcrystal disorders, myositis, vasculitis, and other arthropathies. Aging musculoskeletal tissues are less resilient due to the loss of ligament elasticity, redistribution of fat, osteoporosis, and subsequent decrease of bone strength. *Sarcopenia,* the loss of skeletal muscle mass, is a nearly universal aging phenomenon, contributing to disability and functional loss in older patients. The elderly are also at higher risk for infections that may affect the joints due to the comorbid predisposing disorders (peripheral vascular disease, diabetes mellitus), immunosuppression, and surgical interventions that are prevalent in this population. Falls are both a risk factor for incurring injuries that may result in chronic pain and a consequence of chronic pain.

Sixty to 70 percent of all joint disease in the elderly is osteoarthritis, often comorbid with regional pain syndromes. A common complaint in ambulatory patients over the age of 75 is chronic low back pain, while knee osteoarthritis remains the most common cause of disability in older persons. Rheumatoid arthritis is to blame for 10 percent of all joint pain complaints, with patients who are taking biological disease-modifying

drugs being at highest risk for depression, suicidal ideation, and poor quality of life. The number of older adults with arthritis or joint symptoms is projected to be around 41.1 million by the year 2030.

Chronic pain is undertreated in older adults for several reasons, among them poor access to care, patients' concern about the meaning of pain and cost of its diagnosis and treatment, and the patients' and providers' belief that pain is concomitant with aging, although there's evidence that a significant portion of older patients with chronic pain hope that physicians will pay more attention to their pain complaints. Physicians may fail to assess the patients' pain, or believe in it when it is reported. There's also a persistent fear that prescribing opioid medications, often necessary for control of pain when it doesn't respond to other agents, will result in addiction. A recent survey of hospitalized geriatric patients found prevalence of pain around 67.3 percent but only 49 percent of these cases were treated; 75 percent of patients felt their pain medication was of low or no efficacy. Patients with cognitive impairment, particularly those with severe dementia and inability to communicate, are at risk for undertreatment of pain, due to failure to identify pain and use appropriate tools for measuring pain.

Treatment of chronic pain in older adults is a complex undertaking, requiring multidisciplinary approach. A comprehensive assessment should include a thorough history of pain, past medical history, history of substance abuse, physical and mental status examination, thorough review of medications, and examination of how pain affects the patient's quality of life and function. Self-report of pain is the gold standard for evaluation of pain in any patient, although this may be challenging in cognitively impaired, noncommunicative patients.

Pharmacological treatment should be individualized for each patient; options for treatment of pain exist but each one has its pros and cons. While opioids are an effective way to treat noncancer and possibly neuropathic pain, their duration of action in older adults is prolonged, and long-acting medications may be of particular concern. The consensus statement by the expert panel from the International Forum on Pain Medicine recommends that doses of opioids should be lower, and a longer time interval should be used between doses. Further, consideration of any concomitant medications affecting respiratory function and pulmonary conditions should occur, so as to avoid problems with hypoventilation and respiratory depression. The use of opioids in patients with history of substance abuse should be carefully monitored. Further, it should be remembered that opioids may cause depression, the risk of which increases with the duration of exposure to opioids. TCAs, gabapentin, and pregabalin can manage neuropathic pain, but they are sedating. TCAs are also anticholinergic with risks of cognitive impairment, urinary retention, constipation, visual changes, and cardiac conduction disorders, among

others. Some NSAIDs may cause gastrointestinal bleeding and discomfort.

Nonpharmacological treatments should be utilized whenever possible: these include biofeedback, physical therapy, chiropractic, acupuncture, aquatic therapy, weight control, corticosteroid joint injections, and surgery if indicated. Psychoeducation, psychotherapy (particularly, CBT and/or mindfulness) and psychiatric medications such as antidepressants should be recommended if depression and/or anxiety symptoms are comorbid with pain. Due to increasing interest regarding assessment and treatment of pain in older patients, recent years have seen publications of excellent guidelines. The authors recommend "*Guidance on the Management of Pain in Older People*" published in *Age and Ageing* 2013;42:i1–i57, by the British Geriatrics Society.

A high index of suspicion regarding the presence of untreated pain should be applied when working with patients with dementia. A change in their behavior, including aggression and agitation, could be related to pain. Other pain manifestations may include changes in facial expression, verbalizations, body movements, as well as onset of crying, irritability, and increased confusion. Using scales developed specifically for evaluation of pain in patients with cognitive impairment will improve outcomes. An example of such a scale is the Pain Assessment in Advanced Dementia (PAINAD), applicable in long-term care and acute geriatric care settings. Investigation of possible causes of pain should be undertaken with assistance of collateral information, full medical history, and physical examination. Finally, a trial of an analgesic resulting in improvement in behavior may confirm the diagnosis of pain.

An 81-year-old man with previously diagnosed dementia related to Alzheimer disease sustained a fall resulting in a right elbow fracture. After the orthopedic surgery, he had a difficult postoperative course complicated by severe confusion and disrupted sleep–wake cycle. A geriatrician who examined the patient found a confused, thin, elderly man with a marked level of rigidity and cogwheeling in the left arm (right arm could not be examined due to pain). He was disoriented and his level of consciousness fluctuated markedly during the interview. He had difficulty focusing on the content of questions, and was unable to state the reason why he was in the hospital. The patient's son reported that his father's memory and executive functioning have been declining for over 4 years, and the course of this disease was marked by visual hallucinations, usually of animals like cats, which were distressing for the patient and for his family. Rigidity and falls became a problem 2 years after the onset of cognitive impairment. After the surgery, the patient was described as markedly below his recent cognitive baseline. The geriatrician diagnosed the patient with delirium, related to the recent surgery and the number of sedating medications on board, including morphine, fentanyl, zolpidem, and lorazepam. Discontinuation of the above medications and initiation of scheduled acetaminophen and tramadol for pain led to significant improvement in the patient's mental status and eventual discharge from the hospital to a rehabilitation facility. The geriatrician subsequently reexamined the patient and diagnosed him with dementia with Lewy bodies rather than Alzheimer disease, recommending avoidance of long-acting opioids and sedating medications, as well as initiation of rivastigmine patch to address cognitive impairment. The patient also worked with a physical therapist to improve balance and coordination, and prevent falls.

SPECIAL ISSUES IN THE CARE OF ELDERLY PATIENTS

Impaired Vision and Hearing

The importance of sensory impairments in patients who develop psychiatric disorders in later life justifies special attention to these issues during evaluation and treatment. Degenerative diseases of the eye and ear impair responsiveness to the interpersonal and social environment, increase feelings of vulnerability among older persons, and cause hallucinations in the affected sensory modality in some individuals. For example, visual hallucinations in the absence of psychiatric disease (Charles Bonnet syndrome) occur in 10 to 50 percent of patients with low vision, a potentially distressing experience. In addition, deafness originating in childhood disease but exacerbated by presbycusis appears to be a risk factor for late-onset paranoid illness, and hearing and visual loss both contribute to the onset and persistence of depression. Patients with hearing loss are at higher risk for accelerated cognitive decline. Cognitive impairment is also frequently present in patients affected by glaucoma, which may jeopardize their adherence to treatment and cause otherwise preventable vision loss. Treatment of eye disease, improvement in corrective lenses, appropriate prescription of hearing aids, and attention to environmental lighting and sound may enhance the efficacy of specific interventions for psychiatric disorder in sensory-impaired patients.

Falling

Falling and fall-related injuries occur in 30 percent of older adults living in the community and in more than 50 percent of those living in nursing homes each year. According to the recent data from Centers for Disease Control and Prevention, the number of deaths related to falls among older adults increased by 7,000 from 2005 to 2013. Complications of falling include hip fractures (25 per 1,000 women over age 85), other fractures, lingering painful soft tissue injuries, and head injuries with behavioral complications. Such injuries are widely feared by the old as harbingers of death. Risk factors for falling include conditions that cause postural instability, general muscular deconditioning, painful or deforming food conditions, visual, auditory, vestibular, proprioceptive, and central neurological impairments, decrease in cognition and speed of processing information, depressive symptoms, environmental hazards, inadequate ambulatory supports, and all classes of psychotropic medications. In hospitalized patients, the presence of mental status deficits is one of the strongest risk factors for falls. Overall, the use of medications with sedative effects is the single most powerful predictor of falling in the elderly, all other things being equal. These include drugs used for the management of insomnia, anxiety, depression, and agitation (prescribed and over the counter), alcohol, and drugs used in the treatment of medical diseases that

sedate by themselves or enhance the sedative effects of other drugs. The presence of multiple risk factors geometrically increases hazard.

Psychiatric complications of falls include acute cognitive disturbance due to head injury, and a common but rarely recognized phobic anxiety state (fear of further falls, which leads to limiting participation in activities of daily living, further deconditioning and curtailment of opportunities for social exchange, and sometimes permanent retirement to a wheelchair). Persistent fall phobias may become less common with aggressive rehabilitation after hip fracture and dissemination of exercise programs for frail elders.

Urinary Incontinence and Urinary Tract Infections

Urinary incontinence affects up to one-third of older adults living in the community and can cause significant suffering and functional impairment, usually worsening as the problem becomes more severe. Notably, urgency urinary incontinence causes a higher degree of disability than stress urinary incontinence. Patients may not mention urinary incontinence to their physician unless specifically asked and may suffer silently, limiting their trips away from home and their opportunities for social activities. There are a number of causes for urinary incontinence, including urinary tract infections, altered mental status, restricted mobility, medications such as diuretics, or more chronic anatomical changes. Urinary tract infections are one of the most common infectious diseases in this age group, and are significantly associated with multiinfarct dementia in very old women. Patients with acute or untreated chronic urinary symptoms should be referred to their primary care physician or to a gynecologist or urologist for a thorough work-up.

Frailty

Frailty is a clinical syndrome comprised of several physical symptoms, including weight loss, exhaustion, poor hand-grip strength, slow walking speed, and physical inactivity, according to the definition most commonly accepted in the literature, by Fried et al. Other commonly encountered symptoms of frailty include weakness, inactivity, balance and gait abnormalities, and decreased food intake. Frailty is generally thought of as an age-related state of vulnerability related to reduced reserve and capacity of the organism to withstand stress and maintain homeostasis, a syndrome characterized by the decline of multiple physiological systems. A number of medical problems can lead to frailty, including chronic infections and inflammatory conditions, cancer, congestive heart failure (CHF), and thyroid abnormalities. Some common psychiatric problems may also manifest as frailty, among them depression, psychosis, grief, and dementia. Frailty is associated with, and predictive of, physical disability, falls,

hospitalizations, and increased mortality. The prevalence of this syndrome in the elderly is between 14 and 24 percent, depending on the definition of frailty, and is generally higher among women and African Americans.

Recent data indicate that cognitive function is significantly poorer in patients who are frail; moreover, a higher level of physical frailty is associated with a faster rate of global cognitive decline. Impaired cognition and frailty may be independent syndromes, but they often overlap and share common risk factors. Those include hormonal changes, nutrition, cardiovascular risks, and mental health and, most importantly, increasing age. The systemic changes related to chronic inflammatory conditions, poor nutrition, and declining function of endocrine and immune systems affect neurons in the hippocampi and microglia, placing the brain at risk for cognitive impairment, delirium, and dementia.

An association of significance also exists between depression and frailty. A recent study of men older than 75 years of age found that those with current symptoms of major depressive disorder had a fourfold increase in mortality, mostly due to comorbidity with frailty. Another cross-sectional study of elderly men found that those with frailty were much more likely to also suffer from anxiety and depression. Among hospitalized patients, frailty is often comorbid with delirium, conferring a poorer prognosis and decreased survival than either condition alone.

The best approach to treatment of frailty and associated mental health conditions starts with a comprehensive geriatric assessment, whether conducted during an acute admission or on outpatient basis. Encouraging studies of using exercise to improve endurance and increase strength and balance in frail patients have been conducted, but there is little known at this time on the potential value of nutritional changes or pharmacological agents. Interventions of most benefit are likely to be multidisciplinary and multidimensional, addressing the whole person rather than a single disease or organ system at a time, and paying attention to the mental health problems of an aging, frail patient.

Overreliance on Drugs for Managing Mental Disorders

Psychiatrists and other physicians tend to underutilize psychotherapeutic techniques in the care of sick or frail older patients. Judiciously prescribed medications are likely to remain the mainstay of treatment with these patients. However, care of psychiatric illness can be greatly enhanced by a psychotherapeutic orientation, and there's evidence to suggest that older adults prefer counseling and psychotherapy to pharmacotherapy. While access to formal office-based individual psychotherapy is often a limited resource, there is accumulating evidence that brief therapeutic interventions, delivered in the primary care setting, can provide considerable benefit and are easier to access for these patients. As mental health care becomes more available in an integrated care setting,

psychotherapeutic interventions may prove highly efficacious as a complement to, and at times an alternative to, long-term medication use. For example, a recent review examining prevention of major depressive disorder among older adults with subsyndromal depression found psychotherapy to be a safe and cost-effective method to reduce the burden of the disease on the patients and to the society. Psychotherapy could potentially be of benefit in reducing the risks of adverse effects from medication overuse and polypharmacy as well. Brief structured psychotherapies can be delivered individually, with key family members, or in groups in both specialty mental health and primary care settings. More broadly, the psychiatrist's use of psychotherapeutic techniques from diverse orientations can include the capacity to develop emotional connections with patients and empathic integration of the needs of the patients, their families, and professional caregivers into a comprehensive and workable treatment plan. In this way, elements of psychotherapy can make substantial contributions both to medical management and to patients' comfort and capacity to persevere in the face of demoralization from serious and ongoing illness.

A HEALTH-SYSTEMS APPROACH TO THE CARE OF THE MEDICALLY ILL GERIATRIC PATIENT

Older adults are less likely than younger patients to seek and receive specialty mental health services and, when referred by their primary care providers, are less likely than younger patients to follow through on such referrals. Older adults, their family members, and their physicians often attribute enduring but treatable psychiatric symptoms to "normal aging," stressful life events, grief, social isolation, losses, financial difficulties, care-taking responsibilities, dementia, or medical illness, resulting in hopelessness and therapeutic nihilism in patients and providers. Older adults may also fear stigmatization associated with mental disorders or psychiatric treatments. As a result, the majority of this subset of population receives care for mental and emotional problems exclusively in the general medical sector, and many who could benefit from treatment of psychiatric disorders do not receive it. It is worth noting that Caucasian men over the age of 85 are at highest risk for suicide in the United States, primarily due to their use of firearms during suicide attempts, and that many older adults visit primary care providers in the weeks leading up to the suicide attempt. Primary care visits should be an opportunity to intervene; however, there is evidence that depression in older adults is often unrecognized in this setting, which is particularly problematic for men and members of ethnic minority groups. Recent data indicate that accuracy of diagnosis of depression in primary care usually improves with repeated visits, and it is recommended that those patients suspected to have depression should be reassessed rather than have one-off visits; use of rating scales can also aid

the diagnosis.

Even if depression is diagnosed, only a minority of patients receive successful treatment despite robust evidence for the efficacy of treatments such as antidepressant medications and psychotherapy in old age. In recent years, the rate of antidepressant prescribing in primary care has increased substantially, but many depressed older adults are started on an antidepressant with little follow-up. As a result, many stop taking medication prematurely, stay on inadequate doses for too long, or do not change medication or receive psychotherapy if an initial trial of an antidepressant fails.

Despite most practice guidelines recommending that primary care providers should play a central role in the detection of cognitive impairment and dementia, there is a concerning lack of diagnosis of dementia in this setting, with rates of underdiagnosis ranging between 50 and 80 percent. Thus, patients with declining cognitive ability, usually in great need of treatment and advice on planning for the future, are not able to take advantage of interventions available to them. The lack of diagnosis is partly due to lack of recommendations for systematic screening of all at-risk patients, and partly due to lack of comfort on the part of primary care physicians when it comes to mental health in geriatric patients, since their training does not emphasize geriatrics or mental health. Further, when dementia is diagnosed, the diagnosis is often undisclosed to patients and their caregivers, and treatment is not offered—largely due to providers' lack of confidence and comfort with the pharmacological options available.

Older adults may have difficulty accessing specialty mental health care, especially when it is provided only in off-site specialty clinics. This problem is only compounded by the dearth of geriatric psychiatrists: by the year 2030, there will be only one such specialist per 20,195 older Americans. Some improvements in access have been made in the recent years, such as the Medicare Improvement for Patients and Providers Act of 2008 reducing the copayment for outpatient mental health services to 20 percent, down from 50 percent, but barriers in private insurance plans regarding psychiatric medications and mental health services such as psychotherapy still exist.

Efforts to improve care of common mental disorders in primary care have included training of primary care providers, development of treatment guidelines for depression or dementia, and the incorporation of routine screening into primary care practice as recommended for depression by the National Preventive Services Task Force. Attention must be paid to medical education—encouraging physicians to specialize in geriatric medicine and psychiatry, making an effort to promote geriatric education in medical schools and residencies, even changing the structure of medical textbooks that are often organized in chapters covering a single disease entity, rather than teaching management of patients with

multimorbidity. Clinical guidelines should be redesigned to address multimorbidity. All these measures are necessary, but they should be accompanied by promoting effective models of care.

The present overarching organization of primary care is designed for short visits meant to take care of one problem at a time—and geriatric patients with mental health problems such as depression or dementia, especially those with several comorbid medical conditions or frailty, fall so far outside of such a simplistic paradigm that there is no schema in which to tackle their complex presentations. Collaborative models of care have been demonstrated to substantially improve clinical outcomes. In these approaches, mental health specialists collaborate with primary care providers to manage individuals with comorbid medical and mental disorders within the primary care setting. Such interventions have included systematic case finding using simple screening instruments such as the Patient Health Questionnaire-9 (PHQ-9), patient and family education and activation, clinician education and support, systematic assessment and treatment matching, proactive outcomes tracking, and integration of primary care and specialty mental health services. These models may use a geriatric psychiatry care manager with special expertise in the recognition and treatment of common mental disorders or a mental health specialist such as a psychologist or psychiatrist working with a primary care clinic to provide consultation and treatment on site. On-site services can reduce barriers to access and communication between primary and specialty providers, maintain the comfort of patients accustomed to receiving their care in a single setting, and result in better care for both medical and psychiatric problems. In a similar fashion, geriatric psychiatrists have also developed successful models for integrated care provided on site in nursing homes. Psychiatrists and other mental health specialists working in these general medical settings can also help refer patients to further specialty mental health care as needed or link them to helpful community services.

This kind of collaborative care may be especially important for older adults with multimorbidity, management of which requires close attention to both medical and mental disorders. This most common chronic medical condition requires a comprehensive treatment approach that addresses all problems and syndromes present in one elder patient seamlessly, accounting for interactions between treatments and conditions and patient's own preferences. The National Quality Forum, in its publication of *Multiple Chronic Conditions Measurement Framework*, proposed focusing on patient-centered quality measures such as optimizing function, ascertaining patient-important outcomes, and avoiding inappropriate care. Centers for Medicare & Medicaid Services and private health insurance plans should redesign payment from focusing on specific diseases and procedures to value-based quality services promising relief for individuals with multiple medical and mental health problems. In this regard,

accountable care organizations (ACOs) and patient-centered medical homes (PCMHs) hold particular promise. Through their emphasis on high-quality primary care, ACOs and PCMHs may help transform the failing health care system.

The PCMH is a model or health care delivery of a "medical home" where a primary care provider will design and coordinate comprehensive, evidence-based, cost-effective care for the patient. All aspects of care, including end-of-life care and mental health care, are coordinated and provided through the PCMH. An essential component of success of the PCMH is a trusting relationship between the primary care provider and the patient. While this is a new and emerging model of health care, emerging data encourages optimism—we can expect that the PCMH will increase patient satisfaction and decrease health care costs. Following the paradigm of providing quality coordinated care, the last few years have seen emergence of the ACO, defined by the Centers for Medicare and Medicaid Services as "an organization of health care providers that agrees to be accountable for the quality, cost, and overall care of Medicare beneficiaries enrolled in the traditional fee-for-service program who are assigned to it." Similar to the PCMH, the ACO has a strong basis in primary care. The ACO is also driven by intertwining the quality and cost of care, and by magnifying outcome improvements. As new PCMHs and ACOs continue to emerge, and already existing organizations continue to improve, it should be remembered that providing care for a whole patient, geriatric or not, means attending to their psychosocial concerns including mental health, substance abuse, living and family situation, and caregivers if applicable (for patients with physical and mental disabilities, dementia, etc.). Financial incentives that reward addressing behavioral health care on par with medical problems, and reward for improved outcomes rather than fee-for-service approaches, must be implemented.

57.3c Sleep–Wake Disorders in Older Adults

JEANNE E. MAGLIONE, M.D., PH.D., JANA R. COOKE, M.D., AND SONIA ANCOLI-ISRAEL, PH.D.

INTRODUCTION

Up to half of older adults report chronic difficulties with their sleep. A number of changes occur in sleep architecture and sleep patterns with normal aging. However, problems with sleep are not an inevitable part of aging and are associated with significant morbidity. Sleep disturbances in older adults are generally related to specific sleep disorders, comorbid conditions, or both.

SLEEP AND AGING

Older adults report a number of subjective sleep complaints including difficulty falling asleep, waking up often during the night, waking up too early in the morning, and needing to nap during the daytime or evening. Studies using polysomnography (PSG) to objectively measure sleep have confirmed that older people spend more time in bed, have more awakenings at night (decreased sleep efficiency), and take longer to fall asleep compared with their younger counterparts. The proportion of time spent in the lighter stages of sleep (stages 1 and 2) is greater and the amount of slow-wave (deep) and rapid eye movement (REM) sleep are decreased in older adults compared to young adults. Almost all of the above changes in sleep architecture occur between early and middle adulthood. A meta-analysis that included 65 studies and 3,577 subjects ranging from 5 to 102 years in age suggested that sleep efficiency (the percentage of time in bed spent sleeping) alone continues to decrease after the age of 60 years, whereas the other sleep parameters remain relatively stable. Older adults are, on average, sleepier than their younger counterparts during the daytime when tested objectively, suggesting that they are less likely to obtain an adequate amount of restorative sleep at night.

CONSEQUENCES OF POOR SLEEP IN OLDER ADULTS

Insufficient sleep is associated with significant morbidity and increased mortality. Patients with difficulty sleeping report decreased physical health status, mental well-being, and quality of life compared to those without sleep difficulties. In older adults, subjectively and objectively assessed sleep problems are associated with an increased risk of falls, along with ambulation balance, and visual difficulties—even after controlling for medication use. Chronic sleep difficulties at any age can lead to deficits in attention, response times, short-term memory, and performance level. In older adults subjective reports of too little sleep (less than 4.5 hours per night), objectively measured difficulty falling asleep, and fragmented sleep

have all been associated with poor cognition. Accordingly, poor sleep is also associated with increased risk for long-term care placement. Subjective sleep difficulties and objectively measured sleep disturbances are also associated with increased mortality. In a longitudinal study of 185 healthy older adults, lower sleep efficiency (less than 80 percent) increased the risk of all-cause mortality almost twofold. In another large prospective study, women over the age of 69 who reported sleeping 9 to 10 hours in a 24-hour period (including napping) were almost 60 percent more likely to die from cardiovascular or other noncancer causes compared to women who slept between 7 and 8 hours.

SLEEP–WAKE DISORDERS IN OLDER ADULTS

Contributors to sleep disturbances in older adults can include comorbid medical or psychiatric illnesses, medications, circadian rhythm disturbances, or certain specific sleep–wake disorders.

Comorbid Medical and Psychiatric Illnesses

Complaints of sleep difficulties are strongly correlated with complaints about health and depression. In the 2003 National Sleep Foundation survey of adults aged 65 years and older, those with more medical conditions reported significantly more sleep complaints. As the number of medical conditions increased, the likelihood of having sleep difficulties increased. Studies of the prevalence of sleep disturbances in patients with chronic medical diseases have reported that patients with arthritis and chronic pain have difficulty falling asleep and staying asleep. Shortness of breath (due to chronic obstructive pulmonary disease or congestive heart failure), nocturia (due to benign prostatic hypertrophy), and neurological deficits (related to residual stroke deficits or Parkinson disease) are all associated with complaints of insomnia.

Psychiatric disorders including mood disorders and anxiety are also commonly comorbid with insomnia. In a large cross-sectional survey, insomnia was present in 65 percent of respondents with major depression, 61 percent of those with panic disorder, and 44 percent of those with generalized anxiety disorder. Older adults are more likely to experience some major life stressors such as the death of a spouse, medical illness and injury, disability and functional decline, and lack of social contact, all of which can increase their risk for developing depression and anxiety.

Medications

Medications used to treat chronic medical and psychiatric conditions can contribute to or even cause sleep disruptions. It is particularly important to consider the effects of medications in older adults who are often taking multiple prescription and over-the-counter medications. A number of

medications are known to disturb sleep, including β-blockers, bronchodilators, corticosteroids, decongestants, and diuretics, as well as other cardiovascular, neurological, psychiatric, and gastrointestinal medications. Clinicians should advise patients to take sedating medications prior to bedtime and stimulating medications and diuretics earlier in the day to avoid further disruptions in sleep.

Insomnia Disorder

The DSM-5 defines insomnia as a disorder with "a predominant complaint of dissatisfaction with sleep quantity or quality," associated with at least one of the following: difficulty initiating sleep, maintaining sleep, and/or early-morning wakening. The symptoms must cause significant distress or impairment in functioning and must occur at least 3 nights per week for at least 3 months. All possible etiologies (e.g., primary sleep disorders, comorbid medical or psychiatric conditions) must be considered before making this diagnosis.

Treatment of Insomnia. Research has found that behavioral therapy may, in many cases, be more effective than medications for insomnia. In older adults who are at greater risk for serious adverse events related to pharmacotherapy for insomnia and who are often at greater risk for polypharmacy, nonpharmacological approaches should be the first treatment options considered.

BEHAVIORAL TREATMENTS. Cognitive-behavioral therapy (CBT) for insomnia has been shown to have excellent short- and long-term efficacy in both younger and older adults. This approach combines stimulus control and/or sleep restriction with cognitive restructuring, good sleep hygiene (a set of guidelines for healthy sleep–wake habits), and relaxation. A program of CBT typically consists of 6 to 10 weekly sessions administered by a specially trained clinician. Stimulus control is based on the belief that insomnia may be the result of maladaptive classical conditioning. Patients are instructed to eliminate all in-bed activities (i.e., reading, watching television) other than sleep. If they are unable to fall asleep within about 20 minutes, they are told to get out of bed and to do something relaxing outside of the bedroom such as sit quietly reading or listening to music. Once they feel sleepy, they are told to return to bed and attempt to fall asleep. If they are again unable to fall asleep within about 20 minutes, the pattern of getting out of bed until feeling sleepy repeats itself. The goal is to break the connection between the bed and wakefulness. Sleep restriction limits the time spent in bed beyond the amount spent asleep at night. Patients are allowed to be in bed for the amount of time they believe they typically sleep plus 15 minutes. As sleep efficiency increases, the amount of time allowed in bed increases in 15-minute intervals. Cognitive restructuring involves

changing unrealistic beliefs or irrational fears about sleep and/or the loss of sleep. Finally, patients are also educated about ways to modify sleep hygiene practices that may be interfering with their sleep (Table 57.3c–1).

In some settings, the use of CBT for insomnia has been limited by a shortage of clinicians trained to administer the therapy. This obstacle, combined with the burden to patients associated with the required 6 to 10 session therapy course has inspired the development of brief behavioral interventions for insomnia. For example, brief behavioral therapy for insomnia (BBTI) was designed to be administered by nurses within the primary care setting. The treatment is administered over four sessions, three of which last 30 minutes or less and two of which occur by phone. BBTI has an exclusively behavioral focus; the core components being stimulus control and sleep restriction. Several randomized trials have shown BBTI to be effective in older adults.

PHARMACOLOGICAL TREATMENTS. In some cases it may be appropriate to use medications to treat insomnia (Table 57.3c–2). In general, the most effective way to include medications in a treatment plan is in combination with a nonpharmacological intervention so that the medication provides short-term relief while patients undergo CBT or brief behavioral interventions, which are associated with lasting benefit.

Although benzodiazepines are commonly prescribed for insomnia in older adults, there are significant risks associated with this class of medications, particularly in older adults, including an increased risk of falls, cognitive impairment, and driving accidents. In 2012, after reviewing all available data, the American Geriatrics Society updated the Beers Criteria for potentially inappropriate medication use in older adults to include a strong recommendation based on high-quality evidence to avoid benzodiazepine use in older adults. As such, this class of medications should no longer be considered a first-line treatment for insomnia in older adults.

Table 57.3c–1.
Sleep Hygiene Rules

1. Do not spend too much time in bed
2. Maintain a consistent sleep–wake time
3. Get out of bed if unable to fall asleep
4. Restrict naps to 30 minutes in the late morning or early afternoon
5. Exercise regularly
6. Spend time outside each day
7. Eat a light snack (i.e., milk, bread) before bed
8. Avoid caffeine, tobacco, and alcohol after lunch
9. Limit liquids in the evening

Table 57.3c–2.
U.S. Food and Drug Administration–Approved Nonbenzodiazepines for Insomnia

Name	Indication	Time in Bed Required (hours)	[a]Medication Appears in Beers Criteria Recommendations
Zaleplon	Sleep initiation	4	Yes
Zolpidem	Sleep initiation	7–8	Yes
Zolpidem MR	Sleep initiation/sleep maintenance	7–8	Yes
Eszopiclone	Sleep initiation/sleep maintenance	8+	Yes
Ramelteon	Sleep initiation	—	
Low-dose doxepin	Sleep maintenance	—	Yes
Suvorexant	Initiates sleep/maintains sleep	7–8	n/a

[a]See text for specific Beers Criteria cautions regarding potentially inappropriate use of sleep medications in older adults.

The more selective short-acting nonbenzodiazepines (type 1 γ-aminobutyric acid [GABA] benzodiazepine receptor agonists), including eszopiclone, zaleplon, and zolpidem, have been shown to be effective in the short-term management of insomnia in the older adults. Despite an improved side-effect profile, safety concerns remain including increased risk for falls, cognitive symptoms, and complex sleep-related behaviors. The 2012 Beers Criteria strongly recommends avoiding use of these medications in patients who are at risk for falls, delirium, or for patients with neurocognitive disorders and recommends against chronic use in older adults.

A handful of industry-sponsored studies suggest that low doses of the tricyclic antidepressant doxepin (≤6 mg/day) may be effective and safe for promotion of sleep maintenance in older adults. The 2012 Beers Criteria strongly recommends avoiding use of doses >6 mg/day in older adults due to concerns about its significant anti-cholinergic properties, sedating properties, and tendency to induce orthostatic hypotention. A strong recommendation to avoid use of doxepin at any dose in older adults who are at risk for delirium, or who have neurocognitive disorders was also included. Tertiary TCAs can also worsen urinary retention and constipation, common problems in older adults.

Ramelteon, a melatonin receptor agonist is another consideration. A few studies suggest Ramelteon may be safe and effective in older adults, but more research is required in this area. Industry-sponsored phase 2 and 3 clinical trials thus far suggest that the newest FDA-approved sleep medication, suvorexant, an orexin receptor antagonist, may also be safe

and effective in older adults with insomnia though experience with this medication is, at this point, limited.

Although it is still not uncommon to see other classes of medications (e.g., antihistamines, antidepressants, antipsychotics, anticonvulsants) prescribed for insomnia, there is no systematic evidence to support this practice and, in fact, the risks likely outweigh the benefits in older adults.

Circadian Rhythm Sleep–Wake Disorders

In humans, the sleep–wake cycle is controlled by an endogenous clock operating over an approximate 24-hour period called the circadian rhythm. This rhythm is synchronized by external time cues ("zeitgebers") such as the light–dark cycle, which serves as the major external time cue in humans. Circadian rhythm sleep–wake disorders (CRSDs) may develop if dyssynchrony between the endogenous clock and external environmental zeitgebers occurs.

A number of factors associated with aging can contribute to the development of CRSDs. The circadian pacemaker, located in the suprachiasmatic nucleus, is known to degenerate with age, which may result in weaker, more disordered rhythms. The nocturnal secretion of endogenous melatonin, known to play an important role in the sleep–wake cycle, gradually decreases with age, which may result in disrupted circadian rhythms. In addition, the environmental cues needed to synchronize the circadian rhythm of the sleep–wake cycle may be absent or weak in older patients. For example, one study showed that daily bright light exposure averages about 60 minutes for healthy older adults, 30 minutes for patients with Alzheimer disease living at home, and 0 minutes for nursing home patients. Studies of sleep in institutionalized patients have found that this low level of light exposure is associated with sleep fragmentation and CRSDs. Gradual decreases in the amplitude of the circadian rhythm is also associated with aging and may lead to an increase in the frequency of nighttime awakenings and the severity of daytime sleepiness.

The most common CRSD experienced by older adults is advanced sleep phase syndrome (ASPS), which is characterized by habitual (and involuntary) sleep and wake times that are several hours earlier than societal norms. Individuals with ASPS will typically get sleepy in the early evening, timed with the drop in body temperature, and wake up in the early morning (Fig. 57.3c–1). Although sleep itself is normal, delays in sleep onset due to obligations or societal customs may result in insufficient sleep time (as these individuals experience an early-morning awakening regardless of what time they went to bed) and excessive sleepiness during the day. The prevalence of ASPS is about 1 percent in middle-aged and older adults, increasing with age. Men and women are affected equally. A careful and detailed sleep history, sleep diaries, and activity monitoring with wrist actigraphy can all be useful in making the diagnosis.

Treatment of Advanced Sleep Phase Syndrome. For older adults with ASPS, it can be sufficient treatment for them to adopt an earlier bedtime which would then allow for a sufficient amount of total sleep. For many patients, however, this may not be desirable as it may interfere with lifestyle or quality of life. Treatment of CRSDs focuses on strengthening and synchronizing the sleep–wake cycle. Bright light is the strongest cue for circadian entrainment and is therefore the most common and the most effective treatment for circadian rhythm shifts. For older patients with ASPS, including those who reside in nursing homes, evening light exposure has been shown to strengthen the sleep–wake cycle and to delay circadian rhythms. Patients with ASPS should be advised to avoid bright light during the morning and educated on sleep hygiene practices, including adherence to a regular sleep schedule. Early-evening artificial bright light via a bright light box has also been shown to improve sleep continuity in both healthy and institutionalized older patients.

Melatonin supplements given in the evening, could, in theory, result in a phase advance in older adults causing or worsening ASPS, although this has not been studied. Given its popularity as a "natural" treatment for insomnia, clinicians should review the medication list carefully and consider discontinuation of evening melatonin in patients being treated for ASPS. There is currently no evidence base to support prescribing morning melatonin therapy to delay sleep phase in ASPS. Given its sedating properties, clinicians should use care when considering a trial of melatonin therapy in this population.

Obstructive Sleep Apnea Hypopnea

Obstructive sleep apnea-hypopnea syndrome (OSA) describes a spectrum of intermittent respiratory events occurring during sleep, ranging from primary snoring, to increased respiratory effort without an increase in airflow which results in arousal from sleep (flow-limitation events, typically called upper airway resistance), to substantial decreases in airflow (hypopneas), to complete cessation of airflow (apneas), or some combination of these events.

The prevalence of OSA increases or stabilizes with age, as has been shown in most longitudinal and cross-sectional studies. In a large series of randomly selected community-dwelling elderly 65 to 95 years of age, researchers reported that 81 percent of the study subjects had an apnea-hypopnea index (AHI) of 5 or greater, with prevalence rates of 62 percent for an AHI of 10 or greater, 44 percent for an AHI of 20 or greater, and 24 percent for an AHI of 40 or greater. In a longitudinal study, the prevalence only changed with associated changes in body mass index. The Sleep Heart Health Study reported prevalence rates of OSA by 10-year age groups, finding increasing rates with increasing age for subjects with an AHI of 15 or greater.

FIGURE 57.3c–1. Standard phase of sleep versus advanced phase of sleep. (From Ancoli-Israel S. *All I Want is a Good Night's Sleep*. St. Louis, MO: Mosby; 1996.)

Institutionalized elderly patients appear to have higher rates of OSA than those elderly patients who live independently. Patients with dementias involving degeneration in brainstem areas, responsible for regulating respiration and other autonomic functions relevant to sleep maintenance, may have a higher risk of developing OSA. Institutionalized elderly patients with more severe dementia have been reported to have more severe OSA than those older patients with milder or no dementia. This study also reported that patients with more severe OSA had lower cognition scores during testing, suggesting that more severe OSA was associated with more severe dementia.

Risk factors for OSAs in the older adult are similar to those found in the younger population, including increasing age, gender, and obesity. Recent data suggest that the pathological mechanism of OSAs may differ from that of younger adults with a more collapse upper airway playing a great role in older adults. Other conditions that increase the risk of developing OSAs include the use of sedating medications, alcohol consumption, family history/genetic factors, menopausal status, race, smoking, and craniofacial morphology.

Snoring and excessive daytime sleepiness (EDS) are the predominant symptoms of OSAs in the elderly. Less common presentations include insomnia; particularly sleep maintenance complaints, nocturnal confusion, nocturia, and daytime cognitive impairment such as difficulty with concentration and short-term memory loss. Unintentional dozing and falling asleep at inappropriate times during the day are common manifestations of the EDS in older patients with untreated OSAs. As with younger adults, excessive sleepiness can lead to both social and occupational difficulties as well as cognitive dysfunction, which is of particular relevance in those patients with underlying cognitive impairment at baseline.

The presence of OSAs is associated with significant morbidity, including cardiovascular disease, depression, and cognitive dysfunction. The presence of untreated OSAs has recently been linked to an increased risk of developing dementia. Older patients with severe OSAs (defined as an AHI of 30 or greater) have consistently been found to have impairments in attention, concentration, memory consolidation, immediate and delayed recall, executive tasks, planning and sequential thinking, visuomotor skills, and manual dexterity. Older adults with milder OSAs (AHI 10 to 20/hr) may experience similar deficits.

OSA is an independent risk factor for the development of systemic hypertension; it is one of the only known causes of hypertension. The exact relationship between OSAs and other cardiovascular disease (including myocardial infarction, pulmonary hypertension, stroke, arrhythmias, and congestive heart failure) in the older adult remains unclear, although results from a few recent studies have provided some insight. The Sleep Heart Health Study found a positive association between the severity of OSAs (based on overnight PSG) and the risk of developing cardiovascular disease, including coronary artery disease, congestive heart failure, and stroke. A recent study in acute ischemic stroke patients reported that OSAs was common, particularly in older male patients with diabetes mellitus whose stroke occurred at night.

As with younger adults, clinicians should use a stepwise approach in evaluating elderly patients with suspected OSAs. A complete sleep history focused on symptoms of OSAs, specifically EDS, unintentional napping, snoring, trouble with maintaining sleep, and symptoms of other sleep disorders (e.g., restless legs syndrome [RLS], insomnia), should be obtained, preferably in the presence of a bed partner or caregiver. The patient's medical history should be reviewed, with particular attention paid to OSAs-associated medical conditions, along with medications, the use of alcohol and/or tobacco products, and evidence of cognitive impairment. If these are suggestive of OSAs, an overnight sleep recording should be obtained for diagnostic purposes.

Treatment of Obstructive Sleep Apnea-Hypopnea Syndrome. Continuous positive airway pressure (CPAP) is the gold standard and most effective treatment of OSAs and has been shown to improve cognition functioning cardiovascular disease outcomes and EDS in older adults. CPAP compliance can be an issue for any patient with OSAs, regardless of age, and clinicians should not assume that elderly patients will be noncompliant simply due to age. Studies support the idea that patients with mild and moderate Alzheimer disease can also be compliant with CPAP treatment, the only factor associated with poor CPAP compliance in these studies was the presence of depression—not age, severity of dementia, or severity of OSAs.

Alternative treatments for OSAs include use of an oral appliance and upper airway surgery. An upper airway stimulator ("pacemaker"), that must be surgically implanted, has recently been approved by the FDA for treatment of OSAs. Clinicians should counsel all patients on weight loss, smoking cessation, and abstinence from the consumption of alcohol if indicated. Sedating medications, especially those known to result in respiratory depression, including benzodiazepines, muscle relaxers, narcotics, should generally be avoided in older adults with OSAs because these agents can increase the number and duration of apneas.

Most experts agree that the treatment of OSAs in the elderly should be guided by the patient's symptoms and the severity of the OSAs. If an older adult has comorbid conditions such as hypertension, depression, cognitive dysfunction, or cardiovascular disease or if the OSAs is severe, treatment should be considered. Age alone should not be a determining factor in treatment decisions.

Periodic Limb Movements in Sleep/Restless Legs Syndrome

Periodic limb movements in sleep (PLMS), a disorder characterized by clusters of repetitive leg movements during sleep, is common in older adults. The leg jerks or kicks occur typically every 20 to 40 seconds and may recur several hundred times over the course of the night. Each jerk may cause an arousal or brief awakening, resulting in sleep fragmentation, and therefore patients with PLMS may complain of daytime sleepiness. The etiology of PLMS is unknown, although it can be seen in patients with fibromyalgia and in combination with other sleep disorders, including sleep disordered breathing (SDB) and narcolepsy. The diagnosis of PLMS requires an overnight polysomnogram showing a calculated periodic limb movement index (PLMI; the number of limb movements per hour of sleep) greater than or equal to 5.

The prevalence of PLMS increases dramatically with age, with reported prevalence of up to 45 percent in community-dwelling adults older than the age of 65 years. It is equally prevalent in older men and women. Despite its high prevalence in older adults, the severity of PLMS does not appear to progressively worsen with increasing age.

RLS, a disorder strongly linked to PLMS, is characterized by leg dysesthesia ("a creepy crawling" or "restless" sensation) that occurs while the person is in a relaxed awake state and can only be relieved by movement. Epidemiological studies reveal the prevalence of RLS in older adults ranges from 9 to 20 percent and, like that of PLMS, increases with age. Studies have also found that RLS occurs twice as often in older women than in older men. RLS can be secondary to anemia or end-stage renal disease, and there is a growing body of evidence linking other chronic illnesses with RLS, including rheumatoid arthritis, chronic obstructive pulmonary disease, asthma, fibromyalgia, diabetes, Parkinson disease, and

multiple sclerosis.

Table 57.3c–3.
Four Essential Questions for Restless Legs Syndrome Diagnosis

1. Do you experience the urge to move your legs (or other parts of your body), typically accompanied or caused by an uncomfortable and/or unpleasant sensation in the affected body part?
2. Does the urge to move or the uncomfortable sensation begin and/or worsen during periods of rest or inactivity?
3. Is the urge to move or uncomfortable sensation partially or totally relieved by movement?
4. Is the urge to move or the uncomfortable sensation worse in the evening or at night compared to the daytime, or does it only occur in the evening or at night?

The diagnosis of RLS is a clinical one, based on history alone—PSG has no role in the diagnosis. Table 57.3c–3 lists the four essential questions that clinicians should ask to make the diagnosis of RLS. Questionnaires such as the Cambridge-Hopkins diagnostic questionnaire for RLS (CH-RLSq), and the RLS Diagnostic Index (RLS-DI) can also be helpful. Exclusion of other conditions that may be mistaken for RLS, such as neuropathy, myalgia, lower extremity edema, leg cramps, positional discomfort, arthritis, pruritus, and vascular insufficiency, is critical. In patients with significant cognitive impairment, signs of discomfort in the legs such as rubbing or kneading the legs and increased motor activity, which are present or worse during inactivity and which are lessened by activity, may be observed.

Treatment of Periodic Limb Movements in Sleep and Restless Legs Syndrome. Medications that suppress the leg movements and/or the related arousals are the therapies currently recommended for both RLS and PLMS. Several dopamine agonists (ropinirole, pramipexole, and rotigotine transdermal) and more recently gabapentin enacarbil have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of RLS. Off-label use of carbidopa/levodopa has also been shown to be effective in some studies.

Rapid Eye Movement Sleep Behavior Disorder

REM sleep behavior disorder (RBD) is more common in older adults, with a predilection to affect men (about 90 percent). The prevalence, which increases with age, is reported to be 0.5 percent in the general population and may be as high as 2 percent in those over 60 years of age and 6 percent in those over 70 years of age. Nearly 80 percent of patients with RBD eventually develop neurodegenerative conditions; specifically synucleinopathies, including Parkinson disease, multisystem atrophy, or neurocognitive disorders with Lewy bodies.

RBD is characterized by elaborate and complex motor activities

associated with dreams ("acting-out dreams") due to the intermittent absence of normal skeletal muscle atonia during REM sleep. Patients may punch, kick, yell, or jump/run out of bed, and these actions usually correlate with dream imagery. Vivid dreams consistent with the patient's aggressive and/or violent behavior may be recalled on waking. Sleep behaviors can place the patient and/or bed partner at risk for physical injuries, which occur in 32 to 64 percent of cases.

The diagnosis of RBD requires a thorough sleep history, in the presence of the bed partner if possible, and an overnight polysomnogram with video recording to confirm the relationship between REM sleep and the complex motor behaviors.

Treatment of Rapid Eye Movement Sleep Behavior Disorder. The most important intervention for all patients with RBD is to make appropriate modifications to ensure environmental safety. Patients should remove heavy or potentially injurious objects from the bed's vicinity and consider locking doors and windows at night. Measures can be taken to avoid being injured by falling out of bed, such as the use of bedrails, a low-profile bed, or mattress on the floor. Historically cautious use of clonazepam has been the mainstay of pharmacological treatment for RBD. However, this practice is based on low-level evidence including exclusively retrospective case series reports, and use of clonazepam can be especially problematic in older adults due to significant associated risks (e.g., cognitive impairment, delirium, falls, fracture, and motor vehicle accidents). Studies also suggest that melatonin may be effective and better tolerated in older adults. High-quality prospective clinical trials comparing these two medications for the treatment of RBD in older patients are needed. Maintaining good sleep hygiene and educating the patient and their bed partner are also important aspects of RBD treatment.

SLEEP IN NEUROCOGNITIVE DISORDERS

Recent studies support a potential connection between sleep disturbances, especially obstructive sleep apnea, fragmented sleep, abnormal duration of sleep, and development of cognitive impairment suggesting that the sleep–wake cycle may play an important role in cognitive aging. Patients with neurocognitive disorders, both those living independently and those institutionalized, experience disrupted sleep which may be due, in part, to neurodegeneration in areas of the brain responsible for sleep regulation. It has been reported that 19 to 44 percent of community-dwelling patients with dementia complain of sleep disturbances, and the prevalence is estimated to be even higher in patients with dementia who are institutionalized. Disrupted sleep commonly results in napping, both intentional and unintentional, and can be manifested as abnormal nocturnal behaviors, including wandering and confusion, which are

significant contributors to caregiver stress and the need for patient institutionalization.

Patients with neurocognitive disorders can have primary sleep disorders such as SDB, PLMS, RLS, or RBD or may have disturbed sleep related to pain, medications, circadian rhythm changes, or depression. Therefore, disturbed sleep related to a neurocognitive disorder should be a diagnosis of exclusion.

As with all older adults, treatment of specific sleep disorders in older patients with neurocognitive disorders should be targeted for that specific sleep disorder. Patients with SBD should be treated with CPAP if appropriate, whereas patients with circadian rhythm disturbances should be treated with bright-light therapy. Given the higher risk-to-benefit ratio of many of the pharmacological treatments in this patient population, nonpharmacological interventions such as regular physical activity and restricting time in bed are preferred. Medications, including sedative–hypnotics, antihistamines, and antipsychotics, all have significant side effects such as residual daytime sleepiness (the so-called "hangover effect") and impairment motor and/or cognitive function. Further, the efficacy and safety of sleep medications have not been adequately studied in patients with neurocognitive disorders and so there is little evidence base to support their use.

SLEEP IN NURSING HOMES

Institutionalized older adults experience more fragmented and disturbed sleep than those living in the community. Nursing home patients have poorer sleep quality, more fragmentation of sleep, more advanced sleep–wake cycles, more daytime sleepiness, and are given sedative–hypnotics more frequently than older adults living in the community or in assisted living facilities. During any 24-hour period of time, institutionalized patients with major neurocognitive disorders may not spend a single hour completely awake or completely asleep.

Excessive nighttime noise and inadequate ambient light exposure both significantly contribute to sleep disruption in nursing home patients. In a study of institutionalized patients, most were found to be exposed to less than 10 minutes of bright light per day and patients with more light exposure had fewer sleep disruptions. Finally, nursing home patients may spend large amounts of time in bed, and inactivity is known to disrupt circadian rhythms.

Patients should have a careful sleep evaluation including assessment for the presence of primary sleep and circadian rhythm disorders. Assessment for contributing medications and for medical and psyciatric illnesses should also be performed. Where appropriate, reduction in nighttime light and noise, increases in daytime light exposure, and improvements in sleep hygiene should be implemented. The authors recommend avoiding the use

of sleep medications wherever possible. If medications are employed they should be used sparingly, cautiously, and only short term.

FUTURE DIRECTIONS

For many older adults, aging is associated with significant changes in sleep. There are a variety of potential contributors including medications, comorbid conditions, circadian rhythm disruption, and specific sleep–wake disorders. As with younger adults, the diagnosis requires a thorough sleep history and often an overnight sleep recording. Furthermore, also as with younger patients, treatment should address the primary sleep problem and can result in significant improvement in both quality of life and daytime functioning.

57.3d Anxiety Disorders

CAROLYN I. RODRIGUEZ, M.D., PH.D., AND MURRAY B. STEIN, M.D.

INTRODUCTION

In DSM-5, the chapter on anxiety disorders has been revised to include separation anxiety disorder and selective mutism. No longer included are obsessive-compulsive disorder (OCD) (which is included with the obsessive-compulsive and related disorders) or posttraumatic stress disorder (PTSD) and acute stress disorder (which are included with the trauma- and stressor-related disorders). The term "anxiety disorders" used in this chapter nonetheless is used to refer to the all the DSM-5 diagnoses within anxiety-, trauma- and stressor-related, and obsessive-compulsive and related disorders. When we refer to these disorders in aggregate (i.e., when there are no specific distinctions between them we are highlighting), we will use the term "anxiety disorders" otherwise we will specify the distinctions. The majority of research described in this chapter employed a DSM-IV framework. If applicable, we included recent research findings using the revised DSM-5 nosology.

Recently, there has been an increasing evidence base that anxiety in late life has greater clinical consequences and is more prevalent than previously thought. Although much less is still known about late-life anxiety than about other common late-life psychiatric conditions such as depression or dementia, current studies show that in community samples, anxiety is more common than depression in older adults. In addition, anxiety disorders in later life can greatly impact quality of life, increase disability levels, and impact recovery from illness. When compared to the body of research of anxiety in younger adults or children, limited data suggest that older adults present with the same anxiety disorders as do younger adults, although several additional anxiety syndromes may be particularly relevant to the elderly. Virtually all epidemiological research is consistent in finding that the prevalence of anxiety, trauma- and stress-related, and obsessive-compulsive and related disorders is lower among older adults than among younger adults, particularly with respect to panic disorder and social anxiety disorder (social phobia). Rates vary considerably by study, however, leading to contradictory conclusions: either anxiety, trauma- and stress-related, and obsessive-compulsive and related disorders in the elderly are extremely rare or they constitute the most common class of geriatric psychiatric conditions, with substantially higher prevalence rates than mood disorders.

Diagnostic issues are complicated by medical illness and medications,

which can cause or contribute to anxiety-like symptoms. Clinicians may also attribute symptoms to realistic, age-appropriate health problems, worries, or fears.

Although these factors may lead investigators to believe that anxiety disorders are uncommon in older adults, it is also possible that anxiety is underdiagnosed in the presence of medical conditions or depression. Some clinicians may conclude that anxiety or avoidance is an inevitable or adaptive response to aging and therefore not pathological; in many cases, this conclusion may be inaccurate. Differences in the presentation of certain anxiety disorders in older adults may also muddy the diagnostic waters. Finally, there is insufficient research on differences in presentation or etiology between late-onset anxiety disorders and disorders originating earlier in life that have persisted until or recurred in old age. Additional research on these topics is necessary to clarify the many unresolved issues surrounding anxiety in the elderly.

DEFINITION, HISTORY, AND COMPARATIVE NOSOLOGY

The definition, history, and comparative nosology of anxiety, trauma- and stressor-related, and obsessive-compulsive and related disorder diagnoses, as defined by the various versions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and the *International Statistical Classification of Diseases and Related Health Problems* (ICD). To date, no geriatric-specific anxiety disorders have been included in the diagnostic nomenclature.

EPIDEMIOLOGY

Prevalence

The prevalence of anxiety disorders in the elderly is controversial. Investigations have found rates ranging from 0.7 to 19 percent. A recent review of epidemiological studies in Europe found a range of 4 to 14 percent. Because only one of those studies surveyed PTSD, it is likely that the true prevalence of anxiety disorders may be underestimated. By comparison, another recent review found prevalence rates of major depression ranging from 0.9 to 9 percent among community-dwelling older adults. Thus, it appears likely that, as in younger adults, anxiety disorders as a class are more common than major depression in the elderly.

The prevalence of anxiety disorders most likely decreases among older adults, and the gender difference, with women reporting higher rates than men, appears to attenuate among the oldest old. There appears to be a lower comorbidity of anxiety disorders and alcohol abuse among older adults than among younger adults, although this may be influenced by low rates of substance use disorders among the elderly. Most studies conclude that generalized anxiety disorder (GAD) and phobias are the most common

anxiety disorders among older adults, with panic disorder and social anxiety disorder (social phobia) much less common than in younger age groups. Estimated prevalence rates for specific anxiety disorders are listed in Table 57.3d–1.

Table 57.3d–1.
Prevalence Estimates of Anxiety Disorders in Older Adults

Generalized anxiety disorder	0.7–9%
Specific phobia	3–5%
Social anxiety disorder (social phobia)	0.2–2%
Panic disorder	0.1–1%
Agoraphobia	0.4%
Obsessive-compulsive disorder	0.1–2%
Hoarding disorder	14%
Posttraumatic stress disorder	8.7%

Incidence

Incidence studies of late-life anxiety are relatively rare, so most data on the age of onset come from retrospective reporting. The incidence of agoraphobia and possibly OCD in women may increase in late life, whereas specific phobia, OCD in men, and panic disorder are typically continuations from earlier life or the result of another psychiatric or medical illness. Approximately 30 to 40 percent of GAD cases arise for the first time in later life.

Prevalence within Special Groups

Anxiety disorders are common in diseases of the elderly. Rates as high as 30 percent have been reported in patients with cardiac conditions such as coronary heart disease and atrial fibrillation. In chronic obstructive pulmonary disease patients, prevalence rates of panic disorder range from 8 to 32 percent, with GAD rates ranging from 10 to 16 percent. GAD may occur in 15 to 20 percent of patients with neurological conditions such as stroke and Alzheimer disease.

Although rates of anxiety disorders in special populations are typically higher, this is not the case for nursing home patients, among whom the rate is approximately 5 percent. A review of prevalence data on anxiety disorders among caregivers for individuals with dementia found rates ranging from 4 to 16 percent. In a review and meta-analysis of studies involving widows, prevalence rates were 12 percent for PTSD, 10 percent for panic disorder, and 31 percent for GAD. By comparison, the prevalence of major depression was 22 percent.

Some data suggest that anxiety may be more common in older individuals from minority groups, although a recent study of older African

Americans found 6.6 percent reporting an anxiety disorder (vs. 2.4 percent for major depression), consistent with other research. The distribution of disorders, however, was different from what has been reported in other samples. For example, the most common anxiety disorders in this sample were PTSD (2.9 percent) and social anxiety disorder (social phobia) (2.1 percent). The oldest old and those in the South were less likely to report anxiety disorders. Almost one-fourth (24 percent) of older Puerto Rican primary care patients met criteria for an anxiety disorder, primarily specific phobia (12 percent), GAD (11 percent), or panic attacks (11 percent). Across all ethnic groups, phobias appear to be associated with lower income.

Although older veterans report rates of PTSD that are substantially lower than the rates found in younger veterans (e.g., 6 vs. 19 percent in one study), rates of PTSD are high among aging former prisoners of war (POWs) (e.g., 20 percent). The prevalence of PTSD appears to be highest among Holocaust survivors (e.g., 45 percent).

Comorbidity with Mood Disorders

As is the case with younger adults, comorbidity of anxiety and mood disorders is very common. Data from the Epidemiologic Catchment Area survey and two recent Dutch studies found that 21 to 37 percent of community-dwelling patients with an anxiety disorder (as defined by DSM-IV) experienced comorbid depression. Among nursing home patients, 42 percent of those with a DSM-IV anxiety disorder experienced comorbid major depression. Although these rates suggest that the disorders frequently overlap, it appears that most DSM-IV anxiety disorders in older adults are unaccompanied by a mood disorder. Studies using DSM-5 criteria are not available.

ETIOLOGY AND RISK FACTORS

Although much less research has been conducted on anxiety disorders than on depression in older adults, it appears that risk factors are similar for both conditions. Female gender, cognitive impairment, chronic health conditions, poor self-rated health, and functional limitations are among the most important factors increasing vulnerability. Psychological risk factors for both anxiety disorders and depression include personality traits (i.e., neuroticism), dysfunctional coping, and psychopathology. Marital status (unmarried) appears to be associated with depression but not anxiety, and being childless, having lower income, and experiencing traumatic events are more typically associated with anxiety than with depression. Older age appears to be protective for anxiety but a risk factor for depression. Of interest, one study that examined depression and anxiety disorders simultaneously found that although risk factors were similar for both classes of conditions, odds ratios associated with virtually all risks were

higher for anxiety disorders than for depression.

In nursing home patients, anxiety disorders appear to be related to younger age, lower levels of social support, better cognitive performance, depression, and history of stroke. Comorbid anxiety and depressive disorders are associated with the presence of pain, loneliness, and perceived lack of adequate care.

With respect to specific anxiety disorders, female gender, marital status (divorced or widowed), and comorbid psychiatric illness (specifically major depression and social anxiety disorder [social phobia]) are risk factors for agoraphobia in older adults. Late-onset agoraphobia is often associated with medical illness or traumatic events such as victimization or falls. Panic disorder is more strongly associated with disability than with health problems. Phobic disorders are associated with lower income and early parental loss. Risk factors for PTSD include female gender, neuroticism, low self-efficacy, and childhood trauma, and there are some reports of new-onset or worsening PTSD symptoms with cognitive decline.

DIAGNOSIS AND CLINICAL FEATURES

There is no evidence that anxiety disorders in older adults present substantially differently in older than in younger adults. Similar to what has been reported in younger samples, frequency and difficulty controlling worry, sleep disturbance, fatigue, and muscle tension appear to be the cardinal features of late-life GAD.

Older adults with panic disorder report fewer and less severe panic symptoms, lower levels of arousal, and less depression than younger individuals. Late-onset panic disorder appears to be associated with lower levels of cognitive and somatic distress during panic attacks. OCD may differ somewhat between older and younger patients, with older persons reporting more contamination and religious obsessions but fewer rituals involving symmetry or counting.

Older adults appear to develop PTSD and other anxiety syndromes after exposure to traumatic events less frequently than do younger adults. Older PTSD patients report more social dysfunction than younger patients, and in older adults, external locus of control appears to be associated with more avoidance, social dysfunction, and depression. Older PTSD patients may present more somatic than psychological symptoms and may report less severe PTSD symptomatology.

Anxiety Syndromes of Particular Relevance to the Elderly

Agoraphobia, fear of falling, hoarding, and complicated grief merit special mention because they may be anxiety syndromes with particular relevance to the elderly.

Agoraphobia. As shown in Table 57.3d–1, prevalence rates of

agoraphobia vary widely in older adults, suggesting a lack of diagnostic clarity. Distinguishing between adaptive and excessive avoidance is challenging, and patients typically believe that their behavior is reasonable, given age-associated medical conditions and physical limitations. Because panic disorder is rare in the elderly, Agoraphobia Without History of Panic Disorder (DSM-IV) is the most common symptom presentation. In DSM-5, where Panic Disorder and Agoraphobia have been diagnostically uncoupled, the diagnosis of Agoraphobia would apply.

In one study of older adults that used conservative criteria that defined agoraphobia as avoidance due to a panic attack rather than panic-like symptoms, the prevalence of comorbid panic disorder was still much lower (8 percent) than the prevalence of major depression (25 percent) or social phobia (20 percent). This suggests that older adults may limit their activity (i.e., develop agoraphobia) more often than do younger adults in response to panic attacks that do not meet criteria for panic disorder. Only 11 percent of late-onset patients with agoraphobia had histories of panic attacks in another investigation with looser criteria for agoraphobia; instead, they developed their fear in response to medical illness or traumatic events.

Across the lifespan, clinical features of agoraphobia are fairly consistent; however, age may impact the type of situation feared. The most common situations feared in older adults include being in line, being in shops, and being in open spaces. Older individuals may fear or avoid these situations due to thoughts that help may not be available in the event of embarrassing symptoms (e.g., fear of falling, fear of incontinence).

Fear of Falling. Although under DSM-5 diagnostic criteria, fear of falling can only be classified as a Specific Phobia, Other Type if the patient perceives it to be excessive or unreasonable, it is a common and disabling anxiety syndrome in older adults. As many as 25 percent of community-dwelling older adults report fear of falling. Although individuals with a past fall are more likely to develop fear of falling than those without such history, most individuals reporting fear do not have a history of falls.

Fear of falling has potentially serious consequences, including, paradoxically, increased risk of falls. Approximately half of those with fear of falling restrict their activities due to fear, and the risk of falling is highest among those who do, even among those who have never experienced a fall. Fear of falling may lead to maladaptive changes in gait parameters, further increasing the risk of future falls, and may interfere with rehabilitation following a fall. For example, in one investigation of patients recovering from hip fracture surgery, fear of falling predicted poor functional recovery, although pain and depression did not.

As is true with other anxiety syndromes, fear of falling is frequently, although not always, comorbid with other anxiety disorders and depression. In one sample of individuals with high fear of falling and a

recent fall, 36 percent had depression and 19 percent had an anxiety disorder, most commonly agoraphobia without panic, and anxiety was a strong predictor of fear of falling even after controlling for factors such as dizziness, visual impairment, number of medications, and depressive disorders and symptoms.

Hoarding. Once considered a subtype of OCD, hoarding disorder is now considered a separable syndrome and is a new diagnostic category in DSM-5. Nationally representative epidemiological studies of hoarding disorder with DSM-5 criteria are not available, but recent smaller epidemiologic surveys estimate a 1.5 to 6 percent prevalence of hoarding behaviors (not necessarily at the level of a hoarding disorder diagnosis) in the general population. Hoarding symptoms may be nearly three times more prevalent in older adults compared with younger adults. Older adults may also show more severe hoarding symptoms than do middle-aged adults.

Elderly hoarders are typically female, never married, and living alone. Hoarding is typically a chronic condition with an early onset and progressive course. For those with a late onset of symptoms, hoarding likely begins secondary to a disease process occurring in later life, such as dementia. Pest infestations, fire hazards, and falling are risk factors for older adults with hoarding behaviors.

Persistent Complex Bereavement Disorder. Older adults experience bereavement at much higher rates than do younger adults, and as many as 20 percent of bereaved individuals suffer prolonged distress and disability. However, approximately 10 to 12 percent of individuals will continue to experience persistent symptoms that do not resolve naturally and interfere with functioning. Persistent Complex Bereavement Disorder is a proposed disorder included in the section of "Conditions for Further Study" in DSM-5. Symptoms may include persistent yearning, sorrow, and preoccupation with the deceased or the circumstances of the death, reactive distress to the death or social/identify disruption. Risk factors for persistent complex bereavement disorder include dependency on the deceased person prior to death, death of a child, and being female. Further research is needed to establish the validity and utility of this diagnostic entity.

PATHOLOGY AND LABORATORY EXAMINATION

Most research on the biology of late-life anxiety has focused on PTSD, and much of it has been performed by a single research team in samples of Holocaust survivors and older veterans. Studies in PTSD and other late-life anxiety disorders have examined cognitive performance, hypothalamic–pituitary–adrenal (HPA) axis function and other markers of autonomic arousal, neuroimaging, and genetics.

Posttraumatic Stress Disorder

With respect to neuropsychological functioning, older persons with PTSD display poorer explicit memory, visuospatial functioning, attention, and working memory than those with trauma exposure but no PTSD and those without trauma exposure. Among those with PTSD, improvement in recall may be associated with improvement in PTSD symptoms.

Other research shows evidence of HPA axis dysregulation associated with late-life PTSD. Individuals with PTSD show flatter circadian salivary cortisol patterns and lower urinary cortisol excretion than do those without PTSD, and better explicit memory performance is associated with lower salivary cortisol levels. Urinary cortisol excretion and glucocorticoid receptor–mediated responsiveness appear to be associated with age of first trauma exposure, and cortisol level may be associated with severity of childhood trauma. Moreover, cortisol administration may enhance working memory performance in older veterans with PTSD. Glucocorticoid receptor, plasma adrenocorticotropic hormone (ACTH), and cortisol suppression in response to dexamethasone administration are greater in older PTSD patients. Older PTSD patients may have higher levels of dehydroepiandrosterone (DHEA) and DHEA sulfate ester (DHEAS) and a lower cortisol/DHEA ratio. The cortisol/DHEA ratio appears to be predicted by the severity of childhood trauma and current PTSD symptoms, and both variables are predicted by symptom improvement and coping.

In terms of brain structure, although one investigation found no differences in hippocampal volumes in Holocaust survivors relative to controls, among those with PTSD, smaller left hippocampal volumes were found in those who had no prior history of trauma before the index trauma. These findings suggest that smaller hippocampal volume may be a risk factor for the development of PTSD.

Other Anxiety Disorders

Elderly female social anxiety disorder (social phobia) patients in one sample showed greater hemodynamic responses, cardiac vagal attenuation, and sympathetic vasomotor activation than those without social anxiety disorder (social phobia) in response to a public speaking challenge. Older adults with specific phobias and GAD show greater and longer-lasting cortisol response to stress than nonanxious older adults. Older GAD patients may have memory and executive function deficits comparable to those of patients with major depression relative to normal older adults, and older adults with depression and comorbid anxiety disorders show greater memory declines over time than those with depression alone. In GAD, working memory deficits have been associated with higher levels of anxiety symptoms, and errors in temporal orientation are associated with poorer response to cognitive-behavioral therapy (CBT).

There is limited information to date on how—and indeed, if—separation anxiety disorder and selective mutism manifest in older adults. Both of these are disorders that are typically diagnosed in childhood, and the extent to which they persist or have onset in later adulthood is unknown.

Genetic Factors

A few studies have explored genetic risk factors for late-life GAD. As in younger adults, genetic influences appear to be shared with depression and partially, although not entirely, with neuroticism. A large, population-based study of middle-aged and older adults (mean age 60 years) found no associations between a brain-derived neurotrophic factor coding variant (Val66Met, rs6265) and current or lifetime GAD.

DIFFERENTIAL DIAGNOSIS

The most common differential diagnoses are medical conditions and depression. In primary care or specialty medical settings, somatic symptoms of anxiety may be difficult to distinguish from those of cardiovascular, endocrine, gastrointestinal, metabolic, neurological, or pulmonary disorders or from the effects of medications, including antihypertensives, β-agonists, corticosteroids, digitalis, nonsteroidal anti-inflammatory drugs (NSAIDs), and thyroid medication. A workup to identify medical conditions that may be contributing to anxiety in older adults should comprise a complete medical history and physical examination and laboratory tests including complete blood count, thyroid function, and levels of electrolytes, vitamin B_{12}, and folate. It should be noted, however, that anxiety can coexist with medical conditions and may lead to excess disability and, potentially, exacerbation of the medical condition itself. Treatment of anxiety as a co-occurring disorder may be appropriate, particularly when the medical condition is stable.

Because few older adults with anxiety disorders that are not accompanied by depression present to mental health settings, it is common for comorbid anxiety disorders to be overlooked in depressed older patients. Several symptoms of major depression and GAD overlap, and rates of comorbid anxiety disorders are as high as 40 to 50 percent in samples of depressed older adults presenting to mental health clinics.

Specific training about anxiety disorders for geriatric mental health providers can boost recognition rates, especially in depressed older adults. Table 57.3d–2 summarizes differences in the typical presentation of depression and anxiety in older adults. Because anxiety typically develops before depression and follows a chronic rather than episodic course, questions about symptoms such as worry, feeling tense or nervous, or finding it difficult to relax at times when the individual was not depressed may clarify whether a depressive episode is superimposed on a pre-existing

anxiety disorder.

COURSE AND PROGNOSIS

The course of anxiety disorders in older adults is typically chronic. Prognosis is often poor; recent investigations have found higher mortality risk associated with generalized anxiety and PTSD symptoms and panic attacks, even after controlling for medical factors and depression.

With respect to specific anxiety disorders, GAD may be characterized by periods of remission and relapse occurring over decades but with longer symptomatic periods in older than in younger adults. One influential view holds that late-life GAD and depression exist on a continuum, with GAD representing the mildest form of the disorder and comorbid GAD and depression representing the most severe syndrome. Providing more support for the hypothesis that GAD and depression exist on a continuum, one epidemiological study found that only 12 percent of individuals with GAD at baseline continued to have GAD without major depression at 3-year follow-up. Almost half (48 percent) had remitted and 40 percent went on to develop major depression, either with or without comorbid GAD. Ten-year follow-up data from the same study indicated that excess mortality was associated with depression in men but not in women; GAD either with or without comorbid depression was not associated with mortality. A 40-year follow-up of individuals retrospectively diagnosed with GAD found evidence that the disorder may convert to a somatoform disorder over the lifespan.

A 50-year follow-up study of OCD patients found remission rates of approximately 60 percent. By contrast, a 50-year follow-up of panic disorder patients found only 6 percent of patients not meeting criteria for any psychiatric disorder at the final assessment point. In this study, prevalence of panic disorder with and without agoraphobia began to decline after approximately age 40 years, whereas incidence of somatoform disorders and agoraphobia without panic rose steadily from age 20 through 60 years and then leveled off. Although PTSD symptoms are most prominent immediately after the trauma, they can persist for decades, and some evidence suggests that they may emerge for the first time or increase in later life, especially in the context of cognitive decline.

Consequences

Consequences of anxiety disorders include activity limitations, higher numbers of general practitioner and home health visits, loneliness, poor life satisfaction, poor perceived health, and perceived lack of help. Older GAD patients report poorer role functioning, social functioning, and energy levels than individuals with other chronic conditions such as heart disease and diabetes. Older adults with PTSD, even in the absence of depression,

experience more days spent in bed and days with limited activity and lower levels of life satisfaction than those without PTSD after controlling for factors including age, chronic diseases, functional limitations, social network size, and cognitive functioning. They also make more visits to mental health providers and have higher rates of benzodiazepine use.

Table 57.3d–2.
Characteristics of Depression and Anxiety in Older Adults

Typical Presentation	Depression	Anxiety
Somatic symptoms	Vegetative (e.g., poor appetite, fatigue)	Autonomic (e.g., palpitations, dizziness, gastrointestinal distress)
Activity level	Typically psychomotor retardation	Agitation or subjective feeling of restlessness
Enjoyment of life	Diminished	Not diminished, but patient may claim that he or she has no time to enjoy life
Sleep disturbance	Early-morning awakening	Difficulty falling or staying asleep
Thought content	Rumination about past losses or failures, suicidal ideation	Worry about current or future threats or dangers
Behavior	Decreased activity	May exhibit excessive activity (e.g., cleaning, taking on too many projects or responsibilities)
Family relationships	May be isolated or disconnected from family	May be overinvolved or intrusive with family
Social networks	Diminished	Often not diminished, may hide symptoms from network
Onset	May have early or late onset	More typically early onset
Course	Episodic	Chronic
Attribution	Patient may believe that symptoms are part of normal aging or a natural response to life events	Patient may believe that symptoms are part of his or her personality or a natural response to life events

In nursing home patients, anxiety disorders and depression are associated with lower levels of well-being, although not necessarily with higher levels of disability. Patients with depression, either alone or combined with anxiety, report lower levels of well-being than patients with pure anxiety. Individuals with anxiety and/or depression receive less assistance with activities of daily living (ADLs), make more visits to medical specialists, and take more medications, especially antidepressants. Use of antidepressants is typically more common in patients with combined anxiety and depression relative to others. Patients with anxiety make more visits to medical specialists than those without anxiety or depression.

Anxiety as a Risk Factor for Other Medical Conditions

Anxiety may also serve as a risk factor for common medical conditions of later life. Studies have reported increased risk of vascular problems, respiratory disease, chronic pain, gastrointestinal conditions, and cancer associated with PTSD.

Substantial evidence links anxiety to heart disease. Symptoms of phobic anxiety may predict the onset of ventricular arrhythmias in patients with coronary artery disease. Generalized anxiety disorder, panic attacks, and PTSD symptoms lead to elevated risk of coronary heart disease, even in the absence of major depression. PTSD symptoms are also associated prospectively with nonfatal myocardial infarction. Reported lifetime prevalence of anxiety disorders is considerably higher than current prevalence in coronary heart disease, suggesting that anxiety might represent a risk factor rather than a consequence of heart disease.

TREATMENT

Anxiety disorders in the elderly are frequently undetected and untreated. Older adults are significantly less likely than younger adults to receive treatment for anxiety. When treatment takes place, it usually involves benzodiazepines or other anxiolytic medications rather than antidepressants or psychotherapy.

Pharmacotherapy

Surprisingly little research has been conducted on treatment of anxiety in older adults. Recent evidence suggests that selective serotonin reuptake inhibitor (SSRI) pharmacotherapy is superior to psychotherapy as an acute treatment for geriatric anxiety. Data from controlled trials support the use of escitalopram (Lexapro), duloxetine (Cymbalta), pregabalin (Lyrica), venlafaxine XR (Effexor), citalopram (Celexa), and sertraline (Zoloft) for late-life GAD.

Data are even more sparse with respect to treatment of other anxiety disorders, but evidence from controlled trials and open-label studies suggests the efficacy of sertraline, citalopram, and escitalopram, as well as of imipramine (Tofranil) and alprazolam (Xanax), for panic disorder in older adults. The SSRIs citalopram, escitalopram, and sertraline may be particularly effective treatments for anxiety in the elderly based on their low propensity for drug interactions and short half-lives. Fluvoxamine (Luvox) has demonstrated efficacy in an open-label trial including older patients with GAD, panic disorder, or OCD.

For PTSD, only one small open-label pharmacotherapy study has been conducted in adults with a mean age greater than 60 years, and studies with mean ages of 50 years or older have been veteran samples comprised almost exclusively of men. Randomized, controlled trials in this age group support the use of sertraline and mirtazapine, and an open-label trial

supports the efficacy of citalopram. Prazosin may improve sleep quality and PTSD-related nightmares; its impact on other PTSD symptoms is less clear.

Benzodiazepines are often the only mental health treatment received by older adults with anxiety disorders, and they are prescribed more frequently to older adults than to younger adults. Although benzodiazepines are effective in reducing anxiety and may be useful as an adjunctive, as-needed, or short-term treatment strategy, long-term daily use is associated with falls, fractures, and cognitive decline in the elderly and is not recommended. Among benzodiazepines, lorazepam has a relatively short half-life and no active metabolites and is therefore preferable to alprazolam or clonazepam, which are more likely to accumulate and achieve toxic levels in older adults. Benzodiazepine taper should be very gradual in the elderly, even after a short duration of use.

Comorbid Anxiety and Depressive Disorders. Older adults with depression and comorbid anxiety disorders or significant anxiety symptoms typically demonstrate delayed acute treatment response and increased risk of relapse of depression. They may also report more suicidal ideation. For these reasons, it is especially important to treat older adults with depression and coexisting anxiety to complete remission. Open-label trials support the potential utility of escitalopram for comorbid depression and GAD in older adults.

Augmentation and Maintenance Treatment. No randomized trials have tested augmentation strategies with anxious older adults who fail to respond to a first-line treatment. A group of older adults with anxiety disorders (mostly GAD) who did not respond to an initial trial of an antidepressant or benzodiazepine responded to adjunctive risperidone (average dose 1.2 mg per day).

Although data suggest the continued efficacy of citalopram for GAD after 24 weeks of treatment, with an additional 20 percent of patients responding in the second 12 weeks, no research has examined maintenance therapies for late-life anxiety. Given the chronic course of anxiety disorders, studies on this topic should be a high priority.

Clinical Management. Because SSRIs may initially exacerbate symptoms of anxiety, older adults should be started on a low dose (Table 57.3d–3). In clinical practice, however, older adults with anxiety or depression are frequently maintained on minimum or even subtherapeutic doses, with corresponding limited benefit. If the patient is tolerating the medication, the dose should be increased at least to the minimum target dose within 4 weeks. If the patient has not made a full response (e.g., achieved at least a 50 percent decrease in symptoms) within another 4 to 6 weeks, the dose should be gradually increased, with continued increases up

to the maximum until response is achieved or the patient is no longer able to tolerate the medication.

Older adults with anxiety are frequently more resistant to the idea of pharmacotherapy and more sensitive to perceived side effects than younger adults with anxiety or older adults with depression, attributing to the drug symptoms that preceded the initiation of a medication trial. Therefore, the specific agent may be less important than good clinical management, including information about the safety and nonaddictive potential of the medication, reassurance about the transient and noncatastrophic nature of side effects, availability of the physician at any time in the event of bothersome symptoms, and frequent visits initially (ideally weekly for the first month and biweekly thereafter until response is achieved). Patients may need continued reassurance at every dose change and, in the event of emergent side effects, should be encouraged to stay the course for at least 1 or 2 weeks. Clinicians may need to think creatively to facilitate this process, for example, by suggesting that patients split the dose between morning and evening administration or take over-the-counter medications temporarily to counteract side effects (e.g., Imodium for diarrhea).

Table 57.3d–3.
Usual Starting, Minimum Target, and Maximum Dose of Commonly Used Antidepressants for Older Adults with Anxiety Disorders

Medication	Starting Dose (mg/day)	Minimum Target Dose (mg/day)	Maximum Dose[a] (mg/day)
Citalopram	5	20	20[b]
Escitalopram	10	10	20
Sertraline	12.5	50	200
Fluvoxamine	25	100	300
Venlafaxine extended-release	37.5	75	225
Mirtazapine	7.5	15	45

[a]Higher doses are sometimes used on a case-by-case basis; lower doses are often used in the oldest old.

[b]The U.S. Food and Drug Administration revised recommendations for citalopram are as follows: the maximum recommended dose of citalopram is 20 mg per day for patients older than 60 years of age.

Psychotherapy

Some evidence suggests that SSRI medications may be more effective than psychotherapy as an acute treatment for late-life anxiety disorders. Research, mostly with older GAD patients, provides support for the effectiveness of CBT relative to waiting list and active control conditions such as supportive therapy and attention placebo. One study has demonstrated the superiority of CBT to supportive psychotherapy in a well-characterized sample of older adults with anxiety disorders (52 percent

with panic disorder), and all participants in this investigation were taking medications but had failed to respond prior to receiving psychotherapy. Response to CBT for GAD in older adults may be compromised by memory impairment, executive dysfunction, or failure to complete at-home practice. A recent study has demonstrated that the sequence of antidepressant medication augmented with CBT in older adults with GAD leads to worry reduction in the short term. This study also found that both maintenance medication and CBT could prevent relapse compared with placebo, providing two strategies for improving outcomes in GAD in older adults.

For older individuals who refuse to take medications or for whom they are contraindicated, relaxation training may be the most effective component of a behavioral treatment for GAD or distressing anxiety symptoms that do not meet criteria for a specific anxiety disorder. Recommending a good relaxation tape with breathing or meditation exercises, progressive muscle relaxation, or imagery may be helpful; if after a few weeks of practice the patient does not report sufficient gains, it may be worthwhile to reopen a discussion about medications.

For anxiety disorders other than GAD, some evidence supports the use of CBT for panic disorder in older adults, although results from a study that included a substantial proportion of older panic disorder patients suggest the superiority of sertraline over CBT. There are no published data beyond case reports documenting the behavioral treatment of specific phobia or OCD, all of which use exposure-based protocols, and no data on the treatment of older adults with agoraphobia without panic disorder or social anxiety disorder (social phobia). Case reports of PTSD treatment in older adults have described gains associated with psychodynamic and supportive approaches, CBT, eye movement desensitization and reprocessing, life review, and exposure therapy. A recent pilot study of prolonged exposure therapy in older veterans with PTSD showed significant decrease in their symptoms of PTSD.

Recommendations on CBT with older adults and on behavioral treatment of anxiety are included in Sections 57.4i and 14.7 of this volume, respectively. Recommendations specific to late-life anxiety include (1) ensuring that sufficient time is devoted to learning skills such as relaxation training; (2) practicing skills multiple times in session to ensure that the rationale and procedures are well understood prior to assigning at-home practice; (3) ensuring that anxiety levels become sufficiently high during exposure exercises, which may be facilitated by, for example, having patients hyperventilate briefly before engaging in imaginal exposure; (4) not avoiding difficult or painful issues or worries if appropriate (e.g., imaginal exposure to issues surrounding an ill spouse's death); and (5) deemphasizing more abstract cognitive restructuring techniques in favor of simpler strategies (e.g., coping statements).

Mrs. H was a 69-year-old married white woman with a college degree. She reported that she was "always a worrier" but believed that she was acting in the best interests of her family by looking out for their well-being. She indicated that her worrying had caused problems within her family; for example, her daughter was annoyed with Mrs. H for sending her classified ads and articles about employment resources to encourage her to find a new job. She further stated that her concern about her children led her to telephone them daily, and she had once contacted the police when her call was not returned by the next day.

In addition to worrying about her children, she indicated that she was concerned about her husband's health, their finances, and her health, particularly her recent diagnosis of gastroesophageal reflux disease. Although she believed that her worry was normal under the circumstances and she was resistant to the idea of taking medication, she indicated that sleep disturbance, fatigue, and difficulty concentrating were making it difficult for her to accomplish daily tasks.

Mrs. H was started on 50 mg per day of sertraline but called the psychiatrist's office after 3 days to report that she had discontinued the drug after experiencing an upset stomach and a burning sensation in her throat. She agreed with the doctor's recommendation for her to restart the medication at a reduced dose of 25 mg per day and to take chewable calcium tablets as often as needed. He called her back 2 days later to inquire about the success of this strategy. Although Mrs. H reported that the symptoms continued, she agreed to continue the medication for another week, until her next scheduled appointment. At that point, she was unwilling to consider raising the dose but agreed to stay the course for another 2 weeks, at which point she reported that the side effects were "unpleasant but manageable" and reluctantly agreed to try 50 mg per day. Over the next 3 months, her dose was gradually increased to 200 mg per day, with diminishing side effects. Mrs. H reported that although she continued to worry about her family, the thoughts were less distressing, and she was sleeping better and had more energy.

Mrs. P was an 82-year-old African-American woman whose daughter brought her to the clinic out of concern that she was depressed. Although Mrs. P lived independently and had been sleeping and eating well, she had refused to leave her home unaccompanied since experiencing a noninjurious fall 3 months before the appointment. She denied feeling sad and reported that she enjoyed watching television, listening to music on the radio, and having family and friends from her church visit her in her home. She stated that although she used to take walks for exercise and do her grocery shopping at the corner market, she now experienced considerable anxiety about not having help available should she fall outside of her home. Her family was trying to decide whether she should come to live with one of her children. Because of her strong preference to continue living on her own, she agreed to come to the clinic for an evaluation.

After consulting with her physician, who reported that she did not have orthostasis or other medical conditions increasing her risk of falling, the psychiatrist decided first to have Mrs. P evaluated by a physical therapist, who tested her gait and taught her to use a cane. Although Mrs. P reported that she was using the cane to feel more secure within her home, she continued to avoid unaccompanied trips outside of her home. She was then referred to a psychologist for behavioral treatment.

Mrs. P and the psychologist collaboratively developed a hierarchy of situations involving exposure to trips outside of the home that varied in duration, distance, and availability of family members for support. Her family was enlisted to help with the treatment by initially being available by telephone while she was engaged in exposure. As treatment progressed, she was "weaned" from making calls to family members immediately before, during, and after her walks. At this point, which took six sessions over an 8-week period, Mrs. P reported that she was able to leave her home alone, taking her cell phone but not using it routinely during every excursion. Treatment was deemed successful and terminated.

FUTURE DIRECTIONS

Anxiety disorders are more common than usually recognized in older adults. In the mental health clinic setting, they are typically seen as a co-

occurring diagnosis with depression, although this may change as public awareness about anxiety and its treatment grows. Coexisting anxiety and depression typically represents a more severe disorder than depression alone. Because onset is often early in life, older adults with anxiety disorders have usually experienced a chronic course. Distress and impairment associated with these disorders can be substantial. Data on biological factors involved in late-life anxiety implicate HPA axis dysregulation, and genetic, cognitive, and neuroanatomical influences are under investigation. Although data are still sparse, SSRI medications appear to represent the first-line acute treatment for geriatric anxiety. Very few maintenance studies have been performed, and more research is needed. Psychotherapy has shown some efficacy in older adults for GAD and panic disorder with promising pilot studies in PTSD and has not been adequately investigated for phobias, including agoraphobia. A focus on anxiety disorders across the life span is needed; one practical step toward this is including older participants in clinical trials within multiple settings, including community and residential facilities. Alternatives to CBT and combinations of pharmaco- and psychotherapy have not been investigated.

57.3e Geriatric Mood Disorders

JENNIFER ROSE GATCHEL, M.D., PH.D., JAMES M. WILKINS, M.D., BRENT P. FORESTER, M.D., ROBERT EMMETT KELLY, JR., M.D., AND GEORGE S. ALEXOPOULOS, M.D.

Geriatric mood disorders cause suffering, increase medical burden, worsen the outcomes of many medical conditions, and contribute to disability. Investigators at the World Health Organization conclude that depression produces a greater decrement in health than angina, arthritis, asthma, and diabetes. This finding holds across countries and demographic characteristics. The complexity of geriatric mood disorders and comorbid medical illnesses requires coordination of care among health professionals and continuity of care, often difficult to achieve within the current health care delivery system. Moreover, the behavioral disability of persistent geriatric mood disorders often requires expensive support systems.

Despite the availability of relatively efficacious treatments, geriatric depression continues to be underdiagnosed. The failure to recognize geriatric depression stems from the clinical complexity of the syndrome, symptom overlap with medical comorbidities, social bias, and barriers of the settings in which most depressed elderly patients are treated. Depression does not have pathognomonic symptoms or signs. Many of the symptoms of depression (e.g., loss of interest, lack of energy, physical complaints) can be caused by medical illnesses. Moreover, depressed patients often have several chronic medical illnesses, which make it difficult to determine whether a symptom is caused by depression, a medical illness, or both. Depressed elderly patients often experience anhedonia (depression without sadness) rather than depressed mood, a symptom difficult to ascertain during a brief examination. Ageism among patients and health professionals may lead to diagnostic complacency based on the view that older individuals who lose their physical prowess and social status have valid reasons to be depressed. Finally, two-thirds of depressed elderly patients are treated in busy primary care offices. Such settings are geared to acute care of medical problems. Their fast pace and the emphasis on medical rather than mental health problems are significant barriers to effective diagnosis. Although late-life depression is underdiagnosed, many nondepressed older patients receive antidepressants. Incorrectly attributing physical symptoms to depression may lead to premature discontinuation of medical workup and failure to identify a medical cause for physical complaints. Moreover, inappropriate use of antidepressants may increase the cost of care and cause drug interactions.

The past decade has witnessed an acceleration of the understanding of the neurobiology of late-life mood disorders. Future studies designed using the NIMH Research Domain Criteria (RDoC) guidelines will hopefully

identify critical neurobiological targets paving the way for novel pharmacotherapy and psychotherapy treatment approaches of late-life mood disorders.

EPIDEMIOLOGY

The National Comorbidity Survey Replication discovered that the overall prevalence of major depression among persons aged 65 years or older was estimated to be 1.5 percent in women and 0.2 percent in men, with an overall prevalence of 1 percent, approximately one-fourth of that in younger adults. However, when combining symptoms of major or minor depression with reported treatment for depression, the cumulative depression prevalence in later life is noted to be as high as 11.19 percent with similar rates for men (10.19 percent) and women (11.44 percent). Further, in this population study of late-life depression, Caucasians and Hispanics had nearly three times the prevalence of depression found in African Americans.

Subthreshold depression has a median community point prevalence of 9.8 percent, approximately two to three times more prevalent than major depression. Subthreshold depression is lower in community settings versus primary care settings and highest in long-term care settings. Approximately 8 to 10 percent of older persons with subthreshold depression developed major depression per year. Subsyndromic depression is more frequent than syndromic depression and similarly does not increase with age.

The prevalence of major depression has been increasing in recent birth cohorts compared to cohorts born in the early part of the 20th century. Depression appears to have an increasingly earlier onset in cohorts born in recent years, and there is a narrowing in the differential risk for depression between genders.

Depression frequently occurs in medical populations. For patients treated in primary care settings, depression was identified in 17 to 37 percent of patients. Approximately 30 percent of these patients had major depression, and the remainder had a variety of depressive syndromes that could benefit from medical attention. Major depression occurs in roughly 25 percent of older home care patients, 11 percent of medically hospitalized patients, and up to 48 percent for individuals in long-term care settings.

As the world population ages, prevalence rates for older adults with bipolar disorder (BD) are rising, now estimated to account for 25 percent of all bipolar patients. While the estimated lifetime prevalence of BD in the U.S. population for individuals aged 60 years and older is 1 to 2 percent, rates in specific clinical populations vary from 3 percent of nursing home residents, up to 7 percent of psychiatric outpatients, 10 percent of psychiatric inpatients, and 17 percent of individuals presenting for psychiatric treatment in ER settings. Further, approximately 70 to 95 percent represent cases with onset prior to age 50 years that has persisted

into later life. Approximately 69 percent of late-life bipolar patients are women.

In summary, mood disorders occur in the older geriatric population at a rate lower than that of younger adults. However, significantly higher rates of depression occur in medically ill, disabled, or institutionalized elderly persons. With the aging of birth cohorts who appear to be particularly prone to depression, an unprecedented number of older adults are expected to require psychiatric attention.

SUBTYPES OF LATE-LIFE DEPRESSION

Depression in Medically Ill Patients

Geriatric depression typically occurs in the context of medical disorders. Sometimes these conditions predispose or trigger depression. For example, subclinical hypothyroidism increases the risk for depression more than fourfold while nearly a third of patients develop depression within a year after a myocardial infarction. Overall medical severity and disability appear to be important risk factors for depression. For these reasons, geriatric depression is viewed as a heterogeneous entity.

Older adults with chronic disease have a 50 percent greater risk for depression than older, medically healthy adults. Depression increases the risk of coronary disease by over 60 percent while also increasing the risk of cancer and a shortened survival time, regardless of cancer etiology. Individuals with malnutrition, metabolic syndrome, and post hip fracture surgery are all at elevated risk of depression. Data from a large health maintenance organization population suggest that the health care cost of depressed medical patients is twice that of nondepressed patients with similar levels of medical morbidity, though only a small proportion of the increased costs are spent on specialty mental health care.

Depression impairs social function more than heart and lung disease, arthritis, hypertension, and diabetes and leads to greater impairment in physical function than arthritis, hypertension, and diabetes. This effect seems to be mediated through decreasing adherence to treatment, as well as through biological mechanisms such as changes in sympathetic–parasympathetic balance, changes in serotonin-mediated thrombogenesis, and changes in the immune system.

Depression is underdiagnosed and undertreated in primary care settings. Approximately 11 percent of depressed high utilizers of primary care services receive adequate antidepressant treatment, whereas 34 percent receive inadequate treatment and 55 percent receive no treatment. The pattern of inadequate treatment of depression also extends to long-term care settings where 23 percent of nursing home residents diagnosed with depression receive no treatment.

Depression in Patients with Dementia

In DSM-V, cognitive disorders are described on a spectrum: mild and major neurocognitive disorders (MaNCD) and their etiological subtypes. Despite a recent change in nomenclature, the term dementia continues to be used frequently in clinical settings, and is retained here for consistency. Depressive manifestations of varying intensity occur in approximately 50 percent of patients with dementia. Examination of the interval between the occurrence of depression and development of dementia suggests that depression is both a risk factor for AD and a prodrome. A meta-analysis concluded that a history of depression doubles the risk for developing dementia in late life. Depression occurs in approximately 25 percent of patients with cerebrovascular disease and in up to 50 percent of those with Parkinson disease. The similarity of depressive manifestations with symptoms and signs of dementing disorders, for example, loss of interest, decreased energy, agitation or psychomotor retardation, poor concentration, and apathy often poses diagnostic problems. Sad mood and psychic rather than vegetative features have been found useful in distinguishing depressed patients with dementia from patients with dementia alone.

Depression with Reversible Dementia

Some elderly depressed patients develop a dementia syndrome that improves or completely subsides after remission of depression. This syndrome has been termed *pseudodementia*, *dementia syndrome of depression*, or *depression with reversible dementia*, and it has attracted considerable clinical interest. Abnormal executive function, processing speed, and working memory may persist after remission of mood symptoms in many patients with geriatric depression.

Depressed elderly patients who remain with some cognitive impairment even after improvement of depression usually have an early-stage dementia whose cognitive manifestations are exaggerated when the depressive syndrome is superimposed. Although some disagreement exists, it appears that even those individuals with nearly complete cognitive recovery develop high rates of irreversible dementia (about 20 percent per year) on follow-up. Many of these patients may remain nondemented for 1 to 2 years before the development of irreversible dementia. The heterogeneity of the course of depression with reversible dementia suggests that patients suffering from this syndrome can be ordered along a continuum. At the one end of the continuum lie cases in which the cognitive disturbance results predominantly from the depressive syndrome itself. On the other end are cases in which the intellectual impairment originates from a progressive subclinical neurodegenerative disorder with some contribution by the depressive syndrome. Therefore, identification of a reversible dementia

syndrome in elderly depressive patients constitutes an indication for a thorough diagnostic workup and frequent follow-up aimed at the identification of treatable neurological disorders.

Psychotic Depression

Psychotic depression occurs in 20 to 45 percent of hospitalized elderly depressives and in 3.6 percent of elderly depressives living in the community. Patients with psychotic depression have delusions, whereas hallucinations are less frequent. The usual themes of depressive delusions are guilt, hypochondriasis, nihilism, persecution, and sometimes jealousy. Depressive delusions can be distinguished from the delusions of patients with dementia, in that the latter are less systematized and less congruent to the affective disturbance.

Late-Life Bipolar Disorder

Although community prevalence rates of BD are lower in older adult populations than in younger adult ones, recurrent episodes of mania and hypomania persist into later life and affect 5 to 10 percent of psychiatric patients. Late-onset mania often occurs in patients who have had recurrent depression episodes since early life. Unipolar mania, though relatively uncommon, is an early-onset disease. Similar to unipolar depressive disorder, late-life BD occurs in the context of cognitive impairment, high medical burden, disability, and limited psychosocial support. These factors influence the course of late-life BD. Importantly, decrements in physical health-related quality of life in this population are not an inevitable consequence of aging, and adequate attention to medical comorbidity at any age may have a tangible impact.

Cognitive impairment occurs in 40 to 60 percent of symptomatic elderly bipolar patients and may endure after improvement. Deficits in attention, executive functions, and memory have been noted. Elderly bipolar manic patients may have more severe executive function deficits than unipolar depressed elders. These impairments may reflect, in part, processes involved in the pathophysiology and pathogenesis of mood disorders, including dysfunction of corticostriatal circuits and other limbic pathways. Cognitive impairment may be a prodrome of dementia and may also be associated with poor outcomes in late-life mania.

Older adults with BD have higher stroke risk factors than both aged controls and unipolar elders. Late-onset mania is especially associated with vascular burden and high mortality due to cerebrovascular disease. Neuroimaging studies have revealed a high frequency of signal hyperintensities and silent strokes in older bipolar patients. Structural abnormalities are most prominent in BD with late age at onset of first episode. Cardiac pathology, renal impairment, and thyroid dysfunction are

also common in aged bipolar patients.

BD leads to behavioral disability that worsens the symptom course in BD. Disability in the elderly can lead to institutionalization and influence morbidity and mortality. Geriatric bipolar patients report low perceived social support compared to same-age controls. Bipolar patients with a history of frequent or lengthy episodes of illness lack social support. The effect of social support on treatment outcomes of BD in old age requires further investigation.

Depression and Disability

According to the World Health Organization, unipolar depression alone is responsible for more than 1 in 10 years lived with disability worldwide. Depression is among the 10 diseases that increase disability-adjusted life years (DALYs) the most. DALY is a measure of years of life lost to premature death and years lived with a disability. In a 12-year follow-up study, individuals with major depression at baseline were four times more likely to report incident disability after controlling for medical illness and sociodemographic factors. Whereas depression increases the risk of disability, the opposite is also true. Increases in disability over time predict the emergence of depressive symptoms. Impairment in instrumental activities of daily living is related to depressive symptomatology and particularly to anxiety, helplessness, hopelessness, and worthlessness. Disability is associated with executive dysfunction and with late-onset depression.

Bereavement

Depressive symptoms or syndromes often follow a significant loss. In DSM-IV, bereavement within 2 months of the death of someone close was an exclusion criterion for the diagnosis of depression. Older persons appear to be at lower risk for developing depressive symptoms or syndromes than younger adults during the first months after loss of a spouse. However, by the end of the second year, older and younger individuals have the same rates of major depression. In fact, the prevalence of major depression continues to increase during the second year of bereavement. At the end of the second year after loss, 14 percent of bereaved elderly individuals have major depression.

SUICIDE RISK

Older adults are at significant risk of death by suicide relative to younger adults. Caucasian men older than 80 years are the group with the highest suicide risk. Severity of depression, psychotic depression, alcoholism, recent bereavement, abuse of sedatives, and recent development of disability are the most important risk factors in depressed elderly.

Accumulation of chronic medical conditions and isolation that comes with divorce or widowhood as well as cognitive difficulties may also contribute to the increased risk in this population. Aging reduces suicide attempts but increases their lethality. Suicide victims are demographically different from individuals who attempt suicide. About 60 percent of those who commit suicide are men while 75 percent of those who attempt suicide are women. The majority of suicide victims use guns or hang themselves while 70 percent of suicide attempters take a drug overdose, and 20 percent cut or slash themselves. In late life, suicide attempts are often more carefully planned and are preceded by fewer warnings of suicidal intent.

Indeed, unlike the high frequency of suicide attempts in late life, reports of suicidal ideation decrease in older adults. Despite its lower frequency, suicidal ideation is a risk factor for suicide in elderly patients. Severity of depression is the strongest predictor of the course of suicidal ideation. In elderly patients with major depression, suicidal ideation is most common in those with previous serious suicide attempts, high severity of depression, and poor social support.

Depression is the most common psychiatric diagnosis in elderly suicide victims, unlike younger adults in whom substance abuse alone, or with comorbid mood disorders and psychosis are the most frequent diagnoses. Major depression is identified in 80 percent of suicide victims older than 74 years of age. Many elderly suicide victims are widowed and fewer are single, separated, or divorced, compared with younger adults. Depressive symptoms, medical status, perceived health status, cognitive difficulties, and perceived burdensomeness and hopelessness were identified as risk factors for suicidal ideation and death in older adults. Insomnia, one of the most common symptoms of depression at any age and particularly in late life, is an independent risk factor for suicidal ideation in adults and suicidal death in the elderly. It is unclear whether treatment of insomnia can mitigate this risk.

Suicide is also a leading cause of death in patients with bipolar illness. By one estimate, 25 to 50 percent of all patients with BD will attempt suicide at least once in their life, and 8 to 19 percent will die of suicide. Risk factors for suicide in BD include younger age of illness onset, history of past suicide behavior, family history of suicide acts, comorbid borderline personality disorder, substance use disorders, and hopelessness.

The clinical characteristics of depressed elderly suicide victims suggest that identification of depression and appropriate care can reduce the incidence of suicide. The majority of elderly suicide victims see their physicians within a few months of their death and over a third, within a week of their suicide. Among depressed elderly seen in primary care in the 12 months prior to a suicide attempt, less than 5% received appropriate depression treatment prior to the attempt. Therefore, reliable assessment of suicide risk is critical, since protective measures may avert suicide. There

is no evidence that questions about suicide can increase the likelihood of suicidal behavior. Aggressive treatment of depression may prevent suicide, as suicidal ideation is closely associated with depressive symptomatology in older adults. Worsening depression and suicidal ideation may indicate the need for psychiatric hospitalization and/or ECT.

BIOLOGICAL DYSFUNCTION

The Late-Onset Hypothesis

An early hypothesis of late-life depression postulated that major depression with the onset of first episode in late life includes a large subgroup of patients in whom neurological brain abnormalities contribute to the development of the depressive syndrome. Clinical findings supported the "late-onset hypothesis." Relative to older adults with early-onset major depression, individuals with late-onset major depression have less frequent family history of mood disorders, higher prevalence of dementing disorders, and higher rate of dementia development on follow-up, although, some disagreement exists. Most elderly patients with major depression and an initially reversible dementia have late-onset depression. Despite improvement of cognitive functions with remission of the depressive syndrome, many of these patients develop irreversible dementia during long-term follow-up. The "late-onset depression" hypothesis pointed out the importance of aging and disease-related brain changes in late-life depression.

The Depression-Executive Dysfunction Hypothesis

This hypothesis postulates that a "depression-executive dysfunction (DED)" syndrome exists with a clinical presentation resembling medial-frontal lobe syndrome. Clinical studies documented that the DED syndrome is common and characterized by psychomotor retardation, reduced interest in activities, apathy, impaired insight, and severe behavioral disability, but less pronounced depressive ideation and vegetative signs. Patients with depression and executive dysfunction have poor, slow and unstable response to antidepressants. Similarly, depressed older adults who reported executive functioning complaints at baseline had a slower response to escitalopram treatment than those without executive functioning complaints.

The DED hypothesis assumes that executive dysfunction is the clinical expression of frontolimbic dysfunctions predisposing to late-life depression. The limbic system evaluates reward-related stimuli and organizes stress responses, and higher neocortical structures exert control over these processes. A recent study provided evidence for insula metabolism as a treatment-specific biomarker in major depression. Specifically, insula hypometabolism was associated with remission in

response to cognitive-behavioral therapy and poor response to escitalopram, while insula hypermetabolism was associated with remission to escitalopram and poor response to cognitive-behavioral therapy in a mixed-age sample. Reduced bilateral activation of the dorsal-anterior cingulate and the hippocampus was demonstrated in severely depressed, nondemented elderly patients performing a word-activation task. Low resting functional connectivity within the cognitive control network and high-resting functional connectivity within the default mode network distinguished depressed from normal elderly subjects. Low resting functional connectivity within the cognitive control network predicted low remission rate and persistence of depressive symptoms and signs, apathy, and dysexecutive behavior after treatment with escitalopram. In contrast, resting functional connectivity within the default mode network was correlated with pessimism but did not predict treatment response. Patients with the DED syndrome often present with apathy. Resting functional connectivity studies of apathy in late–late-life depression showed that apathy is characterized by abnormalities in the cognitive control network as well as in reward and salience networks.

White matter abnormalities compromising connections between limbic and dorsal cortical structures may interfere with limbic–dorsal balance and lead to chronic depressive syndromes. Subcortical white matter hyperintensities (WMHs) have been associated with both executive dysfunction and nonremission of late-life depression. Complementing these findings, diffusion tensor imaging studies documented that reduced white matter integrity in distributed cerebral networks (dorsal and rostral anterior cingulate cortex [ACC], dorsolateral-prefrontal cortex [DLPFC], hippocampus, posterior cingulate, insula, neostriatum, and the midbrain as well as select temporal and parietal regions) is associated with poor response of late-life major depression to a serotonin reuptake inhibitor. Depressed, older, short serotonin transporter 5-HTTLPR allele carriers had both a lower remission rate than long allele homozygotes, and more microstructural white matter abnormalities in frontolimbic areas. These abnormalities may be caused by inflammatory responses, vascular disease, prominent aging-related changes, degenerative brain disease, or an accumulation of those and other factors.

The Inflammation Hypothesis

The inflammation hypothesis postulates that aging related immune processes promote changes in the emotional and cognitive neural networks predisposing to geriatric depression and/or triggering metabolic brain changes mediating the depressive syndrome in late life. The hypothesis is supported by emerging findings suggesting that: (1) aging leads to a proinflammatory state; (2) immune responses of the CNS can influence the function of some of the emotional and cognitive networks pertinent to

geriatric depression; (3) elevation of peripheral cytokines is associated with depressive symptoms in older adults; (4) some antidepressants reduce the expression of several inflammation markers in the periphery; and (5) pretreatment cytokine plasma levels may influence the response to antidepressants.

Aging promotes a chronic state of neuroinflammation, and animal and human studies suggest that this proinflammatory state may compromise neural systems related to depression. In aged rodents, the cerebral cortex produces more inflammatory cytokines than the cortex of adult animals. In older animals, the inflammatory cytokine IL-6 has higher concentrations in the hippocampus, cerebral cortex, and cerebellum than in the same regions of younger animals. In normal human adults, enhanced activity of the subgenual anterior cingulate cortex and reduced functional connectivity (FC) of the subgenual anterior cingulate with the amygdala, medial-prefrontal cortex and nucleus accumbens during emotional face processing was modulated by a peripheral inflammatory response (IL-6). An SNP encoding IL-1b has been associated with both reduced activity of the anterior cingulate and the amygdala in response to emotional probes and with poor response of major depression to antidepressant. Patients treated with the cytokine interferon-α have greater activation of the dorsal-anterior cingulate than controls. In brain autopsies of suicide victims, increased cytokine concentrations have been found in the orbitofrontal cortex and the DLPFC.

Epidemiologic studies have shown an association between elevation of peripheral cytokines and depressive symptoms in older adults. Increased IL-6 was the most consistent finding. Elevation of IL-1Ra was a risk factor for developing depressive symptoms during a 6-year follow-up in older adults. Clinical studies of depressed patients, documented a plasma elevation of several inflammatory markers (TNF-α, IL-6 and IL-1b) and a correlation with the severity of depressed mood and cognitive symptoms of depression.

Some tricyclic antidepressants (TCAs) may reduce some proinflammatory cytokines, increase anti-inflammatory cytokines, and reduce polysaccharide-induced “sickness behavior” in animals. Pretreatment cytokine plasma levels may influence the response to antidepressants in humans. Selective serotonin reuptake inhibitor (SSRI)-resistant patients had higher TNF-α plasma levels while euthymic patients with a history of depression had TNF-α levels similar to those of normal controls. A higher level of TNF-α was shown to predict failure of depression to respond to escitalopram. The largest study to date reported that patients with baseline low C-reactive protein (CRP <1 mg/L) levels had greater improvement of depression when treated with escitalopram than with nortriptyline. In contrast, patients with higher CRP levels had greater improvement when treated with nortriptyline than with escitalopram. In

treatment-resistant major depression, baseline concentrations of high--sensitivity CRP (>5 mg/L), TNF and TNF-soluble receptors were associated with favorable response to the TNF antagonist infliximab.

The Vascular Depression Hypothesis

This hypothesis postulates that cerebrovascular disease predisposes, precipitates, or perpetuates some late-life depressive syndromes. The hypothesis was based on the high comorbidity of depression and vascular risk factors; the high incidence of depression in stroke; the high prevalence of WMHs in late-onset depression; the high frequency of cognitive impairment in depressed patients with vascular risk factors; and the similarity of cognitive abnormalities of depression to those associated with WMH. Recent studies show greater WMH severity in specific white matter fiber tracts in late-life depression, including the cingulum bundle, uncinate fasciculus, and superior longitudinal fasciculus. Fiber tract structural connectivity is positively correlated with resting state functional connectivity of connected regions.

A syndrome of "subcortical ischemic depression" has been proposed based on WMH literature. This syndrome is defined by the combination of depression and MRI evidence of subcortical ischemic changes. Age, lassitude, and a history of hypertension were positively associated with the diagnosis of subcortical ischemic vascular depression, whereas a family history of mental illness and loss of libido were negatively associated with this diagnosis.

WMH and microstructural brain abnormalities predict poor response of late-life depression to antidepressants. Increases in WMH volume over 2- and 4-year intervals are associated with nonremission or relapse. Microstructural white matter abnormalities in multiple frontolimbic brain areas, including the rostral- and dorsal-anterior cingulate, DLPFC, genu, hippocampus, posterior cingulate, left superior corona radiata, and right inferior longitudinal fasciculum are associated with nonremission.

Disconnection of structures regulating mood and cognition may be one of the mechanisms by which cerebrovascular disease promotes late-life depression. Another mechanism may be vascular dysregulation leading to reduced cerebral blood flow (CBF). Mild CBF reduction may impair cognitive and affective processes, while greater CBF reduction in the context of autoregulatory deficits may cause ischemic injury.

Vascular diseases impair vascular regulation. Vascular changes, including increased intima-media thickness, increased arterial stiffness, and endothelial dysfunction are pronounced in late-life depression and endothelial function may be most impaired in nonresponders to antidepressants. In late-life depression, perfusion deficits are more severe, particularly in the medial- and lateral-prefrontal cortices, subcortical, and temporal structures.

Arguably, at least three interconnected processes may lead to "vascular depression," that is, disconnection of networks responsible for regulation of mood and cognition, reduced regional CBF, and inflammatory responses related to vascular disease. As an example, inflammation leads to vascular remodeling, accelerates vascular damage, and may contribute to perfusion deficits. In turn, regional perfusion deficits adversely affect gray matter function and contribute to the development of WMHs that disrupt regional structural and functional connectivity.

Genetic Studies

Polygenic inheritance has been hypothesized in depression. Multiple genes are associated with common psychiatric disorders, which immeasurably complicates the analysis of associations between psychiatric illness and genetic makeup. Despite convincing evidence for genetic factors contributing and predisposing to depression, there have been few robust molecular genetic findings. A genome-wide associated study (GWAS) of more than 9,000 cases of major depressive disorder (MDD) did not reveal loci that exceeded genome-wide significance. This is consistent with a model of a heterogeneous disorder and/or one in which the majority of genetic variance is due to joint effects of multiple loci of small effects.

Candidate gene studies focusing on biological pathways implicated in MDD have provided conflicting results. Meta-analysis of 26 candidate genes yielded 7 genes with significant findings: *5-HTTP/SLC6A4, APOE, DRD4, GNB3, HTR1A, MTHFR, SLC6A3*, though these genes have not been detected in GWAS.

Based on the observation that SSRIs have antidepressant actions, genetic polymorphisms in the serotonin transporter gene have been the subject of intense research activity. Some promising initial findings included (1) an association between a serotonin 2A-receptor gene variant and citalopram antidepressant treatment response (individuals homozygous for the A allele had an increased rate of treatment response); and (2) glutamate receptor SNPs associated with the development of suicidal ideation during citalopram treatment. Only the serotonin 2A-receptor finding has been replicated, though showing an inverse allelic association as compared to the initial finding.

In many cases, it is possible to identify associations between particular genes and characteristics (endophenotypes) that may predispose an individual toward the development of depression. One such endophenotype is hippocampal volume loss. In a cohort of 138 older adults aged 60 and above, genetic variants at three *AGTR1* SNPs (a gene encoding the angiotensin-II type 1 receptor of the renin–angiotensin system [RAS]) were independently associated with accelerated hippocampal volume loss in the right hemisphere over a 4-year follow-up period. In addition, the *AGTR1* risk alleles predicted worse episodic memory performance and interacted

with the *APOE4* allele to accelerate right hippocampal volume loss. These initial findings suggest that targeting molecules in the RAS may have the benefit in late-life depression. Future work will involve investigating the effects of genetic variation on other relevant endophenotypes of MDD and BD in older adults.

Genetic studies using SNP heritability approaches have provided evidence suggesting that some loci may contribute to both conditions, particularly involving calcium channel signaling. GWAS in BD has identified several risk-conferring variants including markers within the *CACNA1C* gene (encoding the α subunit of the L-type voltage-dependent calcium [Ca2+] channel CaV1.2) and the *ANK3* gene (encoding ankyrin G, a cytoskeletal protein involved in scaffolding in the axon initial segment and in nodes of Ranvier), which may be mechanistically linked through providing signaling integrity in GABAergic neurons. Initial findings have shown that variants in these genes may functionally impact neuronal circuitry involved in affective processing in individuals with BD carrying the risk variants. An additional study analyzing four independent genome-wide data sets along with data contributed to the Psychiatric Genomics Consortium Bipolar Group identified the *CACNA1C* gene as well as pathways involved in hormonal regulation, second messenger systems, glutamate systems, and neuronal development, as contributing to the genetic predisposition and underlying neurobiology of BD.

A Model of Late-Life Depression

Accumulation, and perhaps a synergy, of noxious factors is consistent with the clinical reality of geriatric populations in whom a variety of processes contribute to brain dysfunction, leading to depression and to cognitive impairment. Etiological factors, directly or by causing brain abnormalities increasing vulnerability to depression, promote metabolic changes mediating the expression of depressive syndrome. Etiological factors include cerebrovascular lesions, perfusion-related abnormalities, and inflammatory and repair responses. Abnormalities in frontolimbic and frontostriatal functional architecture resulting from these processes may serve as vulnerability factors for depression. Heredity, epigenetic factors, and psychological vulnerability represent additional predisposing factors. Biological responses to stress may promote processes serving as etiological or vulnerability factors of late-life depression.

Brain Structure Studies

Neuroradiological studies suggest frontostriatal and limbic impairment in depression. WMHs prevalent in geriatric depression are mainly located in subcortical structures and the medial-orbitofrontal cortex. Increase in volume of WMHs over a 2-year period predicted lower rates of sustained

late-life MDD remission during the same period; and worsening of white matter grade in the elderly over a 5-year period has been associated with cognitive decline.

Histopathological and neuroimaging studies of individuals with mood disorders have provided evidence of microscopic and macroscopic changes to several brain regions. Low volumes of the subgenual anterior cingulate, the head of the caudate nucleus, the putamen, and the hippocampus have been noted in mixed-age depressed patients. Reduced hippocampal volume has also been found in depressed elderly patients. Small left hippocampal volume in geriatric depression was associated with later development of dementia. Reduction in orbitofrontal cortex volume has been reported in depressed elderly patients compared to normal controls. Abnormalities in neurons of the DLPFC have been observed in unipolar and BD. Moreover, reduction in glia of the subgenual prelimbic anterior cingulate gyrus has been reported in unipolar-depressed patients. Finally, amygdala volume findings in depressed patients have been mixed.

Brain Function Studies

Increased metabolism has been noted in limbic regions, including the amygdala, the rostral-anterior cingulate, and the posterior orbital cortex. In contrast, dorsal neocortical areas, such as the lateral and DLPFC, and the dorsal-anterior cingulate, as well as the caudate have reduced blood flow during depression. Reduced bilateral activation of the dorsal-anterior cingulate and the hippocampus was demonstrated in severely depressed, nondemented elderly patients performing a word-activation task.

The limbic system evaluates reward-related stimuli and organizes stress responses. Reciprocal pathways link limbic structures with striatal and neocortical sites. It has been proposed that abnormalities in the reciprocal relationship between ventral limbic and dorsal cortical neural systems are a critical physiological disturbance in depression. White matter abnormalities compromising connections between limbic and dorsal cortical structures may interfere with limbic–dorsal balance and lead to chronic depressive syndromes.

A recent study provided evidence for insula metabolism as a treatment-specific biomarker in MDD. In this positron emission-based study, insula hypometabolism (relative to whole-brain levels) was associated with remission in response to cognitive-behavioral therapy and poor response to escitalopram, while insula hypermetabolism was associated with remission to escitalopram and poor response to cognitive-behavioral therapy in a mixed-age sample. This finding will require replication in an independent prospective sample and also in an older-aged sample, but offers promise for the use of brain-based biomarkers in guiding treatment selection in MDD.

COURSE AND OUTCOME

Geriatric Depression

Knowledge of risk factors and periods of high risk for particular adverse outcomes enable the clinician to use appropriate diagnostic methods and offer preventive treatments with favorable risk–benefit ratios. Despite advances in antidepressant therapies, longitudinal studies of 1 to 6 years duration suggest that 7 to 30 percent of geriatric patients have a chronic major depression. If partially remitted subjects are considered chronic, the rate of chronicity reaches 40 percent. Chronicity of depression may be predicted by history of a long current episode or long previous episodes, coexisting medical illness, high severity of depression, nonmelancholic presentation, and delusions.

Naturalistic treatment studies of geriatric populations observed a 13 to 19 percent rate of relapse/recurrence at 1 year, while a 15 percent relapse rate is observed in patients receiving controlled antidepressant treatment. This percentage is lower than the relapse/recurrence rate (34 percent) reported in younger adults. However, if the follow-up of elderly patients with depression is extended from 3 to 6 years, the recurrence rate increases to 38 percent. A 20-year follow-up study of mixed-age patients with depression showed that 95 percent of patients had a recurrence. Patients with only minor or subsyndromal depression have an increased risk (approximately fivefold) of major depression compared with unaffected individuals after 1 year. Depression outcomes are also predicted by initial medical burden, self-rated health, and subjective social support.

Relapse/recurrence appears to have different predictors than recovery of depression. The likelihood of relapse/recurrence may be high in patients with history of frequent episodes, late age of illness onset, history of dysthymia, intercurrent medical illness, and possibly high severity and chronicity of the index depressive episode.

Geriatric Bipolar Disorder

In geriatric BD, relapse and hospital readmission after manic episodes are common as episodes become more frequent and the interval between episodes becomes shorter with age. In comparison to younger patients with BD, there is evidence to suggest that geriatric BD patients have less severe manic episodes, are more likely to relapse into depression after a manic episode, are less likely to experience psychotic symptoms, are more likely to experience rapid cycling between episodes, and are less likely to attempt suicide.

EVALUATION AND TREATMENT OF GERIATRIC DEPRESSION AND BIPOLAR DISORDER

Overview of Geriatric Depression Evaluation and Treatment

The objectives of geriatric depression treatment include the following: (1) remission of depression, (2) reduction in the risk of relapse and recurrence, (3) improvement of cognitive and functional status, and (4) development of skills or provision of supports needed for coping with handicaps and psychosocial adversity. Clinicians should expect an improvement in both disability and excess medical morbidity with adequate treatment.

Geriatric depression can be effectively treated with psychotherapy, pharmacotherapy, or combination treatment. Appropriate behavioral rehabilitation techniques should be combined with antidepressant treatment in order to enable elderly patients to regain function as the depressive syndrome subsides. Long-term outcomes of elderly depressed patients can be improved by (1) identifying and treating comorbid psychiatric and medical conditions, (2) minimizing medication side effects, (3) striving for full remission of acute symptoms, and (4) providing psychoeducation for patients, families, and health care professionals about the illness and the importance of adhering to treatment recommendations, both acutely and after symptom remission.

The evaluation of geriatric depression should include assessment of psychopathology, medical and neurological status, functional impairment, and psychosocial factors as well as suicide risk. For instance, dementing disorders, use of drugs that may cause depression (e.g., steroids), and benzodiazepine and alcohol abuse often contribute to late-life depression and worsen its course. Therefore, attention to these problems should be part of the assessment of depressed elders. A further complexity of assessment includes the risk of missing a bipolar depression diagnosis, as such a diagnosis would alter clinical management and contraindicate the use of antidepressant monotherapy. Rating scales, including the Hamilton Depression Rating Scale, the Cornell Scale for Depression in Dementia, the Geriatric Depression Scale, and the Mini-Mental State Examination or Montreal Cognitive Assessment (MOCA) can be useful in assessment.

Adults with comorbid medical illness including both chronic/deteriorating processes and acute/debilitating events are preferentially affected by late-life depression. Further, a number of other medical conditions such as viral infections, endocrinopathies (e.g., thyroid and parathyroid abnormalities), vitamin B_{12} deficiency, and malignancies (e.g., lymphoma and pancreatic cancer) are often associated with depression. Medical conditions likely to respond promptly to treatment (e.g., amphetamine withdrawal) should be treated first and antidepressants used only if depression persists. For many other medical conditions, however, depression may not remit until an antidepressant agent is used. For example, depression in a hypothyroid elderly patient rarely responds to thyroid supplementation alone. Similarly, an antidepressant trial often is

ineffective before hypothyroidism is corrected. Thyroid supplementation and an antidepressant drug, however, offer the highest probability of antidepressant response.

Some drugs can contribute to or cause late-life depression, such as steroids, antiparkinsonian drugs, benzodiazepines, and β-blockers. If the depression occurs in a patient receiving methyldopa (Aldomet), cimetidine (Tagamet), clonidine (Catapres), hydralazine, propranolol (Inderal), or reserpine, switching to another medication is recommended. If the depression occurs in a patient treated with digitalis, estrogens, tamoxifen (Soltamox), vinblastine, or vincristine, the medication should be continued and depression should be treated with antidepressants. There is no agreement on the best strategy for depression that occurs in patients treated with benzodiazepines, corticosteroids, progesterone, propoxyphene (Darvon), or psychostimulants. As interferon-α treatment frequently is associated with depression, increased frequency of psychiatric follow-up and starting or increasing antidepressant treatment prophylactically should be considered before initiating such treatment in patients with a history of depression.

The evaluation of geriatric depression should also include assessments of the psychosocial situation and functional capacity of a patient, as functional difficulties can lead to physical limitations and social isolation, which can further worsen the course of depression. As a more extreme example, poststroke patients experience a "psychosocial storm" characterized by individual strain (e.g., difficulties with ADLs, demanding rehabilitation for the patient) as well as family/caregiver strain (e.g., alteration of usual family roles in accommodating the increased need of the poststroke family member) that increase feelings of helplessness, hopelessness, and depression in both the patient and the family/caregiver. Indeed, depressive symptoms seem to be increased in caregivers for patients with chronic illness, which is particularly pronounced in caregivers for patients with dementia. Other psychosocial factors to consider include race and ethnicity, as there is evidence for disparities in antidepressant medication prescriptions and symptom severity between different racial and ethnic groups. Further, evaluation of adverse childhood experiences (e.g., physical, sexual, and emotional abuse) should be a part of the assessment, as the negative effects of repeated adverse childhood experiences do not diminish in later life and are associated with depression in older adults.

Psychotherapy for Geriatric Depression

For the treatment of major depression in later life, current practice guidelines recommend a combination of pharmacotherapy and psychotherapy, with psychotherapy alone often sufficing as a first-line treatment for minor depression in later life. Psychotherapy may play an

essential role in the care of bereaved depressed elderly patients or in patients who have significant life crises, lack social support, develop disabilities, or lack coping skills to deal with their life situations. Psychotherapy may be helpful in supporting elderly patients to cope with their symptoms and adhere to treatment before antidepressant drugs take effect, and should be considered in patients who cannot tolerate biological treatments. Telepsychiatry may offer an efficacious option for psychotherapy delivery for homebound elders.

A number of psychotherapeutic modalities including interpersonal therapy, cognitive-behavioral therapy, and problem-solving therapy have been found effective in depressed elderly patients without significant cognitive impairment or medical burden. For patients with executive dysfunction, a number of psychotherapies have been found effective including a modification of problem-solving therapy (PST) where the therapist is more directive, the focus is on less complex problems to facilitate learning, and the program is more structured. Additionally, problem-adaptation therapy (PATH) was developed for older individuals with major depression and intermediate cognitive impairment and disability; this modality combines problem-solving therapy, environmental adaptation tools, and caregiver involvement to target the behavioral limitations inherent in depression and disability.

Extending the focus on the environment, ecosystem-focused therapy (EFT), has been developed to support patients through the "psychosocial storm" of an acute medical illness where depression is often a major contributor to disability and a hindrance in recovery. EFT has been developed as a treatment for poststroke depression. A meta-analysis showed that antidepressants are only weakly efficacious in poststroke depression and the efficacy of conventional psychotherapies is questionable. The aim of EFT is to help the patient develop new perspectives and skills to confront the significant changes to their ecosystem brought on by these acute changes. A preliminary study showed that EFT is more efficacious than education in stroke and depression.

Although psychotherapy has proven to be an effective treatment in this population, it appears to be an underutilized resource. One idea behind the underutilization is that the complexity of available psychotherapies makes their implementation difficult in a general community setting. To streamline both the delivery and language of psychotherapy interventions, it has been proposed that neurobiological constructs be used to identify biologically meaningful behavioral targets that can serve as the basis for simplified and effective treatments. This view of treatment is supported by the RDoC project and has been successfully applied to treatment of late-life depression with the development of "Engage," a psychotherapy using simple-to-learn strategies that target accepted neurobiological domains of late-life depression.

Pharmacotherapy for Geriatric Depression

Overview. Elderly patients benefit from the same psychopharmacological agents as younger patients. Benzodiazepines should generally be avoided. Residual insomnia in depressed elderly patients should be treated with trazodone (Desyrel) and, if it fails, with zolpidem (Ambien), or zaleplon (Sonata). Residual anxiety should be treated with an increase of the dosage of the antidepressant to maximum levels rather than prescribing a benzodiazepine.

Clinical practice guidelines recommend that SSRIs and other second-generation antidepressants (e.g., serotonin-norepinephrine reuptake inhibitors [SNRIs], bupropion, mirtazapine) are the first-line treatment for late-life depression. Late-life depression responds more slowly to antidepressants than depression of younger adults. Executive dysfunction, slow cognitive processing speed, WMH, microstructural white matter abnormalities, and small hippocampal volumes each predict a slower and less complete response to antidepressant treatment. Elderly patients who respond to antidepressant treatment usually require 8 to 12 weeks to achieve full remission. The minimal length of an antidepressant trial should be 3 to 4 weeks before a switch to another antidepressant or an augmentation agent is used. Patients who show no signs of improvement by the 4th week, however, will not likely respond to further treatment with the same agent.

Selective Serotonin Reuptake Inhibitors. Studies of elderly outpatients have shown that SSRIs are equally effective as tertiary amine tricyclics in the acute treatment of late-life depression. The dosages of SSRIs should be increased gradually. The starting daily dosages are 10 to 20 mg for fluoxetine, paroxetine, and citalopram, 5 to 10 mg for escitalopram, and 25 to 50 mg for sertraline. For some patients, daily dosages of 20 mg of fluoxetine, paroxetine, and citalopram, 10 mg of escitalopram, and 100 mg of sertraline are sufficient, although higher dosages may be required. The most frequent side effects of SSRIs are insomnia, akathisia, nausea, anorexia, and pseudoparkinsonism. Inappropriate secretion of antidiuretic hormone (SIADH) leading to hyponatremia is much more common in the elderly than in younger adults. Further, SSRIs may lead to an increased risk of bleeding, fragility fractures, poor mobility, and stroke.

Drug interactions should be considered in elderly patients receiving SSRIs. Fluoxetine and paroxetine inhibit the cytochrome P450 2D6 liver cytochrome isoenzyme. This pathway is essential for the hydroxylation of nortriptyline and desipramine, and the metabolism of antipsychotics and type 1A antiarrhythmic drugs (encainide, flecainide), β-blockers, and verapamil, whose plasma levels may be raised when fluoxetine or paroxetine is administered. The metabolite of fluoxetine, norfluoxetine, is

an inhibitor of the 3A4 isoenzyme. The 3A4 isoenzyme is responsible for the metabolism of alprazolam (Xanax), carbamazepine (Tegretol), quinidine, erythromycin, and astemizole and may lead to an increase in the plasma level of these agents. Sertraline, citalopram, and escitalopram have a weak inhibitory action of the 2D6 isoenzyme and do not inhibit the 3A4. Fluvoxamine (Luvox) inhibits the P450 3A4 and the 1A2 cytochrome isoenzymes, but does not significantly inhibit the 2D6 isoenzyme. Drugs metabolized by the 3A4 should be avoided in patients receiving fluvoxamine. Similarly, theophylline should be cautiously prescribed in fluvoxamine-treated patients since fluvoxamine may produce a threefold decrease in theophylline clearance by inhibiting the 1A2 isoenzyme.

Serotonin-Norepinephrine Reuptake Inhibitors. Venlafaxine XR (extended release) leads to high remission rates (asymptomatic states) and has been found effective in hospitalized depressed patients as well as in drug-resistant depression and in depressed patients with chronic pain. For this reason, venlafaxine should be considered in severe depression and in depression unresponsive to other agents. Elderly patients appear to require dosages comparable to those of younger adults. Daily dosages of 112.5 to 225.0 mg are adequate for the majority of elderly patients. Nausea, a rather frequent side effect of venlafaxine, can be minimized by a slow increase of the daily dosage. Blood pressure should be monitored, especially in patients receiving dosages above 225 mg daily, since venlafaxine can increase blood pressure. Venlafaxine has limited drug–drug interactions and may be selected in elderly patients who require treatment with drugs interacting with other antidepressants. Venlafaxine has a short elimination half-life but the extended-release preparation can be administered in a single dose. Nonetheless, abrupt discontinuation of venlafaxine XR may cause a withdrawal syndrome.

Duloxetine, an SNRI with relatively balanced serotonergic and noradrenergic action, has demonstrated efficacy in late-life depression as well as treatment of comorbid pain. Following a week of 30 mg/day, the dose can usually be increased to 60 mg/day after a week of treatment, if tolerated. For patients who remit on a dose of 60 mg, remission will typically occur by week 12 of treatment with additional time on that dose not associated with an increased chance of remission. For patients who remit on a dose of 60 mg, remission will typically occur by week 12 of treatment; additional time o that dose is not associated with an increased chance of remission.

Levomilnacipran is an SNRI with higher selectivity for norepinephrine reuptake inhibition than other SNRIs and has proven effective for major depression, although studies specific to late-life depression are lacking. However, there is evidence to suggest that individuals older than 60 years of age may have a greater antidepressant response to this medication than

younger individuals. Levomilnacipran is largely metabolized by cytochrome P450 3A4. The medication is intended for once-daily dosing with a starting dose of 20 mg daily. The target dose range is 40 to 120 mg daily.

Tricyclic Antidepressants. The secondary amines, nortriptyline and desipramine, are the most frequently used TCAs in geriatric depression. They have lower anticholinergic and sedative effects than the tertiary amines amitriptyline, doxepin, and imipramine. Nortriptyline appears to have a lower potential for orthostatic hypotension than do other TCAs. The plasma levels of antidepressants required for the treatment of depressed elderly patients are similar to those needed by young adults (nortriptyline plasma levels of 60 to 150 ng/mL and desipramine above 115 ng/mL). Elderly patients often develop therapeutic blood levels of nortriptyline or desipramine while on low daily dosages (nortriptyline 1.0 to 1.2 mg/kg of body weight and desipramine 1.5 to 2.0 mg/kg). Older patients are more likely than younger patients to develop delirium, constipation, urinary retention, dry mouth, and orthostatic hypotension. For this reason, the dosages of antidepressants should be increased at slower pace than in younger adults. Elderly patients on nortriptyline often develop higher plasma levels of the nortriptyline metabolite 10-hydroxy-nortriptyline than do young adults, even when the plasma levels of the parent compound are similar. High 10-hydroxy-nortriptyline levels may contribute to cardiac conduction defects in elderly patients.

Orthostatic blood pressure, the electrocardiogram (ECG), and urination should be monitored frequently in elderly patients receiving nortriptyline or desipramine. Pretreatment systolic orthostatic hypotension has been found to correlate with antidepressant response to nortriptyline in some elderly patients. Therefore, nortriptyline, rather than desipramine, should be considered in such patients and orthostatic blood pressure and subjective symptoms of orthostasis should be monitored carefully. TCAs have anticholinergic properties. For this reason, these drugs should be avoided in patients with prostatic hypertrophy or patients with narrow angle glaucoma. Nortriptyline and desipramine have properties similar to those of type 1A antiarrhythmic drugs (quinidine-like drugs). When administered to patients with right or left bundle branch block, tricyclics may cause second-degree block in approximately 10 percent of cases. For this reason, an ECG should always precede the use of tricyclics in the elderly. A multicenter study (CAST-II) demonstrated that type 1A antiarrhythmics increase cardiac mortality in postmyocardial infarction patients. Although TCAs were not used in this study, the type 1A antiarrhythmic properties of TCAs suggest cautious use in depressed patients with ischemic heart disease.

MAO Inhibitors. Limited information exists on the use of these agents

in the old-old. The MAO inhibitors, however, have been studied in depressed patients who are in their late 60s to early 70s. MAO inhibitors are effective in patients with major depression as well as depressed patients with panic attacks. Low dosages of MAO inhibitors (e.g., phenelzine [Nardil] 30 to 45 mg daily or tranylcypromine 20 to 30 mg daily) should be used in the elderly. Orthostatic hypotension is the most frequent important side effect of MAO inhibitors. This side effect is of concern in the elderly because it may lead to falls and fractures especially of the hip or the humerus. Other side effects include weight gain, insomnia, lack of energy, and daytime somnolence in phenelzine-treated patients and nervousness, insomnia, and excessive perspiration in tranylcypromine-treated patients. Peripheral neuropathy occurs in a small percentage of patients on MAO inhibitors and often responds to pyridoxine. Sympathomimetic amines, monoamine precursors, TCAs, SSRIs, venlafaxine, concomitant administration of two MAO inhibitors, and tyramine-rich food may cause a hypertensive crisis and should be avoided in patients on MAO inhibitors. The selegiline patch (Emsam) does not require diet restrictions at the lowest 6-mg dose and may be safer during diet violation than other MAOIs at higher doses. The advantage of transdermal administration is that intestinal monoamine oxidase is not inactivated to the same degree as for oral administration, reducing the risk of hypertensive crisis triggered by ingested monoamines.

Other Antidepressants. Bupropion, a noradrenaline and dopamine reuptake inhibitor, has proven efficacy in younger adults as well as older adults with major depression based on a number of limited trials of the IR, SR, and XL formulations. Bupropion does not cause cognitive impairment or sedation, is safe in overdose, and lacks significant cardiotoxicity; it should be considered in elderly cardiac patients. Bupropion has few drug interactions, but it should not be prescribed in patients receiving MAO inhibitors. Bupropion may exacerbate pre-existing hypertension and regular monitoring of blood pressure is required. Seizures have been reported in 0.4 percent of patients treated with bupropion, but the risk of seizures can be minimized by the use of sustained release preparations, slow introduction of bupropion (100 mg daily), and restriction of the total daily dosage to 450 mg. Most elderly patients require a total daily dose of 300 mg.

Mirtazapine has been increasingly used in frail depressed nursing home patients with anorexia. Mirtazapine antagonizes the α-2 presynaptic inhibitory receptor as well as the 5-HT2 and the 5-HT3 serotonin receptors. Mirtazapine is an antagonist of histaminergic receptors and has a mild antagonist effect on the α-1 adrenergic and muscarinic receptors. These effects account for the sedative, hypotensive, and anticholinergic side effects of mirtazapine. Mirtazapine is not an inhibitor of the P450

cytochrome. Side effects include somnolence, dizziness, increased appetite, weight gain, and hyponatremia. Mild increase of cholesterol and triglycerides has been observed in 15 and 6 percent of patients, respectively. The starting dosage of mirtazapine is 15 mg and should be administered at bedtime to reduce sedation. Daily dosages from 30 to 45 mg are sufficient as a rule for the treatment of late-life depression.

Vortioxetine inhibits the serotonin reuptake protein, is an agonist of the serotonin 1A and an antagonist of the serotonin 3 receptor. It is also an antagonist of the serotonin 1D and 7 receptors and a partial agonist of the serotonin 1B receptors, although with somewhat lower affinity. Vortioxetine has been found effective in late-life depression and it may improve memory and executive dysfunction, although the clinical significance of the cognitive findings is unclear at this point. The starting dose is 10 mg daily, and a range of 5 to 20 mg dosages is efficacious. Vortioxetine neither inhibits nor augments liver enzymes. But it is metabolized by the 2D6 isoenzyme and its dosage should be adjusted when coadministered with 2D6 inhibitors or inducers.

Psychostimulants may be ineffective in elderly patients with major depression. Dextroamphetamine and methylphenidate (Ritalin), however, appear to improve apathy and anergy in medical patients or cognitively impaired patients. Dextroamphetamine or methylphenidate at dosages 5 to 10 mg in the morning and at noon is sufficient. Psychostimulants have rapid onset of action, minimal side effects, limited potential for tolerance, and low risk for addiction.

Complementary and Alternative Medicines. There are a number of natural supplements with some evidence of efficacy in geriatric populations. For instance, omega-3 fatty acids, St. John wort, and *S*-adenosyl-*L*-methionine (SAMe) have shown some benefit for depression in a limited number of small studies in older adults. St. John wort must be used with caution in geriatric populations due to drug–drug interactions through induction of cytochrome P450 3A4.

Somatic Treatments

ECT. ECT should be considered in both geriatric depression and mania because of its efficacy, rapid onset of action, and safety. ECT may be chosen in patients with severe mood syndromes unable to tolerate the long waiting imposed by the gradual introduction of antidepressants or mood stabilizers and the slow onset of drug action in the elderly. In addition, ECT can be effective in treating neuropsychiatric comorbidities such as catatonia and parkinsonism often present in the depressed elderly.

ECT treatment characteristics must be chosen with an eye to maximizing treatment efficacy while minimizing cognitive side effects. An example of one such consideration is that ECT administration as often as

three times weekly appears beneficial in producing a more rapid recovery than ECT given twice or once a week, yet less frequent ECT is associated with less cognitive impairment in the time period shortly after ECT. No differences in cognition have been found, however, 1 month after ECT completion between groups that had ECT thrice or twice weekly. ECT treatment variables to consider are electrode placement (right unilateral vs. bilateral), treatment frequency, and stimulus intensity (energy), duration, pulse width, and pulse frequency. The effects of these choices are described elsewhere in this book. High-dose, ultra-brief, right unilateral ECT treatment has become a common choice due to reports of equal efficacy and reduced cognitive side effects compared with bilateral ECT.

The mortality rate for all ages following a single ECT treatment is approximately 1 per 80,000 treatments, corresponding to 1 per 10,000 ECT-treated patients. This rate may be higher in the elderly with severe medical conditions, but it appears to be lower than that for some medication treatments (TCAs), and there is some evidence that it may be compensated for by decreases in mortality following hospitalization (compared with depressed patients receiving other forms of treatment or no treatment at all). The majority of deaths (67 percent) related to ECT are due to cardiac complications and occur immediately after ECT or within a few hours from treatment. Compared to younger adults, elderly patients and patients with pre-existing cardiac disease are more prone to cardiovascular events occurring in the context of ECT, including ischemic syndromes, arrhythmias, decompensation of heart failure, and transient severe rise in blood pressure. With adequate medical evaluation, however, monitoring during and after ECT, and appropriate intervention, most cardiovascular events related to ECT have a benign outcome.

Geriatric patients require a longer time to recover their memory than younger adults, especially after bilateral ECT. Moreover, geriatric patients sometimes develop prolonged confusion after ECT. The increase in falls with ECT has been reported as up to 15 percent of elderly patients. Controlled studies, however, are needed in order to examine whether and to what extent ECT-related confusion is responsible for these falls. The practice of favoring ECT over antidepressants in medically ill depressed patients may have led to inflated reports of ECT-related morbidity. Anecdotal literature suggests that ECT was used uneventfully in patients over 100 years old and in elderly patients with aortic aneurysm, cardiac pacemaker, history of myocardial infarction or stroke, transient ischemic attacks, severe hypertension, arrhythmias, or need for anticoagulants.

Other Therapies

Vagal nerve stimulation (VNS) is an FDA-approved treatment for chronic and recurrent depression. Through an implanted generator, electrical signals are delivered to the left cervical vagus nerve where it is postulated

that stimulation of the afferent fibers leads to modulation of mood-related networks (e.g., amygdala and locus coeruleus). Although studies of efficacy in geriatric depression are lacking, VNS does not carry an increased risk of surgical complications and does not necessarily increase the risk for cardiac abnormalities in this population. Transcranial magnetic stimulation (TMS) is also FDA approved for the treatment of depression. In this noninvasive procedure, an electromagnetic field is generated that depolarizes neurons leading to modulation of cortical activity. Although this procedure is well tolerated with minimal cognitive side effects, there is some evidence that TMS is less effective in older patients. Another preliminary study with TMS, however, showed significant reduction of depressive symptoms in poststroke depression. Bright light treatment is another noninvasive treatment with some evidence of efficacy in geriatric depression.

Treatment of Bereavement

Most bereaved elderly individuals do not develop clinically significant depressive symptoms. For this reason, prophylactic treatment is not recommended for the entire bereaved elderly population. Self-help groups, counseling, group therapy, and individual psychotherapy should be considered for individuals with an intense reaction to loss or history of depression. Bereaved persons with depressive symptomatology that does not meet criteria for major depression may benefit from brief focused psychotherapy. Interpersonal therapy lends itself well for this purpose since it addresses issues related to loss, depression, and change of roles. Although antidepressant drugs can be effective in bereaved elderly with depressive symptoms, clear guidelines are not available. If major depression develops during the bereavement period, antidepressant treatment should be considered. Some clinicians suggest that psychotherapy and/or antidepressant drugs should be administered if bereavement lasts longer than 1 year.

Complicated grief, a persistent complex bereavement disorder characterized by prolonged acute grief, feeling that life has no meaning, avoidance behaviors, and dysregulated emotions, has been identified in DMS-V as a condition in need of further study. Complicated grief treatment (CGT) has been developed as a 16-week treatment with components of prolonged exposure, IPT, and motivational interviewing and has been found to be more efficacious in symptom improvement than IPT in older adults. It appears that antidepressants may enhance the response to CGT but that antidepressants alone may be ineffective.

Treatment of Psychotic Depression

For treatment of psychotic depression, the recommended treatment includes combinations of antidepressants (SSRIs or venlafaxine XR) and

atypical neuroleptics (except clozapine), although there are limited clinical trials for older adults. In one multicenter 12-week double-blind randomized controlled trial (STOP-PD), combination pharmacotherapy with olanzapine and sertraline was associated with higher remission rates during the trial period compared to olanzapine plus placebo in patients. ECT treatment is another option, especially if combination drug treatment fails or is poorly tolerated.

Treatment of Depression in Dementia

In elders with major depression and mild-to-moderate dementia, the historical treatment of choice was combination of an antidepressant with psychosocial intervention, although there are limited data to support the use of antidepressant medication. Indeed in a large, well-powered study not only were antidepressants (i.e., sertraline and mirtazapine) found ineffective in depressed demented patients, but they also were associated with more adverse effects than placebo. Psychosocial interventions such as PATH and caregiver-focused treatment may be a better option for first-line treatment in this population.

Treatment-Resistant Depression

Change in antidepressant strategy should take into consideration that depressed older patients take longer time to respond to antidepressants than younger adults. If a patient has had little or no response to an adequate antidepressant trial, switching to a different antidepressant rather than using an augmenting agent is an appropriate first step. If a patient has had little or no response to an initial SSRI, the patient may be switched to an SNRI, or bupropion SR or XL. If a patient has had little or no response to venlafaxine, the patient may be switched to an SSRI. If the patient has had little or no response to a TCA or bupropion, switching to an SSRI or SNRI is appropriate. Although studies in geriatric subjects are lacking, research in younger patients suggests that switching from one SSRI to another is an effective strategy.

Augmentation therapies are recommended in depressed elders with partial response to the initial antidepressant, although there is limited agreement on the use of augmentation therapies. Bupropion, lithium, or nortriptyline may be added if the initial antidepressant is an SSRI. If the initial antidepressant is a TCA, lithium or an SSRI may be added. If the patient was on bupropion, an SSRI or lithium may be added. An additional augmentation strategy in older adults is the combination of an SSRI or SNRI plus mirtazapine. In a study of middle-aged adults (mean age in mid-40s), mirtazapine (30 mg) plus fluoxetine (20 mg), venlafaxine (225 mg) or bupropion (150 mg) achieved greater remission rates (46 to 58 percent) after 6 weeks than fluoxetine monotherapy (25 percent). Among those who

responded, double-blind discontinuation of one agent led to relapse in 40 percent of the cases.

Addition of methylphenidate may be helpful to accelerate treatment response to an SSRI antidepressant. Treatment with an atypical neuroleptic, alone or in combination with other medications, is sometimes effective for treatment-resistant depression. Augmentation of antidepressants with aripiprazole or quetiapine XR has been found effective in younger adults, but controlled studies are lacking in older adults. It should be noted, however, that the use of antipsychotic agents (both atypical and typical) in older individuals with dementia has been associated with a greater risk of mortality and increased risk of cerebrovascular events. When medication treatment fails, ECT may offer the best chance for response and remission.

Continuation and Maintenance Treatment

The intent of continuation treatment (6 months) is to prevent relapse of the acute episode, while maintenance treatment is offered after the first 6 months of remission in order to prevent a new depressive episode. Continuation and maintenance treatment should use the same dosages of antidepressants as those of acute treatment. Continuation treatment should be offered to all patients with late-life depression. Patients at high risk for recurrence should have maintenance treatment. The strongest predictor of recurrence is a history of three or more lifetime episodes of depression. For such patients, experts recommend treatment for 3 years or longer. Disagreement exists concerning the optimal maintenance treatment duration in elders with fewer episodes. Other predictors of depression recurrence are high severity of the initial episode and persisting anxiety, and in mixed-age populations, late age of illness onset is a strong predictor of recurrence. In patients with psychotic depression who achieve remission following treatment with an antidepressant and an antipsychotic, continuation of the antipsychotic drug is recommended, typically for 6 months, but some experts recommend shorter or longer treatment. For depressed patients who failed antidepressants but responded to ECT, antidepressants (other than those to which the patient previously failed to respond) plus a mood stabilizer should be used for continuation/maintenance treatment. Continuation/maintenance ECT is another option.

Adherence. Approximately 70 percent of patients fail to take 25 to 50 percent of their medications. Older patients and their families often have difficulty accepting the diagnosis of depression and understanding the need for long-term treatment. Concurrent medical illnesses may interfere with antidepressant response or attainment of adequate dosages. Alcohol and other substance use disorders may undercut pharmacotherapy. Difficulties

accessing health care may hinder the ability of elderly, especially functionally dependent elderly, to obtain adequate treatment.

Care Delivery

Several interventions have been developed to improve the treatment of geriatric depression in the primary care setting. The Improving Mood-Promoting Access to Collaborative Treatment (IMPACT) study focused on older adults and offered access for up to 12 months to a depression care manager who was supervised by a psychiatrist and an expert primary care physician. The depression care manager offered education, care management, and support of antidepressant management by the primary care physician or problem-solving therapy (a brief structured psychotherapy). Depressed elderly primary care patients receiving the IMPACT intervention were more likely to receive antidepressants or psychotherapy than usual care patients. They had lower depressive symptomatology and higher overall function, response and remission rates, quality of life, and satisfaction with treatment. These benefits were sustained 12 months after the end of the intervention.

Positive outcomes have also been reported by the Prevention of Suicide in Primary Care Elderly: Collaborative Trial (PROSPECT). The lynchpin of the PROSPECT intervention was the use of care managers, who were trained social workers, nurses, and psychologists who worked alongside with primary care physicians. They followed the patients and monitored their psychiatric symptoms and signs, treatment adherence, and side effects, and provided appropriately timed and targeted recommendations to physicians according to an algorithm. Patients treated in practices offering the PROSPECT intervention had a higher likelihood to receive antidepressant treatment, a greater decline in the rate of suicidal ideation, and a more favorable course of depression over a period of 24 months. The beneficial effects of the PROSPECT intervention were most pronounced in primary care patients with major depression rather than minor depression.

The concept of an integrated care model has been extended to depressed patients with chronic medical illnesses. The personalized adherence intervention for depression and COPD (PID-C) is an integrated approach implemented by care managers to improve adherence to treatment for both COPD and depression with a focus on helping patients to overcome barriers to treatment and offering interventions that support patients in using treatment prescribed by their own physicians. PID-C reduced depressive symptoms and dyspnea-related disability more than usual care.

Overview of Geriatric Bipolar Disorder Evaluation and Treatment

The goals of geriatric BD include symptom amelioration (i.e., resolution of

mania, remission of depression, and maintenance of euthymia) as well as improvements in functional status and prevention of recurrences. The evaluation of geriatric BD should include a comprehensive assessment exploring comorbidity (psychiatric, medical, and neurological), functional status, and psychosocial factors. Further, substance use disorders are common in geriatric BD patients and should be routinely assessed and treatment offered in the evaluation period. Medications should be evaluated as well, given that medications such as corticosteroids and dopaminergic agents such as stimulants and antiparkinsonian drugs can precipitate mania.

Bipolar elderly patients often have limited, slow, or fragile treatment response. Guidelines for dosage and duration of treatment with antimanic agents cannot be extrapolated directly from younger adult studies because aging, comorbid neurological diseases, high medical burden, and poor social support may directly or indirectly, through poor adherence, interfere with treatment response of late-life BD and increase vulnerability to side effects.

Pharmacotherapy for Geriatric Bipolar Disorder

Lithium is the best investigated drug in geriatric mania. Lithium may be less effective in mania with comorbid neurological and medical disorders, than in uncomplicated mania. Age-associated decline in renal clearance in elderly patients leads to high lithium plasma levels even when low dosages are used. Lithium should be introduced slowly, starting with daily dosages of 150 mg. About one-half of the dosage required for young adults is sufficient for the elderly. The half-life of lithium is about 24 to 36 hours in patients who are in their 70s. Therefore, steady-state pharmacokinetics is anticipated 5 or more days after the stabilization of the daily dosage. In some elderly patients, lithium plasma levels of 0.3 to 0.6 mEq/L were found to be effective. Controlled studies, however, are needed to establish the efficacy of low lithium plasma levels in the elderly. The onset of action of lithium is slow and may require several days or weeks.

The side effects of lithium are pronounced in geriatric patients. Elderly patients often develop a fine tremor or myoclonus at lithium plasma levels considered nontoxic in young adults. Lithium can produce parkinsonian symptoms or worsen pre-existing Parkinson disease. Delirium can develop at plasma levels below the therapeutic range. Neuroleptics increase the risk of delirium in elderly patients on lithium. Lithium may worsen cognitive function, especially in demented patients. Sinoatrial block may be caused by lithium in predisposed patients; digitalis and β-blockers increase the risk for sinoatrial block. Salt depletion, thiazide diuretics, and nonsteroidal anti-inflammatory drugs may raise the lithium plasma levels and result in toxicity. Chronic kidney disease appears to be common in older adults treated with lithium.

The antiepileptics sodium divalproex, carbamazepine, and lamotrigine are effective for preventative treatment in BD. Anticonvulsants are effective in both lithium responders and lithium nonresponders. Anticonvulsants may be more effective than lithium in patients with rapidly cycling mania or dysphoric mania. Although there is limited research in elderly populations, they should be considered especially in patients at high risk for lithium toxicity or history of poor response to lithium. Drowsiness and sedation are frequent dose-dependent side effects of valproate and carbamazepine. Many patients are habituated to sedation. Therefore, slow introduction of valproate or carbamazepine may reduce this problem. In the elderly, the principal side effects of valproate are gastrointestinal distress and ataxia. Frequent side effects of carbamazepine are ataxia and confusion. Rarely, carbamazepine can cause hyponatremia. Approximately 0.4 percent of patients receiving valproate and 2.0 percent of patients receiving carbamazepine develop leukopenia with a white count below 4,000/mm^3. Valproate may cause thrombocytopenia in older patients much more frequently than in younger adults. Carbamazepine-treated patients have a reduction in their white blood cell count during the first 2 weeks. For this reason, periodic monitoring of the white count is indicated especially during the early phases of treatment.

Lamotrigine is generally well tolerated and does not cause weight gain, sedation, sexual side effects, or cognitive impairment. It helps mainly for depression, which for most bipolar patients is a greater concern than mania or hypomania. Mild rash is common and the risk of serious, but not life-threatening rash is approximately 1 in 250. The risk of Stevens–Johnson syndrome is approximately 1 in 1,000, or perhaps lower, with cautious uptitration as recommended to reduce the rash risk. Lamotrigine should be stopped immediately if a rash develops. Simultaneous treatment with valproate can more than double lamotrigine's half-life, so such patients should start at no more than 25 mg every other day with dose increases no more than once every 2 weeks in the first weeks. Effective doses are usually 100 to 200 mg/day. Thus, a drawback with lamotrigine is that it can take weeks to reach a therapeutic dose.

Agitated manic elderly patients may be treated with low dosages of lorazepam. Lorazepam is favored over other benzodiazepines because it undergoes only phase II metabolism (glucuronidation), a process minimally affected by aging. Effective alternatives to lorazepam are atypical and high-potency neuroleptics in oral (e.g., risperidone 1 to 2 mg, olanzapine 5 to 10 mg daily) or injectable (e.g., haloperidol 0.5 to 5 mg daily) form. These drugs should be used early in the treatment of acute mania and should be withdrawn when the agitation is controlled and therapeutic plasma levels of a mood stabilizer are established.

In addition to agitated mania, antipsychotic agents may also be useful in the treatment of mania as well as bipolar depression. For instance, there

is evidence that atypical antipsychotics including olanzapine, risperidone, and quetiapine may be effective in the treatment of geriatric mania while quetiapine and lurasidone may have some efficacy in bipolar depression. The increased risk of weight gain, hyperlipidemia, and diabetes associated with at least some atypical neuroleptics raises the risk of cardiovascular disease.

Antidepressant use in BD is controversial due to concern about antidepressant-induced mania or mixed states, although studies of such complications are limited in older populations. Recent work has shown that antidepressant use is as high as 72 percent in older adults with BD.

Other Treatments for Geriatric Bipolar Disorder

ECT is efficacious in late-life bipolar depression. Limited data support the efficacy of ECT in the treatment of mania in older adults. TMS may be a treatment option for geriatric bipolar depression, but further study is needed to further clarify the efficacy and safety in this population. Cognitive-behavioral therapy, family-focused therapy, and interpersonal social rhythm therapy have been shown to be effective as adjuncts to medications in shortening the time to remission from a depressive episode. Psychosocial interventions targeting adherence to treatment such as the customized adherence enhancement (CAE) therapy have been found effective in geriatric BD in improving treatment adherence, reducing mood-related symptoms and signs and global psychopathology, and improving functioning.

FUTURE DIRECTIONS

The medical and neurological comorbidity of geriatric mood disorders, although it complicates care, has served as a window to mechanisms contributing to geriatric mood disorders. The clinical association of depressive symptoms with impairment in specific cognitive functions has been a central stimulus to research in geriatric depression. Studies of the integrity of white matter in distinct brain regions have begun to identify abnormalities leading to disconnection states contributing to late-life depression and executive dysfunction. Advances in neuroimaging and electrophysiology make possible the identification of structural, functional, and processing abnormalities predisposing depressed elderly patients to poor response to antidepressants or to mood stabilizers. Genetics research identified some polymorphisms that increase the risk of resistance to some antidepressants. Neuroimaging studies are underway to identify the mechanisms by which genetic factors increase resistance to antidepressants and also to investigate endophenotypes of geriatric mood disorders and biomarkers that may predict response to specific treatment interventions.

With the recently advanced hypotheses of geriatric depression, there is

the promise to guide novel treatment development. For example, studies of the "DED syndrome" demonstrated that executive dysfunction and structural and functional abnormalities of the cognitive control system are associated with poor response to antidepressant drugs. However, appropriately modified problem-solving therapy reduced both depression and disability more than supportive therapy in depressed, nondemented patients with major depression and executive dysfunction. PATH was developed in order to address the clinical needs of depressed older adults with cognitive impairment up to moderate dementia. A neuroplasticity-based computerized cognitive remediation-geriatric depression treatment (nCCR-GD) was developed to target executive dysfunction in late-life depression. The underlying assumption was that remediation of these deficits may improve the functional brain networks shared by ED and depression. In a preliminary study, nCCR-treated depressed older adults showed greater improvement in executive functions than historical controls treated with escitalopram. Future work may investigate whether nCCR alone or in combination with TMS or pharmacotherapy may ameliorate specific cognitive dysfunction and improve outcomes in geriatric depression and BD.

While the inflammation hypothesis of late-life depression has generated interest in the role of anti-inflammatory agents in the treatment of late-life depression, many questions remain. The position of inflammation in the chain of biological events leading to late-life depression needs to be clarified. Assuming that the brain's inflammatory responses have regional specificity, it is unclear whether the localization of these responses influences the clinical profile of late-life depression and its course. In addition, the role of peripheral inflammatory indices in determining the choice of antidepressants needs to be further understood.

Minocycline, a microglia inhibitor, has been shown to reduce depression-like behavior in animal models of depression. Anecdotal evidence suggests that minocycline can augment the action of antidepressants in major depression. Etanercept, an agent that reduces TNF-α–mediated cellular response, reduced symptoms of depression in a placebo-controlled study of patients with psoriasis. The cyclooxygenase-2 inhibitor, celecoxib, has been found to augment the efficacy of reboxetine and fluoxetine in patients with MDD. In treatment-resistant major depression, baseline high concentrations of high-sensitivity CRP predicted favorable response to the TNF antagonist, infliximab. Adequately powered randomized controlled trials need to clarify which anti-inflammatory agents have antidepressant action and for whom.

Studies need to ascertain whether antihypertensive, antihypercholesterolemic, and antiplatelet agents and diabetes control improve the outcome of vascular depression. Longitudinal assessment of depressive symptomatology during antiplatelet secondary prevention trials

can evaluate the efficacy of these agents in improving the course of vascular depression. Modulators of the RAS improve cerebral perfusion and may improve cognition, although they have not been studied in vascular depression. Finally, anti-inflammatory agents may have a role in vascular depression but studies are lacking.

Advances in biology and psychotherapeutic interventions, along with clinical and psychosocial studies of the comorbidity and social complexity of geriatric mood disorders, are generating knowledge on which to build comprehensive models of care. For programs such as PID-C to become part of the mainstay of clinical treatment of late-life depression, their efficacy, implementation potential, and fiscal feasibility need to be demonstrated. The IMPACT and PROSPECT interventions are concrete examples of treatment models that address the clinical complexity of geriatric depression and the barriers imposed by the primary care setting. Reimbursement constraints remain a barrier to the implementation of such programs. Studies are underway that build on the principles of these models and focus on existing services supported by the available reimbursement system. Such studies offer focused training to clinicians and interventions at the organizational level to increase functional collaborative relationships between primary care practices and already funded independent mental health clinics. Further research is needed to find efficient interventions and to weigh costs versus benefits in various elderly populations with distinct needs.

57.3f Alzheimer Disease and Other Neurocognitive Disorders

GARY W. SMALL, M.D., AND STEPHEN T. CHEN, M.D.

INTRODUCTION

In part because of medical technologic advances, people in industrialized societies are living longer, and the number of older persons is growing rapidly. Because age is a major risk factor for developing Alzheimer disease and other neurocognitive disorders (NCDs), the number of persons suffering from these illnesses has increased as well. In most cases, the cause of Alzheimer disease is not known. Rarely, one of several genetic mutations having an autosomal dominant inheritance pattern causes the disease with symptoms emerging in mid-life. Scientists are actively searching for more effective treatments and possible cures, and improved knowledge of potential risk and protective factors may contribute to preventive strategies. Along with such approaches, accurate early diagnosis, symptomatic treatments, and family interventions are essential to minimize the suffering of patients and family members and to maximize the quality of life for patients.

HISTORY

In 1906, the German psychiatrist and neurologist Alois Alzheimer first described a middle-aged patient who had suffered from a progressive dementia that affected language, memory, and behavior. After the patient's death at age 55 years, Alzheimer applied new staining techniques to the patient's brain tissue and demonstrated the presence of what are now termed neurofibrillary tangles and neuritic plaques in the neocortex and other brain regions. For years, Alzheimer disease was considered a presenile dementia, partially because some plaques and tangles occurred in

elderly persons without dementia and some elderly persons with dementia had few plaques and tangles. Such conflicts were resolved, however, in the late 1960s, when the degree of dementia was shown to correlate with the number of neuritic plaques in neocortical association areas. Moreover, causes of senile dementia other than Alzheimer disease were also recognized.

Over the last few decades, the recognition that cognitive decline may be pathologic rather than normal in aging has helped to drive scientific advances but also served to stigmatize the condition. Many older people have been reluctant to seek help for memory symptoms because of fear that they may be suffering from Alzheimer disease. Thus, symptomatic treatments are often begun after patients are already suffering from moderate degrees of dementia. However, if treatments that delay the onset of Alzheimer disease can be developed, there may be less emphasis on treatment of the disease state and greater attention to prevention and deceleration strategies, reducing the stigma and increasing access to care.

COMPARATIVE NOSOLOGY

A definitive diagnosis of Alzheimer disease can be made only by histopathologic examination of brain tissue, generally postmortem. Therefore, most cases are diagnosed based on clinical information and, in some settings, additional diagnostic studies.

Diagnostic criteria for dementia and Alzheimer disease were recently updated in two important references. In the fifth edition of the *Diagnostic and Statistical Manual* (DSM-5) published in 2013, the syndrome of dementia from the revised fourth edition (DSM-IV-TR) is subsumed under the new category "Major Neurocognitive Disorders." A comparison of their respective diagnostic criteria is shown in Table 57.3f–1. The essential features are similar, with some key differences. While dementia in DSM-IV-TR requires memory impairment plus one other type of cognitive disturbance that are gradual in onset and progressive, a major NCD requires a significant decline in at least one cognitive domain based on subjective concern and clinical assessment. For both diagnoses, specific etiologies, the most common being Alzheimer disease, may be added as specifiers; DSM-5 provides additional diagnostic criteria for these specific NCD subtypes.

In 2011, a work group formed by the National Institute on Aging and the Alzheimer Association (NIA-AA) published diagnostic guidelines for "probable" and "possible" Alzheimer disease. Criteria for both are similar to those for a major NCD, but require cognitive impairment based on history and objective cognitive assessment and a minimum of two cognitive or behavioral domains affected. Probable Alzheimer disease further specifies that cognitive impairment is insidious in onset, progressive, and prominent in memory, language, visuospatial, or executive functioning. Possible

Alzheimer disease should be considered when the course is atypical or cannot be reliably documented and there is evidence of other etiologies, for example, cerebrovascular disease or Lewy body dementia.

Both DSM-5 and the NIA-AA group recognize milder levels of cognitive impairment or a predementia stage of Alzheimer disease. In DSM-5, "Mild Neurocognitive Disorders," which feature "modest" cognitive decline and no functional impairment, was added as a new diagnostic category to encourage earlier diagnosis and intervention, which may more effectively modify the course of illness than that in the later stages. The NIA-AA guidelines refer to the predementia stage as "mild cognitive impairment (MCI)." Core clinical criteria for MCI include concern for cognitive changes, impairment in one or more cognitive domains, preferably measured by serial objective testing, preserved independence in daily activities, and no evidence of dementia and other etiologies of cognitive impairment. While either minor NCD or MCI can be diagnosed with only clinical data, the DSM-5 and the NIA-AA guidelines both refer to research biomarkers for Alzheimer disease that may aid diagnosis, particularly in the earlier stages of disease. Such biomarkers include structural neuroimaging with magnetic resonance imaging (MRI), molecular neuroimaging with positron emission tomography (PET), cerebrospinal fluid analysis, and genetic testing.

EPIDEMIOLOGY

NCDs are the most common psychiatric disorders in older persons and a growing public health problem in the United States. Alzheimer disease accounts for about 60 percent of late-onset NCDs. It is estimated to afflict from 5 to 10 percent of people of age 65 years and accounts for the most striking rise in dementia incidence in the very old. Alzheimer disease and other NCDs cost society each year over $400 billion in direct (i.e., actual dollar expenditures) and indirect costs (i.e., resource losses not involving dollar expenditures). The greatest risk factor for developing Alzheimer disease is age: its incidence and prevalence double every 5 years after age 60 years. Over 5 million Americans suffer from Alzheimer disease. As the baby boom generation (born between 1946 and 1964) ages, this number is expected to triple by 2050, to as many as 16 million. The prevalence of MCI may be as high as 19 percent in people older than age 65 years and 29 percent in those older than age 85 years.

Table 57.3f–1.
Comparison of Diagnostic Criteria for Major Neurocognitive Disorders in Fourth-Text Revision and Fifth Editions of the Diagnostic and Statistical Manual (DSM-IV-TR vs. DSM-5)

	DSM-5 Major Neurocognitive

	DSM-IV-TR Dementia	Disorders
Core Criteria	Multiple cognitive deficits: Memory plus one or more of the following: - Aphasia (language) - Apraxia (motor tasks) - Agnosia (identifying objects) Gradual onset and continuing cognitive decline	Decline in one or more of the following cognitive domains: - complex attention memory/learning - language - perceptual-motor - executive functioning - social cognition
Functional Criteria	Cognitive deficits cause significant impairment in social or occupational functioning and represent significant decline	Cognitive deficits interfere with independence in everyday activities
Exclusion Criteria	Core criteria do not occur exclusively during delirium Not better accounted for by another axis I disorder	Core criteria do not occur exclusively during delirium Not better accounted for by another mental disorder

ETIOLOGY

The search for possible causes for Alzheimer disease remains inconclusive. Scientists have made significant advances, approaching this search from various angles, which include genetics, neurochemistry, neuropathology, and neuroimaging studies. Hopefully, this search will eventually lead to treatments that may delay or even halt the disease process.

Alzheimer disease was first characterized and remains pathogenetically defined by its histopathologic features, neuritic plaques (extracellular deposits of amyloidogenic proteins), and neurofibrillary tangles (abnormal intracellular cytoskeletal filaments). Reduction in neuron number and synapses and an accumulation of plaques and tangles occur in the frontal, temporal, and parietal lobes; that finding is consistent with the involvement of association and limbic brain structures.

Extensive study of the formation of plaques and tangles has led to two prevailing hypotheses to explain the mechanisms that lead to Alzheimer disease: the cholinergic and the amyloid cascade hypotheses. The cholinergic hypothesis says that a dysfunctional cholinergic system causes the symptoms of Alzheimer disease. Clinical evidence suggests that anticholinergic medications impair cognitive function in older adults, and biochemical and neuropathologic evidence confirm a presynaptic cholinergic deficit in brains with Alzheimer disease. The amyloid hypothesis states that Alzheimer disease is caused by the excess accumulation and deposition of β-amyloid to form neuritic plaques. Additionally, the accumulation of β-amyloid is believed to result in neuronal dystrophy and neurofibrillary tangles and induce cholinergic dysfunction, oxidative stress, inflammation, and vascular damage.

Discoveries in the area of genetics and molecular biology have been critical to our understanding of the etiology of Alzheimer disease and

shown relationships between genes and pathogenesis. The increased frequency of Down syndrome (trisomy 21) patients who invariably develop Alzheimer disease neuropathology and dementia by their 40s led to finding significant linkage to chromosome 21 in some early-onset families. Excitement escalated when the gene coding for the amyloid precursor protein (APP) found in senile plaques was localized to the same chromosome 21 region. APP mutations, however, are relatively rare. Most early-onset pedigrees not segregating APP mutations show mutations of a chromosome 14 gene (presenilin 1). Another form of early-onset Alzheimer disease is represented by families of Volga German origin, in whom chromosome 1 mutations (presenilin 2) have been identified.

Studies of the common late-onset disease (symptoms beginning after age 60 years) showed evidence for linkage or association or both for a chromosome 19 region. Apolipoprotein E (APOE) was a candidate Alzheimer disease susceptibility gene partly because APOE and cerebrospinal fluid bound to immobilized β-amyloid peptide and antisera to APOE stain senile plaques and neurofibrillary tangles. In addition, APOE localized to the same region of chromosome 19 identified in linkage studies.

APOE has three allelic variants (2, 3, and 4). Everyone inherits one allele from each parent, so that five common genotypes are possible (2/3, 3/3, 2/4, 3/4, and 4/4). The sixth genotype (2/2) is rare. In the general population, approximately 3 percent of persons have the 4/4 genotype, 20 percent have the 3/4 genotype, and most people have the 3/3 genotype. The APOE-4 allele increases risk and decreases age at dementia onset in a dose-related fashion, that is, Alzheimer disease risk is lowest for the 3/3 genotype, higher for the 3/4 genotype, and highest for the 4/4 genotype. By contrast, the APOE-2 allele has a protective effect, so that Alzheimer disease risk is lower for people with the 2/3 genotype than for those with the 3/3 genotype. Susceptibility to Alzheimer disease from APOE affects many races and has been confirmed worldwide.

More recent research has focused on inflammatory pathways and mediators that contribute to the neurodegenerative process. Pathologic β-amyloid can activate phagocytic microglia and astrocytes to secrete cytokines, chemokines, and other proinflammatory molecules, such as prostaglandins and free radicals, which can have deleterious effects on the brain. A number of inflammatory processes are overrepresented in brains with Alzheimer disease. Microglia are highly activated and surround β-amyloid plaques. Interleukin-1 overexpression promotes the synthesis and processing of APP and thus of amyloid production and plaque deposition, and also induces the activity and mRNA expression of acetylcholinesterase, which reduces cholinergic activity. Chemokines and their receptors are upregulated and may contribute to plaque-associated inflammation and neurodegeneration. Complement activation fragments, reactive astrocytes, and activated microglia are all highly colocalized with plaques containing

aggregated β-amyloid. Chronic inflammation is a well-known contributor to vascular disease, and may be the common pathway to the prevalent coexistence of vascular and Alzheimer disease pathology. Another common link may be APOE-4, a risk factor for developing both atherosclerosis and late-onset Alzheimer disease. These relationships suggest that neurovascular damage is a primary occurrence and that subsequent injuries, including Aβ deposition, amplify and/or exacerbate vascular damage that then leads to neurodegenerative processes and ultimately cognitive decline.

Our current database suggests that Alzheimer disease may be a heterogeneous condition, and therefore have multiple causative factors. Investigations comparing familial (one or more affected first-degree relatives of proband or large autosomal dominant kindreds) and sporadic Alzheimer disease patients, as well patients with early-onset (65 years or younger) and late-onset dementia, have found clinical and biologic differences among them. Other studies suggest differences in disease expression between men and women, cerebral glucose metabolism, and neuroendocrine function, and a possible interaction among age at onset, sex, and family history of dementia. Case-control studies have identified prior head trauma and depression as risk factors for Alzheimer disease, and higher educational achievement, larger brain size, and cardiovascular conditioning as protective factors.

In a sense, finding the etiology of Alzheimer disease is like solving a huge jigsaw puzzle: Although researchers are beginning to piece together a few corners, the puzzle is far from solved. In some cases, the entire cause may lie in a single genetic defect; in others, a mixture of genetic and environmental factors may play a role. The likelihood of multiple causative factors suggests that there are multiple approaches for developing effective prevention and treatment strategies.

DIAGNOSIS AND CLINICAL FEATURES

NCDs in late life usually begin with milder forms of cognitive decline and progress gradually. Early on, pathologic cognitive decline may be difficult to distinguish from normal aging, in which there is commonly an awareness of mild memory changes, but with minimal objective cognitive deficits. However, as neurodegeneration progresses, MCI, often an intermediate state between normal aging and NCD, develops and place patients at increased risk for developing an NCD. Patients with primarily memory deficits may have the amnestic subtype of MCI, which is more likely than other MCI subtypes to progress to dementia due to Alzheimer disease.

The clinical hallmark of Alzheimer disease is memory impairment. Short-term memory is affected initially. Patients have particular difficulty in learning new information, as shown by their inability to recall three

objects after 5 minutes or even after just two distractions. Long-term memory may be affected, and patients may not recall important past personal information. Other cognitive areas may be impaired, including abstract thinking, judgment, personality, and language.

In a typical case of Alzheimer disease, the onset is so insidious that family members have difficulty recognizing when the impairment began. Diagnosis is often missed or delayed because of the insidious onset and gradual progression of symptoms, but also due to lack of attention to cognitive issues during medical screenings. Prevalence studies of community samples have documented high proportions of undiagnosed cases. A complete history of the patient's cognitive and everyday functioning from someone who knows the patient well, physical and neurologic examinations, and a mental status examination are essential in the clinical evaluation. The history should include screening questions for behavioral changes, including apathy, paranoia, agitation, insomnia, anxiety, and depression. On examination, the patient may show *apraxia* (inability to carry out motor commands, even though comprehension and motor function are intact), *agnosia* (inability to recognize objects, despite intact sensory function), or difficulties in visuospatial skills (inability to copy two-dimensional and three-dimensional figures or to assemble blocks). Brief standardized mental status tests (e.g., the Mini-Mental State Examination, the Mini-Cog) are useful screening tools, and more extensive neuropsychologic batteries provide details on the nature and degree of the cognitive deficits.

PATHOLOGY AND LABORATORY EXAMINATION

Because of neuronal loss, the brains of Alzheimer disease patients demonstrate atrophy greater than expected for their ages. In clinical practice, radiologists interpret structural scanning results based on visual readings, which are less sensitive in detecting subtle atrophy. In research settings, image analysis programs are used to quantify regional MRI and CT volumes. These analyses have found that medial temporal or hippocampal atrophy measures can distinguish patients with a clinical diagnosis of Alzheimer disease from controls. Atrophy in the entorhinal cortex and hippocampus is associated with increased risk for progressive memory decline and development of Alzheimer disease.

PET scans measuring regional glucose metabolism after injection of fluorodeoxyglucose (FDG) can differentiate patients with Alzheimer disease from cognitively intact individuals and those with MCI and other NCDs. Patients with Alzheimer disease show hypometabolism in posterior cingulate, parietal, temporal, and frontal regions, and these patterns can be observed in patients with MCI as well (Fig. 57.3f–1). Combining genetic risk assessment with PET is a potential strategy for the early detection of Alzheimer disease. Imaging studies using FDG-PET have shown brain

metabolic deficits in nondemented middle-aged and older persons with the APOE-4 allele. In clinical practice, FDG-PET scans have been approved for reimbursement by the U.S. Centers for Medicare and Medicaid Services to assist with the differential diagnosis of Alzheimer disease and frontotemporal dementia, making this technique more accessible to patients and their physicians.

FIGURE 57.3f–1. Representative examples of brain positron emission tomographic (PET) images from a control subject (**left**), a patient with mild cognitive impairment (**center**), and a patient with Alzheimer disease (**right**), including the use of the agents FDDNP (**top**), FDG (**middle**), and MPPF (**bottom**). For each imaging method, the patient with mild cognitive impairment shows intermediate values between those of the control and the patient with Alzheimer disease. Absolute scales are comparable within subjects with a specific probe, and warmer colors indicate higher values. In the patient with Alzheimer disease, the *arrows* point to frontal, parietal and posterior cingulate **(upper)**, frontal and temporal-parietal (**middle**), and medial temporal (**lower**) regions. (From Kepe V, Barrio JR, Huang SC, et al. Serotonin 1A receptors in the living brain of Alzheimer disease patients. *Proc Natl Acad Sci USA*. 2006;103(3):702–707.)

FIGURE 57.3f–2. PIB-standardized uptake images showing higher Pittsburgh Compound-B (PIB) retention in a 79-year-old patient with Alzheimer disease than in a 67-year-old healthy control. (Reproduced with permission from Klunk WE, Engler H, Nordberg A. Imaging brain amyloid in Alzheimer disease with Pittsburgh Compound-B. *Annals Neurol.* 2004; 55(3):306–319.)

Several small-molecule probes for use with PET imaging have been found to provide in vivo measures of amyloid plaques, and one compound (FDDNP) can measure both amyloid plaques and tau tangles. PET studies using Pittsburgh Compound-B (PIB), a derivative of thioflavin-T amyloid dye, show significantly greater cortical retention in patients with Alzheimer disease compared with controls (Fig. 57.3f–2). PET scans after FDDNP injection have been found to differentiate patients with Alzheimer disease from those with MCI and cognitively intact controls and can predict future cognitive decline (Fig. 57.3f–1). FDDNP-PET scans also can be displayed as three-dimensional cortical surface projections, which show signal patterns remarkably similar to those expected from autopsy studies demonstrating regional brain accumulation patterns of plaques and tangles (Fig. 57.3f–3). Another PET ligand, MPPF, provides visualizations of hippocampal pyramidal neurons, which also demonstrates different signal levels according to the patient's degree of cognitive deficit (Fig. 57.3f–1). In recent years, new PET ligands are being developed to image amyloid plaques or tau tangles. One goal of this approach is to use these imaging tools to accelerate research in disease-modifying drug development for treating Alzheimer.

Single-photon emission computed tomography (SPECT) scanning provides cerebral blood flow patterns of parietal and temporal hypoperfusion, which can be helpful in diagnosing Alzheimer disease. Comparison studies suggest that SPECT has lower diagnostic accuracy than

PET, but advances in voxel-based statistical analysis have improved the diagnostic accuracy of SPECT. Although SPECT has been used more widely because of its availability and low cost, the greater use of PET for oncology studies and reimbursement from Medicare has made it more widely available and accessible.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of Alzheimer disease can be a challenge. Except for measures of regional cerebral glucose metabolism using PET scanning, most potential biologic markers are still in a development phase, and the clinician is left with conventional methods of evaluation: the patient's history, a mental status and physical examination, structural imaging, and laboratory tests. The history provides important information, and several informants should be sought for corroboration. Even with the most thorough evaluation, diagnostic errors occur. When patients are followed to autopsy for neuropathologic confirmation, accuracy of prior clinical diagnosis can be as low as 60 percent.

Major vascular NCD is estimated to account for 10 to 20 percent of major NCDs in late life. Clinically, the disorder is characterized by a sudden onset of illness and stepwise decline in cognitive function rather than the insidious onset and gradually progressive course of Alzheimer disease. The frequent coexistence of vascular disease and Alzheimer pathology (estimated to occur in about one-third of all major NCDs) impairs diagnostic accuracy.

FIGURE 57.3f–3. Three-dimensional cortical surface projection images of FDDNP-positron emission tomography (PET) scans from a control subject and a patient with

Alzheimer disease showing lateral (**upper**) and medial (**lower**) brain surfaces. Warmer colors indicate higher levels of plaques and tangles. (Reproduced with permission from Small GW, Bookheimer SY, Thompson PM, Cole GM, Huang S-C, Kepe V, et al. Current and future uses of neuroimaging for cognitively impaired patients. *Lancet Neurol.* 2008;7(2):161–172.)

Even though Alzheimer disease and vascular disease account for the majority of cases of major NCDs, other conditions must be considered and sometimes can be differentiated from Alzheimer disease by their clinical presentation. For example, frontotemporal lobar degeneration is characterized by marked personality and behavioral changes, executive dysfunction, and relative preservation of other cognitive domains. By contrast, patients with Lewy body disease may evidence visual hallucinations, delusions, fluctuating mental status, and sensitivity to antipsychotic drugs.

FIGURE 57.3f–4. 2-(1-{6-[(2-[18F]fluoroethyl) (methyl)-amino]-2-naphthyl}ethylidene) malononitrile ([18F]FDDNP) binding in a patient with Alzheimer disease, late-life depression, and a healthy control individual. [18F]FDDNP relative distribution volume (DVR) parametric images with Logan graphic analysis with the cerebellum as the reference region are shown.

Alcohol and drugs may cause memory loss and other cognitive dysfunction. For older patients, drugs deserve special emphasis as a cause of memory impairment because of widespread polypharmacy and age-related changes in body function and pharmacokinetics. An older person's brain can be extremely sensitive to change in its environment, and almost any physical illness can effect such a change and produce a dementia-like syndrome. Numerous potentially treatable physical and mental conditions must be considered whenever the diagnosis of dementia is entertained

(Table 57.3f–1).

The clinical presentation of late-life depression may mimic that of an NCD. The earlier term "depressive pseudodementia" is no longer considered useful because the cognitive impairment associated with depression is real. The reported frequency of mistaking depressed patients for patients with an NCD ranges from 5 to 15 percent. Psychomotor retardation, impaired concentration, and apathy characteristic of the depressed patient may be mistaken for symptoms of an NCD, especially when these symptoms are accompanied by memory loss. In the dementia syndrome of depression, however, the complaints of memory tend to exceed the actual memory impairment observed on neuropsychologic testing. The fact that NCDs and depression often coexist further clouds the diagnostic picture. About 30 percent of patients with a progressive NCD also suffer from some form of depression.

Depression is a risk factor and a prodrome of dementia, and common neurobiologic mechanisms may influence both conditions. Although depression occurring in the course of dementia may reflect a psychologic reaction to cognitive losses, PET scanning of patients with late-life depression show increased signals indicating higher levels of amyloid plaques and tau tangles in patterns that overlap with those observed in Alzheimer dementia (Fig. 57.3f–4).

Many people in their 50s and older complain of forgetfulness and worry about its meaning. *Age-associated memory impairment,* as defined by a workgroup convened by the National Institute of Mental Health (NIMH), applies to healthy persons 50 years and older who have subjective complaints of memory loss and mild deficiencies in memory performance compared to young adults. About 40 percent of persons in their 50s and up to 85 percent of those age 80 years and older suffer from age-associated memory impairment. Preliminary data suggest that the condition is stable over intervals of up to 4 years and thus is presumed to reflect normal aging and does not usually progress to dementia. Although it may take them longer to remember, most elderly people continue to recall information they have learned well and important events from the past. Because age-associated memory impairment is so common, it is also referred to as normal aging.

COURSE AND PROGNOSIS

Alzheimer disease is a progressive disease that eventually leads to death, not directly from the dementing process, but usually from intercurrent illnesses. The rate of progression varies, and it is difficult to estimate how rapid a decline a patient may have. Some patients become extremely demented within 1 year; others experience plateaus for several years. The majority experience behavioral disturbances such as agitation and psychosis at some point during the course of illness. Other causes of NCDs,

including frontotemporal lobar degeneration, vascular disease, and Lewy body disease, are gradually progressive as well. Occasionally, treatable causes of dementia (e.g., drug toxicity, hypothyroidism) can be cured when the underlying cause is treated.

TREATMENT

The first step in treating NCDs is attempting to identify any underlying illnesses that may be causing memory impairment and other symptoms of the syndrome. If none is found or if the symptoms persist after appropriate specific treatment, then symptomatic treatments may be tried.

Table 57.3f–2.
Some Potentially Reversible Conditions That Might Resemble Alzheimer Disease and Other Neurocognitive Disorders

Substances
Anticholinergic agents
Antihypertensives
Antipsychotics
Corticosteroids
Digitalis
Opiates
Nonsteroidal anti-inflammatory agents
Phenytoin
Polypharmacy
Benzodiazepines
Psychiatric disorders
Anxiety
Depression
Mania
Delusional (paranoid) disorders
Metabolic and endocrine disorders
Addison disease
Cushing syndrome
Hepatic failure
Hypercarbia (chronic obstructive pulmonary disease)
Hypernatremia
Hyperparathyroidism
Hyperthyroidism
Hypoglycemia
Hyponatremia
Hypothyroidism
Renal failure
Volume depletion
Miscellaneous conditions
Fecal impaction
Hospitalization

Psychopharmacotherapy

A variety of pharmacologic treatments are available for Alzheimer disease (Tables 57.3f–2 and 57.3f–3). Many of these approaches diminish symptoms and increase quality of life, but none of them can halt the dementing process. Most pharmacologic agents now available or in development target a specific symptom (e.g., agitation or memory loss) and are derived from the known neurobiology of the disease (e.g., a specific neurotransmitter deficit) or hypothesized antidementia approaches (e.g., antiamyloid, antitau, anti-inflammation, or antioxidation).

One approach to improving memory function has been to enhance cholinergic activity in the brain. Autopsies of patients with Alzheimer disease have found reduced levels of choline acetyltransferase in the brain, a finding consistent with a central cholinergic deficit. Trials of cholinergic agonists have temporarily improved memory in young and old normal volunteers. Trials of several agents, including physostigmine (Antilirium), choline (Mega-B), and lecithin (PhosChol), have yielded contradictory results (some effects vs. no measurable effects on memory in patients with dementia) or else have not yet been replicated.

Table 57.3f–3.
Medications Used or Under Investigation for the Treatment of Alzheimer Disease

Cholinesterase inhibitors
Tacrine[a]
Donepezil[a]
Rivastigmine[a]
Galantamine[a]
Sustained-release physostigmine
Eptastigmine
Cholinergic agonists
Xanomeline
Milameline
Antioxidants
Vitamin E (α-tocopherol)
Hormones
Conjugated estrogens
***N*-Methyl** D-**aspartate antagonist**
Memantine[a]
Other potential cognitive enhancers
Acetyl-L-carnitine
Curcumin
Ginkgo biloba
Nonsteroidal anti-inflammatory drugs

Omega-3 fatty acids

[a]Approved by the U.S. Food and Drug Administration.

Table 57.3f–4.
Some Drugs Used or Under Investigation for the Treatment of Behaviors Associated with Alzheimer Disease and Other Neurocognitive Disorders

Antipsychotics
Aripiprazole
Haloperidol
Olanzapine
Quetiapine
Risperidone
Anticonvulsants
Carbamazepine
Divalproex sodium
Antidepressants
Citalopram
Sertraline
Paroxetine
Sertraline
Trazodone
Anxiolytics
Buspirone
Lorazepam
Clonazepam
Antiparkinsonian Drugs
Selegiline
β-Adrenergic receptor antagonists
Propranolol
Pindolol

The U.S. Food and Drug Administration (FDA) has approved four cholinesterase inhibitors (tacrine [Cognex], donepezil [Aricept], rivastigmine [Exelon], and galantamine [Razadyne]) and one *N*-methyl D-aspartate (NMDA)–receptor antagonist (memantine [Namenda]) for the treatment of Alzheimer disease. These drugs have proven benefits for memory, other aspects of cognition, behavioral disturbances, overall functioning, and even caregiver burden. Tacrine has the disadvantage of causing reversible elevations of serum transaminase levels and is therefore rarely used.

These symptomatic treatments were originally indicated only for mildly to moderately ill patients with Alzheimer disease. More recently, the efficacy of cholinesterase inhibitors has been demonstrated in severe Alzheimer disease, Lewy body disease, and dementia associated with Parkinson disease. Memantine is indicated for moderately to severely ill

patients with Alzheimer disease. Clinical practice often combines a cholinesterase inhibitor with memantine, supported by data that this combination provides beneficial response compared to cholinesterase inhibitors alone.

Clinical trials point to the importance of early detection and treatment with cholinesterase inhibitor drugs. In randomized, placebo-controlled inpatients with Alzheimer disease, these drugs result in less cognitive decline compared with placebo after 6 months of treatment. During the following 6-month open-label treatment periods, the patients who were originally treated with placebo were given active drug, and at 1 year, better cognitive performance was observed in patients who began drug treatment from the beginning of the trial compared with those who had been placebo-delayed for 6 months.

Studies using cholinesterase inhibitor drugs in patients with MCI have been inconclusive. For example, a randomized, placebo-controlled trial in patients with MCI found that donepezil delayed progression to Alzheimer disease compared with placebo after 1 year of treatment; however, no difference between drug and placebo was found after 3 years of treatment.

Studies have examined a variety of other agents that may improve cognitive functioning, including estrogen, nonsteroidal anti-inflammatory agents, and antioxidant supplements. Unfortunately, any clinical benefit for these various treatments has been inconclusive. The widespread use of over-the-counter preparations should be evaluated routinely, as some do carry risk. For example, while vitamin E (α-tocopherol) at 2,000 IU daily lowered rates of functional decline in patients with moderately severe Alzheimer disease in one study, meta-analyses have found an increased risk of myocardial infarction in patients taking daily vitamin E supplementation, particularly doses greater than 400 IU.

As scientists uncover the basic pathogenetic mechanisms of Alzheimer disease, several therapeutic strategies for preventing or diminishing insoluble amyloid accumulation are under investigation, including secretase inhibitors or modulators, active or passive vaccines, aggregate (oligomer) and tau kinase inhibitors, cholesterol-lowering statin drugs, anti-inflammatory drugs, omega-3 fatty acids, and the yellow curry pigment, curcumin.

Psychiatric medications may be helpful for treating behavioral disturbances associated with dementia, such as depression, agitation, psychosis, and anxiety. Patients who have dementia with concurrent depression may improve following treatment with antidepressant medications, though data are limited. Antidepressants with minimal anticholinergic effects (e.g., serotonin reuptake inhibitors) are preferred over tricyclics in terms of minimizing risk for worsening cognition. One meta-analysis found only five randomized controlled trials that studied the efficacy of treating patients with dementia and depression with

antidepressants. A total of 82 patients were treated with active drug (sertraline, imipramine, clomipramine, and fluoxetine) versus 83 with placebo. Response and remission rates for depression were significantly greater for the pooled antidepressant group than for that receiving placebo. The study found no significant differences in overall rates of withdrawal or those due to adverse events. Antidepressants may also have a role in treating agitation. In controlled trials, sertraline and citalopram have demonstrated efficacy over placebo in patients with dementia and agitation.

Antipsychotic drugs may be effective in treating psychotic symptoms and agitation. Multiple controlled trials and meta-analyses of controlled trials of antipsychotic treatment in dementia indicate that antipsychotics have a significantly greater effect than do placebo, but the effect sizes are mostly less than 20 percent. As there is no evidence that one agent is superior to others, side-effect profile is a primary consideration when choosing a specific agent.

First-generation, or "conventional" antipsychotics may be generally categorized as "high-potency" or "low-potency" antipsychotics, according to how potently they occupy dopamine-2 receptors. High-potency agents such as haloperidol are more likely to cause parkinsonian symptoms, whereas such low-potency drugs as chlorpromazine cause sedation, postural hypotension, and anticholinergic effects. Less frequently, tardive dyskinesia and neuroleptic malignant syndrome may develop with either. Clozapine, while considered an "atypical" antipsychotic, can have similar side effects as low-potency antipsychotics, and also requires routine blood-count monitoring because of the risk of agranulocytosis. Because of the lower associated risk for neuromotor side effects, the newer atypical antipsychotic drugs, such as quetiapine, risperidone, olanzapine, and aripiprazole, have received greater attention in recent years. However, these atypical agents are associated with other adverse effects, including metabolic syndrome, vascular events, and cardiac arrhythmias, which warrant vigilant monitoring. Overall, conventional and atypical antipsychotic medications have been associated with increased mortality rates in elderly patients with dementia, which prompted black box warnings by the FDA for all antipsychotics currently available. Investigators have more recently challenged the basis for these warnings with data showing no significant differences in mortality in this population between antipsychotics and placebo.

Benzodiazepines and anticonvulsants have been used and studied for the treatment of agitation. However, there is little evidence for their use in this setting, and they have undesirable adverse effects, including some particularly noxious to the elderly patient with dementia, such as sedation, confusion, memory impairment, dysarthria, and ataxia. Moreover, benzodiazepines have recently been associated with increased risk for

Alzheimer disease.

Other Interventions

Attention to the Environment. Attending to patients' environments is essential to their well-being, and can mitigate the need for pharmacotherapy for behavioral disturbances. Patients with cognitive losses are sensitive to their surroundings and do best with optimal stimulation. Understimulation may cause withdrawal; overstimulation may cause confusion and agitation. Familiar and constant surroundings and caregivers maximize the patient's cognitive functions and minimize behavioral disturbances. If moves cannot be avoided, placing familiar objects (e.g., photographs and furniture) in the new environment help create a more comfortable and homelike atmosphere. Daily routines—regularly scheduled awakening, bedtime, meals, and physical exercise—increase a patient's sense of security. Memory and orientation can be facilitated by prominent displays of clocks and calendars, daylight exposure, a night-light, checklists, and diaries. Medication schedules should be simplified as much as possible. Newspapers, radio, and television, appropriate to the patient's cognitive level, can be useful in maintaining a patient's contact with and awareness of the outside world. Daily simple yet meaningful tasks that the patient can complete provide a valuable sense of usefulness and accomplishment for the patient. Specific therapies such as music and activity therapies have also been shown to improve behavior.

Family Intervention. Addressing the needs of the patient with Alzheimer disease would not be complete without addressing the needs of the patient's care system. While the identified patient is the one suffering from the disease and in need of treatment, often the adult child initiates contact with the physician and has his or her own reasons for evaluation and treatment. Considerable skill and sensitivity are necessary to maintain an alliance with the adult child while respecting the patient's autonomy, dignity, and privacy. Psychotherapeutic intervention with family members is a critical aspect of treatment. Caregiver and family stress can result in suboptimal care for the patient, as they themselves might experience frustration, anxiety, fatigue, anger, resentment, guilt, and even depression. Interpersonal conflicts among the family members may arise and require resolution to help the patient. Children and siblings might become anxious about their own risk for developing Alzheimer disease. Education and counseling about the nature of the patient's illness help relatives to cope with their feelings. Relatives may need reassurance that their emotional reactions are common and that talking about them can bring relief. Many relatives also need help in grieving the loss of the person they once knew. The Alzheimer's Association, a national organization of family members

with local chapters throughout the United States, has been at the forefront of providing educational and emotional support for family members. Sometimes, a family member's needs may exceed this level of support and require individual attention, in the form of treatment for anxiety or depression, or a full physical and neuropsychologic evaluation, which may either allay anxiety about having the disease or occasionally uncover early signs of cognitive impairment, which may lead to more anxiety, but also the opportunity for early intervention.

FIGURE 57.3f–5. Statistical parametric mapping of results of fluorodeoxyglucose (FDG)-positron emission tomography (PET) scanning shows a 5 percent decline in metabolic activity in the left dorsolateral prefrontal cortex after a 2-week healthy lifestyle program, including memory training, physical conditioning, and healthy diet, whereas no such decline was observed in the control group. The color scale highlights the location of all cortical voxels showing significantly greater decline ($p < 0.01$) in the intervention group compared with the control group. The left image is a left lateral viewpoint; the right image viewpoint is from the top of the brain. The *arrows* point to the voxels of peak significance ($Z = 3.82$, $p < 0.001$). (Reproduced with permission from Small GW, Silverman DHS, Siddarth P, Ercoli LM, Miller KJ. Effects of a 14-day healthy longevity lifestyle program on cognition and brain function. *Am J Geriatr Psychiatry.* 2006;14(6):538–545.)

Prevention Strategies. The MacArthur Foundation studies on aging have shown that early lifestyle choices, more than genes, determine our health and vitality as we age. Epidemiologic, survey, and animal data suggest that these lifestyle choices can specifically impact brain health. Reducing modifiable cardiovascular risk factors, depression, low education, and physical inactivity by just 10 to 25 percent could potentially prevent millions of cases of Alzheimer disease worldwide. Some of these same risk factors have been shown to be associated with subjective memory impairment, a possible precursor to MCI and Alzheimer disease, in cognitively intact persons of all ages. These same individuals reported better memory if they engaged in healthy lifestyle habits such as regular exercise, nutritious diet, and not smoking. One controlled study demonstrated that participating in a healthy lifestyle program combining mental and physical exercise, stress reduction, and healthy diet for just 2 weeks was associated with significant positive effects on cognitive

performance and brain metabolism (Fig. 57.3f–5). Whether lifestyle choices can prevent or delay the onset of Alzheimer disease and other NCDs remains to be determined. However, modifying one's lifestyle to incorporate some of these healthy behaviors come with minimal risk and offer other proven health benefits. Until more effective pharmacotherapies are available, prevention strategies through healthy lifestyle choices may be the safest and most beneficial way to reduce one's risk for developing Alzheimer disease and other NCDs.

A recent telephone survey conducted with Gallup Poll of a representative community sample of 18,614 US respondents, ages 18 to 99 years, addressed whether potentially modifiable risk factors for AD were associated with self-awareness of memory problems. As predicted, depression, less education, less exercise, and hypertension were significantly associated with self-awareness of memory problems, which increased with age and number of risk factors.

57.3g Delirium

SUSAN W. LEHMANN, M.D., AND BENJAMIN LIPTZIN, M.D.

INTRODUCTION

Delirium is an acute cognitive disorder of attention and awareness which disproportionately affects geriatric patients. Reports indicate that delirium is present in one-third of hospitalized older patients and occurs in 15 percent of older patients presenting to emergency departments. The incidence of delirium is high among individuals with dementia, especially Alzheimer disease. Delirium is usually an indicator of severe underlying medical illness or metabolic derangement. However, it may also occur in vulnerable individuals with relatively minor medical provocations, such as constipation or mild dehydration.

Delirium is frequently unrecognized, yet the costs of not detecting

delirium are significant. Delirium is associated with poor outcomes, both in the hospital and after discharge. Patients who are delirious are more likely to have longer lengths of hospitalization. Older patients with delirium are at increased risk for nursing home placement and are at increased risk for prolonged cognitive impairment and dementia. Delirium is associated with high rates of morbidity as well as increased risk of mortality. Indeed, it has been estimated that the US healthcare costs which are attributable to delirium range from 40 to 150 billion dollars annually. Studies indicate that delirium may be preventable in up to 30 to 40 percent of cases, and so assessment for delirium has become a significant focus for patient safety management in acute care hospitals.

DEFINITION

Delirium is a multifactorial syndrome whose hallmark features are that of disturbance in attention, awareness, and cognition. The symptoms develop acutely, usually over hours or days, in the setting of serious medical illness or in the postoperative period. Symptoms include impaired ability to focus or sustain attention as well disorientation to the environment. Delusions or perceptual disturbances such as hallucinations (usually visual) are common, as are incoherent and disorganized speech. Patients usually have disrupted sleep–wake cycles and may be lethargic and drowsy or agitated and hyperalert. A key feature of delirium is that these disturbances tend to fluctuate in severity during the day.

The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) classifies delirium as a neurocognitive disorder. Other terms which are sometimes used by physicians to describe delirium, but are not recognized by DSM-5, are "acute confusional state," "acute brain failure," "toxic encephalopathy," or "metabolic encephalopathy."

HISTORY

The syndrome of delirium has been described in medical writing for over 2,000 years. It was recognized as early as the fifth century BC, when Hippocrates recorded a detailed description of the clinical features of delirium, noted that the syndrome was linked to physical disease, and suggested that it carried a poor prognosis. In the first century ad, the Roman, Celsus, distinguished delirium from major mood disorders and hysteria. In the second century, Galen also noted that the brain could be disturbed *secondarily* in diseases such as pneumonia. In antiquity and in medieval times, delirium was recognized, usually in the context of febrile illness, and was called by a variety of different names.

In his classic textbook, *General Psychopathology,* first published in 1913, the German psychiatrist, Karl Jaspers reported his observations of delirious patients as follows: "Delirium is characterized by the patient

turning away from external reality . . . He is dominated by an anxiety which is often extreme and a drive for aimless activity . . . When left alone the patient is always on the verge of sleep which however is never fully achieved."

In 1935, Harold Wolff and Desmond Curran published a study of 106 patients with delirium hospitalized in the United States and United Kingdom, with a careful cataloging of psychobiologic functions and case reports for 20 of the patients. These authors made several observations of note—for example, that patients recede into vagueness and hallucinations when external stimulation ceases, and that summoning relatives to the bedside of the delirious patient does much to restore function. Most important, however, was that they established for this cohort of patients that symptomatology was independent of etiology in delirium.

In the 1940s, John Romano and George Engel performed a series of EEG studies in delirious patients, and demonstrated that the degree of EEG slowing was correlated with the severity of the disturbance in consciousness. These authors hypothesized that delirium represented a state of "cerebral insufficiency."

More recently Zbigniew J. Lipowski wrote extensively about delirium and emphasized both the prevalence and seriousness of delirium as a public health problem. His work ushered in the contemporary era of research about delirium and his book, *Delirium: Acute Confusional States,* published in 1990, is considered a classic in the field. Sharon Inouye and her colleagues in geriatric medicine have carried out a series of investigations regarding the prevention of delirium which led to the development of a successful preventive multistep approach to delirium prevention and management. This work has highlighted the importance of recognizing delirium as an indicator of quality of care.

COMPARATIVE NOSOLOGY

The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) defines delirium as a neurocognitive disorder whose key features are disturbances of attention and awareness which develop acutely and which fluctuate over time. Typically, these changes in attention and awareness ebb and flow throughout the day such that the patient may appear lucid and talkative at one point in time, and then a few hours later might appear lethargic and confused. In addition, there are impairments in other aspects of cognitive functioning, such as orientation to time and place, memory, expressive and/or receptive language, and visuospatial abilities. Abnormal perceptions, especially visual and tactile hallucinations, are common. There must be evidence from the patient's history and physical examination or laboratory investigations to indicate that these disturbances are due to an underlying medical illness or illnesses or due to substance intoxication or withdrawal.

The DSM-5 criteria include specification about whether the delirium is acute (i.e., lasting a few hours or a few days) or if it is persistent (i.e., lasting weeks or months). In addition, the DSM-5 recognizes three psychomotor subtypes of delirium: hyperactive, hypoactive, and mixed level of activity.

For delirium, due to another medical condition, the DSM-5 requires that there be evidence from the history, physical examination, or laboratory findings that the delirium is due to a specific underlying medical condition. In clinical settings, it is unusual for there to be one single, identifiable cause that is clearly the etiology of the delirious state, and, more commonly, delirium is attributable to multiple causes. DSM-5 also specifies substance intoxication delirium and substance withdrawal delirium, which should be used when the symptoms of disturbed attention, awareness, and impaired cognition are most significant from a clinical standpoint and require clinical attention.

In the *International Classification of Diseases*, 10th revision (ICD-10), delirium due to medications or substances is specified separately by the causative medication or substance.

EPIDEMIOLOGY

Incidence and prevalence rates for delirium vary widely, depending on the clinical setting. Prevalence in the community is approximately 0.4 percent of adults and 1.1 percent of people aged 55 and older. Among patients over age 70 admitted to a hospital, about one-third have delirium. Of these individuals, about half are delirious at the time of admission, and the rest develop delirium during their hospitalization. Onset of the presenting symptoms of delirium is frequently a reason that a patient is brought to an emergency department for evaluation. Overall, the incidence of delirium during hospitalization ranges from 6 to 56 percent, with higher rates being more commonly seen among patients with dementia. Incidence rates of delirium also vary across hospital services. Incidence rates of delirium are highest in intensive care units, postoperative clinical units, and in palliative care settings. Among residents in nursing homes who are aged 75 and older, the prevalence of delirium is as high as 60 percent. Among patients with terminal illnesses, up to 80 percent of individuals become delirious around the time of death.

Table 57.3g–1.
Risk Factors for Delirium

Pre-existing cognitive impairment (dementia, executive dysfunction)
Previous history of delirium
Multiple medical problems
Multiple medications (especially opioids, anticholinergics, benzodiazepines)
Advanced age
Structural brain disease (e.g., stroke or traumatic brain injury)

Alcohol or sedative dependence
Chronic liver disease
Severe medical illness
Terminal illness
Chronic psychiatric illness
Undernutrition (low albumin and prealbumin)
Compromised cerebral circulation
Deafness or hearing impairment
Blindness or visual impairment
Sleep deprivation
Immobilization
Stress, including psychosocial stress

Risk factors for delirium are listed in Table 57.3g–1. These include pre-existing characteristics which predispose an individual to delirium as well as factors which precipitate an episode of delirium. Predisposing risk factors include pre-existing cognitive impairment, advanced age, previous history of delirium, severe medical illness, alcohol or sedative dependence, hearing or vision impairment, and poor nutritional status. Precipitating factors include bed rest or immobilization, medications (especially opioids, anticholinergic medications, and benzodiazepines), physical restraints, sleep deprivation, and low hematocrit. Awareness of risk factors for delirium, especially those which are modifiable, is critical for delirium prevention efforts.

ETIOLOGY

While delirium can be caused by a single etiologic factor, most commonly the etiology is multifactorial. Predisposing risk factors, as described above, confer vulnerability to delirium. Development of delirium depends upon the complex interplay of predisposing and precipitating factors. In older individuals with dementia, a relatively minor new condition, such as a urinary tract infection, can trigger an episode of delirium. At the same time, delirium often develops as a consequence of serious medical and/or metabolic derangement, and therefore, is considered a medical emergency. Recognition of the multifactorial etiology for delirium is essential to clinical management because a multidimensional approach to both prevention and treatment is needed.

Table 57.3g–2presents a list of etiologies for delirium frequently seen in older patient populations. Among hospitalized elders, the most important causes are infections and medications. Infections can include urinary tract infections, pneumonia, and sepsis. Many medications have been implicated as being deliriogenic in vulnerable populations and their use should be avoided, if possible. In particular, opioids, anticholinergic medications, and benzodiazepines are frequent causes of delirium in older patients. Anticholinergic medications include atropine, diphenhydramine,

benztropine, and oxybutynin (Ditropan) as well as medications with strong anticholinergic side effects such as imipramine, ranitidine (Zantac), dipyridamole (Persantine), warfarin (Coumadin), isosorbide, theophylline (Theo-Dur), nifedipine (Adalat, Procardia), and prednisolone (Prelone). Among opioid medications, meperidine appears to be most likely to induce delirium, and hydromorphone is the least likely to cause delirium. Among the benzodiazepines, the most lipophilic drugs with the longest elimination half-lives are most likely to cause delirium, including chlordiazepoxide (Librium), flurazepam (Dalmane), and diazepam (Valium).

Table 57.3g–2.
Etiologies of Delirium in Elderly Patients

Systemic Illnesses
Infections: Pneumonia, urinary tract infection, sepsis, influenza
Metabolic derangements: Dehydration, hypoxia, hypoglycemia, hyperammonemia, uremia, hyponatremia, thiamine deficiency, hyperthyroidism
Cardiovascular conditions: Arrhythmia, congestive heart failure, myocardial infarction, severe hypertension
Medications
Anticholinergics
Benzodiazepines, other sedative hypnotics (e.g., barbiturates)
Opioids
Antiarrhythmics
Certain antibiotics (e.g., fluoroquinolones, clarithromycin)
Digoxin
Interferons
Withdrawal States
Alcohol
Benzodiazepines, other sedative hypnotics
Primary Brain Diseases
Stroke or transient ischemic attack
Trauma: Brain injury, subdural hematoma
Infection/inflammation: Abscess, meningitis, encephalitis, vasculitis
Aneurysm
Epilepsy: Nonconvulsive status epilepticus, postictal states
Surgery or Trauma
Hip fracture repair
Open heart surgery (e.g., coronary artery bypass grafting)

A 79-year-old woman with metastatic ovarian cancer was admitted to the hospital with acute onset of vomiting, inability to stand, and delirium. She had been treated with warfarin for a hypercoagulable state. On admission workup she was found to have a cerebellar hemorrhage with evidence of increased intracranial pressure. Anticoagulation was reversed, the hemorrhaging stopped, and intracranial pressure was normalized. Digoxin was started for newly diagnosed atrial fibrillation. She returned to her baseline level of cognitive function, which was completely normal. She was transferred to a rehabilitation facility to improve her ability to ambulate, which was still affected by the cerebellar hemorrhage. Soon after her admission to the rehabilitation unit, she was reported to be disoriented. She began to accuse the staff of waking her up at 3 AM. Labs were ordered to determine the cause of her mental status change. Her digoxin level was elevated at 2.4 ng/mL (normal range 0.5 to 2.0 ng/mL). Her dose of digoxin was reduced and her symptoms of delirium resolved over several days

without other intervention.

The definitive pathophysiology of delirium remains unclear but evidence indicates that several sets of biologic factors appear to be involved. It is thought that delirium represents a reversible syndrome of neuronal dysregulation caused by disruption of oxidative metabolism. Certain brain structures, such as the cerebral cortex and hippocampus, are relatively more sensitive to this disruption than are other parts of the brain. At the cellular level, disruption of oxidative metabolism results in an inability to maintain ionic gradients. In addition, there is abnormal synthesis, release and metabolism of neurotransmitters, and inability to dispose of neurotoxins.

The two neurotransmitter systems which are believed to have the greatest causal relationship to delirium are the cholinergic and dopaminergic systems. Cholinergic deficiency and dopamine excess have both been implicated in delirium. Decreased cholinergic neurotransmission is believed to underlie the cognitive symptoms seen in patients with delirium. Cholinergic deficiency also correlates with adverse cognitive effects of anticholinergic medications. Acetylcholine is the primary neurotransmitter of the ascending reticular activating system (RAS), which regulates alertness. There are neocortical and limbic inputs to this system which control attention. Cholinergic, dopaminergic, and serotonergic neurons are especially sensitive to oxidative stress. In hypoxia, not only are derangements of these systems found, but there is also an increase in release of glutamate. It has been hypothesized that the presence of dopamine is required for at least some glutamate-mediated neuronal injury in hypoxia. Dopamine blockade, with agents such as haloperidol, may be protective by reducing neuronal damage in hypoxia in vulnerable brain areas such as the hippocampus. Increased dopaminergic neurotransmission is also believed to underlie the perceptual disturbances often seen in delirium and antidopaminergic antipsychotic drugs effectively treat these disturbances. Other neurotransmitter disturbances of GABA, serotonin, norepinephrine, and histamine may also be involved in delirium pathogenesis. GABA hyperactivity, for example, is implicated in hepatic encephalopathy. Delirium tremens is associated with GABA hypoactivity, and hyperactivity of glutamate and norepinephrine.

Neuroinflammation is another likely mechanism of brain injury in delirium and may help explain how systemic infection can disrupt cerebral oxidative metabolism. It has been hypothesized that peripheral inflammation triggers circulating proinflammatory cytokines which, in turn, promote endothelial activation, disruption of the blood–brain barrier, and microglial activation. Neuroinflammation of the brain can lead to microglial overactivation, with further neuronal injury. Elevations in proinflammatory cytokines have been found with diverse etiologies of

delirium, including the postoperative state (e.g., total hip replacement), influenza, heatstroke, and acute hepatic encephalopathy. It is believed that proinflammatory cytokines may have a direct neurotoxic impact on the brain.

DIAGNOSIS AND CLINICAL FEATURES

Delirium is a clinical diagnosis based on the history, physical examination, and mental status examination. However, the first step is suspicion for the disorder based on clinical observation. Because the features of delirium are quite variable and, by definition, tend to fluctuate over time, it is often overlooked or unrecognized by clinicians. Patients with delirium may seem so drowsy that they fall asleep while eating or speaking. At other times, the patient may seem inattentive to questions, with poor eye contact, easy distractibility by irrelevant stimuli and requiring questions to be repeated because of difficulty sustaining focus on the conversation. These fluctuations tend to occur throughout a 24-hour period so that a patient might be relatively alert and lucid with appropriate orientation to the environment for a few hours during different parts of the day, alternating with periods of confusion, incoherence, or somnolence. This waxing and waning of orientation and level of awareness might not be evident to an observer who interacts with the patient during only one of these periods during the day. In the acute hospital or nursing home setting, where clinical staff change with each shift, it is important for physicians to be alert to changing descriptions of the patient's mental state and behavior across different shifts to specifically look for this pattern of symptom fluctuation. It is not uncommon to find that hospital staff who work on evening shifts and day shifts have different views of the patient's level of cognitive and behavioral disturbances.

The speech of the patient with delirium is often incoherent, rambling, irrelevant to the topic and disorganized. Specific language impairments include dysarthria (impaired speech articulation), dysnomia (impaired naming), and dysgraphia (impaired writing ability). The patient's ability to reason abstractly, retain information, and direct his or her thinking is impaired. As a result, in the medical setting, patients with delirium may temporarily lose the capacity for informed consent. Frequently, patients who are delirious have sleep–wake cycle reversals and may waken during the night believing it is time to get washed and dressed. Disorientation to the environment is common, with patients mistaking the hospital for home and beginning to wander out of the hospital bed looking for the kitchen or a family member.

Other features commonly associated with delirium include transient delusional thoughts and emotional disturbances such as paranoia, fear, and disruptive behaviors. Delusional thinking is usually paranoid in nature with patients becoming fearful that routine or specialized medical care is being

done to them with a nefarious purpose. Perceptual disturbances due to delirium can be among the most frightening symptoms to patients and to their families. These problems vary in severity and frequently include misinterpretations of items and people in the patient's environment (e.g., belief that the physical therapist is a family member or mistaking the bang of a closing door for a gunshot). Illusions, which are misperceptions of actual stimuli, are also common in delirium. An example of an illusion might be a delirious patient misperceiving an intravenous line to be a snake. Hallucinations are perceptions in the absence of actual stimuli and are usually visual but they may also be tactile or auditory in nature. The hallucinations which occur in delirium range in severity from simple colored spots or geometric figures to moving objects, such as white handkerchiefs falling, to more complex phenomena, such as animals, people, monsters, panoramic views, and scenes acted out. Typically, these hallucinations are felt as threatening to patients. It is easy to see how they can engender feelings of fear and anxiety.

Disruptive behaviors can be present more or less continuously or they can occur unpredictably. These behaviors range from disorganized, purposeless actions such as picking at bandages or repetitive vocalizations to pulling out Foley catheters or attempting to get out of bed and ambulate without assistance. Distorted perceptual experiences can lead a patient to incorrectly interpret a medical situation as dangerous, leading him or her to attempt to pull out intravenous lines or endotracheal tubes or to respond aggressively to a nurse trying to assist the patient. While disruptive behaviors can occur at any time of the day, they are more common at night.

When delirium is suspected, the process of making the diagnosis includes a careful history, focusing on the timeline of symptom development. A key feature which distinguishes the impairments of delirium from those of dementia is acute development of symptoms. Delirium can present almost immediately after head trauma or it may develop over a period of hours or days in a hospitalized patient with pneumonia or other infection. An elderly outpatient with metabolic disturbances or medication toxicity might develop symptoms more gradually over a period of days to weeks. Unlike other cases of medical diagnosis, important aspects of the patient's history usually come from individuals other than the patient him/herself. Speaking with family members of the patient, or other knowledgeable informants who can provide a clear description of the patient's baseline level of cognitive functioning, is crucial in establishing that an acute change has occurred. When delirium occurs in a hospitalized patient, it is important to review nursing notes to help establish the timeline of abrupt onset of symptoms and the course of fluctuating symptoms. Other important aspects of the history include careful review of all medications prescribed to the patient and the timing of when new medications were begun or when dosages were

changed. A complete medication history review must include over-the-counter medications as well as prescription medications. In older patients, medications are the most common cause for delirium, with sedative-hypnotic, anticholinergic, opioid analgesic, and antidepressant medications being most potentially problematic. A thorough history must also include assessment of alcohol use, history of pain and its treatment, and any new physical symptom.

The physical examination of the patient should include careful evaluation for possible underlying causes, with assessment of vital signs including oxygen saturation and thorough cardiac and pulmonary examination. The neurologic examination should look for evidence of focal findings. Motor system abnormalities that can be seen in delirium include tremors, myoclonus, asterixis, increased deep tendon reflexes and increased tone. Evidence of adrenergic system overactivity can be seen in delirium due to alcohol or sedative withdrawal and also with anticholinergic toxicity states. Signs of hyperadrenergia include tachycardia, hypertension, sweating, pallor, flushing, and pupil dilation.

The mental status examination of the patient begins with assessment of the patient's level of awareness and arousal. It should be noted whether the patient is somnolent or lethargic, and if so, how much stimulation is required to arouse the patient. The patient's thinking and speech should be assessed, including whether speech is coherent or rambling and whether answers to questions are logical or disorganized. A number of simple tests can be used to evaluate the patient's level of attention. Often it is evident through interviewing the patient that he/she is having difficulty sustaining focus on the conversation and/or is being easily distracted by other stimuli in the room. A common test known as digit span requires patients to repeat 5 digits forwards and 3 digits backward. An alternative approach would be to ask patients to recite the days of the week or months of the year backward. In addition to impairment of awareness and attention, patients with delirium will have a change in at least one other area of cognitive functioning. This might include memory, learning, or disorientation. Perceptual disturbances, such as misinterpretation, illusions, and hallucinations should be assessed. A bedside cognitive test can be used to screen patients who are alert enough to cooperate with formal testing. Commonly used bedside cognitive tests are the Mini Mental State Examination (MMSE), Mini-Cog, and Montreal Cognitive Assessment (MoCA).

Several psychomotor phenotypes of delirium are described in DSM-5. Patients who have the hyperactive subtype of delirium exhibit hypervigilance, restlessness, distractibility, and agitation. Individuals with hyperactive delirium are easier to identify but may be more difficult to manage because of problematic behaviors which can include refusing to cooperate with medical care, combativeness, and wandering. Patients with

hypoactive delirium present primarily with withdrawal, lethargy, sparse speech, and decreased motor activity. Patients with mixed level of activity may appear to have a normal level of psychomotor activity even though attention and awareness are impaired. This subtype also includes individuals who have a rapidly fluctuating level of psychomotor activity between hypoactive and hyperactive states.

A number of assessment instruments have been developed to diagnose delirium and evaluate its severity. The most useful and commonly used bedside tool is the Confusion Assessment Method, or CAM. The CAM identifies key features of delirium and has been validated in many studies. The CAM-ICU is a version of the CAM that has been validated for use in the intensive care unit and does not require verbal responses from the patient. The Delirium Rating Scale-Revised-98 (DRS-R-98) has also been validated in both general medical populations and in geriatric populations. While an assessment tool does not take the place of a mental status examination, it can be very useful as a screening measure to help detect patients who are likely to be delirious. Daily use of a standardized screening instrument, such as the CAM, can be important for prompt identification of acute changes and fluctuations in cognition and attention in hospitalized older patients who are at risk of developing delirium. This can also be used to train nurses or other caregivers to recognize delirium.

PATHOLOGY AND LABORATORY EXAMINATION

The syndrome of delirium is diagnosed on the basis of the clinical history and the examination of the patient at the bedside. The diagnosis of delirium requires a prompt and careful laboratory evaluation to determine the etiology or etiologies. Delirium frequently heralds serious medical illness and therefore should be responded to as a medical emergency. A standard laboratory evaluation of delirium is shown in Table 57.3g–3. As indicated in Table 57.3g–3, if the basic evaluation fails to reveal a likely cause, then other selected laboratory investigations may be initiated. Depending on the particular case, further workup may include a brain imaging study or a lumbar puncture for cerebrospinal fluid studies. For instance, a lumbar puncture should be done if there is concern about possible meningitis or subarachnoid hemorrhage. A brain computed tomography (CT) or magnetic resonance imaging (MRI) should be done if there is a high possibility of stroke or head trauma causing brain hemorrhage. Arterial blood gas evaluation should be done if there is concern for hypercarbia in a patient with chronic obstructive pulmonary disease. Detailed neuropsychologic testing is not usually obtained because the attentional impairment of delirium compromises the validity of higher-order testing.

Table 57.3g–3.
Laboratory Workup for Delirium in the Elderly Patient

- Basic evaluation
  - Blood tests
    - Complete blood count (CBC) with differential and platelets
    - Chemistries:
      - Albumin
      - Blood urea nitrogen (BUN)
      - Creatinine (Cr)
      - Creatine phosphokinase (CPK)
      - Electrolytes: Sodium (Na^+), potassium (K^+), chloride (Cl^-), bicarbonate (HCO_3^-), calcium (Ca^{2+}), phosphate (phos), magnesium (Mg^{2+})
      - Glucose
      - Liver function tests
    - Erythrocyte sedimentation rate or C-reactive protein
    - Syphilis serology
    - Medication levels
    - Toxicology screen (serum and urine)
- Urinalysis (with culture and sensitivity testing, if indicated)
- Electrocardiogram
- Chest radiograph

Other laboratory studies to consider, depending on clinical indications: brain imaging (computed tomography or magnetic resonance imaging), electroencephalogram, arterial blood gas, cerebrospinal fluid studies, vitamin B_{12} level, folate level, thyroid-stimulating hormone, heavy metal screening, human immunodeficiency virus testing, and serum anticholinergic activity (available through research laboratories).

Electroencephalography (EEG) has a characteristic pattern in delirium and typically shows generalized slow wave activity in the delta and theta range. In hyperadrenergic states, such as alcohol or sedative withdrawal, the EEG will show increased low-voltage fast (beta) activity. However, the EEG is rarely useful in determining the underlying cause of delirium and is not routinely performed.

DIFFERENTIAL DIAGNOSIS

Although the symptoms of delirium can mimic a number of psychiatric conditions, in the elderly patient, the most important differential diagnosis is between delirium and dementia. To distinguish between delirium and dementia requires obtaining a thorough history from family members and caregivers, or from nursing staff who have recently been caring for the patient, and who can provide a description of the patient's baseline level of function and timeline of recent acute changes. Since dementia is a recognized risk factor for delirium, the two diagnoses often coexist in the same patient. Information from family members about the patient's premorbid functioning—such as when the patient last drove a car, balanced a checkbook, or dressed independently—can help identify a more slowly

developing dementia. Description of a more rapid decline in general and cognitive functioning over days to weeks, and/or a rapidly fluctuating course, suggest delirium evolving in a patient with pre-existing dementia. For patients hospitalized on acute medical units, it is imperative to review reports from evening and night shift nursing staff in addition to day shift staff to look for fluctuations in attention, cognitive abilities, and behavior over the course of a 24-hour period. Table 57.3g–4 lists features that can help distinguish delirium from dementia.

Patients who are delirious can appear depressed or manic and frequently are anxious and psychotic. Patients with the hypoactive subtype of delirium tend to be withdrawn, minimally reactive, with minimal speech, poor oral intake, and flat affect and can be mistaken as being depressed. While older patients who are depressed frequently exhibit impairment in short-term memory and in concentration they do not experience fluctuations in awareness and rapid fluctuations in cognitive functioning that are characteristic of delirious patients. Conversely, patients with the hyperactive subtype of delirium may be agitated, incoherent, and psychotic and may be mistaken as being manic. A patient who presents with an acute change in attention and cognition with fluctuating symptoms should be evaluated for delirium, whether or not the patient has a history of depression or bipolar illness, to prevent the possibility of not detecting a serious underlying medical disorder.

COURSE AND PROGNOSIS

An episode of delirium can be observed to progress through prodromal, overt, and resolving phases. During the prodromal period there are typically symptoms such as anxiety, restlessness, irritability, mild confusion, difficulty concentrating, poor sleep, nightmares, daytime drowsiness, social withdrawal, increased sensitivity to light and noise, illusions, and hypnopompic and hypnagogic hallucinations. There is growing recognition of a subsyndromal delirium, in which patients present with some, but not all, of the characteristic features of delirium. The prodrome may persist as subsyndromal delirium or it may evolve into overt delirium over a period of days or weeks. Patients with subsyndromal delirium have outcomes intermediate between those with no symptoms of delirium and those who meet the full diagnostic criteria.

Table 57.3g–4.
Differential Diagnosis: Delirium versus Dementia

	Delirium	Dementia
Onset	Acute	Often insidious
Duration	Variable; usually brief	Chronic, unless reversible
Consciousness	Impaired, fluctuating	Normal

Orientation	Impaired	Variable
Memory	Impaired	Impaired
Attention	Impaired	May be normal
Thought	Disorganized; transient delusions; content rich	Often stereotyped; content poor
Perception	Florid hallucinations (especially visual)	No hallucinations or simple hallucinations
Insight and judgment	Poor, but may return partially during lucid intervals	Variable, depending on etiology and stage
Mood and affect	Often anxious; may appear depressed	May be depressed or anxious
Sleep	Disturbed	May be normal
Electro-encephalogram	Abnormal: generalized slowing and slow posterior dominant frequency	Normal or mild slowing of posterior dominant frequency

Delirium that develops in the context of severe medical illness, such as sepsis, may progress to stupor, coma, and death if appropriate and prompt treatment of the illness is not administered. With appropriate treatment of the underlying medical illness and metabolic abnormalities, delirium will generally resolve. During the resolution phase, psychotic symptoms lessen, sleep cycles normalize, and clarity of awareness returns but cognitive deficits may be more persistent. The stage of resolving delirium in elderly patients may last from days to months. Persistent delirium is associated with poor functional recovery from surgery and from medical illnesses and is also associated with increased length of hospital stays and with higher medical costs. Patients who are recovering from delirium will usually require additional assistance for activities of daily living and close monitoring of their medical condition and cognitive functioning.

In the absence of neurodegenerative disease or dementia, the signs and symptoms of delirium usually resolve completely. In patients with Alzheimer disease or Parkinson disease, cognitive deficits can remain such that patients function below their previous baseline levels. Recent research has indicated that patients with Alzheimer disease may experience more rapid cognitive decline following an episode of delirium. In addition, there is also growing evidence that in vulnerable older adults, delirium can lead to permanent cognitive impairment and increases incident dementia. The pathophysiologic mechanism underlying delirium-induced dementia is not clear, but may involve processes other than those associated with Alzheimer disease. A serious medical illness that leads to delirium can also be thought of as a “stress test” for the brain that can unmask underlying cognitive deficits that were not obvious previously.

Most patients who have had a serious episode of delirium, retain little or no recall for events they experienced while delirious. Patients who had a mild-to-moderate episode of delirium are more likely to have memories of their experience. Some patients develop residual anxiety or even a posttraumatic stress disorder (PTSD) as a consequence of the fearful emotions and frightening perceptual disturbances they experienced when

they were delirious.

The presence of delirium is associated with a significant elevation in mortality risk for elderly patients, both during the hospitalization and in the 6 to 12 months after discharge from hospital. This association remains even after controlling for severity of underlying illness and other confounding factors. Delirium symptoms which persist at discharge from hospital are associated with a high rate of nursing home placement. Patients who have experienced an episode of delirium and have recovered remain at increased risk for a recurrent future episode of delirium.

PREVENTION

In recent years, there has been considerable interest in efforts to prevent delirium. The most widely used strategy is a multicomponent nonpharmacologic approach devised by Sharon Inouye and colleagues known as the Hospital Elder Life Program (HELP). This multidimensional strategy has been used for hospitalized patients with diverse medical problems. The HELP interventions include cognitive reorientation, therapeutic activities and early mobilization (such as daily exercise and walking), reduced use and reduced doses of psychoactive drugs, nonpharmacologic promotion of sleep, maintenance of oral hydration and adequate nutrition, and provision of appropriate hearing and vision aids. The HELP program has been instituted in over 200 hospitals and has been found to decrease both the incidence and duration of delirium.

Delirium prevention efforts have also focused on patients undergoing surgery since delirium is a common postoperative complication, especially in older adults. Studies have looked at patient baseline characteristics as well as intraoperative and postoperative management and their association with delirium. Current evidence indicates that the route of intraoperative anesthesia (e.g., general, spinal, or epidural) does not affect development of delirium. However, the total dose of anesthetic drugs may have a role in causing delirium. A recent double-blind randomized study found that using lighter sedation for elderly patients undergoing hip fracture repair surgery led to a 50 percent drop in the risk of postoperative delirium. In addition, minimizing use of benzodiazepines and certain opioid pain medications, especially meperidine, in the postoperative period can help decrease the incidence of delirium.

TREATMENT

The most important aspect of treatment is to identify and treat underlying medical illnesses and derangements causing delirium. In many cases, timely and appropriate medical treatment will be lifesaving to the patient. When delirium is detected in elderly patients, it should be considered a medical emergency, resulting in immediate workup to determine the underlying cause or causes and to initiate treatment. In older patients, a

single cause for delirium usually cannot be identified, as delirium is more commonly multifactorial in etiology. Most of the time, an older patient with delirium will be hospitalized in order to adequately evaluate the patient and address treatable causes.

Table 57.3g–5lists critical medical interventions which should be used in managing elderly patients with delirium. Besides diagnosing underlying medical causes, attention should be given to all possible contributors to the delirious state, especially modifiable predisposing factors. These include the elimination of all unnecessary medications, treating hypoxemia and anemia, correcting vision and hearing impairments which lead to sensory deprivations, maintaining good hydration and nutrition, preventing urinary retention and fecal impaction, and minimizing pain. Reducing the use of indwelling urinary catheters can prevent catheter-associated urinary tract infections and associated delirium. Close monitoring is necessary for the patient's safety and to prevent aspiration, falls, or inadvertent self-harm. Physical restraints should be avoided as much as possible. Use of physical restraints has been associated with worsening of psychotic symptoms and with medical complications such as deep vein thrombosis, pulmonary embolism, and cardiac dysrhythmias in delirious patients.

Table 57.3g–5.
Medical Interventions for Delirium in Elderly Patients

Ensure safety	Close observation by family member or staff may be indicated
Ensure adequate hydration and nourishment	Patient cannot monitor intake or feeding; this usually means intravenous hydration is indicated Eating and drinking should be observed to ensure adequate intake, and to avoid choking/aspiration
Ensure adequate oxygenation	Consider supplemental oxygen via nasal cannula to keep O_2 saturation >95%
Attention to bowel/bladder function	Watch intake/output Ensure regular bowel movements via appropriate bowel regimen
Investigate common etiologies of delirium	Perform the following: Chest radiograph to rule out pneumonia Urinalysis to rule out urinary tract infection Physical/lab exam to rule out dehydration/electrolyte disturbance Consider medication effects (not just toxicity, but ANY medication linked temporally to delirium onset) Hold nonessential medications
Treat pain adequately	Recommended drugs include scheduled acetaminophen for mild pain and low-dose hydromorphone for severe pain Avoid meperidine
Increase activity level as appropriate and tolerated	Get patient out of bed to chair as soon as possible Include written plan in chart to maintain mobility

Table 57.3g–6lists environmental, nonpharmacologic interventions which have been shown to be beneficial in the management of patients with delirium. These include taking steps to help restore a normal sleep–wake

cycle by minimizing light, noise, and disruptions during the night while increasing exposure to light and activity during the day. Many patients benefit from being moved closer to a window, where natural daylight and night cues can be appreciated. It is important for staff and family to be educated about appropriate ways to interact with the patient to promote cognitive functioning. Delirious patients should not be left alone for long periods. Family members and close friends of the patient should be encouraged to visit and should be allowed to stay with the patient overnight, if they so desire. Hospital staff and family members should reorient the patient to time, place, and person frequently during the day. Both overstimulation and understimulation should be avoided, as either extreme can exacerbate symptoms of delirium. The patient should be given only one task to do at a time, rather than multistep instructions. For patients who are anxious or fearful, frequent calm reassurance by family and staff can minimize agitation.

Table 57.3g–6.
Environmental Interventions for Prevention and Management of Delirium in Elderly Patients

Appropriate lighting	Bright during day Dark at night
Promote sleep at night	Low nighttime noise level Pagers on silent mode Telephone ring turned down Television turned off Voices kept low Doors closed as patient care permits Minimize necessary awakenings
Frequent reorientation	Staff to reorient patient to time, place, and person verbally each shift Clock and calendar in room Familiar possessions in room
Education	Family to be educated about the cause, course, and prognosis of delirium Staff to be educated about behavioral dysregulation in delirium and its management
Promote sensory function	Hearing aids on and function checked Glasses on and cleaned
Comfort/reassurance	Personal effects from home at bedside Family and close friends encouraged to visit and stay with patient, if possible Reassurance provided to patient

There are no FDA-approved medications to treat the behavioral disturbances in delirium. The first-line approach to managing agitation and psychotic symptoms in delirium is to try the nonpharmacologic interventions previously described, including reorientation, support, and reassurance. However, pharmacologic treatment may be necessary for agitated delirious patients for whom verbal reassurance is inadequate and

for patients who exhibit behaviors which are dangerous to themselves or others. Pharmacologic treatment is also indicated for patients with psychotic symptoms causing significant fear and anxiety.

In deciding which medication to use in treating behavioral symptoms of delirium, it is important to determine whether alcohol or sedative withdrawal is a cause of delirium. For patients experiencing alcohol or sedative withdrawal delirium, benzodiazepines are the medications of choice. Lorazepam or oxazepam may be preferable to chlordiazepoxide, especially in patients with decreased liver metabolism, because they are not metabolized by the liver and have shorter half-lives. It should be noted that benzodiazepines are not without adverse effects, especially in elderly individuals. These drugs can affect respiration and hemodynamics and can cause dysrhythmias. They can increase confusion and the risk of falls, and therefore, hip fractures. Paradoxical reactions, in which increased agitation and disinhibition are seen rather than sedation, are observed with greater frequency among patients with liver disease or low serum albumin levels. In the treatment of alcohol or sedative withdrawal, a common dosing guideline for lorazepam is as follows. Severity of withdrawal is monitored using a structured instrument such as the Clinical Institute Withdrawal Assessment for Alcoholism, revised (CIWA-Ar).

Lorazepam 1 to 2 mg is given orally, intravenously or intramuscularly every 4 hours on a scheduled basis on day 1. This dose is decreased by 50 percent on day 2, and it is decreased again by 50 percent on day 3. Score the CIWA-Ar every 4 hours. If the score increases to greater than 8 to 10, then the frequency of lorazepam doses is increased to every 1 to 2 hours until symptoms are controlled, then the original protocol is restarted. Patients with full blown delirium tremens will likely require higher and more frequent doses.

A 78-year-old male was admitted to the emergency department after a 5-week alcohol binge. He was known to have a long history of alcohol dependence, with multiple prior episodes of delirium tremens and probably alcohol-related dementia. On admission, clinical examination and laboratory testing revealed malnutrition, urinary tract infection, and pneumonia. The patient was started on oral lorazepam, but within 24 hours was transferred to the intensive care unit with tachycardia and visual and auditory hallucinations. A lorazepam infusion was started, along with a beta blocker for control of heart rate. Over the next 24 hours, the patient's condition stabilized. He was switched from the lorazepam infusion to intravenous bolus lorazepam with good control of symptoms. As his medical problems were treated, his mental state improved. The beta blocker was discontinued, and the lorazepam was tapered slowly over several weeks. He was discharged off medications 25 days after admission.

For delirious patients who are not experiencing alcohol or sedative withdrawal, benzodiazepines are avoided because they may exacerbate delirium and increase risk of falls. Antipsychotic medications are the agents of choice for treatment of psychotic and behavioral symptoms. Haloperidol, a typical antipsychotic, is highly effective for this indication, and, when

dosed appropriately, has minimal adverse effects. It does not cause significant hypotension, is not anticholinergic, does not depress respiration and does not cause or impair glucose regulation. Haloperidol can be administered orally or intravenously, and the latter route may be preferred in patients who are medically ill and unable to take oral medications. Intravenous dosing is also usually preferred for patients in intensive care units. The risk of QTc interval prolongation is minimized by staying within dosing guidelines and adhering to recommendations regarding QTc interval checks. Before haloperidol is initiated, a baseline QTc interval is obtained. If the interval is 450 ms or greater in a male, or 470 ms or greater in a female, intravenous haloperidol should not be used. Any patient whose QTc interval is prolonged beyond 25 percent of baseline during treatment should have haloperidol discontinued. There is evidence that intravenous haloperidol is less likely to cause extrapyramidal symptoms than oral doses of haloperidol.

A conservative but usually effective dosing schedule for an elderly delirious patient is as follows: haloperidol 0.25 mg to 0.5 mg intravenously every 8 hours on a scheduled basis, and 0.25 mg to 0.5 mg intravenously every 6 hours as needed to keep agitation and psychotic symptoms under control. If oral dosing of haloperidol is used, higher doses are given (e.g., 0.5 mg to 1 mg by mouth every 8 hours, and 0.5 mg to 1 mg by mouth every 6 hours as needed). Younger patients may require and tolerate higher doses of medication. How long the acute dose of haloperidol is maintained depends on how the patient responds clinically. If the patient becomes calm, and psychotic symptoms lessen within the first 12 to 24 hours (as usually happens), this dose of haloperidol is continued for 2 to 3 days and then is tapered over the next 2 to 3 days. If the patient does not become calm within this time frame, consideration should be given to a missed or inadequately treated medical condition prolonging delirium. In this case, haloperidol would likely be continued for a longer period.

Atypical antipsychotic medications have been shown to be just as effective as haloperidol in controlling symptoms of agitation and psychosis in delirious patients. These medications are generally well tolerated when used for acute episodes of delirium. One limitation is that they are given orally rather than intravenously. The two atypical antipsychotic agents which are most commonly used for delirium in elderly patients are risperidone and quetiapine, with dosing schedules as follows:

Risperidone 0.25 to 0.5 mg twice daily on a scheduled basis, and 0.25 to 0.5 mg every 6 hours on an as-needed basis.

Quetiapine 25 mg at bedtime to 25 mg twice daily on a scheduled basis, and 25 mg every 6 hours on an as-needed basis.

While delirium is recognized as a condition of cholinergic deficiency, a number of studies which looked at using cholinesterase inhibitors to treat

or prevent delirium did not find these agents to be beneficial. As a result, cholinesterase inhibitors should not be newly prescribed to either prevent delirium or to treat delirium in elderly patients.

An 84-year-old man was admitted from home with acute coronary syndrome. Medical history was significant for coronary artery disease, myocardial infarction, left carotid endarterectomy, chronic renal insufficiency, and renal cell carcinoma. He underwent three-vessel coronary artery bypass grafting. On the first postoperative day he was noted to be irritable, combative, and confused. He told his family that he was brought to the hospital for "experimentation," and had persistent tactile hallucinations of leaves and other objects in his mouth. Nighttime restlessness progressed to nocturnal insomnia and agitation. The patient had marked fluctuations in alertness during the day, with worsening agitation in the evening hours. During his agitated episodes, he pulled out his intravenous line several times. During a period of relative lucidity, an MMSE was performed and he scored 10/30. A psychiatric consultant recommended 0.5 mg of haloperidol orally every 8 hours on a scheduled basis for symptomatic treatment of his hallucinations and agitation. Medical complications (which included dehydration, atrial fibrillation, hypotension, and pneumonia) were managed as they arose. Although agitation and psychotic symptoms were improved, the patient required intermittent one-to-one observation by staff. After 7 days, his mental state began to improve as his medical condition stabilized. He was discharged on postoperative day 17, with some residual memory problems and insomnia, but without evidence of psychotic symptoms or agitation.

FUTURE DIRECTIONS

Animal models could be helpful in understanding the underlying pathophysiology of delirium. Studies have looked at the role of interleukins, GABA, dopamine, and acetylcholine—but more studies are needed. An animal model could also be helpful in testing preventive or treatment strategies. More studies of possible prophylactic or treatment effects of different antipsychotics would be useful. A possible role for melatonin or ramelteon, a melatonin receptor agonist, would be helpful based on preliminary studies. Dexmedetomidine has also been looked at in the prevention or treatment of delirium in postoperative patients and should be explored further. Different approaches to sedation for surgery also are promising areas for investigation. In particular, using light sedation, where possible, seems to be less likely to cause delirium.

57.3h Schizophrenia and Delusional Disorders

IPSIT V. VAHIA, M.D., AND CARL I. COHEN, M.D.

Over the past century, the vast majority of schizophrenia studies have primarily involved young adult patients. Indeed, only 1 percent of the literature on schizophrenia is dedicated to issues of aging. There has been a paucity of research on outcome of early-onset schizophrenia into later life as well as schizophrenia of late onset. Although research regarding late-onset schizophrenia is a relatively recent endeavor in the United States, late-onset psychosis has interesting historical ties. Accounts suggest that in 1693, Sir Isaac Newton experienced an episode of psychosis at the age of 51. His presentation included paranoid delusions, social withdrawal, and references to conversations that never occurred. Some individuals have attributed Newton's symptoms to metal poisoning or life events, but others have refuted such claims. This apparent case of late-onset schizophrenia-like psychosis that remitted after approximately 18 months, although debatable, is just one example of cases and ongoing research that seem to challenge the original Kraepelinian notion of dementia praecox in terms of age of onset and long-term course of schizophrenia. Indeed, a case of a new onset case of schizophrenia at age 100 has been reported by Cervantes et al. In this chapter, we examine older persons with early- and late-onset schizophrenia. We also briefly describe delusional disorder in older patients, which is sometimes viewed as part of a continuum with schizophrenia.

HISTORY AND COMPARATIVE NOSOLOGY

Emil Kraepelin's description of dementia praecox as a disorder of progressive decline with onset during adolescence or early adulthood has greatly influenced subsequent conceptualization of schizophrenia. Nonetheless, Kraepelin himself questioned the term *dementia praecox* after observing that the onset of this disorder was not limited to younger patients, nor was the course necessarily progressive. He used the term *paraphrenia* to describe a subset of patients with an onset of delusions and hallucinations that were primarily paranoid in nature and with a better prognosis. This group of patients had a number of symptoms similar to those of dementia praecox but with less alteration of emotion and volition. Kraepelin was said to refer to paraphrenia as the "darkest area of psychiatry."

Subsequently, several other European investigators examined the concept of late-onset schizophrenia in greater detail. The initial studies of late-onset schizophrenia were conducted by Manfred Bleuler, who described late-onset schizophrenia as being similar to early-onset schizophrenia, except for an age of onset after 40 years. Bleuler found that

late-onset cases comprised 15 percent of his schizophrenia patients and that roughly one-half of the patients with late-onset schizophrenia had symptoms very similar to those seen in early-onset individuals. Martin Roth et al. introduced the idea that late-onset schizophrenia could be a distinct entity after applying the term *late paraphrenia* to a group of patients with an onset of the disorder after the age of 60. These patients were generally women with sensory deficits, who had no family history of schizophrenia and presented with delusions and hallucinations. Years later, the term *late paraphrenia* was included in the ninth edition of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-9). Kurt Leonhand and other German contemporaries used the term *paraphrenia* to refer to paranoid schizophrenic patients without specifying age of onset. Felix Post categorized nonaffective paranoid disorders beginning after the age of 50 into three groups: simple paranoid psychoses, schizophrenia–like illness, and paranoid schizophrenia. The former resembled delusional disorder in our current nomenclature, and the latter two categories were distinguished by the absence and presence of Schneiderian symptoms, respectively. The use of the terms *paraphrenia* and *late paraphrenia* led to some confusion because Kraepelin did not consider late age at onset a feature of paraphrenia, and paraphrenia is a more inclusive term and not synonymous with schizophrenia.

Criteria such as age of onset of schizophrenia have changed over the years. The first and second editions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-I and DSM-II, respectively) did not specify age of onset criteria for schizophrenia. DSM-I included the category "involutional psychotic reaction" for psychotic symptoms occurring during the involutional period, and DSM-II used the term *involutional state* or *involutional paraphrenia* to describe a delusional state with onset during the involutional period. DSM-II did not specify an age cutoff for the diagnosis of schizophrenia. Differing from the previous DSM editions, DSM-III criteria restricted the diagnosis of schizophrenia for those with symptom onset before age 45. DSM-III-R included a late-onset category for patients with initial presentations at the age of 45 or later. The revised third edition also replaced the term *paranoid disorder* with *delusional disorder*, modified the diagnostic criteria to include a minimum duration of 1 month, and expanded the scope of delusions to include grandiose, erotomanic, somatic, jealous, and unspecified types. The criteria for delusional disorder in DSM-IV and DSM-5 have not changed. The ICD-10, DSM-IV, and DSM-IV-TR criteria did not include codable diagnoses for late-onset schizophrenia. However, DSM-IV and DSM-IV-TR mentioned differences between cases of schizophrenia with onset after 45 years compared to those with earlier onset. DSM-5 does not distinguish types of schizophrenia based on age, and in fact, has eliminated the syndrome-based subtypes (paranoid, disorganized, undifferentiated, residual, and catatonic).

Research indicates that late-onset forms of schizophrenia are more similar than different from earlier-onset forms, but there may be some subtle distinctions. This remains an area of debate, with some studies questioning the existence of a late-onset form.

To further examine issues surrounding late-onset schizophrenia, such as diagnostic and nomenclature inconsistency and the need for further study, an international late-onset schizophrenia group met to review the literature and reach consensus regarding the previously discussed topics. The group concluded that there was proof to support two late-onset illness classifications and proposed the following: late-onset (onset after the age of 40 years) schizophrenia and very-late–onset (onset after the age of 60 years) schizophrenia-like psychosis. However, subsequent research has frequently combined these categories, and as a result, the literature on distinctions between these subtypes remains limited.

EARLY-ONSET SCHIZOPHRENIA

Course of Illness

Schizophrenia typically develops in the second or third decade of life but greater numbers of schizophrenia patients are surviving into old age. Between 80 and 85 percent of persons aged 55 and over developed schizophrenia before age 45. In the United States, the prevalence estimate for schizophrenia is 0.6 to 1.0 percent in people aged between 45 and 64 years and 0.1 to 0.5 percent in people aged 65 years and older. Over the first quarter of the 21st century there will be a doubling of the number of persons aged 55 and over with schizophrenia, to about 1.1 million in 2025. By that time, about one-fourth of persons with schizophrenia will be in this older age bracket. Likewise, worldwide, the number of people aged 60 years and older with schizophrenia will more than double between 2014 and 2050, and an estimated 10 million people will be in this age category by 2050.

There is substantial heterogeneity in outcome of schizophrenia in later life. Long-term studies observing the symptoms and functioning in early-onset schizophrenia suggest that the course of schizophrenia may not be as pessimistic as previously thought, and findings tend to challenge the notion implied in the term *dementia praecox*. Based on several long-term studies carried out in Europe ranging from 22 to 37 years, Ciompi found that approximately 20 to 27 percent of patients attained complete symptomatic remission, 22 to 33 percent attained mild end states, 24 to 29 percent attained intermediate end states, and 14 to 18 percent attained severe end-states. Within the latter group, there is a very poor outcome group of about 5 to 10 percent, which corresponds most closely to Kraepelin's description of dementia praecox. Studies conducted in seven countries have reported similar results to those reported by Ciompi. However, cross-sectional data

have obscured heterogeneity in course and outcome in later life. Recent studies conducted in New York City by Cohen et al. have challenged the notion of schizophrenia in later life being a quiescent or stable end stage: about two-fifths of persons fluctuated between remission and nonremission. Moreover, outcome in later life is now conceptualized multidimensionally (e.g., positive and negative symptoms, cognition, mood, social functioning, and quality of life [QoL]), and that these dimensions are only weakly intercorrelated and fluctuate over time. Thus, persons may be doing well in some dimensions and not others, and that improvements in one dimension may not induce improvements in other dimensions. Furthermore, looking at a more comprehensive definition of recovery, Auslander and Jeste found only 8 percent of older outpatients attained "sustained remission," based on symptom remission, social functioning, and medication dosage. These findings were similar to Ciompi's findings regarding "global mental health" in which he found only 12 percent was completely free of disturbances, and 19 percent suffered from mild disturbances of some kind. Jeste et al. found that although the course of schizophrenia appears stable in later life, older outpatients remained impaired in various measures of psychopathology, functioning, and well-being as compared to an age-matched comparison group. In other words, schizophrenia continues to be symptomatic in older age in most patients and the possibility of complete recovery exists in only a small proportion of persons.

Overall, life course patterns reflect the wide variations in individual histories, and are consistent with a biologic-personality-environmental model of mental illness. Heterogeneity of outcome is the rule as schizophrenia progresses into later life. Despite scarce data, some findings suggest that the diversity seen in younger individuals might be even greater in older age. Although the extremes of this continuum attract most attention, a majority of older patients with schizophrenia can be identified at some point in between these extremes, moving with time in one direction or the other.

While a prediction of the long-term course of the illness in an individual cannot be accurately made, the general factors associated with favorable outcome include female gender, later onset of symptoms, paranoid subtype, less severe negative symptoms, and better premorbid functioning. However, with age, the strength of association between these variables and outcome weakens. Consequently, predicting a probable long-term course for schizophrenia patients is difficult. Apart from the relatively small group of poor outcome patients who worsen over time and who are largely found among chronically institutionalized patients, community-dwelling persons with schizophrenia—who represent about 85 percent of the older population—have been generally found to have a nonprogressive course, but with likely fluctuations over time in individual dimensions.

Dimensions of Outcome

Recent investigations have focused on dimensions of psychopathology, comorbidity, and functioning in schizophrenia in the elderly.

Positive Symptoms

Long-term studies of outcome have demonstrated that there is an improvement in positive symptoms with age. In cross-sectional prevalence studies, roughly half of patients living in the community demonstrated significant clinical improvement in positive symptoms. However, a longitudinal study (mean 4.5 years follow-up) from a subset of a New York City community sample aged 55 and over found only one-fourth had persistent symptomatic remission.

Negative Symptoms

Negative symptoms are thought to predominate the clinical picture of schizophrenia in later life. However, estimating negative symptoms in older schizophrenia patients can be challenging, as the clinical picture is often confounded by depression, demoralization, cognitive decline, medication effects, and poverty. The few studies of negative symptoms in community dwelling older adults found prevalence rates of between one-quarter to one-half of the sample. Notably, longitudinal data from the New York City sample described above found that 44 percent fluctuated between the presence and nonpresence of negative symptoms. Thus, contrary to earlier notions of schizophrenia progressing to "burnt-out" in later life, negative symptoms do not typically dominate the clinical picture, appear to be no higher than in younger schizophrenia populations, and may fluctuate over time.

Cognition

While cognitive decline in schizophrenia has been well established, there is ongoing debate on whether the trajectory of cognitive function shows a static course over time, in line with the supposed neurodevelopmental nature of schizophrenia, or exceeds that of normal age-related decline, suggesting neurodegeneration. Shah et al.'s review of longitudinal studies of cognitive decline found slightly more studies indicating a faster cognitive decline in later life than expected with normal aging, although this difference disappeared if only studies with control groups were included. Furthermore, any differences in cognitive decline between early- and late-onset groups were inconclusive. Another review by Rajji et al. found heterogeneity of outcomes on the basis of residential status. Community-dwelling patients exhibited stability into their late 60s except for cognitive decline that is expected from normal aging, whereas a greater than age-normal cognitive decline in patients with long periods of

institutionalization, especially after age 65 years. Thompson et al. recently postulated a more granulated picture for community dwelling middle-aged and older persons with schizophrenia (ages 40 to 100). On 3.5-year follow-up, three trajectories were identified: "Stable" 50 percent; "Modest Decline" 40 percent; and "Rapid Decline" 10 percent.

There have been few longitudinal studies examining the incidence of dementia among older persons with schizophrenia. Work in this area has been impeded by challenges in distinguishing cognitive deficits dating back to earlier in the disease course from normal age-associated cognitive decline. Consequently, nearly half of persons with schizophrenia may meet cognitive cut-offs for mild dementia. A recent review noted only three longitudinal studies comparing persons with schizophrenia to controls, and two demonstrated an increased prevalence of dementia and one did not; none of the studies controlled for risk factors or identified the types of dementia that were found. An unresolved issue is whether persons with schizophrenia may be more prone to dementia because of their higher rates of metabolic syndrome, which is a risk factor for both Alzheimer disease and vascular dementia.

Depression

Among the studies on depression in older adults with schizophrenia, prevalence rates of depression ranged from 11 to 75 percent, depending on the level of severity that was examined. At all levels of depression, the prevalence was significantly greater than their age peers in the general population, although rates were similar to those of younger persons with schizophrenia. Because there is a substantial minority of persons who do not experience depression, it may be inappropriate to consider a depression to be a core feature of the disorder, although it is a common feature with prevalence rates that remain high throughout the lifespan.

A recent prospective study found that persistent depression (defined as the presence of syndromal or subsyndromal depression) occurred in 44 percent of persons, 30 percent remained persistently nondepressed, and 26 percent fluctuated between depression and nondepression.

The potential for suicide remains high in later life. Among depressed persons aged 40 and over with schizophrenia, 23 percent had current suicidal ideation and 49 percent had made a previous attempt. In another study that included depressed and nondepressed persons with schizophrenia aged 55 and over, 13 percent had current suicidal ideation, and 30 percent had made a suicidal attempt during their lifetime.

Medical Comorbidity

Life expectancy is dramatically shortened in schizophrenia (by up to 20 years). The mortality risk in schizophrenia is 2 to 3 times higher than in the

general population, and this differential mortality gap may be increasing. There is increasing recognition of high prevalence of cardiovascular disease, diabetes, and metabolic syndrome in patients with schizophrenia, that at least partially can be attributed to lifestyle factors (smoking, poor dietary habits, limited physical activity) and the effects of antipsychotic medication, especially second-generation agents. Studies have also noted significantly higher rates of congestive heart failure, chronic obstructive pulmonary disease, and hypothyroidism. Interestingly, studies have suggested the possibility of lower cancer rates. Kredentser et al. found deaths from cancer to be higher among middle-aged persons with schizophrenia but not in persons over age 59. Cardiac disease is the chief cause of mortality in older schizophrenia patients, who have higher rates of medical illness, greater severity of medical illness, and more untreated medical conditions than their age peers.

In addition, part of the excess morbidity and mortality in schizophrenia may be inherent to the disorder itself. The search for the biologic underpinning of this supposedly intrinsic propensity for accelerated physiologic aging now focuses on inflammation and oxidative stress. Older schizophrenia patients were also found to be less compliant with nonpsychotropic medication. More importantly, although they have access to care similar to their age peers in the general population; older schizophrenia patients tend to receive less adequate care. Higher medical comorbidity has been associated with depression and positive symptoms.

Community Integration and Social Functioning

Social functioning has been defined by Weissman et al. as "the ability to establish and maintain relationships with friends and family as well as to undertake work and leisure activities and cope with day-to-day activities." Daily adaptive functioning refers to the ability to function independently. Long-term studies indicate that social functioning is often restored in older schizophrenia patients and can even develop further after onset of schizophrenia, although as with other domains, there may be movement in positive and negative directions over time. According to one study, up to 30 to 40 percent of schizophrenia patients may be able to regain capacity to work in late life. Higher levels of daily adaptive functioning have been associated with better cognitive function, fewer negative symptoms, better physical health, and independent living. Cognitive capacity is an important predictor of both social and adaptive functioning.

A more recent body of work has focused on community integration in schizophrenia. Community integration can be conceptualized as "normalization" of functioning in society and comprises assessments of functioning and perceived QoL within several dimensions, viz., independence, physical, psychological, and social integration. In the cross-sectional study conducted in New York City, community-living older adults

had roughly twice the level of high community integration than those with schizophrenia (41 percent vs. 23 percent). In a longitudinal study using the same sample, 34 percent of persons fluctuated between high and low community integration, suggesting that there is movement toward improved social integration in later life but also the potential for increased social isolation and diminished functioning.

Quality of Life

QoL indicates an individual's own perception of their position in life in relation to their goals, expectations, and concerns. It is an indicator of individuals' own appraisal of their condition. Lower QoL has been found to be associated with depression, positive and negative symptoms, cognitive deficits, financial strain, poor social support, and impaired social skills. Lower QoL may also predict suicidality. Although QoL indices have been found to be lower in older community-dwelling schizophrenia patients than their age peers matched for race and income, the absolute difference between the groups is small, and both scored in the moderate range of QoL, and substantially higher than persons with chronic pain.

In summary, the research data on the outcome dimensions of schizophrenia in older patients provide some support for optimism in later life. However, based on recent longitudinal studies, we now have a more nuanced understanding of the dynamics of various domains. Thus, favorable outcome in one category does not necessarily result in favorable outcome in another category. This suggests that it may be more profitable to develop treatment strategies that are specific to each outcome category, although treating one category may have some impact on other categories. Because each of the outcome categories has been found to be associated with a variety of clinical and social variables, it is likely that effective treatments will require biologic and psychosocial methods. Jeste et al. have described an exaggerated "paradox of aging" among older adults with schizophrenia. These patients may demonstrate accelerated physical aging (increased and earlier medical comorbidity and mortality). However, their cognitive aging rate appears to stabilize following an initial, persistent, occurrence of mild neurocognitive disorder. Conversely, as these patients age, there is potential for improvement in psychosocial function, decrease in psychosis, relapse and hospitalization, and improvement in self-management and life quality.

Treatment

As we noted above, optimal treatment for older patients with schizophrenia will most likely involve a combination of pharmacology, nonpharmacologic therapy, and community-based approaches. Unfortunately, there are only a few studies assessing treatment approaches in older schizophrenia

patients. However, the limited available data point in the direction of a multimodal approach.

Pharmacotherapy

Evidence-based pharmacologic treatment of the older population with schizophrenia remains problematic given the absence of placebo-controlled, randomized, double-blinded clinical trials that specifically compare efficacy of various antipsychotic medications in this population. A Cochrane review of antipsychotic drugs for persons aged 65 and over with schizophrenia identified only three randomized control trials (RCTs) of 252 people. One RCT assessed drugs that are no longer available. The other two studies noted no differences between risperidone and olanzapine, and olanzapine and haloperidol. The use of antipsychotic agents in older adults has been complicated by recent federal warnings regarding increased incidence of cerebrovascular events and death with their use in older populations with dementia. Most clinicians have relied on evidence based on open-label trials and retrospective reviews that point toward the effectiveness of risperidone, clozapine, olanzapine, quetiapine, ziprasidone, and aripiprazole for use in older schizophrenia patients. No RCTs of the newer antipsychotic agents (paliperidone, iloperidone, asenapine, and lurasidone) have been done in elderly people with schizophrenia, and only asenapine was studied for short-term safety. One controlled study suggested that citalopram can be effective for middle-aged and older adults with schizophrenia and subsyndromal depression. An expert review panel written in 2004 recommended risperidone (1.25 to 3.5 mg/day) as the first line of treatment. Quetiapine (100 to 300 mg/day), olanzapine (7.5 to 15 mg/day), and aripiprazole (15 to 30 mg/day) were viewed as good second-line treatments.

The increased risk of extrapyramidal side effects and tardive dyskinesia (TD) in the elderly population on antipsychotics poses an additional challenge for clinicians. Despite low dosing, the cumulative 1-year incidence of TD is 29 percent among older patients (mean age 65 years) on first-generation antipsychotic agents, whereas in young adults, the annual cumulative incidence of TD is 4 to 5 percent. Atypical antipsychotics have substantially lower risk of TD than conventional neuroleptics, even in very high-risk patients such as middle-aged and older adults with borderline TD. However, the atypical antipsychotics have a less favorable metabolic side-effect profile than conventional antipsychotics. Expert reviews have recommended starting antipsychotic medication at 25 percent of the recommended adult dose and maintenance doses at 25 to 50 percent of the adult dose.

Finally, there is some evidence that two groups of older persons with schizophrenia may be candidates for discontinuing their medications: those who have been in sustained remission and those in whom

medications have been ineffective in modifying symptoms.

Suzuki and Uchida found nonrelapse rates of between 35 and 81 percent in 9 studies of middle-aged and elderly patients with schizophrenia whose medication had been stopped for 2 weeks to 18 months.

Nonpharmacologic Approaches

Use of nonpharmacologic treatment approaches to improve outcomes in older schizophrenia patients has received attention over the last decade. Several RCTs have shown favorable results for the use of cognitive remediation therapy for cognitive deficits, social skills therapy for difficulties with social interaction, and cognitive behavioral therapy for problems with social relatedness, psychosis, and mood. Older schizophrenia patients seem to respond well to behavioral learning techniques and can be taught a variety of instrumental roles and social skills, and these skills seem to provide long-term benefits and improved outcome. For example, a combined approach—cognitive-behavioral social skills training (CBSST)—was found to improve coping skills, social functioning, and facilitate a more objective understanding of subjective psychotic phenomena. More importantly, improvements in functioning as a result of CBSST were found to persist 1 year after conclusion of treatment.

Placing older schizophrenia patients into jobs and providing on-site training and support was found to improve rates of both paid and volunteer work. This approach was significantly more successful than the traditional "train-then-place" approach.

Community-Based Approaches

Assertive Community Treatment (ACT) and case management were both found to improve outcomes in older schizophrenia patients. There is also increasing use of self-help groups and voluntarism. Several model programs have combined collaborative care and case management strategies to confront the medical and psychiatric issues facing many patients as well as the need to facilitate communication between the mental health team and the primary care providers. Case management strategies include augmenting the patient's social and cognitive skills in conjunction with physical health–enhancing strategies.

LATE-ONSET SCHIZOPHRENIA

Epidemiology

The prevalence of late-onset schizophrenia and very-late–onset schizophrenia-like psychosis remains unclear. A review of studies of late-onset schizophrenia found that approximately 20 to 25 percent of patients with schizophrenia had an onset of the disorder after age 40. A Dutch case-register study reported a 1-year prevalence rate of 0.55 percent for

schizophrenia in persons over age 59 years, of which 64 percent had early-onset schizophrenia. These figures suggest that the loss of early-onset individuals (to death or recovery) may at least partially be compensated for by the influx of cases with a later onset. Epidemiologic study of late-onset schizophrenia is complicated by a number of factors, including the use of various definitions of *late onset*, uncertainty in the determination of age of onset, and questions regarding a correct diagnosis. A review of studies of late-onset schizophrenia found that approximately 23 percent of patients with schizophrenia were reported to have experienced the onset of the disorder after age 40, with 13 percent in the fifth decade of life, 7 percent in the sixth decade, and 3 percent in later decades.

Among persons aged 45 to 64 years there is an incident rate of 12.6 per 100,000 per year for new-onset schizophrenia.

Rates of psychotic symptoms or paranoid ideation have been estimated as high as 14 percent in older nondemented community dwelling adults, with rates among urban African Americans being twice that of Caucasians. A study of "very-old" nondemented individuals (aged 85 and 95 years) living in the community or institutions in Sweden found the prevalence of any psychotic symptoms in 85 year olds was 10.1 percent (hallucinations, 6.9 percent; delusions, 5.5 percent) and prevalence in 95 year olds was 7.1 percent (hallucinations, 6.7 percent; delusions, 10.4 percent).

Late-onset schizophrenia affects women between 2 and 10 times more often than men. The robustness of this finding, coupled with the higher incidence rates of early-onset schizophrenia in men, have led to the hypothesis that estrogen-mediated dopaminergic inhibition may protect younger women from schizophrenia, whereas the relative estrogen deficiency associated with menopause may be related to the increased incidence of late-onset schizophrenia in women. However, the incidence of schizophrenia is still considerably higher in younger versus older women, and treatment interventions based on the estrogen hypothesis have been largely unsuccessful. An alternative hypothesis is that older men may be protected in some way.

Etiology

The precise etiology of late-onset schizophrenia (onset age 45 to 60) and very-late–onset schizophrenia-like psychosis (onset over 60) is largely unknown. The International Late-Onset Schizophrenia Group concluded that schizophrenia with onset in middle age is a neurodevelopmental disorder, and that differences with early-onset schizophrenia are more of degree than of kind. The International Late-Onset Group also postulated that "Very-Late–Onset Schizophrenia-Like Psychosis" had some features that suggested a neurodegenerative component including more brain abnormalities and neuropsychologic deficits. A potential problem with this tripartite classification system is its reliance on age rather than clinical

presentation, and some persons over 60 can resemble earlier-onset cases.

Although some studies found that late-onset schizophrenia was less frequently associated with a family history of schizophrenia than the early-onset form, a more recent study reported that the family history of late-onset schizophrenia appeared to be similar to that of early-onset schizophrenia. Familial association of schizophrenia appears to be more common in early-onset and late-onset schizophrenia than in very-late–onset schizophrenia-like psychosis. Late-onset patients function somewhat better than do early-onset schizophrenia individuals during adolescence and adulthood. Late-onset schizophrenia patients seem to have a similar pattern, but lower severity, of cognitive impairments when compared to early-onset schizophrenia patients. Late-onset schizophrenia patients perform significantly worse than do healthy comparison subjects on measures of executive functioning, learning, motor skills, and verbal memory. Making a diagnosis of late-onset schizophrenia can be challenging. The onset of hallucinations and delusions in later life can arise de novo or be associated with mood disorders, sensory deficits, polypharmacy, substance abuse, medical disorders, or dementia.

The role of social and environmental stressors may also have a role in development of schizophrenia and schizophrenia-like psychosis after age 40. A relationship between trauma and onset of schizophrenia in childhood and early adulthood has been established previously in the literature. A relationship between history of trauma and onset of schizophrenia may also exist. A retrospective study that reviewed records of child survivors of the holocaust found that development of schizophrenia after age 40 was associated with higher degree of persecution in concentration camps before age 15. While this study has limitations and the hypothesis needs to be investigated further, the findings were remarkable for the strength of association between late-onset schizophrenia and degree of persecution. Studies in the United Kingdom found that the risk of developing very late-onset schizophrenia like psychosis is greater among older migrant populations than British-born elderly residing in the United Kingdom. In these studies, differences in the background age–gender structure of these populations were insufficient to explain this distribution. Like the study of holocaust survivors, the authors of the British studies have speculated that adverse psychosocial events associated with migration may precipitate schizophrenia in later years in vulnerable individuals.

The role of cognitive deficits in late-onset disorder is not fully understood. A sizeable proportion of patients with very-late–onset-type schizophrenia may go on to develop a type of dementia. Whether this proclivity to develop dementia is a characteristic of this subtype or suggests initial misdiagnosis is unclear. Brichant-Petitjean et al. observed that people with late-onset disorder occupy an intermediate position between those with early-onset type and healthy controls with respect to cognitive

deficits.

No specific biologic markers of schizophrenia with a later onset have been identified.

Hahn et al.'s review of neuroimaging studies that compared early-onset and late-onset schizophrenia reported differences in eight of ten studies, but across studies these were not consistent. Similarly, measures of event-related brain potentials (N400) and neurofibrillary tangle densities found no differences between early-onset and late-onset groups. However, a study reported in 2014, found raised C-reactive protein concentrations in both people with late-onset and very-late–onset schizophrenia. These findings need to be replicated. There also may be some differences with normal controls. For example, MRI studies found that patients with late-onset schizophrenia had larger right temporal horns and larger third ventricles compared to healthy controls, similar to the changes seen in younger patients with schizophrenia. In a study comparing the electroencephalograms of late-onset individuals to age and gender-matched controls, the only significant difference was a generalized slowing in the electroencephalograms of the late-onset schizophrenia patients, which might have been partially accounted for by the effects of antipsychotic medications. The investigators concluded that there did not appear to be an underlying dementia in late-onset schizophrenia.

Few data exist specifically examining functioning in late-onset schizophrenia, although examinations of middle-aged and older schizophrenia patients, of whom some were late-onset patients, have been conducted. In a group of middle-aged and elderly patients with schizophrenia or schizoaffective disorder, patients demonstrated significantly greater disability in all areas of social functioning compared to healthy controls. Although marriage rates have been shown to be higher in persons with late-onset schizophrenia compared to early-onset schizophrenia patients, social isolation was greater when comparing late-onset patients to the general population. As compared with healthy subjects, middle-aged and older schizophrenia outpatients were less likely to be married and have children, and more likely to live alone, and they had fewer friendships. However, older schizophrenia patients did not appear to be estranged from family members.

Although there were no differences between early and late-onset groups in positive symptoms, family history, brain abnormalities, memory retention, or minor physical abnormalities, the late-onset group was more likely to be female versus no gender differences in early-onset, have the paranoid subtype of schizophrenia, have lower levels of negative symptoms, have less impairment in learning, abstraction, and flexibility, better premorbid functioning with respect to work and marriage, and require lower daily dosages of antipsychotic medications. These differences suggest that late-onset schizophrenia may be a neurobiologically distinct form of

schizophrenia.

"Very-Late–Onset Schizophrenia-Like Psychosis" is distinguished from the other two types by more brain abnormalities and neuropsychologic deficits; more females; greater prevalence of persecutory and partition delusions; higher rates of visual, tactile, and olfactory hallucinations; lower genetic load; more sensory abnormalities; and absence of negative symptoms or formal thought disorder.

Diagnosis and Clinical Features

In terms of symptoms, early- and late-onset patients are more similar than different. The essential features of schizophrenia are a mixture of characteristic positive and negative symptoms associated with cognitive impairment and marked social or occupational dysfunction. The most common features of late-onset schizophrenia are persecutory delusions that may be bizarre and auditory hallucinations. The severity of positive symptoms appears to be similar to that in early-onset schizophrenia. A comparative study of early-onset and late-onset schizophrenic patients found no difference between the two groups in the prevalence of delusions of reference, bizarre delusions, or lack of insight. Patients with the late-onset form, however, tended to have more persecutory delusions with and without hallucinations, organized delusions, and abusive auditory hallucinations or hallucinations with a running commentary. The most common symptoms in the late-onset group were delusions, and approximately two-thirds had bizarre delusions. In general, late-onset illness is different from early-onset schizophrenia in that the late-onset type is associated with less severe negative symptoms, lower daily doses of antipsychotics needed for treatment, and less frequently observed loose associations and inappropriate affect. Consistent with these findings, late-onset schizophrenia patients typically meet criteria for the paranoid or undifferentiated subtype of schizophrenia.

In clinical samples, very old age at onset is related to a low prevalence of thought disorder and affective blunting and a higher prevalence of visual hallucinations. Variations in symptom profiles with onset at different ages do not necessarily imply differences in pathophysiology or etiology. Although similar symptoms could arise from different etiologic or pathologic processes, symptom differences could be related to cohort differences or age-associated central nervous system (CNS) differences that are independent of the illness.

Differential Diagnosis

The principal disorders in the differential diagnosis of late-onset schizophrenia include earlier-onset schizophrenia, mood disorders with psychotic features and schizoaffective disorder, delusional disorder,

psychosis associated with cognitive disorders, psychotic disorder due to a general medical condition, and substance-induced psychotic disorder.

Early-Onset Schizophrenia

Determining the onset of schizophrenia can be challenging, as many schizophrenic patients have an insidious onset of symptoms or premorbid personality traits that are difficult to differentiate from prodromal symptoms. Late-onset patients tend to be similar to earlier-onset schizophrenia of paranoid type in symptoms. Earlier onset and thus longer duration of schizophrenia are generally associated with more severe negative and disorganized symptoms and greater cognitive deficits (especially in the areas of learning and abstraction). In addition, late-onset schizophrenia is characterized by less severe symptoms with somewhat better preservation of affect and social functioning.

Mood Disorder

Differentiating schizophrenia from mood disorder with psychotic features and schizoaffective disorder is complicated in that mood disturbances are common during the prodromal, active, and residual phases of schizophrenia. As described earlier, prevalence rates of co-occurring clinical depression have been found in up to three quarters of older persons with schizophrenia, although mood symptoms may not meet criteria for major depression. Furthermore, mood-congruent or mood-incongruent psychotic features may occur in major depression or bipolar disorder, although in both disorders psychotic features tend to be more mood-congruent, for example, grandiosity erotomania, special powers among bipolar individuals and delusions of poverty, guilt, sin, or physical illness among depressed persons. Auditory hallucinations occur less commonly in depression and may be vague or condemnatory. Although uncommon, catatonic features are more commonly seen in severe depressive disorders, a history of mood symptoms may help to discriminate between conditions based on DSM-IV-TR criteria. Mood disorder with psychotic features beginning after 45 years of age is differentiated from late-onset schizophrenia by its affective symptoms that precede psychotic symptoms.

In schizoaffective disorder, there must be a mood episode that occurs simultaneously with the active-phase symptoms of schizophrenia and they must be present for a substantial proportion of the active and residual periods of the illness. Additionally, delusions or hallucinations must be present for at least 2 weeks in the absence of prominent mood symptoms. If the mood symptoms have a duration that is brief in relation to the total duration of the disturbance, occurs only during the prodromal or residual phases, or do not meet full criteria for a major depressive disorder, manic disorder, or mixed episode, then a diagnosis of schizoaffective disorder

cannot be made. Patients with remissions between schizophrenic episodes may be diagnosed as schizoaffective on one occasion and schizophrenia with mood disturbances on another occasion depending on levels of symptom severity and duration.

Delusional Disorder

Delusional disorder is differentiated from schizophrenia by a lack of prominent auditory or visual hallucinations and an absence of deterioration in areas of functioning outside the delusional scope. The delusions are necessarily nonbizarre and involve situations that may occur in real life, such as theft, suffering from a disease, or spousal infidelity. Delusional disorder may be difficult to differentiate from the paranoid type of schizophrenia because the latter is not characterized by prominent disorganized speech, disorganized behavior, or flat or inappropriate affect, and is often associated with less decline in functioning than in some of the other subtypes of schizophrenia. Nonetheless, the presence of auditory hallucinations or bizarre delusions seen in schizophrenia should differentiate the disorders. Furthermore, poor psychosocial functioning in delusional disorder is directly related to the delusional beliefs themselves.

Psychosis Associated with Cognitive Disorders or due to a General Medical Condition. A patient who presents with psychotic symptoms after the age of 45, particularly if the symptoms develop after the age of 60, requires a thorough evaluation for underlying medical disorders. Dementia is a common disorder in elderly persons, and approximately half of patients with a diagnosis of dementia of the Alzheimer type may present with psychotic symptoms at some point during the course of their dementia. Delusions in Alzheimer disease tend to be nonbizarre, episodic, and preceded by cognitive decline. Typically, delusions in Alzheimer disease involve someone stealing from them or entering their house. Visual hallucinations are more common in Alzheimer disease than in schizophrenia, and auditory hallucinations may be slightly less common. Other types of dementia, such as alcohol-induced persisting dementia and vascular dementia, also need to be ruled out. Psychosis due to a general medical condition is diagnosed from the history, physical examination, or laboratory tests that show the delusions or hallucinations are the direct physiologic result of a general medical condition. Metabolic disturbances, neurologic and endocrinologic disorders are the most common causes of psychotic symptoms. Misuse or abuse of prescription and over-the-counter medications must also be considered.

Substance-Induced Psychotic Disorder. The prevalence rates of substance use disorders are estimated at 2 to 3 percent in older woman and 10 percent in older men. These figures are expected to increase as the baby

boomers reach old age. A number of different substances, such as amphetamines, cocaine, and phencyclidine, can produce symptoms similar to those of schizophrenia, such as delusions, hallucinations, or a mixture of positive and negative symptoms. Many substances can induce psychotic symptoms during withdrawal states, for example benzodiazepines, barbiturates, and alcohol. Ideally, substance-induced psychotic disorders would be differentiated from schizophrenia after a period of abstinence; however, other evidence, such as whether the psychotic symptoms appear to be exacerbated by the substance and decrease when it has been discontinued or whether the psychotic symptoms have been instigated and maintained by the substance use, need to be considered.

Course and Prognosis

The course of late-onset schizophrenia is usually chronic but may be interrupted by partial remissions and exacerbations. Over the past decade, there has been substantial change in our understanding of prognosis and outcomes in schizophrenia in late life. The prognosis is somewhat better than that in early-onset schizophrenia. Patients may be quite responsive to antipsychotics used in lower doses. However, mortality (especially from suicide) exceeds that in the general population and is probably comparable to that in early-onset schizophrenia.

Studies of cognitive outcome in late-onset schizophrenia have yielded mixed findings. A 2-year study compared early- and late-onset schizophrenia patients, normal controls, Alzheimer disease patients with psychosis, and Alzheimer disease patients with a Mini-Mental State Examination (MMSE) of at least 24 at baseline. This study suggested that late-onset schizophrenia patients have a rate of cognitive decline that is similar to early-onset patients and normal controls. However, another study which followed late-onset schizophrenia patients and normal controls over 5 years, demonstrated significant cognitive decline in the late-onset schizophrenia group. The course of late-onset schizophrenia therefore remains unclear.

Treatment

A Cochrane review of antipsychotic treatment for elderly people with late-onset schizophrenia reported only one small RCT comparing two drugs and the reviewers concluded that this study provided little usable data. Based on very limited data, late-onset schizophrenia patients appear to have good symptomatic improvement with antipsychotic treatment compared to early-onset illness individuals. Although appropriate therapy requires individualization, it appears that substantially reduced doses of antipsychotics are necessary in late-onset schizophrenia patients. Maintenance therapy is frequently required, because many of these

patients relapse if they discontinue the medication. Elderly patients are more susceptible to certain antipsychotic side effects, such as sedation, anticholinergic toxicity, and extrapyramidal symptoms. As mentioned in the previous section, only a small number of open-label and controlled prospective trials have been conducted to examine the efficacy and safety of antipsychotics in schizophrenia, with the majority of literature pertaining to conventional antipsychotics. Atypical antipsychotics have become the agents of choice for older adults with psychosis, owing to their improved side-effect profile compared to conventional agents. However, there is a lack of published data specifically examining the use of atypical antipsychotics in patients with late-onset schizophrenia, and existing investigations have frequently involved mixed samples of early- and late-onset patients. Thus, results must be inferred from trials of atypical antipsychotics conducted in young adults with schizophrenia.

Psychosocial treatment is a vital aspect of the management of late-onset schizophrenia, and treatments specifically designed for older adults with schizophrenia, such as cognitive behavioral therapy and social skills training also have shown promise.

DELUSIONAL DISORDER

Epidemiology

Studies suggest that between 2 and 8 percent of the elderly population experiences some type of paranoid symptoms. One study indicated that although approximately 2 percent of elderly psychiatric patients met DSM-III criteria for paranoid disorder, another 13 percent had paranoid ideation. DSM-IV-TR estimates the population prevalence of delusional disorder to be approximately 0.03 percent. Delusional disorder usually first appears in middle to late adulthood and the sociodemographic profile is similar across cultures. The overall prevalence of delusional disorder is slightly higher among women than among men, and the average age of onset is earlier for men (40 to 49 years) than for women (60 to 69 years). Owing to its later age at onset, the lifetime morbidity risk is estimated by DSM-IV-TR to range between 0.05 and 0.1 percent.

Etiology

Several factors have been postulated to contribute to the development of delusional disorder: a family history of schizophrenia; avoidant, paranoid, or schizoid personality disorder; hearing loss; or being an immigrant or of low socioeconomic status. The available evidence implicating each of these factors needs confirmation. From the viewpoint of psychological defense mechanisms, delusions are generally attributed to an excess and inappropriate use of projection. The patient tends to hold others responsible for any biopsychosocial losses that may accompany normal

aging. Studies aimed at establishing a genetic component to delusional disorder have been unable to either confirm or establish such a component. This is because all studies to date have been limited by unreliable sampling (owing to the subjective nature of the diagnosis of delusional disorder). Studies that have had relatively sound inclusion criteria have been limited by small sample sizes.

There are no clear neuroanatomical changes associated with delusional disorder. There is mixed evidence that hearing or visual abnormalities might play a role in the development of delusional disorder, with Maher observing that a subset of patients develops delusions in the context of sensory impairment (Reinhardt paper 116).

Family, twin, and adoption studies have suggested that a close association between delusional disorder and schizophrenia is unlikely. Until robust molecular data are available, a genetic role in etiology of delusional disorder or a common link between delusional disorder and schizophrenia cannot be fully appreciated.

Diagnosis and Clinical Features

Persecutory, somatic, or erotomanic delusions in the elderly patient are usually secondary to another neuropsychiatric disorder (e.g., schizophrenia, mood disorder, or dementia). Occasionally, however, a primary delusional disorder is implicated. A clearer understanding and study of this disorder has been held up by inconsistencies in nomenclature and diagnostic criteria.

The essential feature of delusional disorder is one or more persistent nonbizarre delusions that have been present for at least 1 month. Diagnostic criteria for schizophrenia or schizoaffective disorder must not be met. Auditory or visual hallucinations, if present, are not prominent. Psychosocial functioning, although variable, generally is not considerably impaired outside of the delusional realm, and behavior is not noticeably odd or bizarre. The DSM-5 describes the following subtypes of delusional disorder based on the predominant delusional theme: erotomanic, grandiose, jealous, persecutory, somatic, mixed, and unspecified.

Common types of delusions seen in elderly patients with delusional disorder are skin infestation by insects; organs, such as a liver, are cancerous (despite a lack of evidence); the person is being spied on, followed, or poisoned; and the spouse is unfaithful (without factual support). Social, marital, or work problems can result from the delusional beliefs of delusional disorder. Ideas of reference are common, and understanding of such ideas is usually consistent with the content of the patient's delusional beliefs. Anger, irritability, and dysphoric mood can occur, especially in the persecutory and jealous types of delusional disorder. It is thought that major depressive episodes likely occur more frequently in persons with delusional disorder than in the general

population. In addition, individuals with delusional disorder may have high lifetime comorbidity with affective disorders, such as obsessive-compulsive disorder (OCD) and body dysmorphic disorder.

Differential Diagnosis

The considerations in the differential diagnosis of delusional disorder are similar to those for schizophrenia with onset in late life. Delusional disorder can be differentiated from schizophrenia by the absence of other characteristic symptoms of the active phase of schizophrenia, such as prominent auditory or visual hallucinations, bizarre delusions, and negative symptoms. Although mood disorders with psychotic features commonly involve nonbizarre delusions without prominent hallucinations, the temporal relationship between the mood disturbance and the delusions is an important consideration when differentiating the disorders. Somatic delusions and hypochondriasis are sometimes difficult to distinguish; however, in hypochondriasis, the fears of having a serious disease are held with less intensity than in delusions. It is also difficult to distinguish between delusional disorder and OCD. Obsessions may develop into sustained delusional beliefs that may make an additional diagnosis of delusional disorder appropriate. Organic etiology such as Wilson disease and stroke must be ruled out prior to diagnosing delusional disorder.

Course and Prognosis

The course of delusional disorder may vary but tends to be chronic, especially in those with the persecutory type of delusional disorder. A waxing and waning of the preoccupation with the delusional beliefs often occurs, and in other cases, full periods of remission may be followed by subsequent relapses. In some cases, the disorder remits within a few months, often without subsequent relapse. Some evidence suggests that the jealous type may have a better prognosis than the persecutory type. Generally, intellect and occupational activities are maintained, but marital and social functioning is compromised. The data on prognosis are limited, although the likelihood of complete recovery seems low.

Treatment

There are no available studies on the treatment of late-life delusional disorder. Antipsychotic agents often are effective, especially in agitated delusional patients, but they must be administered cautiously in elderly persons. Expert consensus guidelines recommend the use of atypical antipsychotic medications over conventional agents as follows: First line: risperidone 0.75 to 2.5 mg/day; second-line: olanzapine 5 to 10 mg/day or quetiapine 50 to 200 mg/day. Commonly, persons deny their illness. Consequently, nonadherence to antipsychotics is a common problem in the

treatment of patients with delusional disorder. For refractory cases, modified electroconvulsive therapy has been reported as successful. In addition to pharmacologic therapies, psychosocial treatments represent an important therapeutic option. Cognitive-behavior therapy has been demonstrated as an effective treatment approach.

57.3i Personality Disorders

MARC E. AGRONIN, M.D.

Multiple normative and pathologic changes during the aging process affect personality, and these same forces apply to the consideration of personality

disorders in late life. These disorders represent a heterogeneous array of chronic affective and behavioral disturbances that cause enormous personal and interpersonal distress and pose significant challenges to clinical management, especially in the setting of comorbid medical and psychiatric conditions. Changing and inherently limited diagnostic schemes combined with a general lack of previous study make it difficult to understand and plot the trajectory of a given personality disorder in late life. Clinical perspectives on personality stability versus change will vary depending on the methods of assessment. There is limited empirical evidence and a range of unsubstantiated opinions as to whether personality disorders persist with minimal or no change, convert into more age-appropriate forms with similar levels of pathology, or remit over time. Understanding all of these factors is critical to improving diagnosis and optimizing clinical management.

DEFINITIONS

Defining the concept of *personality* itself is key to a fuller understanding of personality disorders. According to the *Bantam Medical Dictionary,* personality is "an enduring disposition to act and feel in particular ways that differentiate one individual from another." George Vaillant qualifies this definition, suggesting that the enduring aspects of personality, which he terms *temperament,* consist largely of various inherited elements such as personality traits and IQ. He bases this belief on longitudinal studies of core personality traits (e.g., extroversion, introversion) that have generally found stability with aging. On the flip side, Vaillant holds that elements of personality or *character* defined by adaptive styles can change significantly with aging, affected by both "environment and maturation." Putting together both elements of stability and change, Henry Murray's statement that "the history of the personality is the personality" is most helpful when considering aged individuals. Lacking accurate longitudinal data from an older individual's younger days, the average clinician is forced to make decisions about personality functioning based on more recent history.

The distinction between normal and abnormal personalities is based largely on the expression of certain personality *traits* (as opposed to more acute psychopathologic symptoms) that are repeatedly associated with unhappiness, interpersonal conflict, and/or occupational dysfunction. Although everyone has a unique personality with relative strengths and weaknesses, the current diagnostic model requires the categorization of certain personalities as pathologic along the lines of various subtypes. This categorical model has been criticized for the ways in which it provides pejorative labels and obscures the richness of personality. In late life, it is particularly problematic given the large number of physical and psychosocial stresses that can distort an individual's pattern of adaptation.

An alternative dimensional approach was proposed but not adopted in

the *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition (DSM-5). Personality disorders are defined in DSM-5 as chronic psychiatric disorders characterized by enduring and pervasive patterns of inflexible and maladaptive inner experiences and behaviors. These dysfunctional features are rooted in early development, deviate from cultural expectations, and lead to significant social and occupational impairment across several spheres of function: perception and interpretation of experiences, emotional expression, interpersonal relations, and impulse control.

There are ten subtypes of personality disorders listed in the DSM-5 classification, grouped into three broad phenomenologic clusters: cluster A, the *odd* cluster, includes paranoid, schizoid, and schizotypal subtypes; cluster B, the *dramatic* cluster, includes antisocial, borderline, histrionic, and narcissistic subtypes; and cluster C, the *anxious* cluster, includes avoidant, dependent, and obsessive-compulsive subtypes. Depressive and passive-aggressive (or negativistic) personality disorders were two subtypes that were listed in the appendix of the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition text revision or DSM-IV-TR but are no longer included in DSM-5. Each personality subtype is defined by 8 to 10 diagnostic criteria, and an individual must meet a specified number of them in any combination in order to qualify for a diagnosis. Individuals may demonstrate a single disorder or a combination of maladaptive traits from several disorders. Individuals who have symptoms characteristic of a personality disorder in general, but do not meet criteria for any specific disorder, may be diagnosed as having an *unspecified personality disorder*.

Although there are several designated pediatric categories for personality disorders, there are no equivalent, age-adjusted geriatric subtypes, despite growing evidence that changes in both personality and personality disorders in late life can lead to enduring but *different* patterns of personality dysfunction. However, when personality change results from physical damage to the brain from substance abuse or a medical condition, the term *personality change due to another medical condition* can be used (with the medical condition specified and then coded separately), with several designated subtypes: labile, disinhibited, aggressive, apathetic, and paranoid. Common causes of personality change include traumatic head injury, stroke, endocrine dysfunction, encephalitis, and Alzheimer disease.

EPIDEMIOLOGY

Community-based epidemiologic studies have found rates of personality disorders in adults ranging from 10 to 20 percent, with one large sample of over 43,000 individuals in the United States yielding a prevalence rate of 14.8 percent. Epidemiologic studies focusing only on individuals 65 years or older have found a slightly lower prevalence range between 5 and 13 percent. These rates increase two- to threefold in individuals being treated

in both outpatient and inpatient psychiatric settings for comorbid psychiatric diagnoses, particularly major depression. For example, a study of 546 elderly psychiatric inpatient admissions found personality disorders in 13 percent of all patients, which increased to 24 percent of those diagnosed with major depression. In all studies, the method of diagnosis has produced variations in prevalence rates. Epidemiologic surveys and more impressionistic clinical diagnoses have generally found higher rates of personality disorders and yet a more limited spectrum of subtypes compared to criterion-based structured clinical interviews.

The most common personality disorders seen across late-life studies have been paranoid, avoidant, dependent, and obsessive-compulsive subtypes. In late life, nearly two-thirds of those diagnosed with a personality disorder also meet criteria for two or more subtypes, or for the unspecified category. It is important to bear in mind that the lifelong course of specific subtypes will influence prevalence. For example, a decrease in the prevalence of antisocial personality disorder in late life no doubt results from increased rates of remission, death, institutionalization, and avoidance of psychiatric settings with age. Decreasing rates of other personality disorders in late life may be due to the fact that they are difficult to differentiate from other specific psychiatric diagnoses, or may change in ways that obscure their recognition.

There are limited data on the prevalence of personality disorders in long-term care settings, due to the great difficulty obtaining longitudinal data in addition to the challenge of interviewing individuals who may be suffering from varying degrees of cognitive impairment. One survey that based diagnoses on clinical interviews found that nearly 11 percent of a modest sample of nursing home residents had a primary or secondary diagnosis of personality disorder. An identical diagnostic rate was found in a sample of intellectually disabled adults older than 40 years who were admitted to a long-term care institution—although in that study, the congenital diagnosis might call into question the personality disorder diagnoses. A review of referrals to a nursing home found that 15 percent were for unspecified personality problems, although it is not clear how many of these individuals had actual personality disorders. Rates for personality disorder subtypes in long-term care facilities have not been established in any study.

DIAGNOSIS

In spite of the very specific diagnostic criteria provided by DSM-5, clinicians immediately encounter a plethora of diagnostic challenges when assessing older individuals. Sometimes the older personality, viewed from an ageist stance, is erroneously believed to be more dependent, stubborn, and hypochondriacal and less adaptive in the face of stress, compared to younger personalities. Such an attitude may lead clinicians to view many

disordered behaviors as normal in late life, preventing accurate diagnosis. At the same time, many clinicians might not consider the possibility of a personality disorder in an older patient, or might be daunted by the large number of diagnostic criteria. As a result, these diagnoses are often deferred or merely lumped under an unspecified category. Lack of knowledge either of specific criteria or how to apply them in late life has been shown to create discrepancies between largely impressionistic clinical diagnoses and those determined through more rigorous structured interviews.

The criteria themselves foster misdiagnosis since they were developed for adults, and do not take into consideration age-associated changes in lifestyle and behaviors that render many of them obsolete in later life. For example, the diagnosis of antisocial personality disorder includes criteria such as "repeatedly performing acts that are grounds for arrest," "repeated physical fights or assaults," and "consistent irresponsibility" with work or financial obligations. For an older person who is retired from work, residing in congregate living or a long-term care facility with limited mobility, or physically frail, these criteria will simply not apply. Diagnostic criteria for borderline personality disorder such as self-injurious behaviors and self-damaging impulsivity with respect to spending, sex, driving, or eating are also less applicable to older adults, who in general tend to be less impulsive. As of yet, there are no geriatric criteria that can be substituted, and attempts by clinicians to make diagnoses based on fewer criteria, or to "age-adjust" other criteria, threaten the very validity of the diagnosis.

Not surprisingly, a recent analysis of data from the National Epidemiologic Survey on Alcohol and Related Conditions, which studied over 43,000 individuals, found that young and old adults endorsed nearly 30 percent of personality disorder criteria differently, despite having equal degrees of personality dysfunction. The end result was that older adults were more likely to have schizoid and obsessive-compulsive personality disorder diagnoses, while younger adults were more likely to have avoidant and dependent personality disorder diagnoses. The same diagnostic criteria, then, yielded different disorders based on age.

Another diagnostic dilemma is the need for accurate longitudinal descriptions of a personality on which to base the diagnosis. Unlike symptoms of most other psychiatric disorders, which are readily reported or observed, personality disorder symptoms can be more difficult to elicit through self-report given their pejorative nature, and when observed require repeated encounters across different settings to be accurate and reliable. Instead, clinicians often have to rely on clinical records, which typically lack longitudinal data, or on existing informants who can rarely provide critical information dating back to an older patient's young adulthood.

An important caveat for any clinician attempting to make a late-life

diagnosis is that personality dysfunction does not necessarily indicate a personality disorder. Significant, repeated, and sometimes devastating losses in late life, such as the death of a spouse or of a series of close friends, a chronic debilitating illness, chronic pain, physical disability, the loss of finances or livelihood, or the overall loss of personal attributes that once defined an individual (e.g., strength, beauty, athletic, or sexual prowess), can lead to severe adjustment reactions that mimic personality disorders. Without clear longitudinal information, it is difficult to determine whether a patient with pervasive dysfunctional interpersonal relations, for example, is demonstrating a lifelong pattern or a more recent reaction to life events. Many symptoms of major depression and generalized anxiety disorder overlap with depressive, negativistic, avoidant, and depressive symptoms of several personality disorders. Similarly, symptoms of persistent bipolar mania can mimic antisocial, narcissistic, and borderline traits. For this reason, personality disorder diagnoses are best deferred during episodes of acute psychiatric syndromes. Perhaps one of the most difficult decisions to make is whether changes in demeanor brought on by neurocognitive disorders and associated neuropsychiatric syndromes such as apathy are merely expressions of the underlying disorder or represent a true personality change.

CLINICAL FEATURES AND COURSE

Since its inception in 1952, iterative versions of the DSM have provided a heterogeneous and fluid array of personality disorder subtypes up until the more enduring categorization that appeared in the third edition of the DSM (DSM-III) in 1980. Despite the relative stability in the nomenclature since then, the DSM has never been clear on the course of personality disorders into late life, only suggesting that several remain relatively unchanged while others attenuate. The possibility of a late-onset personality disorder is not addressed in the DSM, aside from the diagnosis of a personality change disorder. Unfortunately, there are limited data on most subtypes, and current thinking rests largely on case studies.

For the clinician working with elderly individuals with known or suspected personality pathology, the main question is: What do these disorders look like in late life? Are they fundamentally the same as in previous years, or does aging change them in ways that either attenuate symptoms and cause remission or lead to similar degrees of pathology but with novel, age-appropriate manifestations? Consider the following clinical vignette.

Mr. L was an 82-year-old man who suffered from brittle diabetes, morbid obesity, and chronic obstructive lung disease. After his wife died, Mr. L was unable to manage his own care needs and had to be admitted to an assisted living facility (ALF). He was oxygen dependent and used an electric scooter to get around. Mr. L quickly established a reputation as a rude and aggressive man. He would badger other residents and staff in the elevator when they did not

get out of his way quickly. He would make unrealistic demands of the waiters in the dining room, and insult them when he did not get his way. He accused the nursing staff of deliberately withholding treatment after one of his medications went missing from his tray. Over time, staff grew increasingly tired of his verbally abusive and disruptive behaviors, and was afraid to help him since he often threatened to sue them for shoddy care. They described him as a difficult, paranoid, and hateful person.

These behaviors built to a crisis one day when Mr. L became enraged at a deaf resident standing in front of him in the elevator who could not hear him berating her to move out of his way. He pushed her down and ran over her foot with his scooter, causing a serious skin laceration and bruise. He completely denied his actions, however, accusing the injured woman of deliberately feigning injury after blocking his scooter and getting bumped. He screamed at all staff who tried to intervene, and threatened to kill anyone who got in his way. As a result, Mr. L was hospitalized involuntarily and not allowed to return to the ALF.

Additional information on Mr. L indicated that he had been an extremely aggressive but quite successful real estate broker as a young and middle-aged man. His daughter estranged herself from him due to his abusive behaviors, and his son limited his contact with his father whom he described as arrogant, paranoid, and verbally abusive to those who disagreed with him. Mr. L's behaviors were chronic but seemed to have improved in the several years prior to his becoming ill, perhaps because his business success enabled him to get involved in several gratifying philanthropic endeavors. However, with the onset of illness and then the death of his wife, he could not cope with being dependent on others for help. He was completely unable to trust staff or forge stable relationships in the ALF, and became increasingly angry, depressed, and paranoid. Having to adjust to institutional living proved impossible, and his brittle coping style was eventually overwhelmed, resulting in a crisis characterized by aggression and paranoid accusations. Putting together known history and current observations, Mr. L's clinical team diagnosed him with a paranoid and narcissistic personality disorder.

In this clinical vignette, several themes appear that characterize the course and prognosis of many personality disorders throughout life. First, dysfunctional behaviors do not arise de novo but have a history, and have pervaded the individual's life in one form or another since young adulthood. In many cases, there may be long periods of increased stability in middle age that represent symptomatic remission, typically bolstered by stable relationships, successful occupational pursuits, and intensive therapeutic assistance. Not all personality disorders, however, will benefit from these stabilizing factors—particularly those with avoidant, schizoid, and schizotypal features. As seen in the illustrative case, major late-life stresses can exacerbate existing pathologic traits or lead to reemergence of previous traits in ways that are different in kind but equally problematic as earlier in life. Lacking a longitudinal history and based strictly on observed behaviors, many personality-disordered individuals are typically diagnosed with major depression, bipolar disorder, or even late-onset schizophrenia given the intensity of their symptoms. Although these diagnoses may present comorbidly, they are driven in part by the underlying personality disorder.

Cluster A Disorders

In late life, the diagnostic criteria for the three odd cluster disorders coalesce around a lack of desire for and openness toward interpersonal relationships. The tendency of the paranoid personality disorder to read

malevolent intent into the actions of others leads to a lifetime of angry conflicts with others, while the aloof and strange demeanor of the schizoid and schizotypal individual precludes the formation of close relationships. As a result, odd cluster personality disorders tend to enter later life without the benefit of past interpersonal experiences that can, for less dysfunctional individuals, teach social skills and provide emotional support. It is believed that the pathologic cognitive and behavioral patterns of the odd cluster disorders tend to remain the same or even worsen with aging.

Paranoid, schizoid, and schizotypal individuals face age-associated stresses with variable responses. On the one hand, the lack of close relationships means that these individuals may feel less emotional impact from the inevitable loss of family members or longstanding social contacts. However, when medical illness and disability occur, these same individuals often have great difficulty seeking help and coping with forced dependency on others, especially when placed in long-term care institutions. The result is often the increased expression of longstanding dysfunctional behaviors and defense mechanisms, including paranoid ideation, social isolation, and odd or idiosyncratic beliefs or rituals. There may also be an increased risk of psychosis, to the extent that these disorders are considered potential precursors for late-onset schizophrenia.

Cluster B Disorders

Although lumped together under the "dramatic" cluster domain, these four personality disorders are heterogeneous in both expression and course over the life cycle. A central theme, however, is that while their psychopathology results in severe and, in some cases, deadly consequences, there is potential for symptomatic quiescence, improvement, or even remission in middle age when there are significant personal or occupational achievements or the presence of consistent interpersonal relationships. In addition, individuals with more personal, social, and/or financial resources and with less psychiatric comorbidity tend to fare better. By the same token, age-associated losses in relationships, social and occupational roles, physical attributes such as strength and beauty, and financial status can reverse many of these gains and prove devastating to the personality. For those individuals who had improved over their lifetimes, the stress of major losses can lead to the reemergence of previous dysfunctional cognitive and behavioral patterns, but in ways not always recognizable by the current diagnostic nomenclature. These relapses are inevitably complicated by comorbid psychiatric disorders such as major depression, neurocognitive disorders, anxiety disorders, and substance-related and addictive disorders.

There are several factors that limit the number of older individuals with antisocial personality disorder who are seen in clinical settings. First, their history of reckless and criminal behaviors and high rates of substance

abuse often result in either death or incarceration long before they reach middle age. Second, these individuals have poor insight into their problems, few supportive relationships, and lack of motivation to get help unless there is an acute issue that prevents their ongoing activities. As a result, both young and old antisocial individuals tend to avoid psychiatric settings.

Despite this rather grim assessment, clinical data reveal, somewhat surprisingly, that up to a third of antisocial individuals demonstrate significant clinical improvement if they survive into middle age, and about 12 to 33 percent no longer meet diagnostic criteria after 10 to 15 years. Individuals with poor social skills and higher degrees of aggression tend to do worse. The most salient changes include a shift away from aggressiveness, promiscuity, and criminal behaviors but replaced, in part, by substance abuse, depression, and somatization. All of these changes may reflect a general trend of decreased impulsivity and aggression with aging.

In long-term care settings, antisocial behaviors may include resistance to care, surreptitious substance abuse, abuse of other residents, and disregard for institutional rules regarding personal safety, hygiene, and schedules. Based strictly on observable behaviors, these older individuals might not meet criteria for antisocial personality disorder, even though a longstanding lack of conscience—the hallmark of the disorder—is driving more age-appropriate dysfunctional behaviors.

In a similar fashion, individuals with borderline personality disorder demonstrate the potential for significant improvement and even remission in middle age, with one longitudinal study of 100 individuals finding that 75 percent no longer met criteria after 15 years. This improvement was bolstered by personal and occupational successes and associated with increased physical attractiveness, higher intelligence, and self-discipline. Poorer outcomes were associated with a history of abuse, antisocial tendencies, high levels of aggression, and substance abuse. Even with improvement, however, there remained a significant risk for depression, substance abuse, and suicide.

Clinical case studies have described borderline individuals who demonstrate reemergent symptoms later in life, but with a different appearance. Earlier defining symptoms of self-mutilation, impulsive and risky behaviors, and poor self-identity are attenuated and replaced by mood lability and depression, nonadherence to treatment, overuse of prescription medications, and alcohol abuse. In long-term care settings, however, the erratic and rageful interpersonal style seen in younger individuals with borderline personality disorder is often still present, creating havoc on the milieu.

Over their lifetimes, individuals with narcissistic personality disorder often leave a wake of hurt and disgruntled personal and business relationships in their path, and though aware of their own anger or

estrangement from others, they rarely attribute it to their own behaviors. Their sense of entitlement and demands on others may bring success in middle age, but with time they are particularly vulnerable to age-associated losses of personal attributes, gratifying occupational and social roles, and supportive if not somewhat subservient relationships. It becomes increasingly difficult for them to replace lost or jettisoned relationships over time, and they may find themselves in great need due to illness or disability but without adequate social supports. The very process of aging proves to be a significant narcissistic injury, only worsened when they have to rely on the help of others they deem below them. In long-term care, the narcissistic personality disorder often presents as simultaneously depressed, rageful, and imperious toward staff, leading to frequent conflicts.

Histrionic personality disorder is probably the least studied in late life, and has not been reported much in epidemiologic surveys or in clinical case studies. Like the narcissistic individual, however, histrionic individuals often lack deep, supportive social relationships, and are equally buffeted by age-associated losses in physical appearance that allowed them to maintain some state of psychological equilibrium in the past. It has been suggested that somatization may be one dysfunctional avenue for older histrionic individuals to obtain attention and social gratification.

Cluster C Disorders

The anxious cluster disorders are thought to involve a lifetime of chronic personality dysfunction without significant remission, perhaps explaining why they tend to be some of the most commonly seen personality disorders in late life. Comorbid major depression is common and is often the presenting diagnosis when the underlying personality disorder is not appreciated. Avoidant and dependent individuals, in particular, often enter later life without having been able to cultivate many supportive relationships. As a result, the loss of a spouse or someone who served as their main support can be devastating and precipitate severe anxiety, depression, and incapacity. Given their poor social skills and inability to activate the social resources to meet their daily needs, these individuals may end up in dire circumstances, bereft of support and at high risk in the community of abuse and neglect. The same psychopathology may be somewhat adaptive in long-term care settings, however, where forced dependency is a welcome respite for them and alleviates the difficult responsibility of having to assume self-care.

Individuals with obsessive-compulsive personality disorder tend to be less isolated in later life than avoidant or dependent individuals, and have often cultivated sufficient social supports due to their rigid insistence on routines and schedules. These individuals are more self-sufficient and may do relatively well with aging as long as they are able to find activities, part-

time jobs, or other tasks to keep them busy and organized. Cognitive and physical disability can threaten this stability, however, especially when obsessive-compulsive personalities are unable to control their daily life according to preset rules and routines and have to depend on less reliable caregivers or long-term care staff. The latter circumstances can lead to significant conflicts with caregivers, as well as angry behavioral outbursts, anxiety and panic attacks, and depression.

TREATMENT

Given both the chronicity and pervasiveness of personality disorders, the initial goal of treatment is not to provide a cure, but to reduce the frequency and intensity of symptoms. True symptomatic improvement is challenging and takes months, if not years to accomplish, and will always be slowed down when comorbid medical and other psychiatric disorders are present. Similarly, treatments for major depression have been found to take longer and to be less effective in the presence of underlying personality disorders. Thus, realistic target symptoms should be established at the outset of treatment so as not to fall into the trap of building up excessive expectations that end up disappointing the patient and his or her social supports as well as burning out the therapist.

There are several necessary treatment approaches for any older individual with a personality disorder. First, a general survey of active medical, neurologic, and medication-related factors that may be causing acute changes in personality expression must be ascertained to ensure that adequate treatment is being provided. Many of these factors, including cerebral dysfunction, metabolic abnormalities, pain, and unmet physical or emotional needs, may be triggering and/or fueling the interpersonal conflicts or disruptive behaviors that represent the personality disorder. Normal psychotherapeutic or pharmacologic strategies will fail unless these factors are addressed. This first step will necessitate significant involvement of multidisciplinary treatment team members, other treating physicians, and caregivers in order to implement the treatment plan as well as to serve as informants on response—particularly for individuals with cognitive impairment and/or physical disabilities.

Second, comorbid psychiatric disorders such as major depression, panic disorder, and substance-related and addictive disorder, among others, must be under treatment in order to reduce the psychological stress on the personality, as well as to clarify the personality disorder diagnosis. Diagnostic false positives are more likely during episodes of other psychiatric disorders, prompting many clinicians to defer personality disorder diagnoses during this time. A particular challenge at this juncture involves dealing with personality disorders within the setting of Alzheimer disease or other types of neurocognitive disorders, which can change personality itself or distort previously dysfunctional expressions of

personality in ways both positive and negative. Some individuals may be more labile and impulsive, while others may be more apathetic and less likely to act out, especially when there is frontal or temporal lobe dysfunction. Unfortunately, it is difficult to predict the course of any given individual personality or personality disorder within the setting of neurocognitive disorders, even when the specific regions of cerebral or subcortical damage are known. Although there are a number of existing acetylcholinesterase agents and one glutamate-receptor antagonist that can treat the cognitive, behavioral, and functional symptoms of Alzheimer disease, there is no evidence that any of these agents will have a discernible effect on personality disorders.

Third, clinicians must be willing and able themselves or have available to them a multidisciplinary team that can actively engage the older personality-disordered individual over time and through a variety of treatment modalities in order to foster a stable alliance. For older borderline, histrionic, narcissistic, dependent, and obsessive-compulsive subtypes, episodic clinical visits with an unpredictable schedule and therapy with too narrow a focus on medication management are liable to impair the therapeutic relationship. It is best to have several team members working together to provide an adequate density of time and attention in order to maintain stability and manage crises. On the flip side, older schizoid, schizotypal, paranoid, and avoidant subtypes might do best with shorter and more intermittent clinical visits, with a specific focus geared toward their stated needs. In all circumstances, there are inevitable medical and social issues—and often crises—that arise and require the involvement of a clinician who has made a firm commitment to the patient. Although such an approach seems obvious, it is all too often overlooked in a time-limited and overstretched mental health system.

Fourth, older individuals with personality disorders are often seen in long-term care settings, providing a structured setting in which to engineer environmental or behavioral plans. These plans require the input and creativity of mental health, social work, and nursing staff to be developed, implemented, and revised if necessary. The following clinical vignette illustrates how these plans may work.

Mr. P was a 78-year-old man with severe spinal stenosis who suffered from chronic back pain and was confined to a wheelchair. He had previously been diagnosed with both narcissistic and obsessive-compulsive personality disorders, as well as major depression. Shortly after being admitted to a nursing home, he frequently became enraged and verbally threatening toward nurses whom he accused of not adequately maintaining the battery on his electric wheelchair. On one occasion he struck a nurse who was trying to reconnect a lead to the battery, accusing her of failing to follow his detailed instructions. A multidisciplinary clinical team met to discuss the situation, and decided to condition Mr. P's access to the electric wheelchair on his cooperative behavior. A single staff member was assigned to work with Mr. P to maintain the battery, which limited the targets of his wrath. He earned hours in the electric wheelchair for each day that he went without cursing or abusing staff. As a result, the treatment team noticed a significant reduction in his abusive behaviors.

The key to success with any plan lies in the concerted and well-coordinated efforts of staff to implement its elements, monitor for improvement, and maintain communication. Pitfalls include disputes among staff members that often reflect the personality disorder's inner dynamics, lack of consistency, and lack of patience. When plans fail, staff members may inappropriately resort to punitive actions to deal with dysfunctional behaviors or attitudes, such as withholding attention or care, neglecting legitimate needs, or using chemical restraints unnecessarily. In long-term care settings, there are federal guidelines stemming from the 1987 Omnibus Budget Reconciliation Act or OBRA that ideally should prompt attention to behavioral strategies as well as protect residents from unnecessary and excessive use of psychotropic medications.

Psychotherapy

In older individuals with several subtypes of personality disorders and minimal to no cognitive impairment, both individual and group psychotherapeutic modalities may be helpful. Schizoid, schizotypal, paranoid, antisocial, and avoidant individuals tend to be more reluctant to engage in insight-oriented therapy, and might do best through the indirect fostering of therapeutic relationships. In long-term care settings, this can be achieved through nonpsychiatric therapies (e.g., physical or occupational therapy) or activities (small jobs, arts and crafts, and music) that provide vital involvement, socialization, and meaning. Older individuals with borderline, narcissistic, histrionic, obsessive-compulsive, and dependent personality disorders will do better with direct forms of psychotherapy, especially cognitive-behavioral therapy (CBT). Dialectical behavior therapy (DBT) is a particularly useful form of CBT that was originally developed for individuals with borderline personality disorder but has been adapted for individuals with major depression and personality disorders. DBT focuses on helping individuals become mindful of both the triggers and the consequences of their behaviors and then develop strategies to change them. Studies in younger individuals with DBT have found less overall depression and anxiety, fewer suicidal and self-injurious behaviors, and a decreased number and length of psychiatric hospitalizations.

Group psychotherapy can take on many forms for elderly individuals, ranging from psychoeducational forums to single-focus groups for socialization, bereavement, or caregiving to more formal therapy groups such as are found in a structured outpatient program. Group selection for the older personality-disordered individual will depend on his or her tolerance for a group setting, ability to participate without either monopolizing the group or acting out, and level of motivation. Cognitively

intact individuals with reasonably good social skills are the best candidates.

Pharmacotherapy

Psychotropic medications can be used across several levels in the older patient with a personality disorder: (1) crisis management; (2) treatment of comorbid psychiatric disorders, such as major depression; (3) treatment of the personality disorder itself; and (4) treatment of the most salient target symptoms associated with the personality disorder. The first two levels are covered extensively in other parts of this text, and are inevitably faced with every personality disorder. Treatment of the personality disorder itself is quite difficult given the heterogeneity of presentations, and the literature has almost exclusively focused on borderline, schizotypal, and antisocial subtypes. Even in the majority of those studies, the main focus of treatment was on selected target symptoms that were most problematic, such as impulsivity, aggression, and psychosis. All three of these common symptoms in both dramatic cluster and odd cluster personality disorders have been found to be partially responsive to antipsychotic agents, antidepressants, and mood stabilizers such as divalproex (Depakote) and carbamazepine (Tegretol). Many of the early studies looked at the use of tricyclic antidepressant agents and monoamine oxidase inhibitors to treat symptoms of personality disorders. Although they demonstrated some degree of efficacy, these latter agents are less practical in elderly patients due to their anticholinergic properties and propensity to cause orthostasis. In general, there is no evidence to date that clearly supports one particular agent or medication class as more efficacious than another for any particular symptom or personality disorder. As it stands, given the lack of data for older individuals, the selection of specific psychotropic medications for both young and old individuals with personality disorders will follow the same guidelines.

In older individuals, clinicians must hearken to the familial caveat to "start low, go slow, but go" when prescribing medications. However, another equally important caveat is to know when the use of medications might actually be counterproductive. It is risky to prescribe to patients with poor adherence to medications or hazardous use of them due to cognitive impairment, denial of illness, or impulsivity. In all of those cases, more structure is needed to administer the medications, either through a trusted family member or a visiting nurse, or by transferring the patient to an assisted living or long-term care facility. Patients with obsessive-compulsive and dependent traits sometimes become fixated on medication doses and dosing schedules and spend excessive time discussing this with the prescribing doctor instead of dealing with more relevant issues. Taking a medication becomes a way for them to pathologically structure their relationship with the doctor, such as through increased dependency. In all of these situations, the clinician must weigh the potential benefits of the

medication against the potential harm to the patient through misuse or the resultant exacerbation of dysfunctional behaviors.

57.3j Alcohol and Substance Abuse in Older Adults

STEVE KOH, M.D., MICHAEL C. HANN, M.D., AND DAVID W. OSLIN, M.D.

The demographics of the United States are shifting as the "baby-boom" generation ages and advances in medical science and public health lead to longer life spans. Projections based on U.S. Census data indicate that by the year 2030, approximately 18 percent of the U.S. population will be over the age of 65 years. This aging trend is not unique to the United States. The United Nations Department of Economic and Social Affairs projects that those above age 60 will account for about 21 percent of the total global population by 2050. Even within the older adult group, the oldest old (above age 80) is increasing. Furthermore, the ratio of males to females is increasing due to improvements in male life expectancy. In 2013, this ratio in those above age of 60 was 76:100. By 2050, this will increase to 87:100. Population trends indicate that the aging cohort of adults who are currently considered middle age will reflect the substance use and misuse trends of younger cohorts.

As the U.S. population ages, classically held views on alcohol and substance misuse are becoming increasingly inaccurate. Indeed, although alcohol and drug misuse are among the foremost causes of disability worldwide and contribute to negative health outcomes, the misuse of and addiction to alcohol, prescription medications, marijuana, and illicit substances are often not examined or addressed in the geriatric population and have grown to the levels of an "invisible epidemic." Data from the National Household Survey on Drug Abuse suggests that by the year 2020, 2.7 million Americans aged 65 years or older will misuse prescription drugs and 4.4 million older adults will require some form of substance abuse treatment. Other beliefs include the view that older women do not misuse substances and that older adults do not benefit from substance misuse treatment. Form of ageism is currently common in clinical practice and these issues are not well explored by clinicians.

Table 57.3j–1.

Barriers to Detection of Substance Misuse in the Geriatric Population

Barriers to the Clinician	Barriers to the Older Adult
Assumptions of lower prevalence of substance misuse in the geriatric population	Poor insight into substance misuse and reluctance to voluntarily seek help
Failure to screen appropriately for substance misuse in older population	Lack of knowledge about the mental health system and treatment options
Masking of symptoms of substance misuse by other comorbid physical and mental/cognitive ailments	Feelings of shame, denial, desire to continue using, pessimism about treatment and recovery
Discomfort with addressing substance misuse with older adults	Cognitive problems–substance-induced amnesia, underlying neurocognitive disorder
Absence of collateral information from family members and caretakers	Family members and/or caretakers may not adequately report concerns of substance misuse
Assumption that older adults may not benefit from substance misuse treatment and prevention	Belief that other medical issues may be more important to address than substance misuse

Adapted from Crome I, Dar K, Janikiewicz S, Rao T, Tarbuck A. Our Invisible Addicts: First Report of the Older Persons' Substance Misuse Working Group of the Royal College of Psychiatrists. College Report CR 165, June 2011.

Several common barriers impede the identification of substance misuse in the elderly, some of which are outlined in Table 57.3j–1. Many stereotypes of the typical older adult with substance abuse are prevalent in clinical care. For example, an older patient needing addiction treatment is often deemed to have been a life-long heavy drinker with failing health related to alcohol use and a limited to nonexistent social network. Also, the relatively healthy older adult who is drinking "moderately" is not considered to be in need of help and is often not assessed fully for the potential effect of alcohol on overall health and well-being. As the baby-boom cohort enters the geriatric population, unique challenges will face providers; along with the increased size of this cohort with changes in age distribution, there will be higher rates of excessive drinking, binge drinking, and illicit drug use.

An additional potential barrier to identification is the relative rarity of severe use disorders in the elderly, where the prevalence of moderate to severe alcohol use disorder is less than 4 percent and even lower in women, and illicit drug use disorders are currently less than 1 percent. On the other hand, 10 to 20 percent of older adults are drinking above recommended limits and are therefore at risk of having or developing problems even if they do not meet criteria for a use disorder.

For older adults, lack of understanding regarding the definition of at-risk use and who may benefit from treatment interferes with assessment or treatment-seeking behavior, which may be further compounded by denial. Similar to providers, patients may perceive physical symptoms (e.g.,

fatigue, sleep problems, anxiety, confusion) as normal or attribute them to a comorbid condition. Furthermore, age- and substance-related declines in memory may result in underreporting of past and current substance use. These complications in dealing with older patients in identifying alcohol and/or substance misuse is illustrated in Table 57.3j–2.

DSM-5 TERMINOLOGY

The *Diagnostic and Statistical Manual of Mental Disorders*, 5th Edition (DSM-5) criteria for substance use disorder are considered identical for younger and older adults. Whereas distinctions were made between substance abuse and dependence in previous editions of the DSM, DSM-5 combines these diagnoses into a single disorder measured on a continuum from mild to severe. The essential feature of a substance use disorder is a cluster of cognitive, behavioral, and physiological symptoms indicating that the individual continues using the substance despite significant substance-related problems. Each of the 10 separate classes of substances is addressed as a separate use disorder (e.g., alcohol use disorder, stimulant use disorder, etc.) and is assessed clinically along a severity spectrum scale.

Table 57.3j–2.
Case Study on the Barriers to Identification of Alcohol and/or Substance Misuse in the Geriatric Population

Mr. Doe is a 74-year-old man who was evaluated in the Emergency Department (ED) after a fall in which the patient sustained a hip fracture. In addition to hip pain, the patient endorses some ill-described upper abdominal discomfort. The patient's blood alcohol level (BAL) was 0.04 in the ED. The patient lives alone but takes care of himself, and has a small social network of a few friends. He has family but they do not live nearby, and he is financially independent. When asked about general health habits, he reports that he does not smoke, but drinks every day at dinner and before bed. The ED physician asked the CAGE questions, which upset the patient who responded negatively to all items. The patient is taking hydrochlorothiazide and Lisinopril for hypertension and was recently prescribed Ambien as a sleep aid and a histamine antagonist for gastritis by his primary care physician (PCP). The ED physician documented that the patient's fall was likely secondary to use of Ambien, and declined to investigate the patient's drinking habits further due to the patient's irritation with the topic.

Review of the patient's medical record indicated that the patient received a mental health evaluation 6 months earlier at the request of his family. The family was worried about him living alone and wanted him to move into an assisted living facility. He was determined to be able to perform daily activities, although he was somewhat slow,

The case study illustrates several diagnostic dilemmas faced by clinicians who treat older drinkers:

- Mr. Doe did not seem to meet any dependence criteria.
- The patient, the ED physician, and the psychiatrist failed to make the connection that alcohol misuse was probably contributing to Mr. Doe's gastritis and to his presentation in the ED.
- Mr. Doe was, however, drinking well above the recommended limits and was therefore an at-risk drinker, even if he did not present as the typical "alcoholic."

Take home points:

- Diagnostic criteria and symptoms for alcohol and prescription drug misuse are not as applicable for older adults and may be confounded with comorbid medical illnesses.
- Lack of recognition by health care providers is often compounded by lack of understanding of the benefits of reduced substance use when the

and he rarely left home. There was no sign of dementia, but there was minor impairment in reaction time and problem solving. When asked about alcohol use, he reported that he drank one drink at dinnertime and two drinks of sherry before bed. He described this pattern of drinking since he was widowed 15 years ago.

patient is not physiologically dependent or there is a general belief that there are few, if any, effective, accessible treatments to target substance misuse.

► Improved dissemination of current treatment methods and their efficacy as well as continued development of other effective treatments is essential.

DSM-5 defines substance use disorder as a maladaptive pattern of substance use occurring within the previous 12 months leading to clinically significant impairment or distress. Diagnostic criteria include recurrent substance use resulting in failure to fulfill major roles or obligations, recurrent substance use in physically hazardous situations, and continued substance use despite persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance. Other criteria include the presence of tolerance and withdrawals, intense cravings, consumption of the substance in larger amounts or time periods than intended, persistent desire or unsuccessful attempts to cut down, and excessive time spent obtaining, using, or recovering from the substance. Finally, an individual with a substance use disorder may reduce or sacrifice important social, occupational, or recreational activities and continue to use the substance despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance. A patient's substance use disorder is categorized as "moderate" if they meet two to three criteria and "severe" if they meet four or more criteria.

For the purposes of terminological clarity and to reflect the transition to DSM-5 criteria, the term "abuse" will only be used generally in this chapter and will not be used to refer to the clinical entity described in previous versions of the DSM. However, "physiological dependence," which is defined as evidence of tolerance or withdrawal (Severity Spectrum Scale Items 4 and/or 5), continues to be clinically relevant and will be used in this chapter in accordance with the DSM-5 conceptualization of this term.

Although the diagnostic criteria for substance use disorders are the same for younger and older adults, some of the criteria may be less relevant for the latter. For example, problems related to work or the family may not be relevant for a retired or widowed older adult. Older women tend to drink at home alone, thus would be unlikely to have legal or work-related difficulties. Similarly, an older adult with physiological dependence on a benzodiazepine with chronic insomnia may have no other symptoms of a sedative, hypnotic, and anxiolytic use disorder and may be more prone to falls and cognitive impairment from the benzodiazepine use itself. On the other hand, health problems are often more prominent in the geriatric

population and may be a motivating reason for changing alcohol and substance use.

HISTORY

Substance misuse among older adults as a distinct entity was first described in the research literature in 1964. In the 1960s and 1970s, researchers believed that substance misuse was rare in the elderly and thus devoted little attention to this population as compared to younger adults. Health providers assumed that individuals with life-long addictions either died early or spontaneously improved in later life, and older adults with alcohol misuse were considered to likely have had a long history of drinking. Even the DSM-III-R, published in 1987, reads: "In males, symptoms of alcohol dependence or abuse rarely occur for the first time after age 45." Thus, until the past two decades, alcohol and drug misuse in the elderly was rarely discussed in the substance abuse or in the gerontological literature. Even today, as the frequency of substance problems climbs in older adults, it remains largely an invisible epidemic currently underdiagnosed and undertreated. Screening and preventative measures for older populations are often missing in routine primary care visits. More recently, studies have been conducted examining alcohol and prescription misuse in older adults and investigating treatment approaches better suited to this population. Illicit drug use in the elderly is believed to be uncommon in the general population and is not well researched.

ALCOHOL

Spectrum-of-Use Categories

As the DSM-5 criteria may be less ideally applied for older adults, alternate categories of substance use may be more appropriate, particularly for alcohol use. Individuals who drank less than one or two alcoholic drinks in the previous year are categorized as *abstainers*. Approximately 50 to 70 percent of older adults report abstinence, making this the most common late-life drinking pattern. The reasons for abstaining, however, may have implications regarding treatment and counseling about drinking. Although some individuals do report life-long abstinence, many individuals stop drinking alcohol due to the onset or presence of an acute or chronic illness, while others abstain due to a previous history of alcohol problems. Identification of the latter group allows preventive monitoring and screening to help avoid future relapse and also alerts the clinician to increased vulnerability for mental health problems and cognitive declines. *Low-risk*, *social*, or *moderate drinkers* include individuals who drink within the recommended guidelines and are not using any contraindicated medications or having any problems related to use.

An *at-risk* or *excessive drinker* is defined as someone who does not

meet alcohol use disorder criteria but is drinking at a level that increases the likelihood of problems or negative consequences. Drinking above recommended limits would be included in this category (more than one drink per day and, in particular, more than three drinks in a day). *Problem drinking* is the term often used in place of abuse for older adults drinking at a level that is causing detrimental medical, psychological, or social effects.

The Spectrum-of-Use Categories and the DSM-5 Severity Spectrum Criteria are both based on knowledge from young and middle-aged adults, and the applicability and validity in older persons is questionable. Physiological tolerance may occur in older adults without increased consumption over time due to the physiological effects of aging. DSM-5 diagnostic criteria are also susceptible to self-report biases, including memory impairment, lack of insight, and unwillingness to acknowledge symptoms. Other signs and symptoms may alert the physician to potential alcohol and substance misuse in older adults (Table 57.3j–3). In addition, collateral information, particularly when cognitive impairment is present, from family, friends, employers, or others is an important source of information to supplement or confirm the patient's report.

Epidemiology

Alcohol misuse is often underreported and underestimated in older adults. While typically drinking tends to decrease with age, some studies have shown that aging cohorts' rate of drinking is rising. Furthermore, the aging baby-boom generation, with its higher rates of alcohol and substance use, is more likely than previous generations of older Americans to misuse alcohol. In the past few decades, prevalence estimates of at-risk or problem drinking in the elderly community range from 1 to 15 percent, with the variability attributed to definitional issues and sample variation. In the most recent National Survey on Drug Use and Health (NSDUH), 48 percent of those 60 to 64 years old were reported to have consumed alcohol in the past month, with about 10.1 percent reporting binge use (defined as five or more drinks on the same occasion in the past 30 days) and 2.7 percent reporting heavy use (five or more drinks on the same occasion on each of 5 or more days in the past 30 days). For those over the age of 65, 38.4 percent reported alcohol use in the past month with 6.0 and 1.6 percent reporting binge and heavy use, respectively. It should be noted that these are definitions developed for the general population and are not those generally used for older adults.

Table 57.3j–3.
Common Signs and Symptoms of Potential Substance Misuse and Abuse in Older Adults

Anxiety
Blackouts, dizziness
Depression, mood swings
Disorientation
Family problems
Financial problems
Headaches
Incontinence
Increased tolerance to alcohol or medications
Legal difficulties
Memory loss
New difficulties in decision making
Poor hygiene
Falls, bruises, and burns
Idiopathic seizures
Sleep problems
Social isolation
Poor nutrition

Adapted from Barry KL, Blow FC, Oslin DW. Substance abuse in older adults: review and recommendations for education and practice in medical settings. *Subst Abus*. 2002;23:105–131. Available at http://www.informaworld.com

Gender-related changes in alcohol consumption are also quite relevant diagnostically in screening for alcohol misuse. Women have historically tended to curb their drinking as they age more than men; however, it is unclear if that pattern will continue as women from the baby-boomer generation enter older age. Older women are more susceptible than their male counterparts to the adverse effects of alcohol misuse, including medical morbidity, and are more apt to have comorbid medical conditions, depression, anxiety, and abuse of psychoactive medications. Furthermore, as men live longer, it will be important to continue the screening for alcohol misuse and consider preventative measures.

Rates of alcohol use disorders are greater in health care settings relative to community-based samples. In a recent study of older adults in primary care, 4.1 percent were defined as at-risk drinkers (8 to 14 drinks per week), and 4.5 percent were heavy (more than 14 drinks per week) or binge drinkers. Mental health clinics have even higher rates of alcohol use disorders.

Etiology

The etiology of problem drinking in older adults has not been well studied. It is a common myth that older problem drinkers have a life-long history of alcohol-related problems. This myth is more accurate for illicit drugs and nicotine, whereas as many as one-third of older adults seeking treatment for alcohol misuse develop their problems in later life. Thus, although

drinking patterns are often stable over time, increased drinking in later life is not unusual due perhaps in part to more free or unstructured time, a rise in disposable income, and losses of loved ones. Older adults also potentially face several stressful life transitions (i.e., retirement, menopause, the "empty nest" phenomenon, loss of friends, reduced physical function) and the adoption of new roles (i.e., widow[er], caretaker) as they approach an older age, thereby increasing the vulnerability to alcohol misuse. Treatment approaches for late-onset and life-long problem drinkers are currently the same; however, the distinction is important for clinicians as the former are more likely to go undiagnosed and therefore untreated.

Recommended Limits

Certain age-related factors, including physiological factors that increase sensitivity to alcohol and drugs in older adults, have led the National Institute on Alcohol Abuse and Alcoholism (NIAAA) and the Center for Substance Abuse Treatment (CSAT) to set lower recommended limits for alcohol use for older adults. The maximum drinking limit for women and men over the age of 65 is no more than an average of one standard drink per day, versus two standard drinks per day for younger men. Table 57.3j–4 provides a description of how to measure a standard drink. In addition, older adults should not consume more than three standard drinks in 1 day (i.e., binge drinking).

Table 57.3j–4.
Alcohol Conversion Chart

"1 Standard Drink"	
Beverage Type	**Quantity (oz)**
Beer	12
Wine	5
Fortified wine	3
Hard liquor (80-proof distilled spirits)	1½ (i.e., "a shot")
Malt liquor	8
Liqueur or aperitif	4
Additional Conversions	
Beverage Type/Quantity	**# Standard Drinks**
Beer:	
► 1 (6) pack of 16 oz cans/bottles	8
► 1 quart	3
► 1 L (33.8 oz)	2.8
Wine (e.g., red white, chianti):	
► 1 bottle (25 oz)	5
► 1 bottle (40 oz)	8
► Fifth	6

► 1 magnum	12
► ½ gallon	16
Fortified wine (e.g., sherry, port):	
► Pint	7
► Fifth	12
Hard liquor (e.g., rum, gin, tequila, vodka):	
► Fifth	18
► Pint	11
► Quart	20
► ½ gallon	40
► 1 bottle (25 oz)	17
► 1 bottle (40 oz)	27
Malt liquor (e.g., Olde English):	
► 12 oz	1½
► Forty (40 oz)	5

Standardized Screening Instruments

Brief and low-cost assessments can be used to screen for alcohol misuse to help in the prevention or early intervention of older adults at risk and can also be used to facilitate a diagnosis of alcohol use disorder. These instruments may be administered by verbal interview or by paper-and-pencil or computerized questionnaire with equal reliability and validity. Including follow-up questions about consequences, health risks, and interpersonal issues related to substance use can assist in the determination of a DSM-5 diagnosis of substance use disorder.

The most appropriate screening assessments used in the geriatric population are the Short Michigan Alcoholism Screening Test–Geriatric version (SMAST-G) and the Alcohol Use Disorders Identification Test (AUDIT). The SMAST-G was developed specifically for screening older adults in a variety of settings, and its psychometric properties exceed those of other screens for identification of alcohol use disorders in this population (Table 57.3j–5). The AUDIT and the abbreviated version, the AUDIT-C (Table 57.3j–6), assess frequency of drinking and binging in the past year. The AUDIT-C score ranges from 0 to 12, with a higher score indicating increased likelihood of alcohol use impacting health and safety. For older adults, a score of 2 or greater suggests the need for further assessment or recommendation of a brief alcohol intervention.

Other screening instruments that are commonly used in younger patients are not ideal for older adults for various reasons. The CAGE questionnaire is the most widely used alcohol-screening test. However, while the CAGE questionnaire has shown high specificity for detecting alcohol use disorders, there is a relatively low sensitivity for problem

drinking. Poor insight into drinking is often a barrier for older adults' self-reporting of amount of drinking and for isolated older adults there may not be enough social interaction to report if others are criticizing the drinking pattern. If a CAGE questionnaire is used, a modified version that only inquires about recent problems is most appropriate for older adults, and the threshold for indicating possible problems is one positive response.

Table 57.3j–5.
Short Michigan Alcohol Screening Test—Geriatric Version (SMAST-G)

In the past year:	Yes	No
1. When talking with others, do you ever underestimate how much you actually drink?	(1)	(0)
2. After a few drinks, have you sometimes not eaten or been able to skip a meal because you didn't feel hungry?	(1)	(0)
3. Does having a few drinks help decrease your shakiness or tremors?	(1)	(0)
4. Does alcohol sometimes make it hard for you to remember parts of the day or night?	(1)	(0)
In the past year:		
5. Do you usually take a drink to relax or calm your nerves?	(1)	(0)
6. Do you drink to take your mind off your problems?	(1)	(0)
7. Have you ever increased your drinking after experiencing a loss in your life?	(1)	(0)
8. Has a doctor or nurse ever said they were worried or concerned about your drinking?	(1)	(0)
9. Have you ever made rules to manage your drinking?	(1)	(0)
10. When you feel lonely, does having a drink help?	(1)	(0)
TOTAL SMAST-G SCORE (0–10)		
Two or more positive responses are indicative of an alcohol use problem.

Table 57.3j–6.
AUDIT-C Alcohol Screening

1. How often did you have a drink containing alcohol in the past year?

—	Never	(0 points)
—	Monthly or less	(1 point)
—	Two to four times a month	(2 points)
—	Two to three times per week	(3 points)
—	Four or more times a week	(4 points)

If you answered "never," score questions 2 and 3 as zero.

2. How many drinks did you have on a typical day when you were drinking in the past year?

—	1 or 2	(0 points)
—	3 or 4	(1 point)
—	5 or 6	(2 points)
—	7 to 9	(3 points)
—	10 or more	(4 points)

3. How often did you have six or more drinks on one occasion in the past year?

—	Never	(0 points)
—	Less than monthly	(1 point)

—	Monthly	(2 points)
—	Weekly	(3 points)
—	Daily or almost daily	(4 points)

Possible range = 0–12. For older adults, a score of 3 or more is considered positive.

Differential Diagnosis

Clinicians must be careful when diagnosing psychiatric conditions that occur only in the presence of intoxication or withdrawal as both of these states may mimic psychiatric symptoms, including depressive, anxiety, and psychotic symptoms. Diagnosing based on historical self-report of symptoms leads to questionable reliability and validity, particularly with older patients and alcoholics who may have cognitive deficits as part of their illness.

Alcohol problems and depression are common comorbid conditions in late life. Depression symptoms can precede (primary or independent depression), occur simultaneously (indeterminate), or develop as a consequence (reactive or secondary depression) of significant alcohol use. Repeated use of depressants can induce mood disturbance and may affect the mood enough to meet criteria for a major depressive episode. A diagnosis of primary depression may lead to a treatment plan targeting both disorders, whereas a secondary depression diagnosis would suggest treating the addiction and monitoring the depression. In the latter case, treatment with antidepressants is not likely to be effective, whereas termination of the substance use can resolve the mood disturbance. In one notable study, of 42 percent of patients who began detoxification with significant symptoms of depression, only 6 percent reported continued significant depressive symptoms at 4 weeks.

The high prevalence of chronic medical conditions in older adults may affect the ability of the clinician to determine decreased functioning due to substance misuse. Alcohol problems contribute to cognitive deficits in later life. Wernicke–Korsakoff syndrome is well defined and often caused by alcohol dependence, but alcohol-related dementia may be difficult to differentiate from Alzheimer disease due to a lack of well-specified criteria. A study of older adults seeking treatment found 23 percent had dementia associated with alcohol dependence. In older adults, sedative intoxication can also be confused with progressive dementia. Withdrawal of the substance tends to stabilize cognitive and functional status for substance-related cognitive impairment and not for dementias.

Sleep disorders also frequently co-occur with excessive alcohol use. Alcohol use and aging are both associated with changes in sleep patterns. Alcohol has been shown to decrease sleep latency, decrease stage IV sleep, and precipitate or aggravate sleep apnea. Age-related changes, which can be exacerbated by alcohol use, depression, comorbid medical conditions, and medication use, include increased rapid eye movement (REM)

episodes, decrease in REM length and stage III and IV sleep, and increased awakenings. On the other hand, abstinent alcoholics with poor sleep due to insomnia, frequent awakenings, and REM fragmentation demonstrate normalization of sleep periodicity and temporary suppression of REM sleep upon drinking, suggesting that alcohol may also be used to self-medicate sleep disturbances. Differential diagnosis, again, involves a historical account of the initiation of sleep problems and determining if symptoms subside with substance abstinence.

Course and Prognosis

As mentioned, drinking patterns often are stable over time but increased drinking in later life is not unusual due to factors idiosyncratic to an older population. In addition, aging patients can experience increased problems due to alcohol without increased consumption due to physiological changes that increase sensitivity to alcohol and drugs, increased medication use, and development of chronic health conditions.

Alcohol misuse is related to adverse effects in several physical health and psychiatric domains. Intoxication can lead to increased risk of falls and motor vehicle accidents, especially in conjunction with medication interactions or other substance misuse. Chronic alcohol misuse is associated with multiple disease outcomes in several organ systems. More than 90 percent of older patients with a diagnosis of alcohol misuse have a history of depression and depressed older adults are three to four times more likely to have an alcohol use disorder compared with nondepressed older adults. Like depression, late-life anxiety disorders can both be a consequence of problematic alcohol use as well as a primary psychiatric illness. Generalized anxiety disorder is the most common type of anxiety disorder in the older population, and those with the disorder are more than twice as likely to have a substance use disorder as those without an anxiety disorder.

Following depression, substance use disorders, particularly alcohol use disorder, are the second most common category of psychiatric disorders associated with completed suicide in the older population. Drinking among older adults elevates suicide risk through interactions with many factors that are more prevalent in this age group than in younger adults, factors such as depressive symptoms, medical illness, negatively perceived health status, and low socioeconomic support. Together, alcohol misuse and comorbid psychiatric illness are a potentially lethal combination.

Moderate Use

Before discussing the negative prognoses for alcohol and substance abusers, it is important to acknowledge that moderate alcohol consumption may have positive effects on physical health and mental well-being. Low-

risk alcohol consumption has been linked with a reduction in cardiovascular disease risk for men and women. For older adults without cardiovascular disease, moderate alcohol use has been associated with lipoprotein subclass distribution, including fewer small low-density lipoprotein particles and increased large- and medium-sized high-density lipoprotein particles. In addition, moderate alcohol use has been correlated with a lower incidence rate of type 2 diabetes mellitus in older adults and may reduce the risk of cognitive impairment and dementing illnesses.

Despite these potential health benefits, however, abstinence is recommended for individuals taking particular medications and those with a history of alcohol or drug abuse. In addition, although moderate drinking may protect against certain health problems, any alcohol consumption may be detrimental after a diagnosis of a chronic health condition (such as cardiovascular disease or diabetes). Furthermore, there is no evidence that initiation of drinking by nondrinkers will translate into reduced health risks, and moderate use may contribute to several negative health outcomes. Moderate alcohol consumption may reduce stroke risk due to blocked blood vessels but may increase stroke risk due to hemorrhaging or bleeding. The risk of breast cancer in women is increased about 50 percent in women who drink three to nine drinks per week compared to fewer than three drinks per week. In addition, there is a linear relationship between alcohol use and bone mineral density at the hip. Even limited alcohol consumption has been shown to impair one's driving ability and may increase the chance of accidents and fatal injuries due to falls, motor vehicle accidents, and suicides. In addition, depression, memory problems and other cognitive changes, liver disease, cardiovascular disease, and sleep problems have been associated with moderate alcohol use. Mental health providers also need to be cognizant that alcohol can negatively impact other mental health disorders. Even in the moderate use range, greater alcohol consumption adversely affects depression treatment. The converse is also true; reduction of moderate alcohol use during depression treatment enhances treatment outcomes. Limited alcohol use may also negatively impact the course and prognosis of dementing illnesses and may precipitate or exacerbate onset of personality changes and behavioral disturbances in patients with dementia.

Severe Use

Severe alcohol use disorder is associated with increased probability of morbidity and mortality from disease-specific disorders including acute pancreatitis, alcohol-induced cirrhosis, and alcohol-related cardiomyopathy. Comorbidity of substance misuse with other medical and psychiatric conditions may impact the course, treatment, and prognosis of this condition. Substance misuse in earlier life can also impact later life, including increasing the likelihood of developing late-life mental health

problems. Epidemiological surveys have shown that comorbid alcohol use and psychiatric conditions are common in younger age groups. Less is known about later life, although a few studies have shown high frequency of physiological alcohol dependence in older adults with psychiatric problems. In a study of Veterans Administration patients from 60 to 69 years of age, an affective disorder was present in 21 percent of the patients presenting for alcohol treatment, 43 percent of whom had major depression. In another study of community-dwelling older adults, almost half of the 4.5 percent of patients with a history of alcohol misuse had a comorbid depression or dysthymia diagnosis. Comorbid depression and alcohol misuse are not only common in later life but may have a reciprocal effect on each other. Depressed alcoholics are more likely than nondepressed alcoholics to have a complicated course of depression, manifest by increased suicide risk and social dysfunction. In addition, a history of alcohol abuse as a younger adult is predictive of more severe and chronic depression course in late life.

PRESCRIPTION AND OVER-THE-COUNTER MEDICATION

Epidemiology

Due to the elevated use of pharmaceutical drugs in older adults, the chance of misuse of prescriptions and over-the-counter medications, including sedatives or hypnotics, narcotic and nonnarcotic analgesics, diet aids, decongestants, and other medications, is also greater. Although the literature is sparse, it is estimated that up to 11 percent of older women misuse prescription drugs, and by the year 2020, it is projected that 2.7 million adults aged 50 years and older will be using prescription drugs for nonmedical purposes.

Older adults are also far more likely to take multiple medications (polypharmacy); in a study of community-dwelling older adults, 71 percent were taking at least one prescription medication while 10 percent reported taking five or more medications. Community surveys show that 60 percent of elderly adults are taking an analgesic, 22 percent are taking a central nervous system (CNS) medication, and 11 percent are taking a benzodiazepine. Psychoactive medications with the potential for misuse are used by at least one in four older adults, and recent studies estimate the misuse of psychoactive prescription medications by older adults will increase from 911,000 in 2001 to 2.7 million in 2020. Benzodiazepine sedative hypnotics and opioid analgesics are the two main classes of prescription medications with abuse potential used by older adults. It is also important to note that the rate of adverse drug reactions increase with increasing numbers of medications taken and many medications interact negatively with alcohol.

Benzodiazepines

Benzodiazepines, in particular, are one of the most common classes of prescription medications in the United States, and their use increases with age and tend to be chronic in late life. While it is well established that benzodiazepines increase the risk of cognitive impairment, delirium, fall injuries, fractures, and motor vehicle accidents in older adults, there remains insufficient research on the impact of these medications in the older population. Studies on this topic are made more difficult because the prescription medication misuse is often unintentional. According to the CSAT, 23 percent of all prescriptions written for older adults are for benzodiazepines. Despite the wide use of benzodiazepines, the Beers criteria recommends benzodiazepine use be limited in the older population to seizure disorders, REM sleep disorders, benzodiazepine withdrawal, alcohol withdrawal, severe generalized anxiety disorder, periprocedural anesthesia, and end-of-life care. Commonly, sleep disorder is the indication cited for benzodiazepine use in the older adult population, accounting for approximately 59 percent of total prescriptions; this is despite the fact that long-term benzodiazepine use does not help with sleep restoration. Sleep disorders occurring later in life are thought to be related to decreased activity of the suprachiasmatic nucleus, contributing to a disruption of circadian rhythms in older adults including the nocturnal secretion of endogenous melatonin. However, the iatrogenic contribution of medications, including stimulants, antihypertensives, decongestants, chemotherapy, and respiratory medications, cannot be overlooked.

Age-based biases are also commonplace among physicians and caregivers and contribute significantly to misdiagnosis of comorbid conditions and the misuse of benzodiazepines. Physicians and family members often overlook clinical signs of sleep disorders in older adults, including somnolence and fatigue, as signs of normal aging. Common sleep disorders, including sleep-disordered breathing and periodic limb movement syndromes, have been shown to benefit from nonbenzodiazepine evidence-based treatments. Overnight recording of the apnea–hypopnea index is indicated in patients with symptoms of sleep disorder breathing, including high snoring severity, unintentional napping, and/or excessive daytime sleepiness. Primary insomnia in the older adult may be initially treated using numerous nonpharmaceutical tools to improve sleep hygiene, such as limiting naps, adjusting medications, avoiding stimulants like coffee, environmental improvements, examining sleep problems, and other specific treatments. Nonbenzodiazepines sedatives like zolpidem is often considered to be safe and effective in older adults, but recent research shows that they may lead to as many fractures, falls, and delirium as benzodiazepines.

Despite clear indications that benzodiazepines are not the preferred

agent for long-term treatment of anxiety, this is the second most common reason for prescription of a benzodiazepine to an older adult, often in the absence of first-line antidepressant medications. Risk factors for anxiety disorder in the older adults include: female gender, low socioeconomic status, family history, external locus of control, current level of perceived stress, poor primary support, and poor social support. While SSRI and SNRI medications are associated with falls and an increased risk of hyponatremia in older adults, their adverse-effect profile is favorable in the chronic treatment of anxiety compared to benzodiazepines. Evidence for nonpharmacological treatment of anxiety in the older adult population is conflicting regarding cognitive behavioral therapy, physical therapy, and other behavioral approaches.

Opioid Analgesics

Data from multiple agencies, including the Centers for Disease Control (CDC), have documented an alarming rise in prescription opioid analgesic abuse with a concordant rise in attributed mortality. The opiate's impact on the older population is second only to alcohol, accounting for up to 22 percent of substance-related inpatient admissions. While a large percentage of the older population suffers from some form of chronic pain often resulting in pain management with opioid analgesics, there is currently no evidence for the long-term effectiveness of opioid analgesics in the treatment of persistent noncancerous pain conditions in older patients. Despite growing concerns for opioid analgesic misuse, it is important to note that pain continues to be undertreated in adults.

Studies have examined the use of methadone in older adults for the treatment of chronic opioid misuse and physiological dependence and found that they were no different than their younger counterparts in terms of medical and psychiatric problems or employment, but did significantly better in treatment. Despite this more positive prognosis, older adults are thought to be more susceptible to the stigma of drug addiction, old age, psychotropic medication use, depression, poverty, race, and HIV status associated with methadone treatment.

The American Geriatric Society recommends that acetaminophen be used as a first-line agent in the treatment of pain in the older adult population. An appropriate second-line for pain management includes SNRIs, gabapentin, and pregabalin alone or in combination with acetaminophen. NSAIDs should be used sparingly as older adults are considered more susceptible to the potential gastrointestinal adverse effects of these agents. Tricyclics have been shown to be somewhat efficacious in the treatment of pain in the general population; however, their use in the older population is not recommended given their significant adverse effect profile.

Etiology

Declining physical health and physiological changes associated with aging affect the metabolism of medications and thus the potential for medication misuse. Previous and comorbid psychiatric diagnoses, poor health status, social isolation, and female gender also increase the risk for prescription drug misuse. Many cases of psychoactive medication misuse have been shown to be unintentional on the part of the patient or physician. The drugs are usually obtained with an appropriate prescription for a specific health-related purpose, either a physical condition or emotional distress. An older patient may misunderstand the directions, a confusion that may be compounded by multiple medications, or misuse may occur due to a prescription that is not appropriate for an older adult. Unintentional misuse can progress into abuse to obtain the desirable effects. Physiological dependence on psychoactive medications without meeting additional DSM-5 substance use disorder criteria can also result from even therapeutic dosages for brief periods.

Aging also involves increased sensitivity to over-the-counter and prescription medications, with women demonstrating even greater sensitivity. With advancing age, lean body mass and total water volume decrease relative to total fat volume, thereby decreasing total body volume and subsequently increasing the serum concentration, absorption, and distribution of alcohol and drugs in the body. Furthermore, reduction in liver mass and decreased hepatic blood flow results in slower drug metabolism and changes in renal function can lead to build up of some substances. At the same time, the response to CNS-active drugs is frequently exaggerated due to age-related decline in CNS function and increased pharmacodynamic sensitivity for some psychoactive drugs, thus amplifying the response to sedative–hypnotic and mind-altering drugs. The presence of dementia also increases the likelihood of intoxication and impaired functioning. Age-related changes in drug sensitivity vary by drug, however, and pharmacodynamic changes associated with aging continue to be an area of investigation.

TOBACCO

Large-scale epidemiological studies have shown that smoking is harmful for all age groups. Although often overlooked in the elderly, smoking contributes significantly to poor health and disability in older adults. Impressions that late-life smoking cessation does not provide benefit and do not lead to over changes in health outcome are patently false. Even in older age, smoking cessation can decrease overall morbidity and improve quality of life. While smoking rates tend to decrease with age, one of five smokers is 50 years or older. Of community-dwelling individuals, 15.2 percent of adults aged 65 to 74 and 8.4 percent of those older than 75 are

smokers. This rate is even higher in older African American men, where 22.1 percent of individuals 65 to 74 and 12 percent of 75-years-old and older smoke. The importance of clinicians continuing to have low threshold for smoking screening and to work with patients toward smoking cessation do not change while taking care of older patients.

MARIJUANA

The United States is in the midst of a cultural shift regarding its perception of and the potential medicinal applications considered appropriate for marijuana. As of 2014, 23 states have approved some type of medicinal marijuana legislation. The increasingly legal use of and easing access to marijuana is also effecting the substance use patterns of older adults. Data from the NSDUH indicated that 2.8 percent of older adults were past-year marijuana users in 2008. As the baby-boom cohort ages, the rate of increase of past-year use of marijuana is expected to rise given that this cohort is more likely to have used illicit substances than prior cohorts. Marijuana abuse in older adults appears to be concentrated in the "young-old" group, with 2008 NSDUH data indicating that almost all older adult past-year users were aged 50 to 64. Additionally, more than two-thirds of older adult past-year marijuana users initiated use before or at age 18 and an additional 27 percent between ages 19 and 29. The large proportion of older adults with past-year use of marijuana that reported first-time use at these earlier ages suggests that a large portion of this population are long-term users rather than mid- to late-life users who initiated use for medical reasons.

Various studies have been conducted to evaluate the efficacy and safety of medical cannabinoids in a variety of conditions in adult patients, and in a substantial number of studies, older subjects were included. However, there is a general lack of evidence concerning the use of cannabinoids specifically in older patients, resulting in scarcity of data to guide treatment decisions. A review of studies performed that included older patients in the study population indicated no efficacy of medical marijuana on dyskinesia, breathlessness (versus placebo), chemotherapy-induced nausea and vomiting (versus prochlorperazine), or oral THC in the symptomatic treatment of behavioral problems in dementia. However, sample size and methodological quality may have biased these conclusions. Further research on cannabinoids specifically in the older population is needed.

ILLICIT DRUGS

Epidemiological data for illicit drug use in the elderly are limited. Data from the early 1990s in the Epidemiologic Catchment Area Study estimated lifetime prevalence rates for substance misuse to be 0.12 percent for older men and 0.06 percent for older women, and a lifetime history of illicit drug use to be 2.88 and 0.66 percent, respectively. More recent work, however,

suggests that illicit substance abuse is increasingly common in adults seeking treatment. For example, 38 percent of veterans in a Veterans Affairs older adult treatment program reported recent illicit substance use. The recent NSDUH showed an increase from 2.7 to 4.3 percent for illicit drug use in the past month for adults aged 50 to 59 years from 2002 to 2006; other age groups demonstrated no change or declines in use. This trend likely reflects the aging of the baby-boom cohort and is predictive of further increases in illicit substance use and abuse in older adults in the next decades.

SCREENING

Given the high utilization of medical services by older adults, and because a large percentage do not self-identify as substance misusers, physicians and health care staff can be critical for identifying individuals with alcohol and drug problems. Screening for alcohol and other drugs should be included as part of the routine mental and physical health care for adults over the age of 60 and should be updated annually or whenever problems arise that may be related to alcohol or drug use. To ensure successful incorporation, screening should be simple and consistent with clinical screening practices already in place. Routine screening including toxicology screening (urine, salvia) enables identification of those with problematic substance use along with those at risk of misusing drugs and alcohol and helps determine if additional assessment is necessary.

ASSESSING FREQUENCY AND QUANTITY OF USE

Despite these barriers, successful screening techniques have been developed and implemented. Assessing the quantity and frequency of alcohol and drug use generally involves prospective recording and monitoring of use, retrospective accounts of daily use over a defined period of time (i.e., time-line follow-back method [TLFB]), or questions regarding average use. Although the prospective diary method is the gold standard, it is often impractical for screening assessments, as it requires more time and multiple visits. The TLFB method is the most commonly used technique in addiction studies, and 7-day TLFB assessments are highly correlated with the prospective method. Two difficulties arise with the TLFB. First, the week of measurement may not represent the typical week. Second, the TLFB method tends to underestimate use for less frequent users (compared to nonusers or frequent users). The TLFB also takes longer to administer than general questions about use and is more accurate when administered by an interviewer versus self-administration due to variation in individuals' definitions of a standard drink (see Table 57.3j–3 for description of standard drink).

Although general questions about average quantity and frequency of use over a certain time period is the least correlated with the prospective diary

and likely underestimates moderate drinking, it is the easiest assessment to administer and therefore the choice for many clinicians. Of note, this is the method used in the AUDIT-C and it recommended that this standard questionnaire be used over general questions. These questions may be used independently to screen and identify at-risk patients and can be easily embedded in the context of other health behaviors such as exercise, weight, and smoking. Additional measures should be used, however, when attempting to recognize problem drinking or diagnose substance use disorder to identify how the use is affecting the patient dynamically, socially, and physiologically.

PATHOLOGY AND LABORATORY EXAMINATION

Several laboratory values indicate recent use or misuse, including blood alcohol or blood acetate, a metabolite of alcohol. Long-term markers of alcohol use include γ-glutamyl transferase (GGT), mean corpuscular volume, high-density lipoprotein level, and carbohydrate-deficient transferrin (CDT). High blood levels of alcohol without signs of intoxication indicate high tolerance to alcohol. Illicit drug use can often be determined by a simple urine test. The majority of drugs are detectable in a urine drug screen for 4 days or greater, with some detectable after several weeks. Other physical signs of intoxication for different substances can be determined by physical examination. Intoxication with sedative, hypnotic, or anxiolytic substances or opioid medications results in decreased blood pressure, respiratory rate, pulse, and body temperature, while amphetamine or cocaine intoxication generally induces the reverse.

TREATMENT

Previous addiction studies have often excluded patients over the age of 65, resulting in a significant knowledge gap regarding treatment outcomes and the neurobiology of addiction in later life. Nevertheless, naturalistic studies have shown that older adults respond as well as or better to treatment than middle-aged adults, and they are more likely to complete the treatment. Furthermore, brief interventions have been demonstrated to be effective at reducing alcohol consumption for older, at-risk drinkers. Therefore, older adults can be receptive and responsive to treatment, and providers need to recognize that they need not be a substance abuse professional to play a significant role in addressing addiction issues and improving the lives of patients.

Despite the limited research, a variety of treatment strategies are available for and have been used with older adults, including individual, family, and group-based approaches, cognitive-behavioral and medical or psychiatric therapies, community-based services and outreach, and formal substance abuse treatment. Ideally, treatment approaches are individualized given the specific medical, psychiatric, social, and cultural

needs of the patient. More practically, treatment modalities may be limited by managed health care environments and community availability. Currently there is no best treatment option for older adults; however, less intense options are recommended first in this population. Future studies are needed to determine when patients need to be referred to specialty addiction care versus receiving treatment in primary care or mental health clinics. It is likely, however, that older patients with less severe disease can be treated most appropriately in primary care and mental health care settings, where it has been shown they would be more apt to engage in care, and patients with more severe disease should be treated in conjunction with specialty care.

Brief Interventions/Therapies

Low intensity, brief interventions or brief therapies are cost-effective, practical techniques that may be useful as an initial treatment approach with at-risk and problem drinkers across a range of clinical settings. Brief interventions are time limited and nonconfrontational and range from unstructured counseling and feedback to more formal therapy. As the interventions were developed using concepts and techniques from the behavioral self-control literature, one trademark of brief interventions is to encourage individuals to change their behavior through motivational interviewing. As older adults with substance misuse often experience shame about their substance problem, nonconfrontational and supportive approaches are well suited and labels (addict, alcoholic) are best avoided.

Randomized clinical trials of brief interventions for alcohol problems among older populations have demonstrated efficacy of the treatment, that is, reduced alcohol consumption in at-risk drinkers compared to controls, while also demonstrating that older adults can be engaged in brief intervention protocols and find the protocols reasonable. Most trials to date have been conducted in primary care settings using only one to four sessions, including some telephone contacts, and follow-up over 1 year. Brief interventions for older adults are likely to be effective in mental health settings as well; thus, geriatric mental health care providers are encouraged to gain familiarity with brief intervention therapy both as a treatment tool and as a way to increase adherence to specialty treatment.

Psychosocial Treatments

Little research has been conducted on the efficacy of psychological treatments for substance misuse in older adults. One study of older veterans found that individuals who completed a 16-week relapse-prevention group intervention, including cognitive-behavioral and self-management approaches, were more likely to be abstinent at a 6-month follow-up than noncompleters. Another study that included older adults (7

percent were aged 60 or over) demonstrated effectiveness for three different manual driven individual psychological treatments (cognitive-behavioral therapy, motivational enhancement therapy, and 12-step facilitation) that spanned 12 weeks. In this study, alcohol consumption was reduced 1 year posttreatment in adults with alcohol dependence.

Twelve-Step Programs

Community-based programs for many years have centered on the traditional 12-step peer support model of recovery and rehabilitation, which includes group support and encouragement to help group members achieve and maintain sobriety. Studies have shown that older adults engage in and attend 12-step programs with comparable frequency to other age groups. On the other hand, the degree of involvement in the programs has been shown to be less in older adults, and the likelihood of engagement in subsequent formal aftercare is reduced. The 12-step model has clearly been successful for many individuals; however, more treatment options are available now than there was when 12-step programs were developed. In addition, certain factors need to be considered including perceived stigma, level of comfort disclosing personal information in a group setting, degree to which age-appropriate issues are discussed, and transportation and health problems that may interfere with the likelihood of attendance.

Pharmacotherapy

Pharmacological agents have been demonstrated to be effective in treatment of physiological dependence in conjunction with psychosocial treatments. Historically, long-term treatment of older physiologically alcohol-dependent adults did not involve pharmacological approaches. Disulfiram, inhibitor of aldehyde dehydrogenase, was initially the only medication approved for alcohol treatment, and it was used infrequently in older adults due to the likelihood of adverse effects. The U.S. Food and Drug Administration (FDA) approved the opioid receptor antagonist naltrexone in 1995 based on clinical trials demonstrating its safety and effectiveness in preventing relapse and reducing alcohol cravings, making it the first pharmacological agent in 50 years to be approved for treatment of alcohol misuse. The original clinical trials were conducted in middle-aged adults; however, naltrexone has also been shown to be effective in older adults. Results from a double-blind, placebo-controlled, randomized trial demonstrated that in veterans aged 50 to 70 years, twice as many placebo-treated subjects relapsed to significant drinking as compared to those receiving naltrexone. Most recently a depot formulation of naltrexone was approved and potentially offers an advantage in improving adherence to treatment. Acamprosate was approved by the FDA in 2004 and has demonstrated safety and efficacy similar to naltrexone, although the

response in geriatric populations has not yet been well studied. The mechanism of action is unclear but is believed to involve normalization of the glutamate and γ-aminobutyric acid neurotransmitter systems which then modifies the reward pathway of alcohol use. Disulfiram is not recommended because of the potential complications of a disulfiram reaction in a medically compromised patient. Topiramate, which is not FDA approved for alcohol use disorders is also gaining popularity but should be considered with caution in patients with cognitive impairment.

Pharmacological treatments for illicit and prescription drug misuse have not been well studied in older adults. In general, when prescribing for older adults, health care providers need to consider lower initial doses and time-limited dosing for psychoactive medications as well as avoidance of substances with long half-lives. In addition, preference should be given to less complex drugs with simpler pathways and fewer side effects, and close monitoring of patient's reactions is advised. Buprenorphine, an FDA-approved treatment for opioid addiction, has not been studied in older adults, but there is no particular reason the treatment should not be effective and well tolerated in older adults. Depot naltrexone is considered a safe first-line treatment for opioid addiction even in older adults.

Detoxification and Withdrawal

When patients discontinue or drastically reduce substance use after a period of heavy use, withdrawal symptoms are likely. A risk of alcohol and benzodiazepine withdrawal exists during hospitalizations when the treatment team is unaware of the patient's use of these substances. Due to potentially life-threatening complications, clinicians treating substance abusers need a fundamental understanding of withdrawal symptoms and potential difficulties. Familiarity with the most common withdrawal symptoms and anticipated symptom time course is crucial for all clinicians. The first steps should consist of performing a history and physical examination, and considering the patient's medications and medical comorbidities. The goal of the clinician treating a patient potentially in withdrawal from alcohol is patient safety, and preventing potentially serious complications such as seizure, delirium, and death. Consideration of treating the older patient in highly monitored setting should be made. Competence in detoxification management is particularly important for clinicians practicing in settings where withdrawal management is available. Understanding the management of alcohol withdrawal with benzodiazepines is necessary; however, detoxification of older adults should not include stabilization with high doses of benzodiazepines or barbiturates with intermediate to long half-lives. These drugs have the potential to accumulate, and the resulting toxicity can cause cognitive impairment and may affect overall functioning and continuation of treatment. Off-label use of gabapentin in alcohol withdrawal is another

alternative and may have less side effects for older adults than benzodiazepines. The Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar) is a guideline for administering pharmacological agents for the treatment of alcohol withdrawal based on a review of symptoms and physical examination findings that has been validated on a younger population. While useful, it should be carefully applied to older patients, especially in context of potential cognitive impairment.

Use of medications to treat alcohol withdrawal must be balanced between adequate treatment of withdrawal symptoms and the avoidance of over treatment, which can lead to over sedation and other adverse events. As older adults tend to be on a number of medications, medication interactions should be considered prior to initiating treatment. Commonly used benzodiazepines used to treat alcohol withdrawal are oxazepam, diazepam, chlordiazepoxide, and lorazepam. Diazepam and chlordiazepoxide require less frequent dosing and lead to fewer interdose symptoms. However the pharmacokinetics of these medications is altered not only as people age, but also by hepatic dysfunction. Due to its short half-life and metabolism through glucuronidation only, lorazepam is best for treatment of alcohol withdrawal in older adults. In inpatient hospital settings, lorazepam is also preferred because it can be given intravenously.

Alcohol withdrawal symptoms range from mild and almost unnoticeable to severe and life threatening. Classic symptoms include autonomic hyperactivity (increased pulse rate, blood pressure, and body temperature), restlessness, disturbed sleep, anxiety, nausea, and tremor. Severe withdrawal can involve auditory, visual, or tactile hallucinations, delirium, seizures, and coma. Benzodiazepine, opioids, and cocaine are also associated with potentially life-threatening withdrawal symptoms. Physiological benzodiazepine dependence in the elderly requires very gradual tapering to avoid withdrawal symptoms, which may be different from younger age groups. More specifically, benzodiazepine withdrawal may include confusion and disorientation in older adults as opposed to anxiety, insomnia, and changes in perception. Prescribers should also be aware that withdrawal symptoms have been demonstrated to have a longer duration in older adults and can potentially complicate other medical and psychiatric conditions. Nevertheless, there is no evidence currently suggesting increased susceptibility to withdrawal or longer treatment for withdrawal symptoms in the elderly population.

Moderators and Correlates of Treatment

Certain factors may impact treatment response and adherence in older adults receiving treatment. Age-appropriate treatment is considered important in improving treatment completion and attendance rates at group meetings as compared to treatments that do not consider the unique aspects of aging. Older adults in a study of male veterans with alcohol

problems randomly assigned after detoxification to age-specific or standard mixed-age treatment were 2.9 times more likely at 6 months and 2.1 times more likely at 1 year to report abstinence when in the age-appropriate treatment group.

Matching the treatment to the patient also affects treatment outcome, although this has not been well evaluated in older adults. In one study of older primary care patients who were at-risk drinkers, 60.4 percent of patients referred to an integrated care model using a brief intervention modality attended at least one session versus 33 percent of patients referred to specialty care. This result occurred despite elimination of copayments, availability of insurance claims at most sites, and appointment availability within 2 weeks of the initial assessment.

Certain patient-level characteristics may also impact treatment outcomes. At a 6-month follow-up assessment of patients treated at a private outpatient chemical dependency program, older women with severe alcohol use disorder were significantly more likely to report abstinence from drugs and alcohol for the previous 30 days than men (79.3 vs. 54.0 percent). Among patients who were not abstinent, men reported a mean of 4 heavy drinking days, whereas women denied any heavy drinking. Favorable outcomes for older adults have also been associated with longer treatment retention and the absence of social network members who encourage substance use.

FUTURE DIRECTIONS

There remains a significant knowledge gap regarding addiction in older adults, including the etiology and neurobiology of addiction for this population. Future studies including individuals over the age of 65 are necessary to improve the understanding of treatment outcomes in older adults, including the impact of nutrition, vitamin supplementation, and comorbid medical illnesses. Further research is needed to validate DSM-5 diagnostic criteria for substance use disorders in older adults and to define the point at which patients with substance misuse should be treated in specialty care as opposed to primary care or mental health clinics. With the aging cohort and substance misuse pattern, more attention needs to be paid to prescription medication overuse and other illicit substances use and their impact in older population. Expansion of knowledge base on the potential risks and benefits of marijuana use and misuse in the geriatric population, given the current trend of legalization and expanding use, will be important.

▲ 57.4 Treatment of Psychiatric Disorders

57.4a Treatment of Psychiatric Disorders: General Principles

BRUCE G. POLLOCK, M.D., PH.D.

Age-related health problems lead to a disproportionate use of prescription medications in older patients. Nevertheless inappropriate prescriptions, excessive dosage, preventable drug interactions, and unrecognized adverse drug reactions contribute substantially to morbidity and mortality. It is not uncommon to find side effects from one medicine treated with another medication and for a prescriber not to be aware of all the medications a patient is taking. The average older American uses four prescription drugs and an additional four over-the-counter medications or herbal preparations putting them at particular risk for drug–drug interactions. Moreover, pharmacokinetic and pharmacodynamic changes associated with aging and illness render older patients more sensitive than younger adults to adverse effects of medications.

For the above reasons, it is perhaps not surprising that the most common treatable illness in older patients is iatrogenic. Two-thirds of admissions to an acute geriatric medical unit were found to be preceded by at least one inappropriate medication. Importantly, psychotropics are among the most common medications associated with preventable adverse drug events among the aged.

Despite, or perhaps because of, their extensive medication use, the old are often excluded from clinical and regulatory trials. Without randomized, prospective drug trials, it is not truly possible for clinicians to decide whether a treatment is efficacious or even harmful. The absence of controlled studies makes it difficult to determine the optimal drug class or

drug within a class for treating elderly psychiatric patients. Encouragingly, there has been progress in pharmacotherapy trials for the cognitive and psychiatric symptoms accompanying Alzheimer disease as well as for late-life depression and generalized anxiety disorder.

Although elderly patients frequently require lower doses of medications to mitigate side effects, age, alone, does not entirely guide appropriate dosage. Often, there is greater physiologic variation among individual elders than there are group differences between young and old. It is important to consider individual patient characteristics, such as cardiovascular or renal function and genetic and acquired differences in body composition or drug metabolism, together with a drug's physicochemical properties.

In addition to using rational pharmacotherapy, the physician must form an alliance with patients and their families to improve adherence to treatment. Nonadherence with therapy is a major problem for psychiatric patients, and this dilemma is exacerbated with age. Moreover, the cost and complexity of medication regimens, inherent to the multiple illnesses of the aged, are further complicated by communication difficulties arising from impaired hearing, cognitive impairment, and language and cultural differences.

PHARMACOKINETIC CONSIDERATIONS

Pharmacokinetics provides a way of describing and predicting drug concentrations in plasma and various tissues over time. It has been estimated that 70 to 80 percent of adverse drug reactions are dose, and therefore concentration, related. Concentration relationships for adverse effects were clearly evident with tricyclic antidepressants (TCAs) and neuroleptics. Cholinesterase inhibitors have been associated with dose-related, cholinergic (nausea, vomiting, diarrhea) side effects, which can be particularly severe if doses are escalated too rapidly, or if cytochrome P450 (CYP) 3A4 metabolism is inhibited for those treated with donepezil (Aricept) or galantamine (Reminyl). For newer antidepressants and antipsychotics, explorations of drug concentration variability, let alone response relationships, were deemed unnecessary. Nonetheless, therapeutic indices for most drugs narrow with age and regulatory trials conducted in younger, healthier subjects are often conducted at or near their maximum-tolerated dosages to increase the probability of demonstrating efficacy. Failure to address this issue resulted in notable difficulties with the introduction of bupropion (Wellbutrin) and clozapine (Clozaril) (seizures at high doses), as well as fluoxetine (Prozac) and risperidone (Risperdal) (agitation, akathisia, extrapyramidal syndromes with excessive doses) in older patients. Olanzapine (Zyprexa) has shown a curvilinear dose–response relationship for treating elderly patients and quetiapine (Seroquel) is currently used over a wide dose range in elders. In

fact, more than 25 percent of neuropharmacologic drugs introduced in the past two decades have undergone recommended postmarketing dosage reductions for safety reasons.

The selective serotonin reuptake inhibitors (SSRIs) are first-line treatments for depression in the elderly. Although they have relatively flat dose–response curves, unnecessarily high SSRI drug concentrations may increase side effects and cost. For example, SSRI plasma concentrations have been linearly associated with adverse cognitive and psychomotor effects in older subjects. Dose-dependent effects of SSRIs have also been reported for fragility fractures, falls, and decrements in bone density.

It is important to appreciate the critical lack of pharmacokinetic information relevant to the majority of elders encountered in clinical practice. The limited information that does exist for older subjects is largely derived from "classic" or "two-stage" pharmacokinetic modeling. Although single- and multiple-dose pharmacokinetic studies are a standard part of phase I drug development, they are almost exclusively carried out on young, physically healthy, unmedicated men. For example, the only published geropharmacokinetic data on the disposition of fluoxetine (which has a geriatric indication) is limited to a study of single doses in 11 healthy subjects (ranging in age from 65 to 77 years). Traditional pharmacokinetic methodology requires an intensive sampling regimen (i.e., a large number of precisely timed samples) usually obtained from a small number (e.g., 6 to 12) of volunteers. The pharmacokinetic parameters are determined for each individual separately and average pharmacokinetic parameters are calculated as the mean of the individually determined parameters. Single-dose studies often fail to provide accurate estimates of pharmacokinetic parameters for older patients. Multiple-dose kinetic studies are especially important to detect nonlinear phenomena wherein metabolic clearance ceases to be proportional to dose.

An alternative method is that of population pharmacokinetics using mixed-effects modeling. This statistical approach permits identification of individual and overall population pharmacokinetic parameters based on only a few samples per subject and using each data point to inform the entire analysis. Because a greater number of typical patients are evaluated, the results are much more applicable to clinical practice than those of traditional pharmacokinetics. Incorporating population pharmacokinetic analyses into clinical trials with older subjects may prove to be a significant addition to the ability to determine sources of variability in psychotropic plasma concentrations and response in elders, particularly those with medical comorbidity.

Age-associated pharmacokinetic differences may be due to changes in absorption, distribution, metabolism, or elimination of a drug.

Absorption

With age, there is a decrease in the rate of gastric emptying and intestinal blood flow. Most studies evaluating drug absorption, however, have shown no difference in the rate or extent of absorption in geriatric versus younger patients. Nevertheless, antacids, high-fiber supplements, laxatives, and the cholesterol-binding resin cholestyramine (Questran) may significantly diminish the absorption of medications, such as TCAs and anticonvulsants. Drugs with anticholinergic properties may decrease absorption of L-dopa (Larodopa), owing to delayed gastric emptying in conjunction with the gastric metabolism of L-dopa. The potential gain in compliance achieved by administering medications at the same time should be weighed against the possibility of drug interactions in the absorption phase.

There is increasing interest in the genetic differences and drug interactions affecting functioning of the important drug efflux transporter, P-glycoprotein (MDR1), which can transport a large number of clinically used drugs out of the intestine, thereby playing a significant role in absorption. For example, variants in the *ABCB1* gene, which encodes P-glycoprotein, have been found to influence the bioavailability of digoxin (Lanoxin).

Distribution

Clinicians frequently overlook the fact that a drug's half-life is directly proportional to its apparent volume of distribution. Adipose tissue increases from 33 percent of body mass in younger women to 48 percent in the old, and from 18 to 36 percent in men. For drugs that distribute in body fat (the vast majority of psychotropics), the volume of distribution increases with age, leading to a longer half-life and drug accumulation. For water-soluble drugs, such as lithium or digoxin, volumes of distribution will be diminished in older patients, reducing the margin of safety (i.e., transient increases of these drugs' plasma concentrations will not be buffered to the same degree in elders). Lipid-soluble benzodiazepines (e.g., diazepam [Valium] and clonazepam [Klonopin]) with long half-lives have been associated with an increased risk of falls and hip fractures in contrast to more water-soluble benzodiazepines with intermediate half-lives, such as lorazepam (Ativan).

The volume of distribution is also affected by the extent of drug bound to plasma proteins. Age-associated illness may cause reductions in serum albumin and possible increases in α-1-acid glycoprotein. The majority of psychotropics are transported in the blood extensively bound to these plasma proteins. Drug displacement interactions from plasma proteins were previously the subject of considerable concern, because the protein-bound drug acts as an enormous, pharmacologically active reservoir. It is now recognized that not only is free drug pharmacologically active, but it is also more available for metabolism and tissue distribution. Therefore, an

increase in the absolute concentration of free drug, caused by reduction in plasma proteins or a displacement interaction, would be buffered and equilibrium rapidly reestablished if there is no concurrent metabolic inhibition caused by the interacting drug. When plasma drug monitoring is used to adjust TCA or anticonvulsant doses, it should be appreciated that the total drug concentrations (free + protein bound) are usually reported. In the face of hypoalbuminemia or a displacement interaction (e.g., phenytoin and aspirin), the total drug level may appear low and doses may, in consequence, be inappropriately increased. If the displacing drug also causes inhibition of drug metabolism (e.g., valproic acid [Depakote] and aspirin), total drug levels may appear to be acceptable, while free drug concentrations are in fact significantly elevated. The use of unbound (free) drug levels in these situations has been found to be essential for lidocaine (Xylocaine), theophylline (Theo-Dur), valproic acid, phenytoin (Dilantin), and digitoxin (Crystodigin).

The blood–brain barrier forms an interface between the circulating blood and the brain and possesses various carrier-mediated transport systems for small molecules to support and protect central nervous system (CNS) function. For example, the blood-to-brain influx transport systems supply nutrients, such as glucose and amino acids. Age and illness, such as diabetes, may affect the integrity of the blood–brain barrier, increasing the drug exposure of the brain. P-glycoprotein, located at the luminal membrane of endothelial cells, functions as a clearance system for drugs entering the brain as well as for metabolites and neurotoxic compounds produced in the brain. Drugs recognized by these transporters are expected to show lower blood–brain barrier permeability. Examples of drugs now known to be substrates for P-glycoprotein include digoxin, erythromycin (Ery-Tab), lidocaine, morphine (Astramorph), nifedipine (Adalat), nortriptyline (Pamelor, Aventyl), propranolol (Inderal), risperidone, and verapamil (Calan). Several P-glycoprotein substrates may also inhibit its function, such as erythromycin, risperidone, and verapamil, permitting greater CNS penetration.

Metabolism

The purpose of drug metabolism is to transform lipid-soluble compounds into more water-soluble derivatives that can be more effectively eliminated and may be less active pharmacodynamically. Biotransformation of drugs is categorized as belonging to either phase I (oxidation or reduction) or phase II (conjugation). A large group of heme-containing enzymes, which vary in substrate preferences, collectively called CYP enzymes, is responsible for oxidative (phase I) drug metabolism. As more is learned about both the diversity and specificity of the CYP enzymes, a structure is emerging for categorizing potential drug–drug interactions and possible age-associated changes. Available evidence suggests that there is not a uniform age-

associated decline in the quality of activity of these enzymes. Nonetheless, reductions in hepatic mass and blood flow with aging place greater emphasis on interindividual differences in drug metabolic capacity. These metabolic differences may be genetic or the result of interactions from multiple medications. Isoenzyme specificity suggests that inhibition or induction of a given CYP will affect all drugs metabolized by that specific enzyme. A drug may act as a substrate for one CYP at a time or simultaneously for more than one. A drug can act as both a substrate and a competitive inhibitor for the same isozyme, or it can act as a noncompetitive inhibitor for a different enzyme.

CYP 2D6 is the isozyme specifically responsible for hydroxylation of many antidepressants (e.g., nortriptyline, desipramine [Norpramin, Pertofrane], duloxetine [Cymbalta], paroxetine, venlafaxine [Effexor], and vortioxetine [Brintellix]) and several antipsychotics (perphenazine [Trilafon], thioridazine [Mellaril], iloperidone [Fanapt], and risperidone). Approximately 7 percent of the Caucasian population are genetically poor 2D6 metabolizers, which has been shown to impact on nortriptyline doses and adverse effects of perphenazine in older patients. Concern has also been raised about the potential cardiotoxicity of venlafaxine in poor 2D6 metabolizers or those taking concomitant diphenhydramine (a CYP 2D6 inhibitor). Studies conducted in older, unmedicated volunteers have not found an age-associated decline in CYP 2D6 activity. Nevertheless, many drugs commonly used by older patients competitively (e.g., perphenazine) or noncompetitively (e.g., paroxetine, fluoxetine, bupropion) inhibit this enzyme, leading to potentially significant interactions.

CYP 2C19 is responsible for the metabolism of diazepam, mephenytoin (Mesantoin), escitalopram (Lexapro), and omeprazole (Prilosec), as well as several barbiturates. In addition, the demethylation of tertiary TCAs is also partly dependent on 2C19. The incidence of the poor metabolizer phenotype in a young Caucasian population is approximately 3 percent but was 18 percent in a Japanese sample. There is some evidence that 2Cl9 functioning may decline with age. CYP 2C19 is responsible for metabolizing the narrow-therapeutic-index drugs phenytoin, tolbutamide (Orinase), and warfarin (Coumadin), and is inhibited by fluvoxamine (Luvox) and fluoxetine.

CYP 3A4 is the most prevalent drug-metabolizing enzyme and is responsible for metabolizing the most medications. Because it is normally a high-capacity enzyme, serious and surprising toxicity has occurred when the 3A4-mediated clearance of terfenadine (Seldane), astemizole (Hismanal), cisapride (Propulsid), midazolam (Versed), triazolam (Halcion), mibefradil (Posicor), and cerivastatin (Baycol) was diminished. Also, because hepatic metabolism of CYP 3A4 drugs is typically so rapid, many of these drugs are perfusion limited (i.e., dependent on hepatic blood flow, which may decline by 40 percent between ages 25 and 65 years).

Therefore, it often appears that drugs specifically metabolized by CYP 3A4 decline with age—for example, alprazolam (Xanax) and triazolam clearances in the elderly are only 50 to 80 percent of those in young adults. In particular, gender- and age-related pharmacokinetic differences have been demonstrated for several 3A4-typed drugs, such as sertraline (Zoloft), mirtazapine (Remeron), and nefazodone (Serzone). CYP 3A4 activity may be inhibited by grapefruit juice, protease inhibitors, "mycin" antibiotics, and "azole" antifungals. Among antidepressants, nefazodone and fluvoxamine are the most potent inhibitors, followed by fluoxetine, through its demethylated metabolite. The very long half-life of norfluoxetine may result in interactions occurring many weeks after initiation of fluoxetine. Similarly, the inhibition of the CYP 3A4-mediated clearance of "statins," resulting in muscle weakness, may be misattributed in depressed patients. The 3A4 enzyme also may be induced by other drugs, such as carbamazepine (Tegretol), phenytoin, topiramate (Topamax), modafinil (Provigil), barbiturates, steroids, and St. John's wort, increasing the risk of therapeutic failure for CYP 3A4 drugs. Many CYP 3A4 inhibitors (e.g., verapamil) and inducers (St. John's wort) also have been found to interact at the P-glycoprotein drug transporter, amplifying their CYP 3A4-mediated effects.

CYP 1A2 metabolizes clozapine, olanzapine, fluvoxamine, asenapine (Saphris), and theophylline and contributes to the demethylation of some tertiary TCAs. This isozyme is induced by cigarette smoking and eating cruciferous vegetables and charcoaled meats, as well as by certain medications, such as omeprazole and phenobarbital (Luminal). Estrogen replacement therapy in postmenopausal women has been found to inhibit CYP 1A2 metabolism, whereas treatment with growth hormone causes induction. Inhibition and induction magnify an already marked, 60-fold variation in 1A2 activity. This degree of metabolic variation mandates that theophylline and clozapine be closely monitored.

There is more limited information about CYP 2B6, which substantially metabolizes bupropion. In vitro evidence has suggested that fluoxetine, paroxetine, and sertraline may cause CYP 2B6 inhibition. Given bupropion's risk of concentration-related seizures and the frequency of its use with SSRIs, this may be of potential concern.

Beyond oxidative metabolism, phase II metabolism in older patients has been a neglected area for systematic study. In general, drugs such as lorazepam and oxazepam (Serax) accumulate less than more lipid-soluble drugs and undergo single-step conjugative elimination. Glucuronidation, however, may not be an immutable process, being significantly affected by malnutrition. Despite the common assertion that phase II metabolism does not change with age, significant reductions in oxazepam's elimination have been found in those older than 80 years.

Excretion

The average glomerular filtration rate decreases by 50 percent between the ages of 20 and 70 years. Age alone, however, cannot be used to predict renal function, because at least one-third of older patients may maintain relatively stable renal function. Serum creatinine may not appear elevated in the face of declining renal function because there is often a decline in muscle mass, the major source of creatinine, with age and debilitation. Minimally, the use of estimates from standard nomograms or equations should be used to estimate creatinine clearance, given that it is often impractical to collect a timed urine sample. Decline in renal clearance may directly affect excretion of such medications as lithium, gabapentin (Neurontin), pregabalin (Lyrica), topiramate, amantadine (Symmetrel), paliperidone (Invega), memantine (Namenda), rivastigmine (Exelon), and desvenlafaxine (Pristiq). The clearance of hydrophilic (polar), psychotropic drug metabolites may also be reduced in older patients. Paliperidone is the active 9-OH metabolite of risperidone and accumulations of active hydroxylated metabolites of antidepressants, such as nortriptyline, bupropion, and venlafaxine, have been observed in older patients with uncertain clinical consequences.

The nonsteroidal anti-inflammatory drugs (NSAIDs) and angiotensin-converting enzyme (ACE) inhibitors reduce lithium's clearance (possibly through effects on renal blood flow). Given the widespread use of these medications in elders and their increased risk of lithium toxicity, this potential interaction deserves emphasis. Low-salt diets and the possibility that SSRIs may cause inappropriate antidiuretic hormone secretion, with concomitant hyponatremia, are additional sources of interactive complications with lithium.

PHARMACODYNAMICS

As patients age, there is a general reduction in homeostatic mechanisms (e.g., postural control, orthostatic circulatory responses, thermoregulation, visceral muscle function, laryngeal reflexes, hypoxic responses, cognitive function). This reduction may interfere with adaptation to environmental changes and may be manifest as adverse drug experiences. All psychotropics may increase risk of falls and hip fractures and may increase cognitive impairment. Physiologic (postural or action) tremors may be exacerbated by numerous drugs, including β and dopamine agonists, xanthines, valproic acid (valproate), steroids, and antidepressants. Reduced β-receptor sensitivity with aging contributes to diminished baroreceptor reflex responses, whereas coronary artery disease, reductions in the heart's intrinsic sinus rate, and damage to conduction pathways predispose to arrhythmias. The fact that SSRIs may exacerbate bradycardia should also be borne in mind. In older patients chronically treated with

antipsychotics, the prevalence of obesity, poor nutritional status, and increased triglycerides may contribute additional cardiovascular risk factors.

Specific receptor and neurotransmitter changes associated with senescence, such as reductions in dopamine or acetylcholine content, result in increased sensitivity to D2 antagonists and antimuscarinic agents. Side effects from conventional antipsychotics and tricyclics were common and frequently troubling in older patients. In particular, the association of these medications with significant cognitive impairment, declines in activities of daily living, and significant falls (with concomitant risk of hip fracture) was of grave concern in the frail elderly. Prospective studies demonstrated that there was a very rapid and high incidence of onset of tardive dyskinesia in older patients taking conventional antipsychotics for relatively brief periods (cumulative incidence reported as 26 to 45 percent over 1 year). Although atypical antipsychotics are now extensively used in older patients, meta-analyses of 17 controlled trials found that these medications increase mortality (4.5 percent) compared to placebo (2.6 percent) in elders suffering from dementia within the relatively short duration of the trials conducted (typically 10 weeks). Moreover, the side effects of these medications may outweigh their potential benefits. Some of these side effects are concentration related, such as extrapyramidal symptoms with risperidone and anticholinergicity with clozapine or olanzapine. Concentrations of atypical antipsychotics may be significantly affected by concomitantly administered medications that inhibit or induce CYPs lA2 (asenapine, clozapine, olanzapine), 3A4 (aripiprazole, iloperidone, quetiapine, ziprasidone), or 2D6 (aripiprazole, risperidone).

Two groups of drugs cause anticholinergic effects: those used therapeutically for their anticholinergic properties (e.g., oxybutynin [Ditropan], benztropine [Cogentin]) and those that have anticholinergic effects that are incidental to their main actions (e.g., amitriptyline [Elavil], cimetidine [Tagamet], digoxin, paroxetine). Peripheral manifestations of anticholinergicity include dry mouth, tachycardia, blurring of vision, urinary retention, and constipation. Common difficulties in older patients, such as constipation, xerostomia, glaucoma, and urinary retention, may be markedly exacerbated by even modestly anticholinergic medications. Anticholinergic effects on the CNS may range from subtle changes, such as mild confusion and impairment of recent memory, to physical decline. Patients with a dementing illness are most at risk from these central anticholinergic effects. Nonetheless, studies have found that even medications with modest anticholinergicity are additive and affect cognitive performance in a wide cross section of elders. In fact, understanding of the nature of cognitive decrements associated with “normal” aging may be distorted by modest anticholinergic burden. It should also be noted that medications with prominent noradrenergic

actions can also cause dry mouth, urinary retention in older men, and tachycardia, in addition to exacerbating hypertension and tremor.

Older patients have been found to require smaller doses of anticoagulants to achieve the same degree of anticoagulation as obtained in younger individuals. Although confounded by effects of other medications and hepatic dysfunction, increased sensitivity of elders to anticoagulants is probable. Anticoagulants figure prominently in drug-related morbidity and mortality. Genetic tests may, in the near future, help to detect the estimated one-third of patients with variants that make them slow metabolizers of warfarin (CYP 2C9) or more sensitive to its effects (vitamin K epoxide reductase activity [VKORC1]). Anticoagulant–antidepressant interactions may be pharmacokinetic as well as pharmacodynamic. Fluvoxamine poses a risk for a pharmacokinetic interaction through inhibition of CYP 2C9, reducing the clearance of warfarin's active S-enantiomer. In addition, inhibition of CYPs 1A2 (fluvoxamine), 2C19 (fluvoxamine, fluoxetine), and 3A4 (fluvoxamine, fluoxetine) will cause R-warfarin to accumulate, which also contributes to reduced S-warfarin clearance. However, increased bleeding times with SSRIs alone or in combination with anticoagulants also may be possible owing to SSRIs' effects on platelet serotonin and thereby attenuating aggregation. Concurrent therapy need not be avoided, but close monitoring is advisable whenever an SSRI is combined with warfarin. Both concerns (increased risk of gastrointestinal bleeding in elders) and potential benefits (protective effects against myocardial infarction in smokers) have been raised by epidemiological studies of SSRIs.

In addition to problems that may be anticipated, because most of the data on a new drug's effects have been obtained in younger patients, unexpected side effects are not infrequent in elders. In older patients, SSRIs and venlafaxine have been associated with the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Although SIADH is a rare adverse effect of many psychotropic medications, the majority of reports of antidepressant-induced SIADH have involved patients older than 65 years. In an analysis of 760 reports of hyponatremia associated with SSRIs, the median time to onset of the hyponatremia was 13 days (range, 3 to 120 days). SSRIs in older patients also have been associated with parkinsonism or worsening of motor disability in patients who have idiopathic Parkinson disease. It is possible that this is a result of serotonergic-influenced reduction in dopaminergic transmission in a population with diminished dopamine reserves. Concern has also been raised recently from large population studies. One found chronic use of SSRIs associated with a twofold increased risk of fragility fractures and lower bone mineral density. Another associated SSRI therapy with a nearly fivefold increased risk of completed suicide in older patients during the first month of treatment compared with other antidepressants. Although the absolute risk of suicide may be low, there is a clear need for close

monitoring of older patients, especially males with comorbid medical illness.

The greatest threats to successful pharmacotherapy in older patients are patient nonadherence with medication regimens and drug–drug interactions. High-risk medications, including anticoagulants, antihypertensives, and antiarrhythmics, have been consistently emphasized in long-term, comprehensive surveys of adverse drug reactions in older patients. Physicians need to be particularly vigilant and knowledgeable when psychotropics are coprescribed with these high-risk medications. As patients age, pharmacodynamic changes and concomitant illness will significantly alter their response to medication. Psychiatrists treating older patients should use a set of routine procedures as follows: (1) identify patient risk factors, such as medical status, use of high-risk medications, diet, and alcohol use; (2) take a thorough drug history involving caregivers and relatives, being sure to include over-the-counter medications and update regularly in a prominent place in the patient's record; (3) educate patients and caregivers about their medications and dosing regimens and monitor adherence; (4) be knowledgeable about drug actions, interactions, and clearance; (5) use the lowest effective doses and carefully graduated increases, and avoid unnecessary polypharmacy, but do not undertreat; (6) frequently reassess psychomotor function, including mental status and balance, as well as orthostatic blood pressures and specific laboratory tests when appropriate; and (7) if there is a deterioration in patients' physical or cognitive states, always suspect an adverse drug reaction.

FUTURE DIRECTIONS

Developments in clinical trial design and the completion of large effectiveness trials serve further to heighten concerns about the efficacy and side effects of currently available pharmacologic therapy for the symptomatic relief of psychiatric symptoms in elders. Controlling for heterogeneous drug exposure in conjunction with improved understanding of the genomic basis of cognitive, mood, and psychotic dysfunction and its complex interactions with age-related ischemic and other environmental CNS changes may lead to more targeted molecular therapeutics. Regulatory policy and public health initiatives must be amplified to increase the representation of older subjects in clinical trials and improve the relevance of the therapeutic evidence base. For medications approved for release, it is to be hoped that the cross-linking of computerized medical records will lead to improved postmarketing surveillance of medications in elders.

57.4b Antidepressants and Mood Stabilizers

CARL SALZMAN, M.D.

GOALS AND RATIONALE FOR THE PHARMACOLOGICAL TREATMENT OF DEPRESSION IN LATER LIFE

Clinically significant depression in late life is a **disorder that encompasses a spectrum of severity** ranging from debilitating major depression that has serious consequences for the life of the patient to minor depression that can impair quality of life. As in younger people, the course of depression in the elderly is characterized by exacerbations and remissions as well as by chronicity. Multiple pathways contribute to late-life depression, including neurobiological and psychological factors, physical illnesses and their treatments, cognitive and sensory decline, as well as common social and economic problems. Among community-dwelling residents over the age of 65, approximately 13 to 27 percent may suffer from subsyndromal depression, 15 percent exhibit depressive symptoms but do not meet diagnostic criteria for any disorder, 1 to 2 percent suffer from major depression, and 2 percent are living with dysthymia. The prevalence of depression of all forms is much higher in nursing homes and in hospitals.

There appears to be considerable heterogeneity in the onset and course of late-life depression. Diagnostic patterns are also variable among older individuals. Clues to depression include frequent medical visits with persistent complaints of pain, headache, fatigue, and insomnia; and high utilization of services. Additional clues to depression in elderly hospitalized patients include delayed recovery, treatment refusal, and problems with discharge. In the nursing home patient, depression should be suspected in the presence of apathy, failure to thrive, agitation, and delayed rehabilitation. Elderly individuals who are depressed may also have structural and functional changes in the brain including ventriculomegaly, white matter hyperintensities, and vascular changes. Depression in later life should be treated because it usually persists in the absence of treatment, causing distress to patients' caregivers, as well as leading to excess health care use and increased substance abuse. Mood disorders also play a greater role in suicides of elderly patients than in those of younger patients; the group at highest risk for suicide is white males aged 80 to 84 years. A majority of suicide victims visited a primary care physician in the last month of life.

Treatment of depression in elderly adults may improve day-to-day functioning and self-care, and can improve physical health and cognitive functioning. Although treatment benefits usually outweigh the risks, late-life depression is often untreated, especially in the frail elderly either

because the depression is not recognized or from fear that treatment will further damage an older individual. The risks of no treatment or of inadequate treatment, however, include chronic depression, cognitive impairment, worsening of physical illness, poor compliance with medical treatment, social impairment, reduced quality of life (satisfaction, ability to cope), and suicide. **Anxiety is a common component of late-life depression and high levels of anxiety may delay the response to antidepressant treatment.**

The goals of pharmacological treatment of both major and minor depressive disorders in later life include remission, if not substantial reduction, of depressive symptoms, as well as the prevention of relapse and recurrence. Hence, long-term use of **antidepressants** is probably the rule, not the exception. Treatment goals also include restoring psychosocial functioning, relieving excess disability, improving patient compliance with other medical therapies that **might be refused** because of hopelessness or pessimism caused by depression. **Antidepressants may also** ease the adaptation to irreversible losses. Expert **consensus guidelines now recommend that antidepressant treatment should be combined with psychotherapy. Since elderly individuals with mood disorders are often taking multiple medications, it is also necessary for the prescribing clinician to remain alert for possible adverse drug interactions. These will be discussed in each of the following sections.**

PHARMACOLOGICAL TREATMENT OF DEPRESSION

Antidepressants used to treat elderly depressed adults include **the same drugs that are given to younger adults. In general,** aging results in altered metabolism and excretion of some antidepressants, **prolonging their effect. For example,** the clearance of some antidepressants such as citalopram **and nefazodone** is delayed, causing drug accumulation and high blood levels. The sensitivity of the central nervous system to **antidepressant drugs is also increased by age: m**ost (but not all) elderly individuals are more sensitive to the therapeutic effects of antidepressants as well as to their side effects. **Since elderly individuals are often taking multiple medications, there is an increased risk of adverse drug interactions with antidepressants.**

Accumulating data suggest that elderly patients respond **as** well to antidepressant treatments **as younger adults.** Data **also** suggest that **the** time to response does not differ from younger adults, **but clinicians often notice that it may** require longer time periods to achieve remission or full therapeutic response.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

SSRI antidepressants are now considered **to be** the first choice for the

treatment of elderly depression because of their efficacy and favorable side-effect profile. Studies of SSRIs do not demonstrate superior antidepressant efficacy of any one member of this class over another. Late-life depressions associated with dementia as well as with medical illness respond to SSRIs. Most SSRIs can be taken once daily which increases compliance especially for elderly patients who are taking multiple medications. **Although** SSRIs do not cause orthostatic hypotension, they have been implicated in an increased prevalence of falls in elderly nursing home residents. **At therapeutic doses, they are** less likely to cause cognitive impairment, or anticholinergic and cardiovascular adverse effects. The limitations of these agents include nausea, headache, restlessness, sexual dysfunction, decreased heart rate, occasional insomnia, and occasionally inappropriate antidiuretic hormone secretion. Some SSRIs, especially fluoxetine and paroxetine (and sertraline, to a lesser extent), interfere with cytochrome-metabolizing enzymes. Since hepatic metabolism is the primary route for drug detoxification and elimination, inhibition of these enzymes (especially CYP450 2D6 and 3A4) may raise the blood levels of other medications, causing unwanted side effects and toxicity. Medications whose metabolism may be inhibited include cardiac antiarrhythmic drugs, antidepressants and neuroleptics, **some** benzodiazepine anxiolytics, steroids, some antihistamines and antibiotics, and antifungal agents. **Fluoxetine and paroxetine, in particular, are strong inhibitors of the metabolizing hepatic enzyme CYP450 2D6. This enzyme is necessary to convert tamoxifen to its active metabolite; inhibition by either of these SSRI antidepressants will prevent this conversion and render the tamoxifen useless. Citalopram and escitalopram do not affect hepatic metabolizing enzymes and may be less likely to cause drug interactions.**

Examination of the role of polymorphisms of the serotonin transporter protein gene indicates that in elderly individuals (as in young adults) the "s" variant is associated with a decreased reduction in serotonin reuptake and a less robust response to SSRI antidepressants.

Starting doses of SSRIs should be low (paroxetine 10 mg, sertraline 25 mg, citalopram 10 mg, **escitalopram** or fluoxetine, 10 mg) **followed by** gradual dosage increases, particularly in those above age 75. **Therapeutic** dosages will **vary,** ranging from 20 to 60 mg a day of paroxetine, 50 to 200 mg a day of sertraline, and 10 to 60 mg a day of fluoxetine or of citalopram **or escitalopram.** Therapeutic blood concentrations of SSRIs are not available for routine clinical use. Studies of augmentation of an SSRI antidepressant with other medications such as methylphenidate, bupropion, thyroid, or estrogen have shown **equivocal efficacy in the elderly.**

Newer antidepressants with selective serotonin reuptake inhibiting properties are now available. All are effective antidepressants; there are no

data to suggest that any are superior to existing SSRIs. These drugs include vilazodone (given in the usual daily dose of 40 mg taken with food) which combines serotonin reuptake blockade with direct effects on synaptic serotonin receptors.

SSRIs, but not tricyclic antidepressants, are associated with an increased rate of bone loss in older women, **especially in** the hip. This bone loss is associated with a twofold increase **of** clinical fragility fracture since there is an increased risk of falls in nursing home residents who are taking SSRI (or tricyclic) antidepressants.

DUAL-ACTING ANTIDEPRESSANTS

There are nine currently available antidepressants that enhance neuronal transmission in central nervous system mood-regulatory circuits by inhibiting the presynaptic reuptake of both norepinephrine and serotonin: venlafaxine, desvenlafaxine, duloxetine, milnacipran, levomilnacipran, mirtazapine, trazodone, nefazodone, and the recently released vortioxetine.

Venlafaxine, an inhibitor of noradrenaline and serotonin reuptake, is an effective and safe antidepressant for the elderly. Compared with other antidepressants, it may induce slightly higher rates of remission of depressive symptoms in nonelderly adults; data are **scant** for the elderly. Patients respond to a relatively wide range of daily doses, and no dosage adjustment is necessary based on age. The use of venlafaxine entails several precautions. Headache and nausea may be minimized by using with lower dosages of 25 mg daily and using the extended-release formulation, gradually titrating up to a therapeutic dosage. Venlafaxine may cause modest increases in diastolic blood pressure which should be monitored. Venlafaxine use is not associated with drug interactions or enzyme inhibition. **Desvenlafaxine is also available for the treatment of depression. This metabolite of venlafaxine is an effective antidepressant at 50 mg/day. Duloxetine is an effective antidepressant at doses similar to those used for younger adults (up to 60 mg/day). Its side-effect profile is mild, and there have been clinical reports that this medication (like other dual-acting antidepressants) may be helpful in controlling pain from arthritis of rheumatoid disorders. Milnacipran is an effective antidepressant for the elderly at doses of 75 to 100 mg/day. At these doses, it does not adversely affect cognitive function or psychomotor performance. Levomilnacipran is now available and is effective in geriatric patients at doses of 20 to 40 mg/day. This antidepressant is primarily cleared through the kidneys, so elderly patients with renal impairment probably should not be treated with this particular antidepressant. Mirtazapine, through its unique receptor activity, is also considered a dual-acting drug. Mirtazapine is an effective antidepressant in the**

elderly at doses of 15 to 30 mg/day. However, it is quite sedating, so starting doses should be low; mirtazapine may be helpful as a sleep-inducing medication even in the absence of depression. A rapidly dissolving tablet is very useful for nursing home patients who have difficulty swallowing a pill.

Although not officially classified as dual-acting drugs, trazodone and nefazodone also affect both norepinephrine and serotonin neurotransmission. These drugs are weak serotonin reuptake inhibitors and are less commonly used to treat depression. Trazodone, however, is an effective drug for inducing sleep onset. Nefazodone strongly inhibits the CYP450 3A4 metabolizing enzyme; it should not be prescribed together with benzodiazepine anxiolytics, steroids, antibiotics, antifungal medications, and certain antibiotics. When prescribed with mood-stabilizing medications (antiseizure drugs such as carbamazepine, lamotrigine, and divalproex sodium), blood levels of the mood stabilizer may rise, producing unwanted side effects.

Vilazodone and vortioxetine and new antidepressants that are available for clinical use. Research has been scant on the clinical efficacy of these two drugs in the depressed geriatric population.

In general, these dual-acting antidepressants are not likely to produce serious drug interactions with other medications. It is good practice, however, to minimize the total number of medications that are coprescribed with these antidepressants and avoid using more than one antidepressant at the same time. Drugs that increase serotonin function may interact with these dual-acting drugs to produce a serotonin syndrome and should be avoided.

BUPROPION

Bupropion is an effective and safe antidepressant that is often prescribed to elderly patients because of its activating properties and relatively benign side-effect profile (no weight gain or significant anticholinergic properties). Advantages of bupropion include efficacy especially in psychomotorically retarded elderly patients, and no adverse effects on cognition. Bupropion does not cause sedation, and may even be stimulating for some elderly patients which may interfere with sleep. Bupropion may be helpful in depressed elderly patients with Parkinson disease. However, because of its activating properties, bupropion may increase anxiety in some elderly individuals, especially those who are already anxious. Bupropion is a strong inhibitor of the metabolizing hepatic enzyme CYP450 2D6. This enzyme is necessary to convert tamoxifen to its active metabolite; inhibition by bupropion will prevent this conversion and render the tamoxifen useless. As with other antidepressants, starting doses should be lower than those recommended for younger adults, and dosage increments should be gradual.

TRICYCLIC ANTIDEPRESSANTS

Tricyclic antidepressants, nortriptyline and desipramine in particular, are effective medications for major depressive disorder in the elderly. Blood levels of these two drugs necessary to achieve therapeutic effect in the elderly are the same as in younger adults, thus providing the clinician with a laboratory value to guide dosing. Hydroxy metabolites of the tricyclics are potentially cardiotoxic in elderly individuals, and may be present at higher plasma levels than in younger adults because **their** renal excretion is decreased by advancing age. An electrocardiogram can be used to monitor patients in order to avoid approaching cardiotoxicity which is signaled by a widening of the QTc interval.

Annoying **peripheral anticholinergic** side effects of tricyclics, particularly constipation and dry mouth, can become severe problems in the elderly leading to bowel obstruction and poor dental hygiene. Central nervous system anticholinergic side effects, which usually consist of decreased memory and attention, can progress to a delirious state with severe confusion, disorientation, and paranoid ideation. Orthostatic hypotension, another common adverse effect of tricyclic treatment of late-life depression may increase the risk of falls; oversedation may interfere with participation in daytime activities.

To prevent these common tricyclic antidepressant side effects, relatively low starting doses with small dosage increments are usually employed. The prescribing maxim "start low (initial dose) and go slow (subsequent dosage increases)" applies to elderly individuals as a class of patients, although not necessarily to any individual patient.

Plasma levels of imipramine, desipramine, and nortriptyline can be routinely obtained. These levels correlate with therapeutic effects as well as with side effects. Prescribing clinicians who wish to use a tricyclic should follow plasma levels of the tricyclic (preferably the secondary amines, desipramine or nortriptyline) as doses are being adjusted to the therapeutic range. Using these levels along with an EKG to monitor the appearance of a potentially dangerous cardiac arrhythmia provides the prescribing clinician with two sources of data to guide the use of these medications.

MONOAMINE OXIDASE INHIBITORS

Monoamine oxidase inhibitors **may be** effective in depressed elderly patients. Their advantages include few anticholinergic effects and no effects on cardiac conduction. **MAO inhibitors are potentially dangerous for elderly individuals and should not be used except by those prescribing clinicians who have experience with these medications. The potential for toxic interactions between these drugs and other medications (e.g., serotonin-enhancing drugs; meperidine or other opiates, tricyclic antidepressants) or**

certain commonly eaten foods (e.g., aged cheese, pickled meats and fish) is high in the elderly population. Consequently, if these medications are to be used, they must be prescribed only to those elderly patients who are able to follow the dietary and drug interaction limitations.

For **appropriate and compliant** elderly patients, problem interactions with food and drugs can be minimized through patient education and collaboration among treating physicians. Limitations in their clinical utility include both hypotension and hypertension, insomnia, and somnolence. The starting dosages of tranylcypromine and phenelzine are 10 mg a day and 15 mg a day in two doses, respectively. In general, maximum dosages do not typically exceed 40 to 50 mg a day for tranylcypromine and 75 to 90 mg a day for phenelzine.

Transdermal selegiline (Emsam) is now available as a skin patch, although there is scant literature regarding its use in the elderly. This MAO inhibitor decreases the problems of drug and food interactions, that may occur when high doses of the patch or the interacting medication or food are ingested.

STIMULANTS

Stimulants, such as methylphenidate (Ritalin) are not classified as antidepressants and should not be used as the solo medication to treat an elderly depressed individual. **However,** low doses of methylphenidate (2.5 to 5.0 mg/day in divided doses) **may be** helpful in activating a withdrawn apathetic older patient, as well as increasing motivation and social participation. Methylphenidate may also enhance the therapeutic effect of antidepressants which have only produced a partial response. Low doses are not associated with tachycardia, hypertension, or cardiac toxicity; doses administered after 3 or 4 PM may interfere with sleep. **Other activating drugs (modafinil, armodafinil) may also be used for mild activating effects. Stimulants and other activating drugs should not be given after 2 to 3 PM in order to avoid interfering with sleep onset at bedtime.**

TREATMENT OF PSYCHOTIC DEPRESSION IN LATER LIFE

Psychotic depression is a severe illness with profound depressive symptomatology accompanied by delusions, often of somatic dysfunction, hopelessness, or guilt. Psychotic depression poses a health risk from progressive weight loss and exhaustion as well as from suicide, usually by violent means. For this reason, recognition and treatment of psychotic depression can be lifesaving. Both young and elderly patients with psychotic depression respond poorly to short-term treatment with antidepressants given alone. Combinations of antidepressants and

antipsychotic medications are effective in psychotic depression, in both controlled studies of younger patients and naturalistic treatment studies of elderly patients. Although tricyclics were the most frequently prescribed antidepressants in conjunction with a typical antipsychotic drug such as perphenazine (Trilafon), clinicians are now using a combination of SSRIs or **dual-acting** antidepressants **together with** atypical neuroleptics to reduce side effects **of older medications.** Electroconvulsive therapy, **often** rapidly effective and safe, remains the treatment of choice **for** severe geriatric psychotic depression.

TREATMENT OF DEPRESSION ASSOCIATED WITH MEDICAL ILLNESS AND WITH COGNITIVE IMPAIRMENT

An NIH Consensus Development Conference on the Diagnosis and Treatment of Depression in Late Life stated that "the hallmark of depression in older people is its comorbidity with medical illness." Compelling evidence from placebo-controlled clinical trials indicates that antidepressant medications are efficacious in patients with common comorbid medical disorders as diverse as stroke, Parkinson disease, Alzheimer disease, cancer, ischemic heart disease, chronic obstructive pulmonary disease, and arthritis. It appears that all antidepressants are therapeutic, at least to some degree, even in rehabilitation units where treatment of depressed patients can facilitate recovery from acute illness or injury and in a residential care setting, where patients were characterized by extreme old age and the interacting effects of many of the common disabling medical disorders of later life. **Until recently,** tricyclic antidepressants were the most widely studied drugs for the treatment of depression associated with another illness. They **have demonstrated** safety and effectiveness for poststroke patients, as well as for elderly depressed patients with Parkinson disease, cardiovascular illness, and cancer. However, interactions between **tricyclic** antidepressants and other **nonpsychiatric** medications used to treat **medical or neurological** illness can make older patients highly vulnerable to the development of side effects. Thus, careful monitoring of both potential adverse effects and plasma concentrations is necessary to optimize safety of these agents in frail elderly patients. SSRI and other nontricyclics are now more widely used in order to avoid this potential for adverse drug events; SSRIs have been shown effective for depressed patients with cardiovascular illness, stroke, Parkinson disease, and cancer.

Depression and cognition intersect in two ways: elderly individuals with failing cognition or who are suffering from a dementia commonly are depressed; depressed elderly individuals frequently complain of impaired memory and concentration. This interaction between depression and diminished cognitive function has been well studied. Regardless of whether the primary illness is dementia or is depression, the

depression should be treated, following the basic principles that apply **to** older patients. Medication use should be supervised, and caregivers should assess the benefits and monitor for adverse effects of treatment. Patients with dementia of the Alzheimer type are highly sensitive to increased cognitive impairment from anticholinergic medications. Therefore, antidepressants with the lowest anticholinergic effects are preferred, which include the SSRIs, **low doses of** bupropion, venlafaxine, mirtazapine **and vilazodone.** Low doses of nortriptyline are sometimes helpful as well. Memory and concentration often improve as a depression responds to medication; in mild to moderate degrees of dementia, successful antidepressant treatment can restore or even transiently improve memory and concentration. However, as the dementia worsens, antidepressants may cause increasing agitation and must be discontinued.

ESSENTIALS OF PATIENT MANAGEMENT

Several principles of clinical practice should guide the clinician who wishes to treat a depressed elderly individual. Careful psychiatric and medical diagnoses go hand in hand; older depressed individuals must be medically evaluated, especially for thyroid dysfunction and levels of B_{12} and folate. For some older people, this evaluation should include a neurological examination to rule out Parkinson disease or dementia. **It is well established that inflammation and inflammatory disorders are commonly associated with mood disturbance, especially with depression. Chronic illnesses such as diabetes are also commonly associated with depression. Poststroke and postmyocardial infarction depressions are similarly well known and failure to treat the depression may increase morbidity or subsequent mortality.** A comprehensive list of all medications (prescribed or self-purchased) including herbs, holistic remedies, and homeopathic preparations must be obtained since medication-induced (or worsened) depression is common in the elderly. The clinician must also determine whether or not alcohol (or other drugs) is being used excessively or inappropriately before embarking on a treatment program. It may be necessary for the clinician to obtain this information from a spouse, child, or other source as the depressed older person may not offer an accurate history.

Managing the depressed geriatric patient also includes educating the patient and family about the nature of depression as a true illness, emphasizing that it is treatable. Patients and their families need to understand that response to medication may take longer than for younger adults, that treatment adherence is essential, and that adverse effects can be expected but are amenable to supportive countermeasures. Weekly contact during the early phases of short-term treatment is recommended for individualizing treatment, providing encouragement and support,

reviewing questions and concerns, and monitoring safety (including suicidal potential). Common errors in practice include underdosing, discontinuing treatment too soon, failure to consider possible drug interactions, and polypharmacy. If a patient has not begun to respond by 6 to 8 weeks, compliance should be reevaluated, dosage or plasma concentration should be optimized, and referral to a geriatric psychiatrist experienced in treatment resistance should be considered.

Late-life depression is often a chronic illness and tends to recur, especially among those whose first depression develops after the age of 60. One must bring a longitudinal model of depression to treatment. Short-term treatment is intended to induce remission but incomplete remissions are not unusual and commonly lead to relapse. Recurrences after a longer period of recovery are also common. Studies continue to demonstrate the therapeutic benefits of long-term treatment of depression, and it is recommended, therefore, that treatment continue at least 6 months beyond recovery and for longer periods after a second or third episode. Many older patients have chronic depression that requires indefinite maintenance therapy. Long-term prevention of new episodes is best achieved by maintaining patients on the same dosage of antidepressant medication that was used successfully to treat the acute episode.

TREATMENT OF BIPOLAR DISORDERS IN LATER LIFE

Bipolar disorders constitute 5 to 10 percent of the diagnoses of elderly psychiatric inpatients. The diagnosis of a manic episode is usually not difficult in older individuals, although advanced age is associated with greater degrees of irritability and less euphoria. Most manic elderly patients have a history of prior manic episodes; onset of a first manic episode in late life is unusual, and often is associated with another illness such as thyroid dysfunction, or alcohol or substance abuse. Elderly individuals who have suffered repeated episodes of mania and depression over the course of their lives are likely to be quite dysfunctional when manic, with rapid shifts of mood. **Episodes of euphoria decrease with advanced age and are replaced by "dysphoric" or "mixed" mood states characterized by anger, irritability, paranoid ideation, and depression.** Diagnostic principles follow the suggestions for evaluation of an elderly depressed patient, therefore, including a careful and comprehensive medical evaluation, laboratory screening, and history of past or current drug and alcohol use.

In principle, the management of mania in elderly patients is similar to that in younger patients, although there may be a relatively poor response to standard pharmacological treatment in patients with long-standing bipolar illness. Treatment of the acute manic episode is focused on two separate categories of dysfunction: (1) management of manic behavior, impaired sleep, and (2) regulation of excessive or inappropriate mood

states. Agitated hyperactive elderly manic patients or those who are psychotic, as well as patients with impaired sleep may be helped by treatment with neuroleptics. All **antipsychotic medications** are effective for these symptoms, although current practice favors the use of **second-generation drugs** in order to avoid excessive extrapyramidal symptoms caused by conventional neuroleptics. Risperidone, olanzapine, and quetiapine are commonly used for this purpose; clozapine is also therapeutic but its use in older patients is associated with numerous potentially serious side effects; **other medications (e.g., ziprasidone, aripiprazole, lurasidone, olanzapine) may also be helpful, but research studies in the elderly of any of these medications are scant and do not provide adequate prescribing information. In general, therefore,** starting doses of an atypical neuroleptic should be low, with gradual dose increases; clinicians should resist the pressure to rapidly increase doses to control behavioral disruption. When an atypical neuroleptic is given at bedtime, sleep is often promoted which, in turn, may help diminish the manic symptoms.

Regulation of mood is accomplished by the use of mood-stabilizing medications; principles of their use follow guidelines for younger adults, although elderly individuals are significantly more sensitive to side effects. Lithium, for example, commonly produces side effects at doses and blood levels that are not toxic in younger people. For example, delirium can develop at lithium concentrations at or even below the **young adult** therapeutic lithium plasma concentration range. Delirium and cerebellar dysfunction may last for weeks after discontinuation of lithium use. Lithium-induced tremor is more frequent in older patients than in younger patients. Lithium can worsen Parkinson disease or produce parkinsonism in neurologically intact elderly patients, **and can also** worsen cognitive function, especially in demented patients. Sinoatrial block can be caused by lithium, a risk that is increased by the concurrent use of digitalis and β-adrenergic receptor antagonists (β-blockers). Elderly patients often receive drugs that increase lithium plasma concentrations, including thiazide diuretics, nonsteroidal anti-inflammatory drugs, or angiotensin-converting enzyme inhibitors. Age-induced decrements in glomerular filtration rates and renal blood flow reduce lithium excretion. Starting dosages of 75 to 150 mg a day may reduce adverse effects and improve compliance. These very low doses may successfully treat the disturbed mood with lower, nontoxic blood levels than in younger adults (e.g., 0.2 to 0.4 mM/L). **Because of the potential for toxicity and impairment of renal function, lithium use should be restricted to selected elderly patients whose physical health and ability to comply with prescribing guidelines and laboratory studies is evident.**

It is now well established that some anticonvulsant medications also are excellent mood stabilizers and may be effective and safe for elderly

individuals. Like lithium, however, anticonvulsants are used primarily to prevent recurrence of dysregulated mood states. For example, the anticonvulsants carbamazepine (Tegretol) and divalproex sodium (Depakote) have demonstrated prophylactic effectiveness in elderly individuals. Current prescribing practice favors the use of lamotrigine (Lamictal) as a stabilizing anticonvulsant for the elderly. Although a few individuals may develop a skin rash with this drug (less likely in the elderly), the side-effect profile is benign and with low therapeutic doses (12.5 to 100.0 mg/day) there may be few or no side effects. Oxcarbazepine (Trileptal) is also sometimes used to stabilize mood in younger adults, but there are no studies of its effectiveness in the elderly. Some evidence suggests that anticonvulsants are more effective than lithium in rapidly cycling patients and in patients with dysphoric mania, although studies have not been conducted in elderly patients.

Most anticonvulsants are metabolized by hepatic metabolizing enzymes, primarily CYP 3A4. Hematological and liver function tests are needed prior to treatment with anticonvulsants to ensure their safe use. Carbamazepine induces its own metabolism so blood levels may need to be adjusted during treatment. This drug can also cause leukopenia (white blood cell counts below 4,000/mm) in approximately 2 percent of cases; it should not be used for routine geriatric patient treatment. Valproate inhibits the CYP450 3A4 metabolizing enzyme and can cause elevations of other medications that use this metabolic pathway (e.g., lamotrigine, some benzodiazepines, and antidepressants). Valproate can also cause increased ammonia levels and toxic neurological states, although it is not clear that elderly individuals are more susceptible to this side effect. Lamotrigine, currently the preferred mood-stabilizing anticonvulsant for the elderly, is metabolized by CYP450 3A4 and its blood levels can be affected by other medications (e.g., valproate, fluoxetine) that inhibit this enzyme. Oxcarbazepine can cause a sudden decrease in serum sodium, followed by a change in mental status that may be mistaken for a worsening psychiatric condition. Levetiracetam has been used as a mood stabilizer in a small number of elderly patients. Other new anticonvulsants have not been tried in the elderly and cannot be recommended.

Prescribing guidelines for lithium and anticonvulsant treatment of late-life mood dysregulation follows the general geriatric prescribing principle: “start low and go slow.”

Continuation and maintenance treatment is necessary in elderly bipolar patients who achieve remission of a manic or depressive episode. Although studies of geriatric populations are lacking, studies of younger patients suggest that lithium, carbamazepine, and valproate are effective in preventing both depressive and manic episodes. For this reason, continuation and maintenance treatment with these drugs should be considered for elderly patients. Elderly patients, in particular, should be

carefully and frequently monitored for alterations in medical condition, especially hepatic function, as well as cognitive function. As the older bipolar patient continues to age, dosage modifications are likely to be necessary.

57.4c Antianxiety Drugs

ALASTAIR J. FLINT, M.B.

Anxiety disorders are common in late life, with 5 to 10 percent of community-dwelling older adults meeting criteria for a current anxiety disorder. Despite this prevalence, there has been relatively little research on the pharmacologic treatment of anxiety in the elderly and most treatment decisions in this group have to rely on research conducted in younger adults. Extrapolating findings from younger to older adults is however potentially problematic, given the pharmacokinetic and pharmacodynamic changes that occur with aging. In particular, the

efficacy, tolerability, and safety of drugs in the elderly can be affected by age-related physiologic changes (such as the increased volume of distribution of lipophilic drugs, decreased function of liver and kidneys, and changes in organ receptor sensitivity), the increased frequency of comorbid medical and neurologic conditions, and the fact that older adults take more medications than their younger counterparts, thereby increasing the risk of drug–drug and drug–body interactions. This chapter will highlight issues that are of particular relevance to the elderly in the pharmacologic treatment of anxiety.

Double-blind randomized controlled trials (RCTs) are the gold standard for evaluating treatment efficacy. Unblinded ("open-label") and uncontrolled studies are of limited use in guiding treatment because of the significant biases and confounds that can affect their findings. There have been 10 double-blind RCTs of the pharmacologic treatment of anxiety disorders in persons aged 60 years or older (Table 57.4c–1), but only eight studies pertain to drugs that are available in North America. Eight of the 10 RCTs focused on generalized anxiety disorder (GAD), while two studies included participants with nonspecific anxiety. The category of anxiety disorders has historically included phobic disorders, panic disorder, GAD, posttraumatic stress disorder (PTSD), and obsessive compulsive disorder (OCD). Why then have treatment studies in the elderly focused almost exclusively on GAD? Knowledge of the epidemiology of anxiety disorders in later life helps answer this question. First, phobias and GAD are the most prevalent anxiety disorders in the elderly. However, the most common presentations of phobia in later life, that is, specific phobia and agoraphobia without panic, tend not to come to psychiatric attention. In addition, the treatment of choice for these two phobic disorders is behavioral therapy, not pharmacotherapy. Therefore, GAD is the most frequently occurring late-life anxiety disorder in psychiatric practice that is medication responsive. Second, panic disorder, OCD, and social anxiety disorder (social phobia) have a low incidence and prevalence in later life, and therefore clinicians and researchers may view them as less compelling compared with disorders with a higher incidence and prevalence. In contrast, approximately half of the cases of syndromal generalized anxiety in the elderly are late onset, often in association with major depression. Finally, syndromal and subsyndromal generalized anxiety is the commonest manifestation of anxiety associated with medical illness and cognitive impairment in older persons, again frequently in association with depression.

[a]Placebo was the comparator agent in each trial.

The 10 RCTs in Table 57.4c–1 have evaluated the efficacy and tolerability of antidepressants, benzodiazepines, nonbenzodiazepine anxiolytics, an anticonvulsant, and an atypical antipsychotic in the treatment of late-life GAD. The remainder of this chapter will discuss these classes of drugs, as well as commenting on miscellaneous drugs that have been examined in younger persons with anxiety.

ANTIDEPRESSANTS

In recent years, there has been growing awareness that antidepressant medications have a broad spectrum of efficacy in the treatment of anxiety disorders in younger adults. RCTs in mixed-age patients have found that antidepressants of various classes are beneficial in the treatment of GAD, panic disorder, social anxiety disorder, PTSD, and OCD (Table 57.4c–2).

RCTs of antidepressant pharmacotherapy in older people with an anxiety disorder found that escitalopram (Lexapro) and citalopram (Celexa) are more efficacious than placebo in treating GAD (Table 57.4c–1). In addition, retrospective analyses of data pooled from RCTs found that venlafaxine (Effexor) and duloxetine (Cymbalta) had greater efficacy than placebo in older persons with GAD. In the escitalopram, citalopram, and venlafaxine studies, approximately two-thirds of older participants were classified as responders after 8 to 12 weeks of treatment. The venlafaxine analysis also compared response rates between younger and older participants and found almost identical rates of response to drug and placebo between the two age groups. Escitalopram, citalopram, and venlafaxine were well tolerated in these trials. On the other hand duloxetine, at dosages of 60 to 120 mg/day, was associated with significantly more nausea and weight loss than placebo and the duloxetine group had a significantly higher rate of discontinuation than placebo (22 percent vs. 0 percent).

Table 57.4c–2.
Drugs Found Efficacious in Randomized Controlled Trials Treating Anxiety Disorders in Mixed-Age Samples

Disorder	Drug
Generalized anxiety disorder	SSRI: escitalopram[a], fluoxetine, paroxetine[a]
	SNRI: duloxetine[a], venlafaxine[a]
	TCA: imipramine
	Other antidepressants: trazodone
	Benzodiazepine: various
	Azapirone: buspirone[a]
	Other: hydroxyzine, pregabalin, quetiapine
Panic disorder with or without agoraphobia	SSRI: citalopram, fluoxetine[a], fluvoxamine, paroxetine[a], sertraline[a]

	SNRI: venlafaxine[a]
	TCA: clomipramine, desipramine, imipramine
	MAOI: brofaromine, phenelzine
	Benzodiazepine: alprazolam[a], clonazepam[a], diazepam, lorazepam
Social anxiety disorder	SSRI: fluvoxamine, paroxetine[a], sertraline[a]
	SNRI: venlafaxine[a]
	MAOI: brofaromine, moclobemide, phenelzine
	Benzodiazepine: alprazolam, clonazepam
Posttraumatic stress disorder	SSRI: fluoxetine, paroxetine[a], sertraline[a]
	SNRI: venlafaxine
	TCA: amitriptyline, imipramine
	MAOI: phenelzine
	Other: prazosin (for nightmares)
Obsessive compulsive disorder	SSRI: fluoxetine[a], fluvoxamine[a], paroxetine[a], sertraline[a]
	TCA: clomipramine[a]

[a]FDA approved.

SSRI, selective serotonin reuptake inhibitor; SNRI, serotonin and norepinephrine reuptake inhibitor; TCA, tricyclic antidepressant; MAOI, monoamine oxidase inhibitor.

Selective Serotonin Reuptake Inhibitors

Of the selective serotonin reuptake inhibitors (SSRIs), escitalopram and citalopram are well suited to older persons. They have linear pharmacokinetics across the dose range (i.e., an increase in dose results in a predictable increase in plasma concentration), no clinically active metabolites, elimination half-lives of 33 hours or less, and little propensity for drug–drug interactions. In addition, sertraline (Zoloft) is also suitable in older persons because of a favorable pharmacokinetic profile. Although data from RCTs in mixed-age patients have demonstrated the efficacy of sertraline in several anxiety disorders (Table 57.4c–2), there are no controlled data pertaining to sertraline in late-life anxiety disorders, although it has been found to be efficacious, safe, and well tolerated in late-life depression. On the other hand, paroxetine and fluoxetine have less favorable pharmacokinetic profiles in older adults and paroxetine has the potential to cause anticholinergic adverse effects such as worsening cognitive function, blurred vision, dry mouth, constipation, and urinary hesitancy; therefore, these drugs are not recommended as first-line SSRIs in the elderly.

If started at too high a dose, SSRIs may initially exacerbate symptoms of anxiety and, therefore, a lower starting dose (e.g., 2.5 mg/day of escitalopram, 5 mg/day of citalopram, or 25 to 50 mg of sertraline) is often indicated in elderly anxious individuals. Once it has been established that the patient is tolerating the starting dose, the dose should then be gradually increased to the usual therapeutic range (Table 57.4c–3). Both citalopram and escitalopram have been associated with dose-dependent prolongation

of the QT interval on EKG and, as a result, it is recommended not to exceed 20 mg/day of citalopram in persons aged 60 years or older and 10 mg/day of escitalopram in persons 65 years or older. Anxious patients frequently misattribute somatic symptoms of anxiety to the adverse effects of medication. Thus, in addition to starting with a low dose of antidepressant, adherence with medication can be enhanced by discussing potential side effects in advance, frequent monitoring of the patient during the first few weeks of treatment, and availability of the clinician by telephone between appointments to address any questions or concerns that the patient may have about treatment.

Table 57.4c–3.
Usual Starting Dose, Initial Target Dose, and Recommended Maximum Dose of Selected SSRIs and SNRIs in Older Adults with Anxiety Disorders

Drug	Usual Starting Dose (mg/day)	Initial Target Dose (mg/day)	Recommended Maximum Dose (mg/day)
Escitalopram	2.5	5	10
Citalopram	5	10	20
Sertraline	25	50–100	200
Venlafaxine ER	37.5	150	300
Duloxetine	30	60	120

SSRI, selective serotonin inhibitor; SNRI, serotonin and norepinephrine reuptake inhibitor.

Based on the above considerations, escitalopram is a reasonable first-line choice for the treatment of GAD in later life, given that it has FDA approval for this condition and there are efficacy and tolerability data specific to the elderly. In the absence of pharmacotherapy, data pertaining to anxiety disorders other than GAD in the elderly, sertraline would be a reasonable first-line SSRI for panic, social anxiety, PTSD, and OCD, for the following reasons: it has FDA approval for the treatment of these disorders based on studies of mixed-age samples, it has a favorable pharmacokinetic and tolerability profile in older patients, and there is considerable flexibility in dosing without the concern of QT prolongation at higher doses.

Serotonin and Norepinephrine Reuptake Inhibitors

Venlafaxine (Effexor) is a serotonin and norepinephrine reuptake inhibitor (SNRI), although it has been postulated that its noradrenergic effect occurs only at higher dosage (possibly 150 mg/day or higher). The doses used to treat GAD in older persons in RCTs were relatively low (75 to 150 mg/day in the majority of older subjects), raising the possibility that the serotonergic action of the drug may be sufficient to treat GAD in many older patients. Like escitalopram, citalopram, and sertraline, venlafaxine

has linear pharmacokinetics and lacks propensity for significant drug–drug interactions. The usual starting dose of venlafaxine ER in older persons is 37.5 mg/day, with dose increments of 37.5 mg every 4 to 5 days to reach a minimum target dose of 150 mg/day. The dose range of venlafaxine ER is wide (75 to 375 mg/day), and the usual therapeutic dose for GAD has not been established in older patients. However, if there has not been satisfactory improvement of GAD after 4 weeks of treatment at a dose of 150 mg/day, the dose should be gradually increased, guided by response and tolerability (Table 57.4c–3). Venlafaxine is a suitable antidepressant for older persons with GAD, and on the basis of RCTs conducted in mixed-age samples, it can also be considered as a first-line option for panic, social anxiety, and PTSD. Given that venlafaxine and SSRIs are different drug classes, switching from one class to the other (i.e., from an SSRI to venlafaxine or vice versa) is a reasonable approach in the case of inadequate response to a therapeutic trial of the first drug.

Other Antidepressants

In addition to SSRIs and SNRIs, selected tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) have been found to be efficacious in a range of anxiety disorders in younger adults (Table 57.4c–2), although there have been no comparable studies in the elderly. With the exception of desipramine (Norpramin), the TCAs that have been examined in younger persons have been tertiary amine compounds, which are potentially problematic in the elderly. In particular, older adults may be vulnerable to the anticholinergic, sedative, hypotensive, and adverse cardiac effects of tertiary amine TCAs, especially if they have concomitant physical or cognitive problems that could be aggravated by these effects. A retrospective analysis of data pooled from three RCTs of the treatment of poststroke depression, found that nortriptyline (Aventyl) (a secondary amine TCA that is preferred over tertiary amine TCAs in the elderly) was more effective than placebo in treating generalized anxiety associated with the depression. Thus, if a TCA is considered for an older anxious person, the recommendations would be despiramine in the case of panic disorder and either nortriptyline or desipramine (which is a metabolite of imipramine [Tofranil]) in the case of GAD. Although OCD rarely starts as a primary disorder in late life, older persons with chronic OCD may present for treatment. Clomipramine (Anafranil), a serotonergic tertiary amine TCA, can be a useful treatment for OCD, especially in cases that have failed to adequately improve with SSRIs. While the use of clomipramine has potential limitations in the elderly because of its side-effect profile, it is worth considering, in combination with cognitive behavior therapy, in selected older persons who have OCD that has failed to respond to other medications.

The first-generation MAOI phenelzine (Nardil) should be kept in mind

as a potential treatment for refractory panic disorder, social phobia, or PTSD, or for refractory anxious depression. However, the need to avoid tyramine-containing foods and certain medications to prevent development of a hypertensive crisis with phenelzine, and the drug's potential to cause significant supine and orthostatic hypotension and weight gain, will limit its use to carefully selected individuals.

BENZODIAZEPINES

Despite their widespread use, benzodiazepines have a limited role in the treatment of late-life anxiety. First, they are not a useful treatment for two of the three most common anxiety disorders in later life, that is, specific phobias and agoraphobia without panic. Second, the frequent comorbidity of GAD with depression in later life suggests the need for a medication with both antidepressant and anxiolytic effects. Benzodiazepines are not an effective treatment for the core symptoms of depression. On the other hand, antidepressant medication is an effective treatment for GAD even when depression is absent. Third, there are a number of risks associated with benzodiazepines in the elderly, including cognitive impairment, psychomotor impairment, excessive daytime sedation, instability of gait, falls, and hip fractures. Finally, anxiety disorders tend to be chronic conditions, with most patients requiring long-term treatment. Long-term use of benzodiazepines can be associated with psychological and physical dependence and tolerance, so that it can be difficult to discontinue the drug if its benefits diminish and/or adverse effects develop. Persons with a history of alcoholism or drug abuse may be at particular risk of becoming dependent on a benzodiazepine.

In situations where benzodiazepines are indicated (e.g., acute situational anxiety or as a short-term adjunct to an antidepressant until the antidepressant becomes effective), lorazepam (Ativan) or oxazepam (Serax) are preferred in the elderly because they have relatively short elimination half-lives (10 to 15 hours), no active metabolites, and they do not undergo oxidative metabolism in the liver (thus their clearance is not affected by age). As a result, these drugs do not have the potential for cumulative toxicity in the elderly which is a risk associated with longer-acting compounds such as diazepam (Valium) or clonazepam (Klonopin). Oxazepam is slowly absorbed, so is not very effective as a hypnotic unless it is taken at least an hour before bedtime. The usual dosage range in the elderly is lorazepam 0.5 to 1.5 mg/day and oxazepam 10 to 30 mg/day. Although alprazolam (Xanax) is FDA approved for the treatment of GAD and panic disorder, there are no data pertaining to its risk–benefit profile in older persons with these conditions. Alprazolam has high potential for dependence and abuse. Its relatively short elimination half-life can result in rebound anxiety, which can lead to patients taking more frequent doses and higher daily doses than prescribed. For these reasons, alprazolam is

not recommended in the elderly.

As noted, most elderly patients who are prescribed a benzodiazepine do not require the drug on an ongoing basis. However, there are occasions when long-term benzodiazepine treatment may be necessary. In particular, some patients who have been maintained on a benzodiazepine for years can experience a significant worsening of anxiety when an attempt is made to withdraw the medication. In such cases, if the benzodiazepine is not causing significant side effects, it is usually least disruptive to leave the individual on the medication and monitor him or her on a regular basis. If side effects do become an issue as the person grows older, dose reduction rather than complete discontinuation of the drug may be the best compromise. In addition, some patients do not experience adequate relief of anxiety symptoms with a nonbenzodiazepine medication alone, and in these cases longer-term treatment with an adjunctive benzodiazepine, given at the lowest possible dose, may be necessary.

BUSPIRONE

Buspirone (Buspar), an azapirone derivative and a serotonin-1A receptor partial agonist, is a nonbenzodiazepine anxiolytic that is more efficacious than placebo in the treatment of GAD. It is not indicated in the treatment of other anxiety disorders. Although buspirone and benzodiazepines have comparable efficacy in patients with GAD who persist with treatment, several studies have found that patients are more likely to discontinue buspirone than a benzodiazepine, for reasons other than side effects. It has been suggested that the higher rate of discontinuation of buspirone compared with a benzodiazepine may be due to buspirone's delayed onset of action.

Although buspirone is an efficacious treatment for GAD, it has a limited role in the treatment of generalized anxiety in late life. First, it is not a substitute for antidepressant medication in the treatment of generalized anxiety that is comorbid with, or secondary to, major depression. Second, because buspirone has a delayed onset of action, it is not suitable as an acute adjunctive treatment of generalized anxiety symptoms associated with major depression. Third, there is evidence that buspirone may have diminished efficacy in persons who have previously been treated with a benzodiazepine. Therefore, its usefulness in the management of elderly patients with chronic GAD, many of whom have been treated with benzodiazepines, is unclear. Finally, the twice-a-day to three-times-a-day dosing schedule of buspirone increases the risk of poor adherence with this medication.

Unlike benzodiazepines, buspirone does not cause sedation, psychomotor impairment, cognitive impairment, or depressed respiratory drive. This side-effect profile suggests that it would be preferable to a benzodiazepine in the ongoing management of generalized anxiety in

nondepressed patients who have chronic obstructive airways disease, sleep apnea, or a neurologic disorder. However, select antidepressants may also be effective for anxiety and well tolerated in these patients.

The usual starting dose of buspirone in older patients is 5 mg twice-a-day, followed by dose increments of 5 mg every 4 to 5 days to reach a target dose of 20 to 30 mg/day, given in divided doses. If a person fails to show significant improvement after 4 to 6 weeks at this target dose, the dose can be further gradually increased to a maximum of 45 mg/day, as tolerated. The main side effects of buspirone are dizziness, headache, and nausea. Gradual dose titration is essential in order to minimize the risk of these effects.

Sometimes a physician elects to switch a patient from long-term benzodiazepine therapy to buspirone. Because buspirone has a delayed onset of action and it does not suppress benzodiazepine withdrawal symptoms, a patient should not be abruptly switched from a benzodiazepine to buspirone. Instead, the patient should take a therapeutic dose of buspirone for 2 to 4 weeks before the benzodiazepine is gradually tapered. Despite this approach, some patients are less satisfied with the anxiolytic effect of buspirone compared with that of a benzodiazepine.

OTHER DRUGS

Pregabalin

Pregabalin (Lyrica) is an anticonvulsant drug that binds to the alpha-2-delta subunit of the voltage-dependent calcium channel in the central nervous system and decreases the release of neurotransmitters including glutamate, norepinephrine, and substance P. Unlike benzodiazepines, pregabalin does not bind to GABA receptors and does not alter GABA metabolism. Several industry-funded RCTs in mixed-age patients have found pregabalin to be more efficacious than placebo in the treatment of GAD, although it does not have FDA approval for this indication. Although a statistically significant difference between 150 and 600 mg/day of pregabalin and placebo was found in patients aged 65 years or older with GAD, the clinical significance of the difference is uncertain: There was only a two-point greater reduction in HAM-A scores with drug versus placebo (12.9 vs. 10.7). Moreover, pregabalin and placebo groups did not differ in response or remission rates at the end of the 8-week study. Pregabalin was well tolerated in this group of older patients.

Quetiapine XR

First-generation antipsychotic medications have long been used in the acute treatment of agitation, but they are not recommended as a treatment for primary anxiety disorders because of the risk of tardive dyskinesia associated with their longer-term use. Quetiapine XR (Seroquel XR) is a

second-generation atypical antipsychotic with a low risk of neurologic side effects. A recent industry-funded study found that 50 to 300 mg/day of quetiapine XR was more efficacious than placebo in treating GAD in older adults, with significant differences in response and remission rates by the end of 8 weeks of treatment. While quetiapine has a low risk of parkinsonism and tardive dyskinesia, it can be associated with significant weight gain and metabolic dysfunction, and as a result cannot be recommended as a routine first-line treatment of GAD in the elderly.

Beta Blockers and Antihistamines

Beta blockers (e.g., 10 to 20 mg of propranolol [Inderal]) can be effective for performance anxiety when given about 1 hour prior to the feared performance. Therefore, they can be useful in patients with specific types of social anxiety disorder such as public speaking or eating in public. However, beta blockers should be avoided in anxious patients with sinus bradycardia, hypotension, or asthma.

RCTs conducted in Europe have found that the antihistamine drug hydroxyzine (Atarax) is more efficacious than placebo and comparable in efficacy to a benzodiazepine and buspirone in the treatment of GAD in mixed-age adults. Hydroxyzine has not been studied as a treatment of GAD in late life, but its sedative and anticholinergic effects (increasing the risk of daytime somnolence, cognitive impairment, and falls and fractures) limit its usefulness in older patients.

57.4d Antipsychotic Drugs

KELLY C. LEE, PHARM.D., M.A.S., B.C.P.P., AND VIVIAN HOOK, PH.D.

Antipsychotic medications constitute the treatment of choice for psychoses associated with schizophrenia or schizoaffective disorder. Antipsychotics are frequently prescribed in the elderly for the treatment of psychosis and severe behavioral disturbances, such as agitation and aggression. Although nonpharmacological therapies may be helpful in milder states of behavioral disturbances associated with cognitive disorders such as dementia, antipsychotics are often necessary to treat severe symptoms. Age-related physiological changes in the elderly can increase sensitivity to adverse events from these medications. Treatment is also often complicated by the frequent presence of comorbid medical conditions and medication interactions in the elderly. Despite the complexities, antipsychotic medications are commonly prescribed to older patients in inpatient, outpatient, residential, and nursing home settings.

Antipsychotics have been broadly classified into two groups. The older agents (i.e., introduced in the United States before 1990) are referred to as typical or conventional antipsychotics and primarily block dopamine

receptors (primarily D2) to exert antipsychotic effects. Typical antipsychotics, while effective for positive symptoms of schizophrenia, are associated with undesirable extrapyramidal symptoms and endocrine changes.

Atypical antipsychotics have absence or decreased incidence of extrapyramidal effects and tardive dyskinesia, as well as an expanded spectrum of activity against negative symptoms associated with schizophrenia. Because of their improved neurological profile, atypical antipsychotics have generally replaced typical antipsychotics. Unfortunately, due to studies that ultimately led to black box warning labeling for antipsychotics when used in elderly patients with dementia, the benefits of using these agents must be carefully weighed against the potential risks.

PHARMACOLOGICAL ACTIONS

Pharmacokinetics and Pharmacodynamics

Pharmacokinetics can generally be described as the body's effect on the absorption, distribution, metabolism, and elimination of drugs. Numerous age-related changes in physiology may affect pharmacokinetics. Changes in pharmacodynamics (the drug's effect on the body) are also likely to occur; however, these mechanisms are not as well understood relative to the knowledge of age-related pharmacokinetic changes. Neurotransmitter and receptor function changes in the central nervous system may increase sensitivity to drugs and toxicity may occur at lower plasma levels. In general, these pharmacokinetic and pharmacodynamic changes may lead to higher blood levels of medications, prolonged pharmacological effects, and a greater risk for side effects.

Receptor Activity

The specific mechanism of action of antipsychotics has not been elucidated, but most of the research attention has focused on receptor blockade of dopamine and serotonin. While the typical or conventional antipsychotics have been shown to work through blockade of the central dopamine receptors (specifically D2), atypical antipsychotics have been referred to as serotonin–dopamine antagonists as they block both 5-HT_{2A} and D2 receptors. Antipsychotic drugs also affect other receptors, usually resulting in adverse effects rather than an enhanced therapeutic response. For example, histamine-1 (H_1) blockade is responsible for sedation and possibly weight gain. Blockade of the 5-HT_{2C} receptor may also play a role in weight gain associated with some atypical agents. Blockade of the α_1 receptors causes orthostatic hypotension, whereas α_2 blockade plays a role in sexual dysfunction. Muscarinic receptor blockade causes the classical

anticholinergic effects such as dry mouth, blurred vision, constipation, and urinary retention. An understanding of the receptor-binding properties of the typical and atypical agents can predict their adverse effect profiles (Table 57.4d–1).

THERAPEUTIC INDICATIONS FOR ANTIPSYCHOTICS

Early-Onset Schizophrenia

Historically, it has been thought that all schizophrenia patients uniformly follow a poor prognostic course with no return to premorbid level of functioning. Fortunately, long-term studies in chronic schizophrenia have been more optimistic. Approximately one-third of the patients either undergo remission or are left with only mild symptoms over the long term, while 15 to 20 percent of patients get worse. The remaining patients appear to have a stable course. Patients who have benefited from maintenance antipsychotic treatment with prolonged absence of psychotic symptoms may warrant a trial off medication. Older patients typically have fewer and less severe positive symptoms than younger patients, while negative symptoms tend to persist into late life. Relapse and exacerbation may occur in older patients with chronic schizophrenia just as they do in younger patients, and investigators have struggled to identify factors that may predict outcome. Hence, if a drug withdrawal is attempted, careful monitoring is required.

Table 57.4d–1.
Relative Adverse Effects for Selected Antipsychotics

Medication	Brand Name	Sedation	Hypotensive Effects	Anticholinergic Effects	Extrapyramidal Effects
Haloperidol	Haldol	+	+	+	+++
Clozapine	Clozaril	+++	+++	+++	–
Risperidone	Risperdal	+	++	+/–	++
Olanzapine	Zyprexa	++	++	+	+/–
Quetiapine	Seroquel	++	++	+/–	–
Ziprasidone	Geodon	+	++	+/–	+/–
Aripiprazole	Abilify	+	+	+/–	++[a]
Paliperidone	Invega	+	+	+/–	++
Asenapine[b]	Saphris	++	++	+	++[a]
Iloperidone[b]	Fanapt	+	++	+	+
Lurasidone[b]	Latuda	++	+	+	++[a]
Brexpiprazole[b]	Rexulti	+	+	+/–	++[a]

Medication effects: –, none; +/–, rare; +, mild; ++, mild-to-moderate; +++, marked.

[a]Includes akathisia.

[b]Risk for adverse effects listed is based on limited experience.

Late-Onset Schizophrenia

Approximately 20 to 30 percent of patients have onset of symptoms after 40 years of age and are considered to have late-onset schizophrenia (LOS). In general, regardless of the age of onset of schizophrenia (LOS vs. early-onset schizophrenia [EOS]), patients with schizophrenia are similar in terms of positive symptoms, such as delusions and hallucinations, chronicity of the course of the disorder, and family history. However, LOS differs from EOS in several aspects. LOS seems to be more common in women, have better premorbid functioning with successful occupations and marital histories, fewer negative symptoms, and less severe neurocognitive impairment. Additionally, patients with LOS typically require lower antipsychotic doses and have less positive symptoms compared with EOS patients. Onset after age 65 usually signifies very LOS-like psychosis, which is typically secondary to general medical conditions such as dementia or neurodegenerative disorder. Additional studies are needed to identify genetic variants, biomarkers, and changes on neuroimaging studies that may differentiate LOS from EOS.

Delusional Disorder

Delusional disorder refers to the presence of one or more persistent, nonbizarre delusions and may be misdiagnosed as schizophrenia. Delusions commonly involve situations that may occur in real life, such as being poisoned, having a disease, or experiencing spousal infidelity. Delusional disorder generally presents in middle or late life and can be differentiated from schizophrenia by the absence of prominent auditory or visual hallucinations and by the lack of functional deterioration outside the area of delusions. Psychiatric comorbidities, especially depressive disorders, are common among those with delusional disorder. Mild symptoms may be treated without medications, but antipsychotics may be helpful for the agitated patient whose delusions have a negative impact on social relationships or functional behaviors. Antipsychotic noncompliance is a common problem in those with delusional disorder, although some suggest that women may be more adherent to pharmacological treatments than men.

Dementia with Psychosis or Severe Behavioral Disturbances

The most common types of dementia are Alzheimer disease and vascular dementia. Patients who develop dementias have cognitive impairment resulting in memory and executive functioning decline but also noncognitive dysfunction that can be more distressful. A majority of elderly patients with dementia develop behavioral disturbances such as aggression, agitation, delusions, and other neuropsychiatric symptoms during their course of illness. These changes in mood, affect, and behavior can lead to

early institutionalization, increased caregiver burden, and increased health care costs. When behavioral problems arise, early recognition and prompt treatment can improve quality of life of patients, their families, and caregivers and reduce health care costs. In addition to medications used for cognitive dysfunction, nonpharmacological interventions and antipsychotics have been widely used for treating behavioral disturbances associated with dementias. Treatment guidelines have generally recommended careful assessment, diagnosis, and nonpharmacological treatment approaches, such as psychosocial and environmental interventions, prior to pharmacological approaches. When nonpharmacological approaches fail, the provider, together with the patient and his or her family, should examine pharmacological options carefully. The family should be informed about the relative risks and benefits of antipsychotics and other treatments, as well as the risks of not using medication, so that they can participate effectively in clinical decision making. Documentation of informed consent should be obtained.

The use of antipsychotics in those with dementia has become controversial due to the FDA black box warning regarding the increased incidence of cerebrovascular events and death. In the CATIE-AD study of atypical antipsychotics in patients with Alzheimer disease, olanzapine [Zyprexa], quetiapine [Seroquel], and risperidone [Risperdal] were also associated with significant decline in cognitive functioning over 36 weeks compared to placebo. While the effectiveness of antipsychotics for noncognitive symptoms in dementia may be marginal, a short-term trial is generally warranted to control symptoms of mania, psychosis, hallucinations, and aggressive behaviors that could endanger others. While there is no significant difference in effectiveness between atypical and typical antipsychotics, atypical antipsychotics are generally preferred due to better side effect profile, particularly in terms of extrapyramidal side effects and tardive dyskinesia. Antipsychotics should be used in the lowest effective doses and careful monitoring for adverse events is recommended.

The decision to discontinue antipsychotics in patients who have responded to the drug must be carefully weighed against the possibility of worsening symptoms. In a study of patients with Alzheimer disease who initially had a response to risperidone for psychosis or agitation/aggression, the rate of relapse was higher among those who were then randomized to placebo versus those who continued risperidone (60 vs. 33 percent, respectively). A Cochrane Database review concluded that chronic antipsychotics may be withdrawn from patients, but the risk of relapse may be greater for patients with severe neuropsychiatric symptoms. Other pharmacological alternatives include benzodiazepines that may be effective for behavioral problems; however, they have been linked to adverse outcomes such as increased confusion, falls, hip fractures, and excessive sedation. Information on the efficacy and safety of other

pharmacological options such as selective serotonin reuptake inhibitors (SSRIs) and other antidepressants, carbamazepine (Tegretol), divalproex sodium (Depakote), and cognitive enhancers is limited and inconclusive. These psychotropics should be used in short therapeutic trials and ongoing use of pharmacological agents for the treatment of behavioral disturbances should be continuously evaluated and adjusted.

Parkinson Disease with Psychosis

Psychotic symptoms can occur in up to 40 percent of patients with Parkinson disease. The symptoms may be present continuously or intermittently over the course of a month and predominantly consist of hallucinations. Most hallucinations are visual and of these, half of the patients also have auditory hallucinations. Hallucinations also tend to be different from schizophrenia and generally have less "emotional content." Delusions can occur in 5 to 10 percent of patients treated with antiparkinsonian drugs and patients are typically paranoid in nature, such as in spousal infidelity. Psychosis is stressful for patients and can potentially cause more distress to caregivers. Psychosis is a poor prognostic indicator for institutionalization, dementia, and mortality. Managing psychosis is one of the most difficult challenges in the care of patients with Parkinson disease. The dopaminergic drugs that can improve the motor disability caused by Parkinson disease are associated with the emergence of psychotic symptoms and appear to be dose-related. Conversely, the use of antipsychotic drugs to reduce psychosis can exacerbate motor symptoms of parkinsonism. Additionally, anticholinergic medications can cause delirium with agitated behavior or psychosis. Management of psychosis in Parkinson disease begins with withdrawal or lowering of the dose of the dopaminergic agent without disrupting motor signs. Due to the complexity of balancing the dopaminergic requirement to control both symptoms, psychosis presents a serious threat to the patient's ability to maintain independence. If psychosis persists, antipsychotic medications with the lowest liability for exacerbating parkinsonism may be helpful (clozapine [Clozaril] and quetiapine). Aripiprazole (Abilify) is considered third line by the American Academy of Neurology task force recommendation, although the drug has been reported to worsen motor symptoms in Parkinson disease patients.

Delirium

Delirium is a cognitive disorder that is characterized by fluctuating levels of consciousness, inattention, memory impairment, and perceptual disturbances. Delirium may be accompanied by illusions, visual hallucinations, and delusions. Delirium can arise from acute onset of a new medical illness, an exacerbation of a pre-existing chronic illness, a drug reaction or interaction, or a fever or trauma. A careful medical,

neurological, and laboratory evaluation to identify the conditions that are contributing to the mental status change is required. Drugs with anticholinergic properties are common causes of delirium in the elderly. Diagnosis in the older patient may be difficult because peripheral anticholinergic signs are not always present. Recognition and treatment of delirium are important to reduce the risks of morbidity and mortality in these patients. Nonpharmacological treatment such as environmental changes, behavioral support, and redirection are key strategies for treating delirium. Antipsychotic medication should be prescribed only when necessary, to maintain safety and basic care, and these medications can contribute to the mental status changes. The lowest effective dosage should be used, and treatment should continue no longer than required to manage marked distress or behavioral disturbance.

Depression

Patients with delirium and dementia are at high risk of depression and depression may be a predictor for cognitive decline. Suicide risk is also important to assess since suicidal ideation can be seen in up to 30 percent of older adults with major depression. Psychotic symptoms may also occur in patients suffering from depression. In contrast to nonpsychotic depression, elderly patients with psychotic depression are at increased risk for relapse, suicide, and hospitalization. Major depressive disorder with psychotic features responds better to treatment with a combination of an antipsychotic and an antidepressant than to treatment with either agent alone. Electroconvulsive therapy is highly effective in major depressive disorder with psychotic features and at times may be considered a first-line treatment, even in the elderly. Aripiprazole is also indicated for adjunctive treatment for nonpsychotic depression; however, the benefit of using multiple medications that may present compliance challenges in elderly patients must be clearly warranted.

Bipolar Disorder

Bipolar disorder is not uncommon in the elderly and often leads to functional impairment and substantial utilization of health care resources. While conventional mood stabilizers such as lithium and valproate are still widely used for bipolar disorder, atypical antipsychotics have also emerged as first-line options for control of manic symptoms. Currently, aripiprazole, asenapine [Saphris], olanzapine, quetiapine, risperidone, and ziprasidone [Geodon] are approved for mania. Aripiprazole, quetiapine, and ziprasidone are indicated for maintenance treatment while quetiapine, olanzapine (in combination with fluoxetine [Prozac]), and lurasidone [Latuda] are also indicated for bipolar depression. Atypical antipsychotics may offer advantages over drugs like lithium due to their wider therapeutic

range and less drug–drug interactions. However, metabolic and cardiovascular considerations should still be considered in elderly patients. Unfortunately, comparative effectiveness or safety data for antipsychotics in elderly with bipolar disorder are lacking.

TREATMENT PRINCIPLES

Pretreatment Evaluation

If an elderly person presents with new-onset psychosis, an exacerbation of psychosis, or severe behavioral disturbance, he or she should have a thorough medical examination (including neurological assessment) prior to initiating a new, or modifying a pre-existing antipsychotic regimen. At minimum, the evaluation should include a comprehensive history, physical examination, and laboratory screening including a toxicology screen for substances of abuse. This may identify medical or substance-induced problems that may be contributing to the behavioral disturbances (e.g., infection or pain), or that may represent a special concern during treatment (e.g., recent myocardial infarction).

Antipsychotic Selection

The choice of an antipsychotic is usually based on a number of factors and selection should be highly individualized. Factors include specific symptoms, experience with previous treatment (efficacy and side effects), simplicity of regimen (available dosage forms, avoidance of drug interactions, ease of obtaining a therapeutic dose), and cost considerations. With few exceptions, there is limited evidence for superior efficacy of one antipsychotic over another and clinicians should base their decision on the above patient-specific factors.

Dosage Forms

Although all of the antipsychotics are available in oral formulations, only a few are available as injectables (e.g., olanzapine, aripiprazole, ziprasidone, risperidone, and paliperidone [Invega]). Short-acting intramuscular preparations of an antipsychotic may be preferred over oral medications if a patient is agitated and not likely to be cooperative. Intramuscular preparations bypass the gastrointestinal tract and the first-pass metabolism, and have a faster onset of action. For example, most short-acting intramuscular antipsychotics reach a maximum plasma level within 30 to 60 minutes and clinical effects are seen within 15 minutes. While short-acting intramuscular preparations offer administration advantages, care should be taken to avoid repeating doses without first assessing for a response. Alternatively, rapidly dissolving tablet formulations (e.g., risperidone, olanzapine, aripiprazole, and asenapine) offer the advantage of improved adherence in some patients resistant to taking medications or

prone to behaviors such as "cheeking" medications. Except for people with schizophrenia or schizoaffective disorder with a history of poor medication-taking behaviors, long-acting depot medications are not usually prescribed for older people with psychosis.

General Dosing Recommendations

There is considerable heterogeneity in age-related pharmacokinetic and pharmacodynamic alterations. Thus, the efficacy and adverse effects of a particular antipsychotic dosage may vary considerably. In addition, the time required for antipsychotic response is typically longer than in younger patients. Initial dosage should be relatively low, and dose increases should be titrated cautiously, but up to an effective level. Antipsychotic medication dosage in an older patient with a primary psychotic disorder (e.g., schizophrenia) is usually one-half the usual dosage in young patients, although some older patients will respond best to the higher dosages typically prescribed for younger patients. Optimal medication dosage for older patients with primary cognitive or neurological disorder (e.g., dementia) and psychosis is usually 25 to 50 percent of doses typically prescribed to younger patients (Table 57.4d–2).

Adherence Issues

Older patients commonly take several medications simultaneously and therefore have an increased risk of adverse drug reactions. A complete drug history should be obtained and concomitant medications simplified, if possible, prior to implementing antipsychotic treatment. Medication adherence is a problem in all age groups but specific problems may be observed in the elderly. Physical problems, such as impaired vision, may increase the likelihood that instructions will be misread or that one medicine will be mistaken for another. Patients with cognitive impairment may forget to take their medication and drug regimens with complex administration schedules should be avoided. Drug administration issues also present challenges for elderly patients, such as special handling requirement for asenapine (no food or liquid for 10 minutes after dose) and dietary requirements for ziprasidone and lurasidone (350 to 500 kcal required with dose). Psychological factors, such as fear of side effects or becoming dependent on medications, may also affect adherence.

Table 57.4d–2.
Recommended Dosing Guidelines for Antipsychotics

	Dementia		Schizophrenia	
	Initial Dosage in Elderly Patients	Usual Maximum Dosage in Elderly Patients	Initial Dosage in Elderly Patients	Usual Maximum Dosage in Elderly Patients

Medication	Brand Name	(mg/day)[a]	(mg/day)[a]	(mg/day)[a]	(mg/day)[a]
Haloperidol	Haldol	0.25–0.50	0.25–2.0	0.5–1.0	5.0
Clozapine	Clozaril	12.5	75–100	12.5–25.0	100–300
Risperidone	Risperdal	0.25–1.0	1.0–2.0	0.5–2.0	2.0–4.0
Olanzapine	Zyprexa	1.25–5.0	10	2.5–5.0	5.0–15.0
Quetiapine	Seroquel	12.5–50	200–300	12.5–50.0	50–300
Ziprasidone	Geodon	20	Unknown	20	Unknown
Aripiprazole	Abilify	5	15	5–10	10–30
Paliperidone	Invega	3	Unknown	3	3–12
Asenapine[b]	Saphris	10	Unknown	10	20
Iloperidone[b]	Fanapt	2	Unknown	2	24
Lurasidone[b]	Latuda	40	Unknown	40	160
Brexpiprazole[b]	Latuda	1	Unknown	1	4

[a]Routine orally administered initial and maximum dosage ranges are listed. Higher or lower doses may be indicated in some cases.

[b]Optimal dosage ranges listed are based on limited experience.

Drug Interactions

Both pharmacokinetic and pharmacodynamic drug interactions can occur with antipsychotic agents. Cytochrome P450 (CYP) enzymes, especially 1A2, 2D6, and 3A4, are responsible for the metabolism of many antipsychotics. In general, antipsychotics are primarily metabolized hepatically by CYP enzymes but are not major inducers or inhibitors of CYP-mediated metabolism. Thus, antipsychotics do not commonly affect the pharmacokinetics of other medications but are themselves affected by other medications. Induction or inhibition of these enzymes by other drugs may occasionally provide clinically important drug interactions. Drugs that have potential to have serious interactions with antipsychotics include fluvoxamine (1A2 inhibitor); erythromycin, ketoconazole, and ritonavir (3A4 inhibitors); quinidine, risperidone, fluoxetine, and paroxetine (2D6 inhibitors); and cimetidine (multiple systems). Conversely, enzyme inducers such as carbamazepine (3A4) or cigarette smoking (1A2) can reduce plasma concentrations of antipsychotic drugs by increasing the metabolism of the antipsychotic agent and lead to less-than-effective plasma concentration. For example, carbamazepine has been shown to reduce plasma concentrations of haloperidol by 50 percent. Cigarette smoking (1A2) has been shown to increase the clearance rate of clozapine and olanzapine. A pharmacodynamic interaction occurs when medications with similar unwanted properties are concurrently prescribed, such as low-potency typical agents or clozapine with other drugs possessing strong anticholinergic effects (e.g., diphenhydramine or hydroxyzine). Pharmacodynamic drug interactions of greatest concern involve additive orthostasis, anticholinergic effects, QTc prolongation, and sedation (Table

57.4d–3).

PRECAUTIONS AND ADVERSE REACTIONS

Mortality

The black box labeling of antipsychotics by the FDA was prompted by 15 placebo-controlled trials that showed a 1.6- to 1.7-fold increased risk of death among those with dementia taking atypical antipsychotics. Specific causes of these deaths were attributed to heart-related events (e.g., heart failure, sudden death) or infections (mostly pneumonia). In the comparative effectiveness review in 2011 that included all currently available antipsychotics, with the exception of lurasidone, there was a small but statistically significant increased risk of death (effect size between 0.12 and 0.20) in elderly patients with dementia associated with atypical antipsychotics. One prospective cohort study showed conflicting results in that the all-cause crude mortality rate was lower than previous reports and age was the only significant predictor for mortality. Another cohort study also showed that antipsychotics were not associated with early time to nursing home admission or time to death and psychosis was the only significant predictor.

Cerebrovascular Events

Cerebrovascular adverse events, such as strokes, transient ischemic attacks, and fatalities, have been observed in elderly patients with dementia-related psychosis prescribed with aripiprazole, olanzapine, quetiapine, or risperidone. In 17 placebo-controlled trials, higher number of cerebrovascular adverse events was observed in patients treated with atypical antipsychotics compared to patients treated with placebo. Data analyses have suggested that increased age (older than 80 years), concurrent use of benzodiazepines, sedation, pulmonary infections (pneumonia), and medical risks (prior strokes, hypertension, coronary artery disease, and hyperlipidemia) may increase the risk of experiencing a cerebrovascular adverse event.

Whether the mortality and cerebrovascular adverse event risks have a similar underlying mechanism is yet unclear. In a study of over 30,000 Medicare and Patient Assistance Program enrollees, typical antipsychotics were associated with higher risks of stroke and death compared with atypical antipsychotics over 180 days. Interestingly, stroke did not explain the difference in mortality risk between the two drug groups. Orthostatic hypotension seems a likely mediating variable in some patients as wells as falls and oversedation.

Weight Gain

Weight gain has been associated with typical and atypical antipsychotics in

young and older adults. Weight gain is most prominent within first 4 to 12 weeks of treatment with antipsychotics, especially atypical antipsychotics. The cause of antipsychotic-induced weight gain is multifactorial and may include a change in food preferences, increased food or fluid intake, carbohydrate craving, or a sedentary lifestyle. Blockade of the histamine and 5-HT_{2C} receptors are also contributory. Histamine H_1 blockade causes sedation that may produce inactivity. H_1 blockade may also increase weight by interfering with normal satiety signals from the gut, resulting in overeating. In the CATIE-AD study, elderly patients who were treated with olanzapine, quetiapine, or risperidone had an average weight gain of 1.0, 0.7, and 0.4 lb, respectively compared with a monthly weight loss of 0.9 lb for those who received placebo. Weight gain was more prominent in those with a BMI of less than 25 at baseline and this is consistently seen in other age groups. Clozapine has also been associated with significant weight gain. Weight gain associated with antipsychotic treatment should be taken seriously because it may contribute to or exacerbate medical conditions such as diabetes, coronary artery disease, and hypertension. If significant weight gain is observed, a switch to another antipsychotic with lower weight gain liability may be considered as long as treatment effectiveness is not compromised.

Table 57.4d–3.
Dosage Formulations and Drug Interaction Potential for Selected Antipsychotics

			Drug Interaction Potential	
Medication	**Brand Name**	**Available Dosage Forms**	**Pharmacokinetic: Major Cytochrome P450 Pathway**	**Pharmacodynamic: Medications with the Following Effects May Exacerbate Adverse Effect Profile of Atypical Antipsychotic**
Haloperidol	Haldol	T, S, IM, LA	2D6	Anticholinergic, CNS effects
Clozapine	Clozaril	T, ODT	1A2, 2D6, 3A4	Anticholinergic, bone marrow suppressors, CNS effects, hypotension
Risperidone	Risperdal	T, S, ODT, LA	2D6	CNS effects, hypotension
Olanzapine	Zyprexa	T, ODT, IM, LA	1A2	Anticholinergic, CNS effects, hypotension
Quetiapine	Seroquel	T, XR	3A4	CNS effects, hypotension
Ziprasidone	Geodon	C, IM	3A4 (minor)	CNS effects, hypotension, QTc prolongation
Aripiprazole	Abilify	T, IM, S, ODT, LA	2D6, 3A4	CNS effects
Paliperidone	Invega	T, LA	2D6 (limited), 3A4 (limited)	CNS effects

Asenapine	Saphris	ODT	1A2, 2D6	CNS effects, hypotension
Iloperidone	Fanapt	T	2D6, 3A4	CNS effects, hypotension, QTc prolongation
Lurasidone	Latuda	T	3A4	CNS effects
Brexpiprazole	Rexulti	T	3A4, 2D6	CNS effects

Dosage forms: C, capsule; CNS, central nervous system; IM, short-acting intramuscular injection; LA, long-acting intramuscular injection; ODT, orally disintegrating tablet/granule; S, solution; T, tablet; XR, extended-release oral tablet.

Metabolic Effects

Diabetes mellitus and other metabolic disorders have been shown to be more common in adult and elderly patients with schizophrenia than in the general population. Typical and atypical antipsychotics that are used to treat schizophrenia can also worsen glucose intolerance, diabetes, and hypertriglyceridemia in those with or without a history of diabetes mellitus. In rare incidences, these events may lead to diabetic ketoacidosis and death. These complications may or may not be associated with weight gain. Clozapine and olanzapine have been associated with 1.3- to 1.4-fold higher prevalence of diabetes, followed by quetiapine and risperidone. Potential mechanisms for the glucose dysfunction include H_1-receptor antagonism, 5-HT_{2C}-receptor antagonism, reduced functioning of pancreatic cells or pancreatic cell damage, and altered regulation of insulin resistance. In older patients with various psychiatric disorders (e.g., schizophrenia, mood disorders, PTSD, or dementia), treatment with antipsychotics (aripiprazole, olanzapine, quetiapine, and risperidone) for at least 6 months was associated with high incidence of metabolic syndrome. Body mass index, blood pressure, fasting blood glucose, LDL and HDL cholesterol, and triglycerides were the primary metabolic markers studied. Patients also experienced serious and nonserious adverse events at the 2-year follow-up (23.7 and 50.8 percent, respectively). In addition, there was no significant change in psychopathology associated with any of the atypical antipsychotics in the study. Hypertriglyceridemia seems to be due to increased adiposity resulting in higher free fatty acid concentration, insulin resistance, and increased VLDL production. Clozapine and olanzapine, again, have been associated with higher risks of hypertriglyceridemia compared to other antipsychotics in nonelderly patients. In the CATIE-AD trial and other systematic reviews, the association of weight gain and BMI was demonstrated with atypical antipsychotics but there was no association with glucose, total cholesterol, and triglyceride levels. The impact of metabolic syndrome and other adverse events on overall health of elderly patients must be considered in the decision to use these drugs and careful and proactive monitoring of weight, glucose levels, and lipid panel is warranted.

Tardive Dyskinesia

Tardive dyskinesia is a syndrome characterized by abnormal involuntary movements, typically involving the orofacial region, limbs, and trunk. Essential features of tardive dyskinesia include involuntary movements of the tongue, face, and jaw. Most tardive dyskinesia cases are relatively mild. In some older patients, a form of tardive dyskinesia may develop that is severe enough to impair functioning. Severe oral dyskinesia may result in dental and denture problems that can progress to ulceration and infection of the mouth as well as muffled or unintelligible speech. Severe orofacial tardive dyskinesia can impair eating and swallowing, which in turn can produce significant health problems. Gait disturbances due to limb dyskinesia may leave patients vulnerable to falls and injuries. Increasing age is the most consistently observed risk factor for the development of tardive dyskinesia. The annual incidence rates of developing tardive dyskinesia are three- to five-fold greater in older patients compared to younger adults. In addition, elderly patients seem to have earlier tardive dyskinesia symptoms and have more persistent symptoms than younger patients. Other risk factors include higher mean daily and cumulative antipsychotic doses, and presence of extrapyramidal signs early in treatment. The risk of antipsychotic-induced tardive dyskinesia is suggested to be lower with atypical agents compared to typical agents. This lower risk was confirmed in a 2-year study of risperidone and olanzapine in antipsychotic-naïve elderly patients. There is some indication that the risk of tardive dyskinesia may be higher in women, nonwhites, patients with affective psychiatric disorders, and patients taking concomitant anticholinergic agents; however, the heterogeneity of available studies makes it challenging to determine this association conclusively.

Anticholinergic Side Effects

Elderly patients are much more sensitive to the anticholinergic side effects of medication than are younger adults. Anticholinergic medications may aggravate previously existing comorbidities or concomitant medications with anticholinergic properties in elderly patients. Peripheral anticholinergic symptoms may include dry mouth, constipation, urinary retention, tachycardia, blurred vision, and aggravation of narrow-angle glaucoma. Dry mouth may cause problems with dentures; constipation may lead to ileus and perforation; urinary retention may be further aggravated by prostatic hypertrophy; and blurred vision may further aggravate pre-existing visual problems.

The central muscarinic blockade in the elderly also increases their risk for delirium and impaired cognition, attention, memory, and self-care capacity. The higher risk of falls and hip fractures in the elderly associated with antipsychotics is due in part to the anticholinergic, sedative, and orthostatic properties of these medications. In more severe cases, anticholinergic toxicity may be mistaken for an exacerbation of psychosis

and the antipsychotic dose may be increased. Severe anticholinergic symptoms due to high doses of antipsychotics may manifest as increased irritability, aggressiveness, and visual hallucinations.

Sedation

Sedation is a common side effect of antipsychotics that can increase the risk for confusion and falls in the elderly. Antipsychotics with sedative properties are often prescribed to calm agitated patients or to treat sleep disturbances. In a comparative effectiveness review, sedation was more common in elderly patients taking olanzapine or quetiapine than risperidone but this was not statistically significant. Sedation is likely to occur in the elderly at much lower doses than those prescribed to younger patients, and elderly patients are at risk for developing daytime sedation from residual effects of nighttime dosing of the antipsychotic. Elderly patients may appear confused or have other cognitive impairments due to oversedation and should be evaluated appropriately.

Hypotension

Because of decreased adrenergic tone and cardiac output, elderly patients may be more vulnerable to orthostatic effects and may have severe orthostasis at relatively low doses. Orthostatic episodes are most likely to appear early in treatment, and the patient should be monitored closely during this period. Patients (or their caregivers) should be instructed to rise slowly after being seated or supine and take extreme care if they awaken during the night. Lowest doses of antipsychotics should be used and patients should be adequately hydrated throughout the day.

Cardiovascular Effects

In addition to orthostatic hypotension, antipsychotics may also cause tachycardia and electrocardiogram (ECG) changes. Tachycardia may occur as a result of the anticholinergic effects of antipsychotic medications on vagal inhibition, or secondary to orthostatic hypotension. ECG changes such as prolongation of the QT and PR intervals, ST-segment depression, and T-wave flattening have been observed with antipsychotics. The most clinically important ECG change is prolongation of the QTc interval (which is the QT interval adjusted for heart rate). QTc prolongation may lead to the development of ventricular tachyarrhythmias such as torsades de pointes and ventricular fibrillation, which can cause syncope, cardiac arrest, or sudden cardiac death. All antipsychotics have the potential to prolong the QTc interval but to varying degrees. Thioridazine, pimozide, ziprasidone, and iloperidone (Fanapt) appear to have the largest effect on QTc interval. Effects are usually dose-related, although that may not be the case for ziprasidone or iloperidone. Other risk factors for QTc prolongation

and torsades de pointes include advanced age, female gender, and electrolyte imbalance (hypokalemia, hypomagnesemia). Patients with a history of syncope, cardiac disease, or electrolyte imbalance or a family history of early sudden cardiac death should have an ECG before antipsychotic treatment. While thioridazine and pimozide are no longer clinically used, ziprasidone and iloperidone are still therapeutic options for patients with schizophrenia. These drugs should be avoided in patients with a known history of QTc prolongation, recent acute myocardial infarction, or uncompensated heart failure. Clinical and ECG monitoring of cardiac function is recommended during antipsychotic therapy, particularly in patients treated with antipsychotics with known higher risks of QTc prolongation or those who have symptoms that could indicate torsades de pointes (e.g., dizziness, palpitations, syncope). These agents should also not be prescribed with other drugs that prolong the QT interval.

Other Adverse Effects

Clozapine use is associated with a dose-related risk of seizure, and is the only antipsychotic agent associated with the rare development of myocarditis. In rare cases, the orthostatic hypotension can be accompanied by cardiac collapse and/or cardiac arrest. Due to clozapine's significant risk of agranulocytosis, mandatory monitoring of white blood cell counts and absolute neutrophil counts are required. Age and certain ethnicities appear to be risk factors for development of agranulocytosis. Clozapine, thus, is used specifically in patients for whom previous therapies were inadequate or not tolerated, or who have severe tardive dyskinesia.

57.4e Antidementia Drugs

LON S. SCHNEIDER, M.D.

The medications available for prescription in the United States for treating Alzheimer disease include the cholinesterase inhibitors, donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne, formerly Reminyl); and the noncompetitive *N*-methyl-D-aspartate (NMDA)

antagonist memantine. The cholinesterase inhibitors are specifically indicated in their U.S. Food and Drug Administration (FDA)–approved labeling for "the treatment of mild to moderate dementia of the Alzheimer type." Donepezil is further indicated for severe Alzheimer disease as well. Memantine is indicated for the treatment of moderate to severe Alzheimer disease; the FDA specifically did not approve an indication for its use in mild Alzheimer disease. A capsule containing both donepezil and memantine is also marketed for moderate to severe Alzheimer disease. These drugs, thus, are considered as "antidementia" drugs.

Antidementia drugs are, by definition, medications intended to improve cognitive function in patients with dementia. The term has regulatory significance with the FDA, because it differentiates these medications from "cognitive enhancers," medications that might be expected to improve cognition without reference to a particular illness, and from medications that might improve such behavioral syndromes as depression, aggression, or psychosis in people with dementia.

Worldwide, a range of putative cognitive enhancing agents is offered with and without prescription, including piracetam derivatives; cholinesterase inhibitors; an NMDA antagonist, memantine (Namenda); selegiline (L-deprenyl); antioxidants; vitamins; food supplements, so-called nutraceuticals; and various plant derivatives, including *Ginkgo biloba* standardized extract. In the United States, food supplements and nutraceuticals are regulated by the FDA only with respect to apparent safety and inappropriate advertising claims. No specific health claim or disease-treatment claim should be made by the marketers of nutraceuticals and food supplements, and efficacy evidence for the conditions being treated does not have to be addressed. Rather, marketers of nutraceuticals and food supplements may make a "structure/ function claim," characterizing the supplement as intended to affect normal structure or function or the mechanism by which it acts to maintain such structure or function (21 CFR 101.93).

Although it has been suggested that other medications available in the United States might have efficacy in patients with Alzheimer disease, clinical trial results indicate that selegiline, vitamin E, vitamin E, *Ginkgo biloba* extract, conjugated estrogens, and anti-inflammatories do not have salutary effects—in some cases they have cognitively impairing effects—and should not be used to treat dementia.

Alzheimer disease is the most common dementia associated with aging and hence is the most common target for antidementia therapeutics. Vascular dementia, dementia with Lewy bodies, Parkinson disease dementia, frontotemporal dementia, and dementias associated with hippocampal sclerosis are less common, although there is a large degree of overlap of the pathology of Alzheimer disease with these other pathologies.

Although the causes of Alzheimer disease are unknown, except for rare

early-onset familial and genetic cases, a substantial part of the pathophysiology is sufficiently understood to allow for the rational development of symptomatic or potentially disease-modifying treatments.

The framework for clinical trials in Alzheimer disease developed slowly during the last two decades, after the advent and general acceptance of research-based diagnostic criteria for the dementia of Alzheimer disease (i.e., the essentially identical National Institute of Neurological Communicative Disorder [NINCDS] Alzheimer's Disease and Related Disorders Association [ADRDA] criteria for probable Alzheimer disease, and the *Diagnostic and Statistical Manual of Mental Disorders,* fourth edition text revision [DSM-IV-TR] criteria for dementia of the Alzheimer type), a better understanding of its underlying pathology, and the development of mechanism-based pharmacological therapeutics. For example, the pathophysiology of Alzheimer disease is characterized, in part, by early loss of synapses, death of neurons, the deposition of insoluble β-amyloid peptide fragments, atypical inflammatory responses, and the excess production of toxic, oxidizing free radicals, thus providing targets for drug development.

Until the 1980s, medications were proposed for dementia treatment based on clinical experience or prevailing theories of dementia and aging. Examples of such earlier claimed treatments (and their rationale) include nonspecific psychostimulants (to increase arousal), vasodilators (to increase blood flow), and hyperbaric oxygen (to enhance metabolism). One medication, ergoloid mesylates, was approved in the United States for the ill-defined condition "senile mental decline," a condition based on vague diagnostic constructs, such as "cerebral insufficiency" or "cerebral deterioration." The mechanism of action of ergoloid mesylates is unknown but may involve effects on complex neurotransmitter and vascular effects. However, it is no longer available or marketed in the United States.

REGULATORY AND METHODOLOGICAL CONSIDERATIONS

FDA guidelines for establishing that a drug has antidementia efficacy include requirements that patients meet accepted diagnostic criteria for a primary well-accepted dementia, such as Alzheimer disease; that trials use double-blind, placebo-controlled parallel-group designs; that at least one trial be of 6 months' duration; and that improvement be obtained on an accepted cognitive instrument and a clinician's global assessment, to ensure a clinically meaningful effect as compared to a potentially measurable but trivial cognitive effect. Improvements in activities of daily living also may be considered as an index of clinical meaning in lieu of clinical global assessments.

From a regulatory perspective, behavioral changes as a result of treatment are of secondary importance despite the clinical importance of such improvement. Specifically, improvement in behavior or functional

activities in the absence of improved cognition is not a sufficient outcome to allow a drug to be labeled "antidementia." A concern is that antidepressants or antipsychotics might be misleadingly advertised as being effective for dementia when their intended use is to treat depressive or psychotic symptoms or aggression.

For clinical trials in Alzheimer disease, the Alzheimer's Disease Assessment Scale—cognitive subscale (ADAS-cog) has become the standard cognitive change measure, and a clinician's interview-based impression of change instrument or an activities of daily living inventory have become the measures of "clinical meaningfulness." The ADAS-cog provides a summary score reflecting measures of word recall, naming, following commands, constructional and ideational praxis, orientation, word recognition, spoken language, comprehension of spoken language, word finding, and recall of test instructions. Although it has proven itself sufficiently sensitive to change with cholinesterase inhibitor treatments in mild to moderate Alzheimer disease, it is not as sensitive to change in mild dementia and mild cognitive impairment due to Alzheimer disease (also known as prodromal Alzheimer disease), and people with severe dementia have difficulty performing the test. More recently, another cognitive battery, the Severe Impairment Battery, has been used as an index of cognitive change in Alzheimer disease trials of patients who are moderately to more severely cognitively-impaired. It is group of brief tests assessing social interaction, memory, orientation, language, attention, praxis, and construction.

For mild Alzheimer disease and mild cognitive impairment due to Alzheimer disease a Neuropsychological Test Battery (an NTB) has been offered that—in its most common form—consists of three tests of immediate and delayed memory, verbal and category fluency, and digit span; and the Repeatable Battery For The Assessment of Neuropsychological Status (RBANS) which similarly assesses memory, language, attention, and visuospatial/constructional ability. Regulatory guidelines for marketing approval do not exist for the treatment of other dementias (e.g., vascular dementia, dementia with Lewy bodies, frontotemporal dementia), mild cognitive impairment (other than MCI due to Alzheimer disease), other cognitive disorders, or age-related cognitive decline (DSM-IV-TR), or for cognitively unimpaired persons, mainly because of a lack of general expert consensus on the validity of the proposed diagnostic criteria. One exception is Parkinson disease dementia, a dementia with onset after the Parkinson disease, and for which rivastigmine is approved by the FDA for this indication.

Recently, however, FDA has proposed draft guidelines for early stage Alzheimer disease, including the entities MCI due to Alzheimer disease and preclinical Alzheimer disease. The guidelines allow for only a composite outcome including assessments of cognition and function combined in order to approve a drug for MCI, and a single cognitive outcome for

provisional approval for a drug for preclinical Alzheimer disease. No drugs have been approved under these guidelines.

Although there are efforts to gain recognition of functionally significant but mild cognitive loss, such as age-associated memory impairment, in which cognition is lower than a young-adult comparison, or age-related cognitive decline, in which memory is impaired compared to an age-appropriate comparison, the vagueness of the definitions and underlying pathology limits their general acceptance, and hence the acceptance of "treatments" for such unrecognized conditions. People with age-associated memory impairment generally do not worsen cognitively at a rate greater than the population, whereas those with mild cognitive impairment have an increased rate of worsening and developing dementia. The results of several clinical trials for improving cognition in mild cognitive impairment using the cholinesterase inhibitors donepezil, galantamine, and rivastigmine and vitamin E, anti-inflammatories, and piracetam (Nootropil) have not shown significant cognitive effects for the drugs.

With respect to unimpaired older persons, nearly all of whom can claim that memory, learning, and other aspects of cognition are not as good as they used to be, there are societal questions of the appropriateness of treatment with cognitive enhancers even if they are demonstrated to be effective. Similarly, generally accepted guidelines do not exist for the treatment of cognitive deficits associated with schizophrenia, attention-deficit disorder, or depression, despite general recognition that these cognitive deficits are important areas of clinical attention. There have been attempts recently to provide clinical criteria for "cognitive impairment associated with schizophrenia" and cognitive outcomes criteria for clinical trials.

PHARMACOLOGICAL TREATMENT OF SYMPTOMATIC BEHAVIORS OR BEHAVIORAL AND PSYCHOLOGICAL SYMPTOMS OF DEMENTIA (BPSD)

The majority of patients with Alzheimer disease experience such behavioral symptoms as depression, anxiety, psychosis, agitation, aggression, apathy, withdrawal, and vegetative disturbances (e.g., sleep or appetite change). These signs and symptoms frequently lead to the use of psychotropic medication treatment (both appropriate and inappropriate), physical restraint, and institutionalization. Behavioral symptoms burden caregivers and are considered among the most stressful aspects of caregiving. A variety of psychotropic medications, however, may be effective for pharmacological intervention and improve many of these symptoms. Evidence suggests that these symptoms occurring in the context of Alzheimer disease can represent manifestations of two syndromes: Psychosis of Alzheimer disease and depression of Alzheimer disease.

The treatment of symptomatic behaviors begins with a careful characterization of the target symptoms. Such symptoms as agitation,

aggression, or delusions can result from chronic or recurrent psychiatric disorders, represent the first manifestation of a new psychiatric disorder, or indicate a change in medical status. (The term *agitation* often is used to describe a range of nonspecific behaviors in the elderly beyond excess psychomotor activity, including wandering, pacing, uncooperativeness, and verbal outbursts. Similarly, the commonly used phrase *behavioral and psychological disorders of dementia* is vague and unspecific, and probably should not be used.) A comprehensive medical evaluation might uncover potentially treatable underlying physical conditions that can exacerbate behaviors. Moreover, patients with dementia are at increased risk for developing superimposed deliria and consequent disruptive behaviors.

Patients with dementia are sensitive to a variety of factors that may influence behavior, including sensory impairment, environmental disruption, and altered daily routines. Consequently, environmental manipulations may be helpful. Many dementia patients experience anger, sadness, and denial, which may improve with psychosocial and psychotherapeutic interventions. Various behavior management techniques, including cognitive-behavioral management, may be helpful for more moderately to severely impaired individuals. Supportive psychotherapy and counseling may be helpful for patients with more mild cognitive impairments. Caregivers often need greater awareness that their own behaviors influence the patient. Counseling about the nature of the patient's illness not only helps relatives cope better, but also is associated with better outcomes for patients, such as delayed institutionalization.

Although the nonpharmacological and pharmacological treatment of symptomatic behaviors in dementia patients is beyond the scope of this section, the suggested interventions are necessary preparatory approaches to the pharmacological treatment of cognitive impairment as well.

DRUGS TO TREAT DEMENTIA

From a conceptual consideration, antidementia drugs can be grouped into two broad categories: Those intended to improve cognitive function symptomatically and those intended to modify the course of illness over the longer-term, as manifested by the potential attenuation of cognitive and functional decline. In practice, these two categories overlap. Medication development for dementia typically focuses on one or the other, depending on the mechanism of action of the new drug. The only drugs currently approved, however, are for symptomatic treatment, and their efficacy and FDA marketing approval was based on 6-month-long, placebo-controlled clinical trials. Table 57.4e–1 lists available drugs to treat the cognitive symptoms of dementia.

Table 57.4e–1.

U.S. Food and Drug Administration–Approved and Marketed Medications for Alzheimer Disease

Medication	Preparations	Initial Dosage	Maintenance Dosage	Comment
Donepezil (Aricept)	5- and 10-mg tablets, and orally disintegrating tablets 23-mg tablet	5 mg q.d.	5 or 10 mg q.d.	10 mg may be somewhat more efficacious, but with more adverse effects. 23-mg tablet is indicated after at least 3 months use of 10 mg; it is not overall more effective than 10 mg.
Rivastigmine (Exelon)	1.5-, 3.0-, 4.5-, and 6.0-mg capsules 4.6-, 9.5-mg, and 13.3-mg transdermal patch	1.5 mg b.i.d. 4.6 mg/24 hrs	Capsules: 3.0, 4.5, or 6.0 mg b.i.d. Patch: 4.6 mg/24 hrs to 13.3 mg/24 hrs	Oral doses of 4.5 mg b.i.d. may be most optimal. May be taken with food. Higher doses of the patch are well-tolerated.
Galantamine (Razadyne)	4-, 8-, and 12-mg capsules; solution, 4 mg/mL 8-, 16-, and 24-mg extended-release capsules	4 mg b.i.d. 8 mg q.d.	8 or 12 mg b.i.d. 16 or 24 mg q.d.	Effective dosage range is 16–24 mg per day; 16 mg per day is the modal optimal dose and has fewer adverse events.
Memantine (Namenda)	5- and 10-mg tablets 7-, 14-, 28-mg tablet	5 mg q.d. 7-mg q.d	10 mg b.i.d. 28-mg q.d.	10 mg q.d. was effective in a trial in nursing home patients. Clinical effects of 28-mg q.d. similar to 10 mg. b.i.d., but has not been compared directly.
Combined memantine and donepezil (Namzaric)	14-mg memantine and 10-mg donepezil capsule; 28-mg memantine capsule; and 10-mg donepezil in one capsule	14-mg memantine/10-mg donepezil	28-mg memantine/10-mg donepezil	Bioequivalence of this combination with co-administration of memantine and donepezil was the basis for marketing approval. Indicated for patients maintained on memantine 10–28 mg per day and donepezil, 10 mg per day.

Note: For the cholinesterase inhibitors: Initial dosages should be maintained for at least 2 and preferably 4–6 weeks before increasing. Adverse events may occur with dosage titration. The U.S. Food and Drug

Administration (FDA)–approved indication for these drugs is "indicated for the treatment of mild to moderate dementia of the Alzheimer type." Donepezil is indicated for severe Alzheimer disease and rivastigmine for Parkinson disease dementia as well. Websites for prescribing information on cholinesterase inhibitors are donepezil, http://www.aricept.com/productinfo.htm; rivastigmine, http://www.pharma.us.novartis.com/product/pi/pdf/exelon.pdf; galantamine, http://razadyneer.com/razadyneer/pages/pdf/razadyne_er.pdf

Galantamine formerly had the brand name Reminyl. For memantine: Starting dose is 5 mg q.d., titrated by 5 mg per day each week to a target dose of 10 mg b.i.d. The FDA-approved indication for memantine is for "moderate to severe dementia of the Alzheimer type." For prescribing information, see http://www.namenda.com. For memantine—extended-release starting dose is 7 mg q.d., increased to 28 mg q.d.

http://www.allergan.com/assets/pdf/namendaxr_pi

Cholinergic Hypothesis

The cholinergic hypothesis of dementia is based on observations of massive decline of the cholinergic basalocortical projections; reductions in the activity of choline acetyltransferase, the key enzyme in acetylcholine synthesis; a marked loss of cholinergic cell bodies in the nucleus basalis in Alzheimer disease; correlations between choline acetyltransferase reduction or nucleus basalis cell reduction and neuritic, β-amyloid–containing plaque densities in cortical areas; and correlation of the cholinergic deficits with the decline in cognitive test performance.

Many other neuronal systems are affected besides the cholinergic system, including pronounced declines in the noradrenergic projections from locus ceruleus to cortex, and general changes in glutamate systems. Notably, there is greater research emphasis on more fundamental pathogenetic processes affecting neurodegeneration, including β-amyloid peptide production and deposition, τ protein phosphorylation resulting in neurofibrillary tangles, inflammatory responses, and the use of medications that might be neuroprotective.

Nevertheless, the observation that cholinergic deficits represent the most pronounced transmitter deficit throughout the dementia process has led to considerable focus on cholinergic restitutive strategies. The cholinergic hypothesis of dementia treatment implies that if the cholinergic deficit is responsible for cognitive or behavioral changes, then potentiation of central cholinergic function should improve cognitive and behavioral impairment associated with Alzheimer disease.

Thus far, there have been three main cholinergic approaches to Alzheimer disease treatment: Use of precursor loading; use of direct, cholinergic agonists; and cholinesterase inhibition.

Precursor Loading and Direct Cholinergic Stimulation

Early investigations focused on the use of acetylcholine precursors,

including choline and phosphatidyl choline (lecithin), analogous to the use of dopamine precursors in Parkinson disease. Numerous trials with precursors, however, have not shown significant results, failing to show a reliable improvement in cognitive function. Thus, even though these products are sold in health food stores, their use cannot be recommended.

Direct cholinergic agonists enhance responsiveness to released acetylcholine and minimize the presynaptic inhibition of further release by intrasynaptic acetylcholine concentrations. Thus far, however, direct muscarinic or nicotinic receptor agonists have not proven useful in enhancing cognition in Alzheimer disease. The older and newer, relatively more muscarinic receptor subtype-specific investigational medications have not proven useful either. Marketed cholinergic agonists, such as arecoline and bethanechol (brand name, Urecholine), cannot be recommended because of their inadequate central nervous system (CNS) penetration, high frequency of cholinergic side effects, and minimal, if any, efficacy.

Although nicotinic agents currently under development, including transdermal nicotine, nicotinic α_7 receptor modulators, and newer nicotinic α_4, β_2 receptor modulators, may improve attention, arousal, and concentration in adults, their usefulness in such cognitive impairment syndromes as Alzheimer disease has not been adequately investigated. They also may have a role in attention-deficit disorder and cognitive impairment associated with schizophrenia. Two α_7 nicotinic receptor modulators are in later-stage clinical development, encenicline (Forum) and MK7622 (Merck) in AD.

Cholinesterase Inhibitors

The most successful approach to the treatment of Alzheimer disease thus far has been cholinesterase inhibition. In early studies, physostigmine demonstrated modest cognitive improvements but required individualized and very frequent dosing because of its very short duration of action (1 to 2 hours), thus limiting any potential clinical usefulness.

Cholinesterase inhibitors inhibit CNS acetylcholinesterase in the synaptic cleft, thus preventing the degradation of endogenously released acetylcholine (Table 57.4e–2). However, progressive presynaptic cholinergic neuron loss continues, so there is a progressively diminishing production of acetylcholine over time.

The three cholinesterase inhibitors that are currently marketed for treatment of the cognitive symptoms of Alzheimer disease, and tacrine which is no longer marketed, can be grouped into two classes according to their structure and mode of inhibition: (1) reversible inhibitor tertiary and quaternary amines (i.e., tacrine, donepezil, or galantamine) and (2) pseudoirreversible inhibitor carbamates (i.e., rivastigmine). The

irreversible organophosphate cholinesterase inhibitor metrifonate was clearly efficacious at higher doses but was not approved for marketing because of myasthenia and respiratory depression, possibly owing to its effects at the myoneural junction in muscles of respiration.

INDIVIDUAL CHOLINESTERASE INHIBITORS: CLINICAL STUDIES, DOSING, AND ADVERSE EFFECTS

For the most part, the several published multicenter trials of cholinesterase inhibitors were designed with the objective of obtaining marketing approval from the FDA. The protocols were fairly similar to each other, generally selecting outpatients with mild to moderate Alzheimer disease, usually with Mini-Mental State Examination (MMSE) scores between 10 and 26, inclusively. Patients in these trials were generally physically healthy, usually treated for 6 months or less, and more likely to be female, and they had a mean age of approximately 72 to 74 years, a decade lower than the median age of Alzheimer disease patients in the United States.

Tacrine

Tacrine is a noncompetitive reversible inhibitor of cholinesterase. It binds near the catalytically active site of the acetylcholinesterase molecule to inhibit enzyme activity. It has other actions as well, including blocking sodium and potassium channels, and direct activity at muscarinic receptors. Statistically significant treatment effects for the 30 mg q.i.d. and 40 mg q.i.d. dosage groups were found on the ADAS-cog, a clinician's interview-based impression of change rating, and activities of daily living in 3- and 6-month clinical trials. Tacrine will not be discussed further because it is no longer marketed. Additional information can be found in the previous editions of this book.

Table 57.4e–2.
Pharmacodynamics and Pharmacokinetics of Marketed Cholinesterase Inhibitors

Drug	Pharmacodynamics	Absorption	Bioavailability (%)	Peak Plasma (hours)	Half-Life (hours)	Protein Binding (%)	Me
Donepezil (Aricept)	Noncompetitive, reversible acetylcholinesterase inhibitor	Not affected by food	100	3–4	70	96	Via
Rivastigmine (Exelon)	Noncompetitive, pseudoirreversible cholinesterase inhibitor, both butyryl and acetyl cholinesterase	Delayed by food	40	1.4–2.6	<5	40	Hy

	inhibitor, may differentially affect different acetylcholinesterase subtypes						
Rivastigmine transdermal patch (Exelon)	(as above)	Not affected by food	100	8–16	3	40	Tra
Galantamine (Razadyne)	Competitive, reversible cholinesterase inhibitor, modulates nicotine receptors	Delayed by food	90	1	7	18	Via

Note: Pharmacodynamic effects of some cholinesterase inhibitors are longer than their elimination half-lives. Drugs that inhibit or induce the cytochrome enzymes above might be expected to increase or decrease blood levels.

Donepezil

Donepezil is a long-acting, piperidine-based, highly selective and reversible acetylcholinesterase inhibitor. Two phase III clinical trials provided pivotal evidence for the drug's FDA approval in late 1996. Additional randomized clinical trials include a trial of 6 months' duration, a Scandinavian study of 12 months, a study of nursing home patients, a 6-month trial in which a large proportion of patients were more severely impaired than in previous trials, and an assessment of activities of daily living.

One non–industry-sponsored, randomized, placebo-controlled trial followed patients over several years, reporting very modest cognitive effects over 2 years but no significant effects on loss of function, nursing home placement, or health economic measures.

Pharmacokinetics. Oral bioavailability approaches 100 percent, with peak concentrations in 4 hours and linear pharmacokinetics. Donepezil is extensively bound to plasma proteins, including α_1-acid glycoproteins. The drug accumulates at a constant rate, reaching steady state in approximately 2 weeks. It has a relatively slow clearance, with a long elimination half-life of 70 hours. It is both excreted unchanged in the urine and extensively metabolized by cytochrome P450 (CYP) 2D6 and 3A4 hepatic enzymes to active and inactive metabolites.

Drug Interactions. Inhibitors of CYP 3A4 and CYP 2D6 (such as ketoconazole [Nizoral] and quinidine [Quinaglute]) and inducers of CYP 2D6 and CYP 3A4 (such as phenytoin, carbamazepine, dexamethasone, and phenobarbital) could inhibit donepezil metabolism or increase its rate of elimination but may not be clinically significant in view of its high protein binding and very low therapeutic concentrations of 2 to 12 nG/mL.

Dosing. Donepezil is initiated at 5 mg per day and then increased to 10 mg per day after 4 to 6 weeks. Raising the dose earlier increases the risk for cholinergic adverse events. Five or 10 mg per day is an effective dose; 10 mg tends to be somewhat more effective than 5 mg when the various trials as a group are evaluated. The efficacy or appropriateness of higher doses has not been established.

A 23-mg formulation was marketed in 2010 intended for patients who are being maintained on 10 mg and for whom a higher dose is thought desirable. In a randomized, controlled trial, efficacy compared to patients who continued on 10 mg per day was not demonstrated.

Rivastigmine

Rivastigmine is a pseudoirreversible, selective acetylcholinesterase inhibitor, and butyrylcholinesterase inhibitor. Four phase III randomized, placebo-controlled, 26-week-long clinical trials were completed of similar design but differing mainly in dosing methods. Two have been published, and the results of the other two have been included in secondary reports.

In the two published trials, doses were titrated weekly during the first 7 weeks to one of two dosage ranges, 1 to 4 mg per day or 6 to 12 mg per day, and dose decreases were not permitted, possibly contributing to lesser tolerability and seemingly more side effects during these stages of treatment.

A transdermal patch formulation has been marketed recently based on a placebo-controlled trial in mild to moderate Alzheimer disease comparing a 17.4-mg patch, 9.5-mg patch, and 6 mg of orally administered rivastigmine twice per day, and another trial using 13.3-mg patch in severe Alzheimer disease.

Pharmacokinetics. Rivastigmine is well absorbed; very little binds to protein. Although the elimination half-life is less than 2 hours, enzyme inhibition lasts approximately 9 hours. Rivastigmine is not metabolized by the hepatic microsomal system. Rather, after binding to acetylcholinesterase, the carbamate portion of rivastigmine is slowly hydrolyzed (hence the "pseudoirreversibility"), conjugated to a sulfate, and excreted renally. Thus, its metabolism is essentially extrahepatic and unlikely to have significant pharmacokinetic interactions.

The pharmacokinetics of the transdermal patch shows a time to maximum concentration of 8 to 16 hours and a 3-hour elimination half-life after the patch is removed.

Drug Interactions. Rivastigmine's metabolism does not depend on liver CYP enzymes; therefore, no drug interactions related to hepatic cytochromes have been observed.

Dosing. The starting dose of rivastigmine is 1.5 mg twice a day, taken with meals. If this dose is well tolerated after a minimum of 2 weeks of treatment, it may be increased to 3 mg twice a day. Subsequent increases to 4.5 mg and then 6 mg twice a day should be based on good tolerability of the current dose and may be considered after a minimum of 2 weeks of treatment. Higher daily doses are associated with better efficacy than are lower doses. The initial transdermal patch is applied at 4.6 mg (5 cm^2) per day and then increased to one 9.5-mg (10 cm^2) patch per day after 4 weeks. The dosage level may be increased to a 13.3 (15 cm^2) mg patch per day after a subsequent 4 weeks; and the usual maintenance doses may be 9.5-mg or 13.3-mg patch per day.

Galantamine

Galantamine, an alkaloid originally extracted from *Amaryllidaceae* (*Galanthus woronowii,* the Caucasian snowdrop) but now synthesized, is a reversible, competitive inhibitor of acetylcholinesterase with relatively less butyrylcholinesterase activity.

Because competitive inhibitors compete with acetylcholine at acetylcholinesterase binding sites, their inhibition is, theoretically, dependent on intrasynaptic acetylcholine concentration in that they will be less likely to bind to sites in brain areas that have high acetylcholine levels. Another characteristic is allosteric modulation of nicotinic receptor sites, possibly enhancing cholinergic transmission by presynaptic nicotinic stimulation.

At least four large clinical trials involving more than 2,400 subjects have been published, generally showing efficacious doses between 8 mg twice a day and 16 mg twice a day, with few adverse effects at the low dose. Four milligrams twice a day was not an effective dose.

Pharmacokinetics. Galantamine is well absorbed and has approximately 90 percent bioavailability, little protein binding, and linear pharmacokinetics, with peak concentrations in approximately 1 hour and an elimination half-life of approximately 7 hours. It is metabolized by CYP 2D6 and 3A4, glucuronidated, and excreted in the urine. There is an approximately 25 percent decrease in clearance of galantamine in CYP 2D6–poor metabolizers.

Drug Interactions. Drugs that are potent inhibitors for CYP 2D6 or 3A4 may increase the availability and plasma levels of galantamine. Coadministration of paroxetine (Paxil) and ketoconazole increases bioavailability of galantamine by 40 and 30 percent, respectively. Galantamine clearance is decreased approximately 25 to 33 percent by concurrent administration of CYP 2D6 inhibitors, such as amitriptyline (Elavil), fluoxetine (Prozac), and quinidine; cimetidine (Tagamet)

increased bioavailability by approximately 16 percent. Galantamine itself does not inhibit CYP 3A4 or 2D6 and has little effect on the metabolism of other drugs.

Dosing. Initial dosing is 4 mg twice a day and should be raised to 8 mg twice a day after 2 to 4 weeks. For patients who are tolerating medication but not responding, the dose can be raised to 12 mg twice a day after another 4 weeks. The initial dose of the extended-release formulation is 8 mg per day and raised to 16 mg per day after 2 to 4 weeks with the option to raise to 24 mg per day.

Adverse Effects of Cholinesterase Inhibitors

The most common adverse events with cholinesterase inhibitors are cholinergically mediated and involve those related to cholinergic excess, including nausea, vomiting, diarrhea, dyspepsia, anorexia, fatigue, and weight loss. In addition, myalgia or muscle cramps occur in approximately 7 to 9 percent of patients, indicating direct myoneural effects (but do not seem to be associated with rivastigmine) which specifically inhibits only certain CNS acetylcholinesterase subtypes. The frequency of the cholinergic side effects generally is less than 15 percent and often no greater than placebo in clinical trials. In general, they tend to be mild and short lived, lasting less than 2 or 3 days, and to occur around the time that dosage is increased. Medication dosage can usually be maintained or temporarily lowered and then raised. Fatigue also tends to occur, and occasionally there is a decrease in heart rate of 4 to 7 beats per minute, possibly due to enhanced vagal effects.

Direct reversible hepatotoxicity was associated only with tacrine, more commonly in women than men, and is the most common abnormal finding with this drug which is no longer marketed.

Contraindications to Cholinesterase Inhibitors

There are few absolute contraindications to cholinesterase inhibitors, and they relate to the unique chemical properties of each drug. Because of the actions of cholinesterase inhibitors, these drugs require caution when used in patients with significant asthma, significant chronic obstructive pulmonary disease, gastrointestinal ulcer disease, cardiac conduction defects, or clinically significant bradycardia. Appropriate considerations are involved in general anesthesia as well, because they may prolong the effects of succinylcholine-type drugs.

Donepezil. The most common gastrointestinal adverse effects of donepezil include nausea, vomiting, diarrhea, and anorexia. Additionally, some patients develop muscle cramps, headache, dizziness, syncope,

flushing, insomnia, weakness, drowsiness, fatigue, agitation, and sleeplessness. Weight loss occurred at twice the rate of placebo in the nursing home study, but not in outpatient trials. Adverse effects occurred at a higher rate when the titration from 5 to 10 mg was made in 1 week compared to 6 weeks.

Rivastigmine. Adverse effects with orally administered rivastigmine were primarily gastrointestinal and occurred in the high-dose (6 to 12 mg per day) group. They occurred mainly during dose escalation and led to withdrawal in one study in 23 percent of the high-dose group, 7 percent of the low-dose group, and 7 percent of the placebo group. Adverse effects that occurred in the higher-dose group were sweating, fatigue, asthenia, weight loss, malaise, dizziness, somnolence, nausea, vomiting, anorexia, and flatulence. In the maintenance phase, dizziness, nausea, vomiting, dyspepsia, and sinusitis occurred more in the 6- to 12-mg-per-day group than in the placebo group.

Adverse effects with the transdermal patch at the 17.4-mg dose were similar to 6 mg twice per day of oral rivastigmine, with the 13.3-mg dose somewhat less, and with the 9.5-mg dose were not significantly greater than placebo.

Galantamine. Galantamine's principal adverse effects were nausea, vomiting, diarrhea, anorexia, weight loss, abdominal pain, dizziness, and tremor. They were more frequent earlier in the course of treatment and during the dosage titration from 16 mg a day to 24 mg a day and higher. In one trial, the effective dosage of 16 mg per day was not associated with overall greater adverse events than experienced by the placebo-treated group.

Clinical Application and Treatment Implementation for Cholinesterase Inhibitors

The differential pharmacology of the cholinesterase inhibitors requires treatment considerations, such as once-per-day versus twice-per-day dosing, oral versus transdermal administration, and acetylcholinesterase inhibition versus butyrylcholinesterase inhibition. Answers are not known.

Donepezil and rivastimine transdermal patch have been demonstrated to be effective in more severe patients as well as in outpatients with mild to moderate Alzheimer disease (MMSE scores between 10 and 26). Some experts believe that cognitive efficacy also is apparent in the more mildly and more severely cognitively impaired, but very few studies have been done in mild Alzheimer disease or mild cognitive impairment and did not show advantageous effects.

Duration of Treatment and Discontinuation

Placebo-controlled clinical trials with cholinesterase inhibitors have lasted only 6 months, with only a few exceptions. In some trials, when medication is discontinued, patients return within 3 to 6 weeks to the cognitive level of the placebo patients, indicating an overall symptomatic effect and that treatment efficacy is longer than 6 months. Three placebo-controlled trials suggest that in some cases efficacy could be longer than 1 year on cognitive and functional measures. A few analyses of databases or open-label extensions of clinical trials suggest that patients who tolerate and continue to take cholinesterase inhibitors over at least 1 year might experience a delay in nursing home placement compared to those who cannot tolerate or do not take them. However, these analyses are biased and probably subject to the "healthy patient effect," whereby patients who are destined to have a milder course of illness or who have active caregivers are the ones who *can* take these medications, so that the apparent long-term effect compared to historical controls is illusory. These observational studies have not been supported by a recent, long-term, placebo-controlled trial.

Discontinuation of cholinesterase inhibitors occasionally has been associated with worsening of cognition and occasional episodes of confusion in some patients. It is generally recommended that medication be tapered before discontinuing. In one trial in which donepezil was tapered and discontinued, or continued, in moderate to severe outpatients who had been treated for at least 3 months, continuing donepezil was associated with slightly better cognitive and functional scores over the course of a year. Adding memantine to donepezil did not show an advantage over continuing donepezil alone; but giving memantine to the patients who discontinued donepezil mitigated any differences in cognitive and function compared to continuing donepezil.

MEMANTINE: CLINICAL STUDIES, DOSING, AND ADVERSE EFFECTS

Overstimulation of NMDA receptors has been implicated as a causative mechanism in Alzheimer disease dementia. In preclinical studies, memantine, a moderate-affinity, uncompetitive NMDA receptor antagonist, protects against the effects of glutamate and calcium-mediated neurotoxicity. It has been available in Germany for the treatment of spasticity, Parkinson disease, and other neurological disorders since 1982, and was approved by the European Union in 2002 and the United States in 2003 for treating moderately severe to severe Alzheimer disease.

Mechanism of Action

Memantine's action is hypothesized as being an open channel blocker without appreciable activity until increased glutamate levels trigger the receptor and cause the ion channel to open. It then enters the channel, occupying a site within it, preventing calcium influx and the depolarization

and hyperactivation of the neuron. Because it is cleared from its site of action quickly, it might provide partial blocking of the channel, depending on intrasynaptic levels of glutamate. As glutamate increases, causing channels to open, memantine may block more, and as glutamate decreases, it may block less, allowing greater neuronal activity. In some respects, memantine can be viewed as a modulator of glutamatergic activity.

Clinical Studies in Moderate to Severe Alzheimer Disease

The effect of memantine on cognition generally has been mixed in clinical trials in moderate to severe Alzheimer disease (i.e., MMSE scores <15). Memantine (10 mg b.i.d.) was investigated for the treatment of moderate to severe Alzheimer disease in a 28-week, placebo-controlled trial of 252 patients. The decline of cognitive function was lessened in memantine patients compared to the deterioration observed in placebo.

Another 24-week, randomized, placebo-controlled trial of memantine in moderate to severe Alzheimer disease showed greater improvement in cognition, global assessment, and function compared to placebo. In this trial, memantine or placebo was administered to patients who had been maintained on stable doses of donepezil for at least 6 months. In fact, average time on donepezil was approximately 2.5 years, with nearly 90 percent on it for more than 1 year before being randomized. Notably, the placebo-treated patients (i.e., patients who continued on donepezil throughout the 6 months of the trial) continued to decline at a rather rapid rate, suggesting that memantine substantially stabilized symptoms over this time, whereas any effect of the cholinesterase inhibitor may have been lost earlier over the disease course. Based on these two trials memantine received marketing approval in the United States.

A third moderate to severe Alzheimer disease trial, however, which was similar in design to the other 6-month trials, failed to show significant effects for memantine compared to placebo.

A fourth moderate to severe Alzheimer disease trial failed to show that memantine was more effective than placebo over the course of a year when given to patients being maintained on donepezil. A fifth clinical trial, also in moderate to severe Alzheimer disease did not find an overall clinical effect for memantine compared to placebo over the longer course of 2 years on average, again in patients maintained on cholinesterase inhibitors, while by contrast it showed positive effects on function for vitamin E.

In a 12-week, randomized, placebo-controlled trial of memantine 10 mg per day in nursing home patients with Alzheimer disease or vascular dementia, memantine showed significant improvement over placebo in global assessment and activities of daily living.

Using the higher dose formulation, memantine, 28 mg and intended for once per day administration showed efficacy over 24 weeks. The 28-mg per day dose has not been directly compared to the 10 mg b.i.d. dose in a single

trial. The placebo-controlled trial of 28 mg per day did not show greater effects than the previous 10 mg b.i.d. placebo-controlled trials.

Clinical Studies in Mild to Moderate Alzheimer Disease

Two of three mild to moderate Alzheimer disease trials (i.e., MMSE scores from 10 to 23), one with patients taking cholinesterase inhibitors, did not show significant results, and a third showed significance only with one analysis. Based on these results, the FDA did not approve memantine for mild Alzheimer disease.

Pharmacokinetics

Memantine absorption is not affected by food intake; bioavailability is 100 percent. Plasma protein binding is 45 percent, and peak plasma concentrations occur 3 to 7 hours after oral intake. It is widely distributed and rapidly diffuses across the blood-brain barrier. The majority of the parent compound is excreted unchanged in the urine, in part by tubular secretion. There is minimum hepatic metabolism; the elimination half-life is 60 to 80 hours.

The 28-mg formulation, an extended-release capsule, shows a C_{max} and 24-hour AUC that is 48 and 33 percent higher than the original memantine formulation with an elimination half-life from 60 to 80 hours.

Drug Interactions

Interactions with memantine are few. There are potential interactions with hydrochlorothiazide, resulting in a lower plasma level of the diuretic or a potentially reduced effect. There are no known interactions with cholinesterase inhibitors. Drugs that alkalinize urine would reduce renal clearance of memantine.

Dosing

Dosing is fairly straightforward, with a titration to 10 mg b.i.d. over the course of 3 weeks, starting at 5 mg q.d. and increasing the daily dose by 5 mg each week; or with 7-mg capsules q.d., and increasing by 7 mg q.d. each week to a dose of 29 mg q.d.

Adverse Events

Interestingly, agitation occurred less often in memantine treatment groups than in placebo groups. In the memantine add-on trial, confusion, generally rated as mild, occurred four times more frequently in the memantine group, and headache twice as frequently. Of note, gastrointestinal symptoms were less frequent, with diarrhea or fecal incontinence occurring half as frequently in the memantine group,

suggesting that the actions of memantine may mitigate some of the cholinergic effects of donepezil.

Clinical Application and Treatment

Memantine is indicated for moderate to severe dementia of the Alzheimer disease type, which generally corresponds to patients with MMSE scores of 14 or less. It generally can be considered as initial treatment for this group if patients have not been treated previously. If they have, then memantine can be added to a cholinesterase inhibitor as well. Because the clinical trials that showed efficacy were no longer than 6 months, treatment duration is unclear, and issues are similar to those of the cholinesterase inhibitors. Whether discontinuation is associated with worsening symptoms is not known.

Although memantine is commonly used with or without a cholinesterase inhibitor in mild Alzheimer disease, clinical trials assessing efficacy in mild to moderate Alzheimer disease have not demonstrated cognitive efficacy for memantine. This is due to a lack of efficacy observed in the mild subgroup of patients in these trials and memantine is not FDA approved for mild Alzheimer disease. Nevertheless, it is commonly used in mild Alzheimer disease with nearly half of mild Alzheimer disease patients in observational research studies receiving it.

OTHER MEDICATIONS AND APPROACHES TO ALZHEIMER DISEASE AND COGNITIVE ENHANCEMENT

Although cholinesterase inhibitors have been the most studied class of medications for Alzheimer disease, a broad range of other drugs and supplements are available for prescribing in some countries or are undergoing clinical trials. Some of these may be approved for marketing in the United States, but for other indications. These approaches might improve symptoms or slow neurodegenerative processes, or both.

Atypical inflammatory responses, production of oxidizing free radicals, and the production from amyloid precursor protein of insoluble and possibly toxic β-amyloid peptide fragments are part of the neurodegenerative process. Therefore, anti-inflammatories and antioxidants might have a role in the treatment of progressive dementias. The neurotrophic and cholinergic properties of estrogens were hypothesized to be useful in women.

Huperzine A

Huperzine A is a plant extract that has selective acetylcholinesterase inhibition. It is sold as a food supplement and is a traditional Chinese treatment. A phase II trial failed to demonstrate efficacy at a lower dose of 200 mcg b.i.d., but with a suggestion of a cognitive effect at 400 mcg b.i.d.

Monoamine Oxidase Type B Inhibitors

Some positive effects have been reported with selegiline (L-deprenyl, Eldepryl®), a monoamine oxidase (MAO) inhibitor that relatively selectively inhibits MAO type B at a 5- to 10-mg daily dose. At this dose, its overall effect may be to increase CNS levels of dopamine and trace neurotransmitters, such as phenylethylamine, without affecting norepinephrine levels. Selegiline is marketed for the treatment of Parkinson disease, for which it has demonstrated effects in maintaining motor function, and in some Eastern European countries as a cognitive enhancer.

From a different perspective, selegiline and other MAO type B inhibitors may have neuroprotective potential. Elevated levels of MAO type B in the brains of Alzheimer disease patients might lead to elevated levels of neurotoxins, such as 6-hydroxydopamine, quinones, and free radicals. It has been postulated also that exposure to substances in the environment could lead to neurotoxic products (via oxidative biotransformation). In either case, inhibition of MAO on a chronic basis could theoretically retard progression of the illness based on antitoxic mechanisms. Also, selegiline may have neuronal "rescue" effects, based on neurotrophic-like properties not involving MAO inhibition. It is notable that rodents and dogs treated with selegiline have increased survival. Selegiline is also marketed in the United States as an FDA-approved veterinary medicine for "canine cognitive dysfunction."

A 12-month placebo-controlled trial of transdermal selegiline in patients with milder Alzheimer disease revealed no significant effects overall. Oral selegiline, 5 mg twice a day, along with and separately from vitamin E, 1,000 IU twice a day, has been associated with prolonged maintenance of activities of daily living and avoidance of nursing home placement in moderately to severely impaired Alzheimer disease patients, but with no improvement in cognitive function. An adequate efficacy trial has yet to be completed in Alzheimer disease.

Another, recent, 12-month, phase II, placebo-controlled trial of the MAO-I, RO4602522 (EVT 302) did not show efficacy in 495 patients with moderate Alzheimer disease.

Ladostigil is a derivative of rasagiline and rivastigmine. It acts as a cholinesterase inhibitor and MAO-I; it has antioxidant properties and modulates the processing of amyloid precursor protein. It is currently being assessed in a mild to moderate Alzheimer disease trial, and in a phase II trial in mild cognitive impairment. In sum, there is little evidence for the efficacy of MAO type B inhibitors.

Ergoloid Mesylates

Ergoloid mesylate was a commonly used putative cognitive-enhancing drug

until the advent of the cholinesterase inhibitors and is no longer marketed in the United States. It was used primarily for patients with dementia, age-associated cognitive symptoms, or memory complaints. The agent has mixed and complex actions on central α-adrenergic, dopaminergic, and serotonergic receptors.

Nootropics

The term *nootropic* is derived from the Greek *noos* (mind) and *troepin* (forward) and refers to a drug class with diverse actions, structurally related to piracetam. They are pyrrolidine derivatives of γ-aminobutyric acid (GABA), although they do not appear to have GABA-like effects, and are postulated to have a neuroprotective effect on the CNS against hypoxia, electroconvulsive treatment, and drug intoxication. They also may enhance the CNS microcirculation by reducing platelet activity and adherence of red blood cells to vessel walls, and may stimulate central cholinergic activity. They include piracetam, oxiracetam (Neuromet), pramiracetam (Neupramir), and aniracetam (Draganon). They may improve memory and learning, but an antidementia mechanism has not been established.

Clinical trials of nootropics in Alzheimer disease have shown mixed results with piracetam in the treatment of dementia in the elderly. Pramiracetam and oxiracetam have been evaluated in large-scale multicenter studies with no sufficiently significant clinical effects in dementia or in mild cognitive impairment. Nootropics, however, are marketed for the treatment of dementia and cognitive impairment in countries other than the United States. There is some evidence for efficacy in attention-deficit disorder.

Ginkgo Biloba

The ability of an extract from the leaves of *Ginkgo biloba* to improve cognitive function in Alzheimer disease patients is the subject of ongoing work. Preclinical evidence suggests that certain flavonoid components in *Ginkgo* might have neuroprotective effects, including scavenging of oxygen free radicals; protection of membranes against lipid peroxidation; inhibition of β-amyloid formation, aggregation, and toxicity; and antiapoptotic effects, and may increase hippocampal muscarinic receptors and enhance choline uptake.

A preparation (EGb 761) is approved in Germany for "disturbances of cerebral function related to dementia syndromes," supported by various clinical studies. However, a clear role for *Gingko,* as a symptomatic agent or in the prevention of Alzheimer disease, has not been determined. One 52-week placebo-controlled, double-blind trial of 309 patients with Alzheimer disease or vascular dementia demonstrated that 120 mg per day of standardized *Ginkgo* extract (EGb 761) conferred a statistically

significant improvement on the ADAS-cog scores compared to placebo. A 6-month placebo-controlled trial of 120 and 240 mg per day of EGb 761 for mild to moderate Alzheimer disease, however, did not show efficacy. A recent Cochrane meta-analysis does not support advantageous effects of *Ginkgo biloba* extract for Alzheimer disease or as a cognitive enhancer. A randomized, placebo-controlled trial (the Gingko Evaluation of Memory Study [GEMS]) funded by the National Center for Complementary and Alternative Medication evaluated *Ginkgo biloba* EGb 761 extract, 240 mg per day, in delaying the onset of Alzheimer disease or mild cognitive impairment in 3,072 subjects aged 75 years and older who were followed over 5 years and found no effect. Another prevention study in 200 subjects 85 years or older, also sponsored by the National Center for Complementary and Alternative Medication, did not find an effect for 240 mg per day of EGb 761 in delaying progression to mild cognitive impairment. Finally, a multicenter prevention trial in France involving 2,854 patients followed for 5 years did not show a positive effect for EGb 761 for delaying dementia or improving cognition.

Based on these studies, there is little or no evidence to recommend *Ginkgo biloba* for the treatment of Alzheimer disease or vascular dementia. Studies in normal elderly subjects have been inconsistent, presenting a confusing picture for its use, perhaps partly owing to variations in dose, duration, and methodological issues such as lack of blinding.

Vitamin E

The antioxidant effects of vitamin E (DL-α-tocopherol) might have an impact on reducing clinical progression. In the prototypical antioxidant trial, vitamin E (1,000 IU twice a day) and selegiline (5 mg twice a day), each given alone to moderately impaired patients with Alzheimer disease, delayed the time until patients required nursing home placement, died, or lost activities of daily living. Overall, the delayed time to these end points was approximately 7 months compared to placebo. There were no effects on cognition on this group of patients, who were more severely impaired than in other studies. Adverse effects included falls and syncope in selegiline patients (9 and 10 percent, respectively), α-tocopherol patients (14 and 7 percent, respectively), and the combination (22 and 16 percent, respectively).

A multicenter trial in amnestic mild cognitive impairment patients reported no significant delay in conversion to Alzheimer disease or in cognitive effects with α-tocopherol over 3 years of treatment. The outcomes of the previous moderate to severe Alzheimer disease trial was supported by a trial comparing vitamin E with memantine and placebo over 2 years on average and showing improved function with vitamin E and not with memantine.

Taken together, considering the absence of cognitive efficacy and the potential risks for treatment, vitamin E cannot be recommended as treatment.

B Vitamins and Homocysteine Reduction

Elevated levels of homocysteine are a risk factor for cardiovascular disease, vascular dementia, and Alzheimer disease. Plasma concentrations rise when homocysteine's metabolism to methionine or cysteine is impaired, which may occur under a number of circumstances, including natural aging. Increased blood levels of homocysteine are associated with damage to vascular endothelial cells through lipid peroxidation and release of endothelium-derived relaxing factor, and may increase the risk of vascular thrombosis. More relevant to Alzheimer disease, homocysteine potentiates the neurotoxic effects of β-amyloid peptides in vitro. Homocysteine plasma levels can be reduced by as much as 30 percent using regimens of B vitamins (e.g., B_{12} 1 mg per day, B_6 25 mg per day, and folic acid 5 mg per day). A placebo-controlled clinical trial of these vitamins over 18 months in patients with mild to moderate Alzheimer disease confirmed that substantial reduction in homocysteine could be achieved but did not show cognitive or functional effects compared to placebo.

HMG-CoA Reductase Inhibitors

Epidemiological evidence suggests that cholesterol lowering and the use of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors ("statins") may impact the development or progression of Alzheimer disease possibly because cholesterol levels modulate the enzymatic processing of amyloid precursor protein and consequently the production of β-amyloid, a main component of neuritic plaques in the Alzheimer disease brain. Furthermore, cholesterol-fed rabbits demonstrate increased β-amyloid in brain, and hypercholesterolemia induced by a high-cholesterol diet results in increased levels of β-amyloid in the CNS. Statin administration in vitro reduces intra- and extracellular β-amyloid levels in neuronal cultures.

Observational studies of patient records demonstrated a 60 to 73 percent lower prevalence of Alzheimer disease in lovastatin (Mevacor)- or pravastatin (Pravachol)-treated patients, and a markedly reduced risk for Alzheimer disease as assessed in an analysis of a clinical database.

Clinical trials, however, generally have not supported the use of statins for Alzheimer disease. A randomized, placebo-controlled trial of pravastatin (the PROSPER study) in 5,804 subjects aged 70 to 82 years with risk factors for vascular disease reported favorable cardiovascular outcomes but no significant effect on cognitive function or disability during an approximately 3-year follow-up period. In a randomized, placebo-

controlled trial of the effect of simvastatin (Zocor) on cardiovascular outcomes in a subgroup of 5,806 patients aged 70 or more years, there was no significant difference in the proportion of patients with cognitive impairment or in the incidence of dementia over the average 5-year follow-up period.

A small-scale trial of atorvastatin (Lipitor) indicated some positive cognitive effects. Two larger placebo-controlled trials, one with simvastatin and another with atorvastatin, including 400 and 641 patients, respectively, treated over 18 months did not show positive effects for the drugs in symptoms or in slowing the clinical decline of Alzheimer disease patients. Thus, these drugs should not be considered as useful for preventing or treating Alzheimer disease.

Docosahexaenoic Acid

A reduced risk of Alzheimer disease associated with fish consumption in epidemiological studies is also associated with omega-3 fatty acids. Docosahexaenoic acid (DHA) is an omega-3 fatty acid found in fish oil, a component of neural membrane phospholipids. Several animal studies show DHA to have antiamyloid, antioxidant, and neuroprotective mechanisms. A carefully conducted multicenter, randomized, placebo-controlled trial of DHA in patients with mild to moderate Alzheimer disease did not show efficacy for DHA.

Souvenaid

Souvenaid (Nutricia N.V.) is marketed outside the United States as a medical food. It contains uridine, choline, phospholipids, eicosapentaenoic acid, DHA, selenium, and vitamins E, C, B12, and B6; folic acid. The rationale is that these are precursors and cofactors for the development of neuronal membranes and intended to support the formation of synapses. This represents both a structure/function food supplement claim and a medical food claim. Clinical trials in Alzheimer disease, however, have not been supportive however of a clinical or functional effect.

Axona

A particular liquid formulation of medium chain fatty triglycerides composed of glycerin and caprylic acid (AC-1204 or Axona®) is intended to create chronic ketosis in an effort to enhance mitochondrial metabolism. A rationale is that reduction in cerebral glucose uptake and utilization is observed in Alzheimer disease. Therefore, the AC-1204 formulation is intended to improve cellular metabolism by providing an alternative energy substrate to glucose. Caprylic acid is metabolized into the ketone bodies acetoacetic acid and β-hydroxybutyric acid which in turn are converted to acetyl-CoA and energy by the tricarboxylic acid (TCA or Krebs) cycle.

The formulation was initially marketed as a medical food for Alzheimer disease and then withdrawn by the FDA because of absent clinical trials efficacy evidence and claims. There is an ongoing phase III trial to assess potential efficacy for its use as a drug rather than as a medical food.

UNPROVEN AND UNSAFE MEDICATIONS TO SLOW CLINICAL PROGRESSION OR DELAY ONSET OF ALZHEIMER DISEASE

Anti-inflammatories

Markers of inflammation in the brains of Alzheimer disease patients suggest a potential therapeutic benefit of anti-inflammatories. Epidemiological studies with nonsteroidal anti-inflammatory drugs (NSAIDs) indicate that these agents may be potentially effective for reducing the incidence or delaying the onset of Alzheimer disease. As examples, (1) patients with rheumatoid arthritis who receive chronic anti-inflammatory treatment have reduced risk for Alzheimer disease compared to controls without rheumatoid arthritis, (2) twins who used anti-inflammatory medications had lesser risk for Alzheimer disease than did their co-twins, and (3) the risk of Alzheimer disease was reduced in cohorts of people using anti-inflammatories in middle-age years before the typical onset of Alzheimer disease.

A placebo-controlled trial of indomethacin (Indocin) initially supported a potential role for at least NSAIDs. Subsequent randomized, placebo-controlled trials of NSAIDs in Alzheimer disease patients have failed to show a clinical benefit. Moreover, 1-year-long, placebo-controlled trials of low-dose prednisone (10 mg) or of NSAIDs by the National Institute of Aging Alzheimer's Disease Cooperative Study and long-term trials of celecoxib (Celebrex) and rofecoxib (Vioxx) did not show advantageous effects.

To investigate the effect of NSAIDs in delaying the onset of Alzheimer disease, an ongoing multisite trial (the Alzheimer's Disease Anti-Inflammatory Prevention Trial) randomized approximately 2,528 patients aged 70 years or older with a family history of dementia to naproxen (Aleve), celecoxib, or placebo, and followed them for 5 to 7 years before the trial was ended early due to cardiovascular toxicity concerns. Results, however, indicated nontherapeutic and cognitively toxic effects with increased risk for Alzheimer disease with both treatments.

In view of the negative clinical trials with NSAIDs and considering their frequent adverse effects, including gastrointestinal bleeding, especially with long-term use, NSAIDs cannot be recommended for the prophylaxis or treatment of Alzheimer disease.

Estrogens

Preclinical evidence amply demonstrates that estrogens improve cognitive

function through cholinergic neuroprotective and neurotrophic effects. For example, estradiol (Estrace) replacement increases choline acetyltransferase and acetylcholine after ovariectomy and enhances learning in ovariectomized rats. Clinical evidence of a possible effect for estrogen replacement therapy (ERT) has included observations of an inverse relationship between ERT and death-certificate diagnoses of dementia, several case-control and cohort studies in which 40 to 50 percent reductions in the risk for developing Alzheimer disease were reported, and several smaller clinical reports suggesting that estradiol, estrone (Estrol), or conjugated equine estrogens (CEE, Premarin) enhance cognitive function in Alzheimer disease.

Acute adverse events with ERT are frequent and generally dose dependent and include endometrial hyperplasia, uterine bleeding (when taken with a progestin), breast tenderness, nausea, and venous thrombosis, among others. Because of the enhanced risk for endometrial cancer when estrogens are given to women with intact uteri, administration of progestins with estrogens has been recommended for women with intact uteri.

During the last few years, a number of clinical trials have been carried out, and except for one very small trial using transdermal estradiol, results with CEE (without a progestin) did not substantiate their efficacy. A 20-week-long and a 1-year-long trial of CEE in hysterectomized women were negative. Indeed, there was a trend in women receiving hormone replacement to worsen cognitively, and—although a relatively small sample size—have greater adverse events, including a few instances of deep vein thrombosis.

Without evidence for efficacy, then, safety is of great concern. The Women's Health Initiative trial followed a large number of women randomly assigned to hormone replacement therapy (CEE with or without the progestin medroxyprogesterone [Provera or PremPro when combined with CEE]) or placebo to assess potential cardioprotective effects of the hormone replacement. In 2002, the arm of the trial that included combination treatment was halted because of a substantial increase of cardiovascular adverse effects. The results of the cognitive outcomes in 4,532 women in the subgroup older than 65 years were reported in 2003, finding that the CEE/medroxyprogesterone-treated women had an increased risk for developing dementia. In 2004, the arm of the trial that included CEE treatment alone also was halted for lack of effect and increased strokes with estrogens. CEE alone was associated with an increased incidence of dementia and worse cognition over the approximately 5-year follow-up period.

It is possible but not at all proven that estrogen treatment in midlife around menopause could be neurotrophic and preventative of the onset of Alzheimer disease, but beyond epidemiological studies, evidence is lacking.

The lack of any salutary cognitive effects, combined with the substantial cardiovascular, stroke, and breast cancer risk over the long term, strongly suggests that there is no role for the use of combined estrogen/progestin or CEE-alone intervention in women over 65 years of age.

ADJUNCTIVE AND COMBINATION THERAPY

It is not known whether combining medications such as cholinesterase inhibitors with NMDA antagonists or vitamins confers added efficacy. There have only been pilot studies comparing combinations of cholinesterase inhibitors with such drugs as selegiline, suggesting only their feasibility and not efficacy. The combination of selegiline and vitamin E did not confer any added benefits over either alone in one study and was associated with greater adverse effects.

The combination of a cholinesterase inhibitor with memantine is another example of the potential use of combined therapy. Although such issues as what drug to use first or whether to start both simultaneously have not been worked out, nor is there evidence that each drug separately has an effect that the other does not, it appears that the medications can be used together safely.

As mentioned, a clinical trial with memantine in patients who were being maintained on donepezil showed positive effects in moderate to severe dementia with an actual reduction in treatment-emergent adverse events in patients who had memantine *added on* to long-term donepezil treatment. However, as above, similar trials in mildly to moderately impaired patients did not show salutary effects for memantine, although the addition of memantine did not increase adverse effects. Nevertheless, it makes theoretical sense that cognitive-enhancing drugs with complementary mechanisms of action may be more effective than monotherapy. Consequently, some experienced clinicians use both drugs in combination even as evidence for efficacy is lacking.

TREATMENT OF MILD COGNITIVE IMPAIRMENT

Operational criteria for mild cognitive impairment are generally taken to include a subjective cognitive (memory) complaint; MMSE within normal limits; neuropsychological tests for memory greater than 1.5 standard deviation below age-appropriate norms; activities of daily living within normal limits; and a Clinical Dementia Rating scale score of 0.5, indicating no dementia. Criteria for mild cognitive impairment due to Alzheimer disease and used for clinical trials, however, are slightly different requiring as well progressive worsening and a delayed memory deficit on the Logical Memory II delayed recall below 9 in most cases.

In research clinics a diagnosis of “amnestic mild cognitive impairment” or “mild cognitive impairment of the amnestic type,” marked by predominant memory impairment, implies a conversion rate to Alzheimer

disease of about 12 to 15 percent per year. However, mild cognitive impairment is not necessarily a predementia stage of Alzheimer disease because many people who fulfill criteria do not progress to dementia and some improve to not being cognitively impaired. The meaning of mild cognitive impairment is further confounded as it is viewed also as a transitional state on the road to the development of Alzheimer disease, as an "at-risk" state with an increased likelihood for dementia over a specified time, and as the very early diagnosis of Alzheimer disease before the full dementia syndrome is recognized.

Although criteria for mild cognitive impairment can be defined by consensus, the diagnosis as variously used suffers from vagueness in conceptualization, with the condition overlapping with Alzheimer disease. The application of mild cognitive impairment criteria seems to vary, however, and the diagnosis does not necessarily predict onset of Alzheimer disease. For example, although all mild cognitive impairment trials nominally used the Mayo Clinic criteria for mild cognitive impairment, when the criteria from three clinical trials were applied to the same clinic cohort, differing prevalences were found from 17 to 51 percent.

Mild cognitive impairment has been a therapeutic target for several clinical trials of cholinesterase inhibitor medications marketed for Alzheimer disease. These trials have ranged from 2 to 4 years in duration. None showed positive effects for the cholinesterase inhibitor in delaying time to dementia onset or at improving cognitive scores beyond 6 to 12 months. Given the vagaries of the definition of mild cognitive impairment, that many people with mild cognitive impairment will not progress, the adverse effects of the medications, and the lack of efficacy in the trials, the use of cholinesterase inhibitors for people with mild cognitive impairment cannot be recommended.

A development for clinical research and trials is to define mild cognitive impairment "due to Alzheimer disease" or the equivalent "prodromal Alzheimer disease" by the above clinical and cognitive criteria but to also require a positive amyloidβ PET scan or low amyloidβ CSF levels to enhance the likelihood that the research participant will progress to Alzheimer disease.

TREATMENT OF VASCULAR DEMENTIA

Although a range of treatments has been proposed for the cognitive deficits of ischemic vascular dementia, more recently conducted trials using particular research criteria for vascular dementia have yielded the best efficacy evidence. Six-month trials of the cholinesterase inhibitors donepezil and galantamine have generally demonstrated very modest cognitive efficacy similar to that shown in Alzheimer disease but often without evidence of global improvement or improvement in activities of daily living. Similarly, two 6-month multicenter trials of memantine also

tended to show improvements in cognition. These trials relied on a cognitive battery designed for patients with Alzheimer disease.

Overall, however, there is insufficient overall evidence for efficacy in vascular dementia. One limitation is that vascular dementia is a heterogeneous condition that is difficult to define clinically and often overlaps with Alzheimer disease. These drugs are not approved for use in vascular dementia. The results of the trials demonstrate that cognitively enhancing medications might be useful in other conditions besides Alzheimer disease.

TREATMENT OF PARKINSON DISEASE DEMENTIA

Patients with Parkinson disease have an increased risk for dementia and about 25 percent may develop dementia after the onset of the illness. The dementia, occurring after the onset of parkinsonian motor symptoms, can be characterized by a particular pattern of impairments in executive function, memory, and attention that is different from other dementias such as Alzheimer disease.

From an FDA perspective, however, a diagnosis of the Parkinson disease dementia is made in patients in whom "a progressive dementia syndrome occurs at least 2 years after a diagnosis of Parkinson disease" in the absence of other causes of the dementia. This definition came about as a result of the FDA approving the cholinesterase inhibitor rivastigmine for "mild to moderate dementia associated with Parkinson disease." Thus, rivastigmine used in the same dosing range as with Alzheimer disease is the only drug indicated for treating the dementia.

β-AMYLOID–BASED RESEARCH INTERVENTIONS IN CLINICAL TRIALS

Other drugs with a broad range of mechanisms are in development. They include β- and γ-secretase inhibitors that prevent the cleavage of amyloid precursor protein into insoluble β-amyloid; vaccines such as synthetic β-amyloid in order to generate β-amyloid antibodies; the use of manufactured antibodies against β-amyloid; blocking the receptor for advanced glycation endproducts (RAGE) from binding amyloid; preventing amyloid fibril formation; and a range of other "antiamyloid" approaches. "Antiamyloid" approaches have been most actively researched and are summarized in Table 57.4e–3.

Table 57.4e–3.
Amyloid-a Peptide-Based Research Interventions in Clinical Trials

Active Immunotherapy

A synthetic Aβ antigen that triggers an immune response. Atrial of AN 1792 (Wyeth) was terminated early due to T-cell, immune-mediated, aseptic meningoencephalitis. No significant differences were found between antibody responder and placebo groups on most outcomes. Other vaccines are under development. A phase II trial of a vaccine consisting of short peptides mimicking native Aβ (AD02 and

AD03, Affiris) was negative. ACC-001(Elan) failed to show efficacy in two phase 2 trials in 520 subjects with mild–moderate and prodromal AD over 24 months. CAD106 (Novartis), an antigen designed to induce N-terminal Aβ-specific antibodies against $A\beta_{1-6}$ without an Aβ-specific T-cell response, is in phase II trials; and ACI-24 (AC Immune) is a liposome vaccine intended to generate an antibody response against aggregated Aβ peptides that is under development.

Passive Immunotherapy

Manufactured monoclonal antibodies may be delivered by intravenous infusion or subcutaneous injection. Bapineuzumab (AAB-001, Janssen), targets fibrillar Aβ, and failed to show efficacy in four, phase III clinical trials. Solanezumab targets soluble, monomeric Aβ; two phase III trials were negative, a third trial, including only mild AD patients is underway. Gantenerumab mainly targets Aβ plaques; a phase 2 trial in prodromal AD was negative; a mild to moderate AD trial is ongoing. Crenezumab targets monomeric or oligomeric Aβ; a phase II trial was negative; a phase III trial is underway, as are trials in autosomal dominant AD. Aducanumab (BIIB037, Biogen) targets Aβ aggregates showed a strong, dose-dependent effect at reducing brain fibrillary amyloid and is in phase III trials.

Human intravenous immunoglobulin G contains polyclonal antibodies against Aβ but did not show evidence for efficacy in a phase II trial.

Secretase Inhibitors

Both β-secretase and γ-secretase abnormally cleave APP creating presumably toxic Aβ protein fragments. Several γ-secretase inhibitors, including semagacestat (Lilly), avagacestat (BMS), and have failed in phase II and III trials because of clinical toxicity.

β-Secretase inhibitors (β-site amyloid precursor protein cleaving enzyme 1, BACE-1 inhibitors) are also under development and in phase II and III trials including the BACE-1 competitive inhibitor MK-8931

Selective $A\beta_{42}$-lowering Agents

Some nonsteroidal anti-inflammatory drugs (NSAIDs) may have direct $A\beta_{42}$ lowering properties by allosterically modulating γ-secretase to produce shorter, less toxic Aβ fragments. The R-enantiomer of flurbiprofen (R-flurbiprofen, tarenflurbil) has no significant cyclo-oxygenase inhibition and is being tested in two phase III, 18-month, placebo-controlled trials with the first to be completed in 2008.

Anti-fibrillogenesis Drugs

Inhibitors of fibrillogenesis or aggregation of Aβ may reduce toxicity and plaque burden. The curry spice curcumin, tramiprosate (homotaurine or Alzhemed), and scyllo-inositol (ELND005) were not shown to be effective. Other drugs are under development.

Moreover, there is a new focus on the development of neuroprotective medications or drugs that might cause neurogenesis or enhance plasticity; and drugs and antibodies directed against tau protein targets. Research and development efforts, of course, continue.

FUTURE DIRECTIONS

Current pharmacological treatment options for improving cognition in Alzheimer disease include the cholinesterase inhibitors and memantine. Other available drugs, food supplements, and vitamins, including anti-inflammatories, available estrogens, B-complex vitamins, vitamin E, medium chain fatty acids, and *Ginkgo biloba* extract have not been proven efficacious, some show considerable toxicity in clinical trials, and cannot be recommended for use.

Ideally, it would be best to treat Alzheimer disease early before the onset of the dementia; however, there are no current drugs for this and

cholinesterase inhibitors have been demonstrated to be ineffective in this regard.

Although no currently available antidementia treatment has shown dramatic effects in improving the cognitive impairments of Alzheimer disease, the improvements nonetheless may be clinically meaningful for some people. Therapeutic results are usually modest, affecting a minority of patients. Cholinesterase inhibitors are the best proven efficacious symptomatic treatments for Alzheimer disease. Patients assessed and treated in clinical trials, however, were usually outpatients with mild to moderately severe dementia and few concomitant medical illnesses. Duration of effect beyond 6 months to 1 year (2 years in one trial) and long-term safety are not known.

The efficacy of these drugs for other cognitive disorders remains to be established, although the FDA has approved rivastigmine for Parkinson disease dementia. The prospects for future treatments with greater efficacy in Alzheimer disease and for cognitive enhancement in elderly patients are encouraging.

57.4f Electroconvulsive Therapy and Other Neurostimulation Treatments

MUSTAFA M. HUSAIN, M.D., SHAWN M. MCCLINTOCK, PH.D., AND PAUL E. CROARKIN, D.O.

Chapters 34.35 and 34.36 comprehensively detail the application of electroconvulsive therapy (ECT) and other neurostimulation therapies, respectively. This particular section applies to the utility of ECT and other neurostimulation therapies in a geriatric population.

ECT is by far the single most effective neurobiological treatment for major depression. In the elderly, it is often the treatment of choice for severe depression. Depressed geriatric patients are especially at high risk for sequela of depression, including psychotic symptoms, malnutrition, weight loss, and inactivity. As a result, ECT is commonly employed in geriatric depression with the added benefit that it is relatively safe and well tolerated compared to medications. ECT often become the first-line treatment recommendation for patients who are acutely suicidal, psychotic, or present with severe melancholia. Recent research studies suggest that among patients receiving ECT, older age is associated with rapid remission. In some instances, mean time to remission is as low as 3 weeks.

After one ECT stimulation, there is increased hippocampal expression in the dentate gyrus of neurotropic and transcription factors, including the neurotropic factors: brain-derived neurotropic factor (BDNF), vascular endothelial growth factor (VEGF), and fibroblast growth factor (FGF) and transcription factors, including: c-fos (which plays an important role in signal transduction, cell proliferation, and differentiation) and the arachidonic acid pathway (COX 2). There are cell proliferation and neurotropic effects of ECT also in the prefrontal cortex, amygdala, and hypothalamus. After several stimulations, there is release of even more neuropeptide factors, including neuropeptide Y, thyrotropin-releasing hormone, and an increase in nerve growth factors. Chronic ECT works by changing gene expression. Thus, relapse after ECT is thought to be due to disrupted re-alteration of genes. Chronic ECT also helps strengthen second messenger systems. With the emergence of treatment-resistant depression, defined as depression that does not improve after adequate and substantial antidepressant treatment, ECT has found a new role in antidepressant algorithms.

Mr. B, a 67-year-old Caucasian man with a long-standing history of depression dating back to his college years, was referred by his outpatient psychiatrist for ECT. In his younger days he self-medicated with cocaine, marijuana, and LSD. He reported worsening depression for the past 10 years, despite medication trials of Prozac, Wellbutrin, Cymbalta, Abilify, Adderall, Pristiq, and 25 years of outpatient psychotherapy. His severely depressed mood made him feel "stuck"; he also complained of anhedonia, poor concentration, anergia, amotivation, poor appetite, and hypersomnia. He was "on the edge" of considering death. Home medications included: Lithium 600 mg daily, Effexor 75 mg thrice daily, Ativan 0.5 mg twice daily as needed, and Trazdoone 50 mg.

He was cleared for ECT and underwent 10 index treatments and his MADRS dropped from 35 to 3. He started playing golf again, gardening, cooking, and per wife was back close to his "normal" self. He transitioned to maintenance ECT, during which time he underwent repair of an ascending aortic aneurysm. After clearance, he continued with ECT because he felt he was on one of the most effective treatment regimens. He continued maintenance treatments for approximately 7 months, but then relapsed, as indicated by a MADRS of 44. He underwent 12 index treatments over 6 weeks duration, was taken off both Lithium (due to interaction with Celebrex) and Effexor, and started on Brintellix, titrated from 10 to 15 mg. Over the next three months he received maintenance treatments, with MADRS back down to a 3 during his last five most recent maintenance treatments and remarkably without any cognitive complaints. Brintellix was discontinued during this time due to GI side effects, and he was switched back to Celexa, titrated to 40 mg.

BRIEF HISTORY AND BACKGROUND

Convulsive therapy was introduced in the early part of the 20th century by Ladislas von Meduna as a treatment for severe catatonia in dementia praecox by use of camphor oil injections. In the late 1930s, Ugo Cerletti and Luigi Bini refined convulsive therapy by using electricity to induce therapeutic convulsions, and this formed the precursor of modern-day ECT. Due to its broad applications, and at times misapplications to a variety of psychiatric diseases in the 1940s, as well as its associated cognitive adverse effects, ECT received substantial criticism from both inside and outside the psychiatric community. These critiques of ECT resulted in its limited use, but they also procured its scientific and systematic development as a clinically beneficial and safe treatment modality.

The use of ECT in elderly populations varies by country. In some countries, particularly those with low to middle economies, its use is limited due to financial limitations and legal restrictions. In the United States, its use is higher in elderly patients relative to younger patients based on its effectiveness and elderly patients' intolerance to pharmacological therapy. The National Institute of Mental Health (NIMH) reported in 1980 that approximately 33,000 patients received ECT across the nation, but there was no age demographic reported. A report of elderly patients who received Medicare between the years of 1987 and 1992 found that the rate of ECT use increased each successive year. For example, from 1987 to 1992, the number of patients treated with ECT increased from 12,000 to 15,560, and the use per 10,000 elderly Medicare beneficiaries minimally increased from 3.9 to 4.2 percent. In 2002, a survey of psychiatric hospitals in the United Kingdom showed that of all the ECT treatments administered, 46 percent of the patients were age 65 or older. Exact estimates of patients who receive ECT in the United States are difficult to ascertain as many states do not require reporting laws. However, in the state of Texas, which does have mandated reporting laws, annual reports of ECT use showed that in 2007 a total of 1,772 patients received ECT and of those, 22 percent were over the age of 65, with the

eldest patient treated age 94. Recent population projections estimate that by 2040 the overall population in general will increase by 41 percent, and those over the ages of 65 and 75 will grow by 160 and 268 percent, respectively. Thus, there could be a substantial increase in ECT use given the higher numbers of elderly patients.

Temporal trends in the use of ECT with elderly patients showed that it has increased over time. Trend analysis that examined 12 million Ontario (Canada) residents between 1992 and 2004 compared ECT use between younger (less than age 65) and older (65 years or older) patients. Results found that ECT use remained stable over the 12-year time span with an overall net increase of only 1.1 percent. Interestingly, relative to younger patients, elderly patients were three times more likely to be treated with ECT.

Surveys conducted outside the United States found conflicting results between practitioners who do and do not favor the use of ECT in elderly patients. Of the 306 geriatric psychiatrists surveyed in the United Kingdom in 2002, the majority felt that ECT is a well-tolerated and beneficial treatment for geriatric patients with severe psychiatric disorders, even those patients who are 80 years of age and older. Importantly, the survey pointed out that the role of the ECT consultant needs to be clarified as often the responsibilities of that position may be ambiguous. On the other hand, a 2004 survey of practitioners in the Netherlands suggested that there is hesitation to utilize ECT in elderly patients as a first, second, or third option. While 84 percent of the 152 psychiatrists noted that the use of ECT should be broadened in elderly patients, approximately 54 percent agreed that it should be a first or second treatment option. Equally important, only 15.1 and 13.9 percent indicated ECT as a first-line treatment for major depression with psychotic features or severe suicidal risk, respectively. Collectively, these surveys suggest that the practice of ECT is influenced by practitioner opinion and experience, and that usage estimates vary per country studied.

CLINICAL INDICATIONS

Elderly patients present with multiple psychiatric and medical illnesses. The frequency of reoccurrences and severity of depressive symptoms often increases with age. Severe depression in the elderly confers high levels of functional impairment and morbidity. The elderly are vulnerable to dehydration, weight loss, immobility, and complications from an array of comorbid medical conditions. ECT is indicated for older patients with severe psychiatric illnesses including affective and psychotic disorders, catatonia of any etiopathology, and, in certain cases, neurological disorders (Table 57.4f–1). Within the affective disorders spectrum, ECT can be used to treat both unipolar and bipolar depression, with and without psychotic features. For unipolar depression, ECT may be especially beneficial for

elderly patients with psychotic or melancholic symptoms.

Mrs. C is a 70-year-old Caucasian woman with 2-year history of severe recurrent major depression and three-and-a-half year history of Parkinson disease, initially treated with Sinemet. She was referred by her outpatient psychiatrist for ECT consultation. She was taking Remeron 45 mg nightly and Wellbutrin XL 150 mg daily. She had been switched from Sinemet to Ropinirole, which due to lack of effect was discontinued in November 2014.

Prominent symptoms included: decreased self-care, decreased appetite with 20 pound weight loss within a year, decreased sleep, marked social withdrawal, spending 22 hours a day in bed, and decreased mobility. She was per family "alive, but not living" and "her smile was not there anymore." She stopped watching TV and preferred keeping the shades down. Mrs. C's Parkinson disease was apparently masking her comorbid depression. She was initiated with ECT treatments. She received 11 index course treatments over 6 weeks and her MADRS improved from 47 to 9 with only mild memory dysfunction, namely with concentration and brief postictal confusion. After the 11th treatment, she began maintenance ECT. She reported feeling less tension and sadness. Her family reported increased interest, initiating outdoor activities with her husband, and overall a brighter affect. She also had improvement with Parkinson disease symptoms after the fifth treatment—both her tremors and handwriting improved. Her outpatient psychiatrist decided once she was in the maintenance phase to switch her from Remeron and Wellbutrin XL to Brintellix, which was titrated from 5 to 10 mg. At last ECT treatment, husband reported continued improvement, especially with motivation.

Table 57.4f–1.
Indications for Electroconvulsive Therapy (ECT)

- ► Major depressive disorder with melancholic features
- ► Major depression with acute suicidality
- ► Major depressive disorder with psychotic features
- ► Major depressive disorder intolerant or resistant to pharmacotherapy
- ► Bipolar disorder with acute mania
- ► Bipolar disorder with depression
- ► Bipolar disorder resistant or intolerant to pharmacotherapy
- ► Catatonia (of any etiopathology)
- ► Schizophrenia intolerant or resistant to pharmacotherapy
- ► Prior positive response to ECT

Severe depression is a common psychiatric illness in geriatric patients with estimates in the range of 2 to 5 million patients with severe and subsyndromal depression, respectively. Depression in all forms late in life results in significant mental and physical complications, impaired neurocognitive function, decreased activities and instrumental activities of daily living, and increased morbidity. The World Health Organization reported that among all medical and psychiatric diseases, severe depression was the second leading cause of world-wide disability. Of significant health interests, patients with depression later in life have an increased risk for developing psychosis, suicidal ideation, suicidal intent, and suicidal completion. Thus, it is critical to provide a therapy that has rapid onset of action in order to abate the acute crises.

Geriatric patients with schizophrenia spectrum illnesses may also benefit from ECT, particularly if the psychotic disorder is a new onset,

acutely exacerbated, or treatment refractory. Schizophrenia affects approximately 1.1 percent of the US population, and most geriatric patients with schizophrenia tend to manifest severe positive and negative symptoms that complicate their clinical prognosis and limit their adaptive functioning. Originally introduced for the treatment of schizophrenia, ECT is helpful in ameliorating both the positive and negative symptoms in patients who are nonresponsive to typical or atypical neuroleptic treatments.

Elderly patients often present with affective or psychotic disorders which are secondary to a medical diagnosis. A thorough examination regarding the etiology of the psychiatric pathology should be undertaken to determine the association. In those instances where the underlying cause is related to the primary medical illness, medical care should be implemented. If no improvement is seen in the psychiatric illness, treatment should be initiated beginning with less invasive options (i.e., pharmacotherapy, psychotherapy, social interventions) and incrementally building up to the administration of ECT. However, in cases where there is increased lethality (i.e., catatonia), ECT may be considered as a first-line treatment. Delirium requires an exhaustive evaluation to identify and address underlying etiologies. However, ECT may improve the neuropsychiatric symptoms of this serious syndrome.

Neurological disorders such as Parkinson disease and refractory epilepsy, which afflict elderly patients and result in severe affective or psychotic disorders, are indications for employing ECT. Elderly patients with Parkinson disease may be at increased risk for severe depression, which may improve with ECT. These patients also often have side effects from drug–drug interactions; hence, ECT may be a favorable alternative to pharmacotherapy. Caution needs to be taken though when administering anesthetic agents during the ECT treatment course. Of note, some of the antiparkinsonian medications can result in depressive and psychotic symptoms. A collection of case studies reporting on a total of 22 patients with Parkinson disease found ECT to be beneficial for depressive and parkinsonian motoric symptoms, though considerable relapse in both motor and affective symptoms occurred. Neuroleptic malignant syndrome, a life-threatening condition related to the use of neuroleptic medications, historically in some cases has been treated with ECT. However, ECT is not recommended as a first-line treatment, and prudent use requires careful monitoring of cardiac adverse effects due to pre-existing unstable blood pressure and muscular rigidity, which could be exacerbated during ECT sessions. Because ECT has anticonvulsant properties as seen with subsequent increases in the seizure threshold after each treatment, ECT can be used to treat elderly patients with treatment-resistant epilepsy or those patients with status epilepticus. The risks and benefits must be weighed when applying ECT as other treatments may be more optimal such

as vagus nerve stimulation, which is approved by the U.S. Food and Drug Administration (FDA) for treatment-resistant epilepsy.

Although not routinely performed, ECT can be administered to elderly patients with dementia. Patients with dementia, such as Lewy body or Alzheimer dementia, frequently develop severe affective disorders, which can be treated with ECT if other therapeutic options fail. Case reports and clinical practice have found ECT to be safe and tolerable and in most cases efficacious, with a 40 percent response rate in elderly patients with dementia. The primary dementia does not appear to be exacerbated by ECT. Although results are discordant, recent work has purported that beta amyloid and apolipoprotein E ε4 allele carriage may serve as biomarkers for ECT outcome in general. Nonetheless, in patients who are diagnosed with dementia, the utmost attention must be paid to the progression of the dementia and other neurocognitive effects in order to minimize cognitive impairments. As such, it is prudent to have a neuropsychological evaluation before commencing with ECT. While ECT is rarely utilized to treat combative or agitated behavior associated with dementia, even when other treatments are ineffective, there is limited research that has documented efficacy for those behavioral symptoms. The use of ECT as a therapeutic modality with patients who are diagnosed with dementia may be legally limited in certain states, and the treatment team would benefit from legal consultation regarding consenting procedures and inclusion of the family in acute and longitudinal care plans.

PRE-ECT EVALUATION

A comprehensive evaluation for elderly patients undergoing ECT should include a complete psychiatric history, neurocognitive evaluation, and medical/surgical history (Table 57.4f–2). The evaluation should examine potential proscriptive factors that could limit the effectiveness of ECT in geriatric patients.

Table 57.4f–2.
Medical Evaluation for Elderly Patients Undergoing Electroconvulsive Therapy

- Physical examination
- Neurological examination
- Complete blood count
- Electrolytes
- Thyroid function
- Electrocardiogram
- Anesthesia workup
- Oral/dental examination
- Brain scan (such as magnetic resonance imaging or computed tomography)
- Chest x-ray
- Spinal series (if clinically indicated)

A thorough and comprehensive psychiatric interview should be conducted that ascertains historical and current psychiatric diagnostic and treatment information. Given that elderly patients may have an extensive psychiatric history, it will be advantageous to obtain prior psychiatric records and to include a family member in the interview process to provide corroborating information. The psychiatric diagnosis needs to be elucidated in order to confirm the utility of ECT. Although elderly patients rarely present with primary personality pathology, this psychiatric domain needs to be assessed as research suggests that personality disorders can limit ECT efficacy. For instance, one small study found that patients with borderline personality disorder had limited benefit from ECT and showed greater relapse after the acute ECT course. However, patients in that study were under the age of 65 and limited research has examined the effects of ECT in elderly patients with personality disorders.

Documentation of the psychiatric treatment history is of vital importance as it will have implications for the ECT treatment course. The historical use of ECT in patients has been found to be a predictor of future safety and efficacy. For instance, patients who benefited from ECT are more likely to benefit from future use of ECT, and those patients who showed no benefit may not benefit from ECT. Nonetheless, the prior ECT procedures need to be examined to ensure that ECT was properly conducted and followed American Psychiatric Association–recommended procedures.

Psychotropic medications that were and were not beneficial need to be recorded in order to determine the level of treatment resistance and to plan the prospective acute, continuation, and maintenance treatment courses. Those psychotropic medications that were found to be beneficial may possibly be added to the acute ECT course to enhance the speed of response and therapeutic advantages, and can be used in the continuation and maintenance phases to prolong remission. Collection of the antidepressant treatment history can be facilitated by standardized forms such as the Antidepressant Treatment History Form (ATHF). For example, the ATHF allows for the quantification of antidepressant medications in order to determine the adequacy of the treatment and the level of therapeutic resistance. Collaboration between the ECT practitioner and the geriatric psychiatrist at the initial psychiatric interview can lay the foundation for successful psychiatric treatment and provide an accurate understanding of the elderly patient's psychiatric pathoses.

A clinician privileged to administer ECT and an anesthesiologist should collect comprehensive medical and surgical histories. Ideally, this evaluation will occur as close as possible to the initial ECT session. Prior surgeries, ECT treatments, and exposure to anesthesia should be

ascertained. Specifically, personal or family histories of malignant hyperthermia or other difficulties with anesthesia must be queried. Elderly patients may have multiple gastrointestinal, dental, cardiac, respiratory, musculoskeletal, or neurological disorders that could complicate anesthesia or ECT procedures. Cardiovascular diseases are a major area of concern for increasing morbidity and mortality in the treatment of elderly patients. These include recent myocardial infarctions (generally occurring within 6 months), congestive heart failure, coronary artery disease, aneurysms, and valvular disease. Brain tumors or conditions that increase intracranial pressure also present unique safety concerns. These conditions require careful clinical judgment, and in some cases (i.e., large, rapidly growing, or metastatic tumors) will present a clear contraindication to ECT. Recent hemorrhagic and ischemic strokes or conditions that predispose patients to cerebral vascular bleeding also pose significant safety risks. Poor dentition, loose teeth, and dentures should be evaluated as special precautions (i.e., customized bite block) may be required during the ECT treatment.

Elderly patients also require a careful physical examination with emphasis on the neurological examination (including funduscopic examinations to assess for papilledema) and dental, cardiac, respiratory, gastrointestinal, and musculoskeletal systems. Medical or specialty consultation for elderly patients can assist the ECT practitioner with the optimization or understanding of an illness rather than providing only "clearance" for ECT. The laboratory evaluation should be individualized and congruent with clinical indications. However, ECT centers should mandate minimum standards for this patient population, which should include a complete blood count (CBC), electrolytes, chest radiographs, and an electrocardiogram. Spinal radiographs should be considered in any geriatric patient with back or neck pain. Brain computed tomography (CT), magnetic resonance imaging (MRI), and electroencephalogram (EEG) are not routine or mandated, but may be more beneficial and prudent in this population as compared to young adults.

The elderly patient's current and prior pharmacotherapy should be reviewed due to interactions between different medications and ECT. Mood stabilizers, such as lithium, taken during the ECT treatment can increase the incidence of delirium after the ECT treatment, and can impact the seizure expression. The unique classes of antidepressant medications differentially impact ECT with certain classes enhancing and others interfering with ECT. Monoamine oxidase inhibitors (MAOIs) can cause drug–drug interactions with anesthetic agents and should be discontinued before beginning ECT treatment. Tricyclic antidepressant medications (e.g., nortriptyline) are usually safe to use with ECT and may increase the therapeutic benefits. Use of selective serotonin reuptake inhibitors (SSRIs) in combination with ECT has received limited attention, but use of selective serotonin-norepinephrine reuptake inhibitors (SNRIs), such as

venlafaxine, has been shown to be beneficial when combined during the acute and maintenance ECT course. Most antipsychotic medications have a synergistic effect with ECT; that is, the combined use of psychotropic medications and ECT can magnify the therapeutic effects. However, augmenting ECT with reserpine should be avoided as it could increase the incidence of mortality. For patients with comorbid anxiety who use benzodiazepines, usage of those medications can reduce the seizure duration and should be tapered or discontinued before treatment initiation. Also, anticonvulsant medications should be tapered or discontinued 24 hours before each ECT treatment as they inhibit seizure induction and may result in increased stimulus dosage relative to seizure threshold in order to elicit beneficial seizure activity. More research is warranted to decipher pharmacotherapy and ECT augmentation strategies, particularly with newer antidepressant and antipsychotic medications.

NEUROCOGNITIVE ASSESSMENT

Neurocognitive assessment of an elderly patient who receives ECT should be conducted before, during, and after the treatment course by a qualified clinical neuropsychologist. The assessment before and after the treatment course should comprehensively assess neurocognitive functions including premorbid intellectual ability, processing speed, attention, verbal and visuospatial memory, working memory, and executive function. Such a comprehensive evaluation allows for the establishment of a baseline to quantify the neurocognitive impact after the treatment course. Also, the baseline testing will aid in ruling out a diagnosis of primary dementia or delirium. Measuring neurocognitive functioning during the treatment course provides treatment-specific information to gauge the effects of ECT.

A thorough neurocognitive examination of patients considered for ECT may not be necessary unless there are indications of severe neurocognitive impairment. For example, research has found that certain cognitive domains such as executive function, attention, and processing speed are minimally impacted by ECT. The cognitive domain that has received the majority of attention is memory. An acute course of ECT has an immediate impact on anterograde learning and memory, but these effects tend to be transient and resolve within a week after the end of the acute phase. Thus, the practitioner designing and administering the neurocognitive battery needs to balance the information to be acquired with patient burden. Especially for elderly patients, neurocognitive assessments can be taxing and counterproductive as the information can be compromised due to fatigue and decreased effort.

Table 57.4f–3.
Neurocognitive Assessment Before, During, and After Electroconvulsive

Therapy (ECT)

Before and after ECT	**Global Cognitive Function** ► Attention ► Executive function ► Learning and memory ► Confrontational naming ► Verbal fluency ► Visuospatial construction **Retrograde Memory** ► Personal information ► Impersonal information
During ECT	**Time to Orientation** ► Eyes open ► Name ► Age ► Day of week ► Place ► Date of birth
After ECT	**Retrograde Memory** ► Personal information ► Impersonal information **Executive Function** ► Cognitive flexibility ► Social interaction

At minimum, before and after the ECT course, the neurocognitive domains to be assessed include global cognitive functioning and retrograde memory (Table 57.4f–3).

In most clinical practices, global cognitive functioning is typically assessed and usually with a standardized measure such as the Mini-Mental State Examination (MMSE) or the Montreal Cognitive Assessment (MoCA). A short measure such as the MMSE or MoCA gathers information to determine whether further tests need to be administered to clarify if any other neurocognitive deficits are present. Measuring global cognitive function succinctly taps into many cognitive domains in a short period of time (e.g., within 5 to 10 minutes), and is usually well tolerated by most elderly patients. Unfortunately, the MMSE, MoCA, and other common measures of global cognitive function are insensitive to the effects of ECT. Consequently, the baseline information will provide limited data to guide clinical treatment. Should those measures be used, it would be beneficial to use age- and education-adjusted normative data, such as found in the Mayo's Older Americans Normative Studies, to account for the age-specific effects on those measures and to fully appreciate the ECT-associated effects.

The data generated from global cognitive function measures can be strengthened by also assessing retrograde memory. To accomplish this,

standard scales can be employed that measure autobiographical information for personal and impersonal details. Personal information regards unique information such as a prior birthday or employment history, whereas impersonal information regards information more of a "pop-culture" nature such as a famous person, famous television program, or a well-known event. If a standard scale is not used, the patient can be quizzed using information gathered from the clinical interview and corroborating information from a significant other. An investigation of 50 patients who were randomized to receive either right unilateral or bitemporal ECT found that patients showed a propensity to recall more personal information as opposed to impersonal information, regardless of the ECT stimulus dosage or efficacy outcome. However, relative to patients randomized to receive right unilateral ECT, those who received bitemporal ECT showed greater retrograde amnesia for personal and impersonal information. An important aspect of this study was the measurement and quantification of retrograde amnesia with a novel scale, which had the advantage of being directly translated into clinical practice. To increase the validity of the retrograde memory assessment, corroborating information should be gathered from a significant other.

During the treatment course, a main domain of cognitive function to assess is orientation, especially the time required to achieve full reorientation after each ECT session. Research has consistently shown that ECT has an impact on orientation and causes a period of disorientation immediately after each ECT session. A historical study compared bitemporal and right unilateral ECT, and found that bitemporal ECT resulted in lengthier times to recover full orientation compared to right unilateral ECT. Although the study involved a small number of patients, it generated invaluable information and set a precedent for quantifying disorientation with an easy-to-use structured method. This method involves a clinician to administer an orientation questionnaire. With a stop-watch or other method to measure time, timing starts as soon as the patient is able to breathe without assistance and ends when the patient accomplishes five out of six orientation criteria. These criteria include opening eyes and correct verbalization of name, place, day of week, age, or date of birth. In one study, time to orientation was associated with the magnitude of retrograde amnesia (i.e., the lengthier time required to achieve orientation results in greater retrograde amnesia); however, this finding has yet to be replicated. Factors such as type of lead placement, dosage level, and pulse waveform, have been found to affect time to orientation, with bitemporal placement, higher dosages relative to seizure threshold, and sine wave resulting in longer times to achieve orientation. Ultimately, neurocognitive functioning is important to assess in order to quantify adverse effects of ECT and to assist in clinical decision making.

CONSENT

Informed consent is not a one-time event; rather, it is a continual process. As such, the initial consenting meeting is a vital component of the ECT treatment as it sets the stage for the consent process. Consenting procedures before ECT is initiated are important, particularly for geriatric patients, given that there may be neurocognitive compromises related to the underlying illness. Many patients with psychiatric illnesses may lack the complete ability to provide informed consent, particularly those with a psychotic disorder, and this can conflict with the provision of treatment. Table 57.4f–4 provides suggested recommendations when obtaining informed consent.

Prior to signing the consent form, prospective patients need a complete and thorough explanation of what ECT consists of, the procedures that will take place, the associated effects (both positive and negative), the length of the treatment, alternatives to treatment, and the continued care after the acute ECT course is completed. All of this should be written in the consent form that the patient will sign. Having an open forum of Socratic questions and answers makes this process informative and respects the patient's autonomy. This initial meeting can be further enhanced by watching a video of the ECT treatment with the patient and clarifying any related questions. The inclusion of the video ensures a comprehensive explanation of the ECT treatment and utilizes multimodal means of learning to help ensure that the patient is fully informed. Further, the initial consenting session can facilitate the establishment of trust between the patient and the doctor, clarify misconceptions, and help demystify ECT as many elderly patients may view it as a negative treatment.

Table 57.4f–4.
Suggested Informed Consent Procedures for Geriatric Patients Receiving Electroconvulsive Therapy (ECT)

- ► Follow all local, state, and federal guidelines for the proper administration of ECT.
- ► Qualify the patient's capacity to provide informed consent.
- ► Engage in an open conversation with the patient and a family member if available regarding the ECT treatment and the rationale for administration.
- ► Utilize multimedia aids such as videos documenting an ECT treatment. Elicit feedback from the patient and answer any questions that arise.
- ► The consent form must describe all aspects of the ECT course including indications and contraindications in individual patients for ECT, ECT treatment procedures, anesthesia, adverse effects and respective benefits, alternatives to treatment, and rights to decline ECT treatment.
- ► Use a standardized questionnaire to assess if the patient understands the consent form.
- ► Have a witness cosign the informed consent form.
- ► Document the consent process in the medical record.
- ► Provide the patient with a copy of the signed consent form and place a copy in the chart.
- ► Informed consent is a process, not a one-time activity, that must be monitored throughout the ECT course.

Building a supportive network for the patient is advantageous during and after the ECT treatment, and the consenting session is an ideal setting to lay that framework. The physician obtaining consent should invite a family member or caregiver to attend the informed consent meeting. This will allow for a thorough discussion of the ECT treatment process, allow the patient to feel that he or she is not alone, and provide the patient with someone to talk to after the discussion. Although it may not be required, having a family member cosign the consent form provides further assurances that consenting procedures are being followed. For example, a retrospective chart review of 62 geriatric patients who received ECT in the New York state area found that 75 percent of those charts contained a family member's cosignature, even in cases where the patient was documented to have capacity to provide informed and voluntary consent. For elderly patients who are cared for at home, the family member is a vital component to the consent process and the overall treatment, as he or she will be primarily responsible for ensuring that the patient receives the appropriate aftercare. Also, the family member may have unanswered questions and negative stigmas associated with ECT that can be clarified in the consenting session.

A common procedure to perform before treating a patient is to assess the patient's capacity to provide informed consent, especially for those patients who may have neurocognitive impairments. To provide informed consent, a patient must have the ability to provide voluntarily and fully informed consent. To assess for consenting, the clinician (i.e., nurse, physician) should review the medical chart, acquire the patient's educational history and information, and administer a global cognitive examination such as the MMSE. These procedures will help guide the clinician in determining the level of capacity by which prospective plans can be arranged. For instance, should the patient have limited understanding of his or her condition and treatment options, additional education regarding ECT, including a family member, and having the patient answer a questionnaire may help to increase the decision-making ability. An empirical study conducted at the Mayo Clinic comparing geriatric (mean age: 75.6, standard deviation [SD] = 5.87) and nongeriatric patients (mean age: 41.9, SD = 8.01) randomized to an additional half-hour session of education regarding ECT provided in a one-on-one format with a psychiatrist found that the provision of extra education increased the patient's knowledge base to inform his or her treatment decision. An elaborate battery of neuropsychological tests can be administered to comprehensively assess for any neurocognitive impairment; however, those procedures may not be necessary and could overburden the patient. Nonetheless, they are available to the physician and could be a source of additional information.

Although it may be rare, some patients may be unable to voluntarily

consent. This could be due to myriad factors including the psychiatric illness (i.e., catatonia), limited ability to make decisions, or blatant refusal. For those patients unable to voluntarily provide consent, the consenting physician should ask for an ECT consultation. The outside ECT consultation, usually performed by the chief of ECT services for the hospital, provides for a secondary opinion of the patient's decisional ability and the immediacy for treatment. Particularly for those patients who refuse ECT, the secondary opinion provides further justification for the dire need of treatment based on the safety of the patient and others, and can be used in legal proceedings to attain court-ordered treatment. As in voluntary consent, it is beneficial to include a family member in this process. The inclusion of the family member can help to mitigate any coercion or perception of coercion of the patient.

The consent process should be completely documented in the patient's medical record including the number of meetings, who was in attendance, educational aids used, neuropsychological tests administered (if any), and the signed consent form. A copy of the signed consent form should be given to the patient. Since the consenting requirements and regulations can vary by state, it is critical to understand the respective laws for the consenting of the patient to receive ECT. For example, in the state of Texas, the patient is reconsented before each ECT treatment is provided. The reconsenting of the patient at each treatment further substantiates that consent is not a one-time decision; rather, it is a continual process and the patient or family member could have new questions arise through each phase of the treatment.

ECT PROCEDURES

Anesthesia

All ECT treatments are provided while the patient is under general anesthesia and for elderly patients an anesthesiology consultation is of significant importance in order to determine the optimal anesthetic doses and minimize side effects. The anesthesia consultation should occur before the first treatment. Anesthetic doses should be re-evaluated before each treatment with subsequent dosage adjustments based on the outcome of the prior treatments. Different classes of anesthetic medications are delivered including neuromuscular blocking agents and hypnotic agents. The interactions between anesthesia and ECT can affect clinical outcome, making it essential to have input and collaboration between the anesthesiologist and the ECT practitioner. For example, certain hypnotic agents can raise the seizure threshold, thereby inhibiting the production of seizure activity and resulting in a postponement of clinical efficacy. Hence, the provision of ECT in elderly patients is dependent upon multidisciplinary team work.

Age-related physiological changes must be taken into account when providing anesthesia during ECT. Many elderly patients age 65 years and older will have slow conduction in peripheral nerves, increased systolic blood pressure, reduced cardiac function, decreased hepatic metabolism, and decreased circulation time. These physiological changes can result in potential delayed onset of anesthetic action as well as prolonged elimination. This can affect the ECT treatment in various ways. For example, as the seizure threshold is already high in elderly patients, proper dosage and timing of administering hypnotic agents must take into account the eliciting of a therapeutic seizure; otherwise, the ECT treatment may be ineffectual. Also, the administration of succinylcholine, a muscle relaxant, must be timed accordingly so that the body is relaxed upon ECT initiation in order to minimize muscle contraction and to allow the patient to regain muscle control in parallel with regaining consciousness.

Different hypnotic agents have been used during ECT treatments, each with their respective physiological properties that impact the ECT expression. A small study that compared the effects of different doses of methohexital, propofol, and etomidate in 10 patients with an average age of 54 years (range: 27 to 81 years) who received bilateral ECT found that propofol and methohexital at high doses significantly suppressed EEG seizure activity. Also, the use of etomidate, although it had minimal effects on seizure expression, resulted in prolonged recovery of cognitive function. A separate small study in seven patients with an average age of 42 years found that methohexital, with part of the dose substituted with remifentanil, produced prolonged seizures relative to methohexital alone. With the different anesthetic agents available and various administration techniques, expertise is paramount in synergistically pairing ECT and anesthesia.

With the use of anesthetic agents, there is the potential risk of increased confusion or disorientation after the ECT treatment. This side effect becomes critical when providing ECT to elderly patients as they are at an increased risk of ECT-associated adverse cognitive side effects in addition to normal age-related cognitive decline. One small study compared the cognitive adverse effects of anesthesia with etomidate or ketamine in ten patients and found that short-term memory, as assessed by asking the patients to recall the names of four objects, was less affected by ketamine. The significance of this study is that it showed that different types of anesthetic medications can differentially affect cognitive function after the ECT treatment; however, the conclusions were limited by a small sample size, underdosage of the ECT treatment (i.e., provided right unilateral ECT at 200 percent above seizure threshold), and the fact that short-term memory was only measured with one nonstandardized cognitive test. On the contrary, in small documented cases, ketamine has been found to result in visual hallucinations, and thus is rarely used in current clinical practices.

Treatment Parameters

ECT treatment parameters can significantly affect its efficacy and tolerability. The three parameters that interact are pulse waveform, electrode placement, and stimulus dosage. Regarding pulse waveform, the first waveform introduced, and the one that generates the greatest neurocognitive adverse effects, is the sine waveform. Although this waveform is rarely used due to technological enhancements in ECT devices and newer pulse waveforms (e.g., ultra-brief), a large-scale research study found that it is employed in some psychiatric practices. However, the majority of academic and public institutions that provide ECT do so with brief or ultra-brief pulse waveform. These two waveforms result in equivalent efficacy of sine wave, but produce minimal neurocognitive side effects. Ultra-brief is the latest waveform developed and has been associated with faster rates of time to orientation after treatment, less neurocognitive adverse impact, and equivalent efficacy.

There has been and there still remains debate as to what is the appropriate site placement for the ECT electrodes. There have been various electrode placement sites studied over the years of ECT research, and three sites have received considerable attention, those being bitemporal, right unilateral, and bifrontal (Fig. 57.4f–1). For all electrode placements, the patient's scalp will need to be prepared by applying a topical prep solution to clean the scalp, which will reduce impedance and allow maximum passage of the electrical stimulus.

For bitemporal electrode placement, each electrode is placed on each temple 1 inch above the midpoint of the line extending from the tragus of the ear to the external canthus of the eye. For right unilateral, one electrode is placed on the right temple 1 in above the midpoint of a line extending from the tragus of the ear to the external canthus of the eye and the other electrode is placed 1 in to the right of the vertex. For bifrontal, each electrode is placed 2.5 in above the outer external canthus of the eye. Bitemporal electrode placement was the first electrode placement used and has been shown to be significantly advantageous relative to the other two placement sites in terms of speed of response and remission. However, right unilateral placement, six times above the seizure threshold, has been shown to produce equivalent response and remission rates despite requiring more time while also having minimal adverse neurocognitive effects. Bifrontal placement has received nominal attention, but has shown high efficacy rates coupled with low adverse neurocognitive effects.

FIGURE 57.4f–1. Electrode placement sites. (From Lisanby SH. Electroconvulsive therapy for depression. *N Engl J Med. 2007;357(19):1939–1945.)*

Stimulus dosing can be performed with one of two methods, either the age-based method or the empirical titration procedure. Both procedures have been found to produce successful inductions of therapeutic seizures. In general, with the age-based method, stimulus dosage is adjusted by age, with younger age groups treated at low doses and older age groups treated with higher doses. Some clinicians prefer age-based titration methods because they may limit the number of subconvulsive stimuli. Regarding this method, either full-age or half-age dosing formulas can be applied. The full-age formula (dose = patient age multiplied by five) is more appropriate to use with right unilateral ECT as it typically equates to doses 250 percent above the seizure threshold. On the other hand, the half-age formula (dose = patient age multiplied by 2.5) is more fitting with bilateral placement and results in doses approximately 250 percent above the seizure threshold. The age-based methods, though, do not account for intraindividual variability, which could equate to the provision of markedly elevated stimulation with significant cognitive adverse effects.

The empirical titration procedure has been shown to sustain efficacy while limiting adverse effects through containment of unnecessary energy. This procedure involves the delivery of an initial stimulus dose, followed by restimulation with increased intensity until a 20- to 25-second interval of motoric or EEG manifestation of a seizure is observed. As found in clinical and research practice, seizure threshold increases with age; thus, elderly patients require higher doses to achieve grand malseizures. Even titration procedures are altered for elderly patients. Whereas with younger patients, those below the age of 50, the first stimulus may be administered at 5 percent, for elderly the starting stimulus is administered at 10 percent. Stimulus dosing is also influenced by the choice of electrode placement. For subsequent treatments after the ECT titration session, bilateral and bifrontal electrode placement dosing is administered at moderately suprathreshold levels, defined as 150 percent above the seizure threshold. On the other hand, right unilateral ECT placement dosing is administered

at moderately to markedly suprathreshold stimulation, which is 250 to 600 percent above the seizure threshold (2.5 to 6 times threshold). These dosing strategies have been extensively researched and tested in order to ascertain the therapeutic effects.

Specific ECT Recommendations

During the administration of ECT, the induced seizure should be monitored via EEG and motoric response recordings. The EEG monitoring shows characteristic patterns of the grand malseizure as well as the postictal suppression. The sites for recording the EEG are the frontal-mastoid and frontal-frontal montage, which will maximize the EEG seizure expression. During the tonic phase, hypersynchronous polyspike complexes are followed by polyspike and slow-wave complexes, and during the clonus phase are followed by sudden or gradual suppression. Most ECT-induced seizures last less than 90 seconds and consequently are deemed inadequate if they do not show bilateral generalization on EEG manifestations. For monitoring motoric expressions, the cuff technique can be used. This procedure involves applying a blood pressure cuff to a limb (i.e., arm or leg) before the administration of a muscle relaxant. Commonly, the cuff is applied just above the ankle of the left leg in order to observe ECT motor manifestations.

Continuous monitoring of hemodynamic functioning continues throughout the ECT treatment session. This is essential for anesthesia and the rapid shifts in parasympathetic and sympathetic outflow that occur after the electrical stimulus. As the patient receives the electrical stimulus, increased parasympathetic tone can produce asystole or significant bradycardia. These hemodynamic effects can be aggravated by subconvulsive stimuli or medications. The ECT-associated bradycardia can be mitigated by pretreatment with anticholinergics such as atropine or glycopyrrolate. During the seizure, heart rate and blood pressure generally elevate and are followed (sometimes after many minutes) by a period of bradycardia. As a result, geriatric patients with any cardiac condition often require additional monitoring, management, and medications to dampen these effects.

Patients with Comorbid Medical Diagnoses. Many elderly patients have pre-existing cardiovascular diseases such as hypertension, angina, arrhythmias, aneurysms, conduction abnormalities, and previous myocardial infractions. Consultation with a cardiologist prior to ECT for optimum management is warranted in these situations. Possible concerns involve the increased vagal (parasympathetic) tone during and shortly after each electrical stimulus, which can evoke brief bradycardia or asystole. The onset of the therapeutic seizure leads to elevations in heart rate and blood pressure. Postictally, there is a second period of heightened vagal tone

evidenced by bradycardia and ectopic beats in some patients. With careful management, cardiovascular risk can safely be mitigated in these situations. Anticholinergics such as glycopyrrolate and atropine given prior to ECT can subvert cardiac arrhythmias. Short-acting β-blockers such as esmolol and labetalol are often helpful in controlling hypertension and tachycardia during treatments. Other cardiac agents (such as nifedipine, hydralazine, trimethaphan, and nitroglycerin) can be used if indicated.

Intracranial mass lesions or increased intracranial pressure presents a serious risk factor for ECT. Optimally, subdural hematomas will be removed prior to treatment. Elderly patients with depression and who present with previous cerebral infarctions can benefit from ECT. However, the amount of time that should pass after a stroke to maximize safety is unknown. Otherwise, the incidence of cerebrovascular complications is minimal.

Osteoporosis, spinal disc disease, and spondylolysis may necessitate a higher level of muscle relaxation during ECT. Neurosurgical consultation for ideal management prior to treatment is advisable in these situations. Pulmonary status must also be maximized prior to treatment. Unique ventilation strategies may be employed for patients with lung disease.

ECT leads to transient increases in intraocular pressures. Patients with glaucoma should receive eye drops prior to treatment. Collaboration with ophthalmologists for patients with retinal detachments and acute close-angle glaucoma is essential. Patients with loose, uneven, or decayed teeth are at risk for dental injury with ECT. Dental consultation and unique block strategies may need to be employed in this setting.

ACUTE CLINICAL SAFETY AND EFFICACY

ECT is regarded as one of the safest and most effective somatic treatments for severe major affective disorders, particularly those for which alternate treatments have been ineffective. Its safety compares favorably to other procedures that require general anesthesia. The American Psychiatric Association Task Force on ECT, National Network of Depression Centers Task Force on ECT, and the National Institute for Health and Clinical Excellence in the United Kingdom suggest that ECT is an efficacious acute treatment. In many systematic controlled trials, ECT has consistently been found to be superior to sham ECT (i.e., patients received only anesthesia) and pharmacotherapy.

The remission rates following an acute course of ECT have been found to vary between 20 and 80 percent with an effect size as large as 0.9. This large range is dependent on an interaction of both ECT treatment parameters and patient clinical factors. For instance, in order for ECT to be effective, it must be appropriately applied with the respective therapeutic dosage, pulse waveform, and electrode placement. A controlled trial that compared fixed high-dose right unilateral and bitemporal ECT in elderly

patients with major depression showed both electrode placements to be similar in terms of clinical outcome with comparable remission rates. In the Consortium for Research in ECT (CORE) study, which investigated the safety and efficacy of continuation ECT, approximately 80 percent of the total sample achieved remission during the acute phase with bitemporal, dose titrated, brief pulse waveform ECT. Patients were treated three times a week and standardized depressive rating inventories were collected within 24 to 48 hours after each treatment to systematically monitor mood change. Thus, a major conclusion of this study was that ECT can result in substantial acute efficacy when treatment is judiciously applied following a standardized therapeutic protocol with continual monitoring of patient symptom severity.

The significant benefit of ECT rests not only with its therapeutic benefits, but also with the speed at which response and remission are achieved. Analyses from the CORE trial of 253 patients found that approximately 54 and 83 percent of the sample achieved response (decrease in depression severity as measured by a standardized rating scale by a minimum of 50 percent) by the third and sixth ECT treatments, respectively. In terms of remission (level of depression severity found in the normal population), 65 percent of the sample met criteria for remission by the tenth ECT treatment. Elucidating the speed with which ECT works, between the fourth and ninth ECT treatment, remission rates increased from 10 to 60 percent. Given that pharmacotherapy may take many weeks to achieve steady state and produce results, and psychotherapy likewise may take time for results to show, ECT is a prime therapeutic choice for those patients who are in critical condition due to acute and severe psychiatric illness.

Early retrospective studies that utilized chart reviews found conflicting results, with some indicating ECT to be ineffective for elderly populations and others finding it to be both safe and efficacious. With technological improvements and advances in ECT practice, recent controlled clinical trials have found ECT to be highly effective in elderly patients. Comparisons with tricyclic antidepressants, monoamine oxidase inhibitors, and even selective serotonin reuptake inhibitors found ECT to be superior. In fact, age has been found to be an influencing factor for the therapeutic effects of ECT. A report from the CORE trial showed that age was positively associated with treatment response and subsequent remission. In that report, 90 percent of the elderly cohort relative to 64 percent of the younger cohort responded with ECT. Further examination of the data discovered that the greater response was only valid for those patients with psychotic features and suggested that the presence of psychosis and older age interacted and resulted in higher response rates. That is, elderly patients without psychotic features and younger patients showed comparable response rates, but elderly patients with psychotic features

showed higher rates of response relative to younger patients.

Electroconvulsive therapy is a highly effective treatment for the majority of elderly patients, even those who are 75 years and older. A prospective study of 268 patients examined three categories of elderly patients: those younger than 60 years of age, those between 60 and 74 years, and those aged 75 or older. Although the younger cohort had relative lower seizure thresholds, no differences were found between groups concerning the number of treatments or electrode placement. The middle cohort was found to have higher response rates compared to the younger cohort, but no efficacy differences were found between the middle and older groups. This study found that ECT is beneficial for the oldest-old and confirmed earlier clinical reports that older age is positively associated with higher seizure threshold levels.

The effectiveness of ECT is paralleled by its timeliness in onset of response, which may result in shorter and less costly hospital stays. A small controlled trial of 13 patients over the age of 65 found a 21 percent reduction in depression severity (as rated on a standardized scale) after the first ECT treatment, and a 36 percent reduction after the second. The depressive symptom impacted most after the first treatment with a decrease of 36 percent was "reported sadness." On average, four treatments resulted in a decrease of depression severity by 50 percent, though the investigators cautioned that response varied per individual case and that further research was required to assess the time to response and remission in elderly patients. To a degree, these data are synonymous with the findings of the CORE trial, which found ECT to have a quick onset of action.

Electroconvulsive therapy may be judiciously applied to a spectrum of geriatric patients with comorbid illnesses including cerebrovascular disease or dementia; however, there is a dearth of information from systematic randomized controlled trials. Retrospectively, chart reviews and clinical reports support ECT to be efficacious in the treatment of severe mood disorders in elderly patients with concomitant dementia, neurocognitive impairments, or stroke. The presence of cerebrovascular abnormalities did not minimize the therapeutic response; nonetheless, when applying ECT to geriatric patients in the presence of concomitant cerebral pathologies and dementias, prudent observation and monitoring of symptomatology and adverse neurocognitive effects become paramount.

Optimal benefit from ECT in elderly patients is dependent upon eliciting therapeutic seizures. Both clinical and research practice have shown that elderly patients have higher seizure thresholds and thus require higher doses of electrical stimulation. One controlled trial reported that in 20 patients, two required stimulus doses that exceeded the levels available on commercial ECT devices in the United States. The FDA has limited the ECT devices to 576 millicoulombs; as such, a small percentage of elderly

patients with remarkably high seizure thresholds may not benefit due to the inability to elicit seizure activity.

CONTINUATION AND MAINTENANCE ECT SAFETY AND EFFICACY

A cogent constraint of ECT is the high relapse rate after completion of the acute treatment course with proneness for relapse being greater during the first week and month after remission. Consequently, though elderly patients may show better response and remission with ECT relative to younger patients, they may also have higher rates of relapse. One study that followed 51 elderly patients for 1 year during and after treatment with either ECT or pharmacotherapy treatment for major depression found that 41 percent of the total sample was rehospitalized at least once within the first year, and 46 percent (6 of 13) of the ECT group was rehospitalized during the first month after acute treatment.

Many factors may contribute to the high relapse found following a successful acute course of ECT including residual depressive symptoms, concomitant physical illness, and psychosocial factors. Residual depressive symptoms are those symptoms that did not abate with antidepressant treatment that could substantially increase the risk of reverting back to baseline status, or could be a precursor to the development of a new depressive episode. Many elderly patients who suffer from comorbid physical illness may be burdened with additional stressors that complicate continued recovery from the acute phase. Poor physical health, specifically cardiovascular disease and diabetes, has been linked to both affective and anxiety disorders. Thus, elderly patients with comorbid physical medical illnesses may be more at risk for re-experiencing a return of psychiatric pathology after a period of remission. Finally, elderly patients with increased psychosocial stressors such as lack of autonomy, living alone, or decreased activities and instrumental activities of daily living may be more susceptible to relapse occurrence. Nonetheless, the goal of continuation and maintenance therapy is to sustain the period of remission while simultaneously limiting the associated adverse effects.

The question that arises is what is the best method to achieve the above goal, a question that has received much attention. The CORE trial was designed to determine whether continuation pharmacotherapy (lithium plus nortriptyline) or ECT (bilateral electrode placement 150 percent above the seizure threshold) resulted in a better outcome, and the results indicated that both were equivalent in prolonging remission. Of the patients randomized to the continuation ECT condition, 37.1 percent relapsed and 46.1 percent retained remission. For those in the continuation pharmacotherapy group, 31.6 percent relapsed and 46.3 percent retained remission. The time to relapse was similar in both groups with patients in the ECT arm relapsing after an average of 9 weeks and those in the pharmacotherapy arm after an average of 6 weeks. Although both of these

therapeutic modalities were deemed better than no treatment after attaining remission in the acute ECT phase, they were moderately effective in retaining the antidepressant benefits produced during the acute ECT phase.

A probable benefit of maintenance therapy with ECT is the lack of drug–drug interaction. Elderly patients usually receive multiple medications for management of physical health-related issues. The resulting polypharmacy from mixing a multitude of medications such as antidepressants, mood stabilizers, analgesics, and cardiac medications could result in iatrogenic effects. Moreover, elderly patients may be sensitive to pharmacological properties of medications and proper administration must be monitored to ensure attainment of the full therapeutic effects while limiting harmful reactions. In such cases where elderly patients are extremely sensitive to the effects of medications, or they have a coexisting medical condition that limits the use of psychiatric medications, ECT can be a viable alternative. However, given the cardiovascular adverse effects of ECT in elderly patients, especially those with pre-existing hypertension or unstable cardiac activity, continued ECT use needs to be combined with careful and comprehensive monitoring of cardiovascular functioning. For instance, one study of patients over the age of 75 found the development of transient hypertension and sinus tachycardia during and after the administration of ECT. Although the transient phenomena were considered "normal," they still merit monitoring and evaluation.

ECT ADVERSE EFFECTS

ECT is one of the safest and well-tolerated somatic treatments with a documented mortality rate of 0.002 percent. The majority of side effects are limited to the time during and immediately after an ECT treatment, with the majority of side effects persisting for a short period of time after a complete acute course, and others lasting for a longer period of time (i.e., 6 months and longer) (Table 57.4f–5). Three broad side-effect categories for ECT are systemic, neurophysiological, and neurocognitive.

Table 57.4f–5.
Side Effects Related to Electroconvulsive Therapy

- Headache
- Hypertension
- Cardiac arrhythmia (bradycardia, tachycardia, asystole)
- Nausea
- Tongue bite
- Temporomandibular joint pain
- Disorientation
- Delirium
- Anterograde amnesia

- Retrograde amnesia
- Prolonged seizure
- Precipitation of mania
- Drug–drug interactions
- Anesthetic complications
- Aspiration
- Breathing complications
- Myalgias
- Dental complications
- Postseizure myocardial infarction
- Postseizure stroke
- Tardive seizure
- Scalp burn (very rare)
- Bone fractures (very rare)
- Spinal disc prolapse (very rare)
- Compression fracture (very rare)

Systemic Effects

Mortality associated with ECT is most commonly attributed to cardiovascular or respiratory complications. Death can result from myocardial infractions or ruptured arrhythmias, ruptured aneurysms, and brain herniations. Pulmonary aspiration is rare, but particularly important to prevent in patients with chronic lung disease. Short-lived increases in blood pressure, pulse, cerebral blood flow, and intracranial pressure present risks for elderly patients, but in the majority of cases are well tolerated. Ideally, the modern practice of using muscle relaxants prevents fractures that often occurred in the early days of ECT practice. Patients can still suffer from dental complications (i.e., fractured teeth, temporomandibular joint pain) or complain of myalgias, but these risks are extremely rare with the advent of anesthesia and placement of bite blocks. Muscle pain can be related to the use of depolarizing agents such as succinylcholine, and headaches can be successfully treated with over-the-counter analgesics and often improve with time. Pretreatment for musculoskeletal pain can also be beneficial in certain cases. Some elderly patients complain of nausea and vomiting following ECT sessions. Antiemetics such as ondansetron, metoclopramide, and prochlorperazine can be administered to treat these symptoms or prophylactically prior to ECT.

Neurophysiological Effects

Research involving humans and animals indicate that neither ECT nor brief seizures impart structural brain damage. This is further substantiated by carefully controlled imaging studies. However, seizures lasting more than 180 seconds should be aborted with an anticonvulsant anesthetic agent or a benzodiazepine. Lengthy seizures and status epilepticus could theoretically lead to neuronal injury if the patient becomes hypoxic. This is unlikely,

though, as ECT patients are well oxygenated and most prolonged seizures are easily suppressed. Spontaneous seizures after treatment are rare, but in their event require careful evaluation and management. Postictal delirium can involve disorientation, agitation, and confusion and is best managed with supportive interventions, minimization of environmental stimuli, and judicious use of medications such as benzodiazepines.

Neurocognitive Effects

The neurocognitive effects of ECT are likely the most limiting factor for the provision of this therapeutically beneficial treatment. Numerous studies have systematically examined the neurocognitive sequelae associated with ECT, taking into account various ECT parameters and neurocognitive domains, as well as the effects of the underlying psychiatric disease. Although research and clinical findings have varied per patient sample and method of ECT administration, the overarching conclusion is that ECT does result in transient negative cognitive effects, particularly in the memory domain.

The ECT parameters studied have included sites of electrode placement, stimulus intensity, and pulse waveform. There are three prominent electrode placement sites used clinically: bitemporal, right unilateral, and bifrontal. Anecdotally, bitemporal is thought to produce the fastest speed of response, but also carries the burden of having the most neurocognitive adverse impact. Right unilateral, on the other hand, is thought to have similar properties in terms of efficacy, yet a more benign neurocognitive profile, and bifrontal too has been suggested to have high efficacy with benign neurocognitive effects. Numerous clinical trials studying the impact of bitemporal and right unilateral ECT have consistently found right unilateral to be more cognitively sparing relative to bitemporal, notably with regard to memory functions.

Examinations of bifrontal ECT have been limited due to small sample sizes and inconsistent procedures in terms of dosing strategies. However, the CORE group in its large-scale, controlled trial of three electrode placements compared the cognitive effects of bitemporal, right unilateral, and bifrontal placements administered with brief pulse waveform during an acute ECT course. The study found that all three electrode placements were equivalent both in efficacy and neurocognitive adverse effects. However, that study was limited by missing data and patients who exited the study early. A study conducted in Belgium compared bifrontal and right unilateral electrode placements administered with ultra-brief pulse-width during the acute course. That study found that both bifrontal and right unilateral were equivalent in both efficacy and neurocognitive outcome.

Studying electrode placement must take into account the interactions of stimulus dosing and pulse waveform. Research has found a consistent direct correlation between stimulus dosage and neurocognitive

impairment. With the introduction of stimulus dose titration in the 1980s, dosage of ECT is limited to the amount needed to provide a therapeutic seizure. This has helped to minimize the negative neurocognitive side effects that were found in earlier use of ECT when higher doses were applied. An empirical example of the effects of stimulus dosage was found in a controlled, double-masked, clinical trial that compared bitemporal and right unilateral ECT. The treatment conditions were bitemporal ECT at 150 percent above the seizure threshold and right unilateral ECT at 50, 150, or 500 percent above the seizure threshold. Efficacy and neurocognitive assessments were performed before the treatment, after the sixth and last treatments, and 1 week after the last treatment. The investigators found that the neurocognitive effects of right unilateral ECT were dependent on the stimulus dosage utilized to provide treatment. When administered at higher doses, statistically and clinically significant differences were found between the right unilateral groups, with the higher dose (i.e., 500 percent above seizure threshold) resulting in greater time to reorientate and more anterograde memory impairment (i.e., memory for new information). However, even at the highest right unilateral dose, bitemporal electrode placement resulted in more cognitive impairment in the domain of retrograde amnesia.

Another controlled investigation examined the acute neurocognitive effects of only right unilateral ECT delivered at either a fixed high dose (403 millicoulombs) or moderate titrated dose (2.25 times the initial seizure threshold). The findings mimicked those of other studies and showed that right unilateral ECT at a fixed high dose produced greater neurocognitive effects than the moderate titrated dose in the domains of time to orientation, global cognitive function, and retrograde memory. Thus, when deciphering the neurocognitive effects, electrode placement and stimulus dose must both be examined in order to sufficiently understand the interaction. With the recent advent in studying the interaction effects of pulse waveform, there has been inconsistent information. For example, randomized, controlled clinical trial found that ultra-brief, relative to brief pulse, was associated with less neurocognitive effects, regardless of electrode placement. However, another randomized controlled clinical trial that compared brief and ultra-brief pulse waveform in patients treated only with right-unilateral electrode placement, empirical dose titrated ECT found that both pulse waveforms produced similar clinical and neurocognitive outcomes. That is, the study suggested that ultra-brief pulse waveform has no neurocognitive advantages relative to brief pulse waveform. Further research is warranted to clarify both the clinical and neurocognitive effects of ultra-brief pulse waveform.

Time to reorientation (i.e., the time needed after the end of each ECT session to regain orientation) is greatly impacted immediately after each treatment with resolution following in time after treatment. Like other

cognitive domains, orientation time is affected by electrode placement, stimulus dosage, and pulse waveform with bitemporal electrode placement, higher stimulus dosages, and sine waveform resulting in lengthier times to reorientation. In a study that compared bitemporal and right unilateral ECT, both electrode placements showed relatively similar patterns of orientation recovery over the course of treatment, indicating that subsequent ECT treatments do not incrementally prolong orientation recovery time. For instance, in that study the first and last two treatments were compared and no within-group differences were found regarding reorientation time, even though between-group differences were observed. Of interest, with right unilateral ECT, age was positively related to recovery time with older patients regaining orientation at a faster rate than younger patients. The positive association between age and reorientation time was mitigated by the lengthy reorientation time in the bilateral group. Research of the pulse waveforms has consistently found that sine waveform results in the longest time to regain orientation, followed by brief pulse, and finally ultra-brief pulse.

When assessing neurocognitive effects, acute and long-term effects must be examined. Acutely, ECT results in modest impairment of many domains including visuospatial and verbal learning and memory, and global cognitive function. However, those effects typically resolve quickly within 1 week to 1 month after the end of the acute ECT course. A study of 45 depressed patients who received ECT (administered with right unilateral or bitemporal electrode placement) compared those above and below the age of 60 on a battery of neurocognitive tests at set time points. The study found that immediately after, and at long-term follow-up, patients showed improvement on neurocognitive measures of attention, verbal fluency, and memory for visual shapes. The investigators concluded that the improvement in neurocognitive function may have been related to decreased depression severity or the ECT-associated activation of dopaminergic and serotonergic neurotransmitters.

Consequently, in terms of short- and long-term neurocognitive effects, the domain of neurocognitive function greatly impacted is retrograde memory. Initially, retrograde memory was thought to resolve over time after the end of the acute phase, with substantial recovery of personal memories. Earlier research found that retrograde amnesia could be predicted by the global level of cognitive functioning before the initiation of ECT.

A recent study of community ECT practices in the New York area, though, showed evidence that retrograde amnesia is a persistent effect of ECT and that some autobiographical information may remain lost. Seven New York hospitals (three community hospitals, two private hospitals, and two university hospitals) were included in the study and a total of 347 patients who were longitudinally followed for 6 months provided outcome

data. Focusing on the neurocognitive outcome, the seven treatment facilities differed due to ECT practice differences at the respective sites. For instance, one center administered ECT with a sine waveform that was associated with more effects on psychomotor speed and memory for autobiographical information. The significance of the site differences indicated that there is no one uniform practice of ECT administration and that outdated methods that result in greater neurocognitive effects are still employed.

More importantly, the study found that retrograde memory deficits persisted for at least 6 months and were related to ECT technique, female gender, lower premorbid intelligence, and advancing age. Of equal importance, the number of ECT treatments with bitemporal electrode placement was associated with the amount of retrograde amnesia, even at the 6-month time point. However, that study was recently critiqued as it used an autobiographical memory interview that has no reported psychometric properties. Thus, those findings have now been called into question, and further research is needed with psychometrically sound measures of autobiographical information to confirm or refute those findings. Nonetheless, elderly patients may be more prone to the ECT-associated adverse cognitive effects and treatment with right unilateral electrode placement, empirical dose titration, and ultra-brief pulse waveform may help to mitigate the cognitive effects.

Autobiographical memory, the area mainly affected by ECT, can be categorized into two types: One that focuses on personal memories and one that focuses on impersonal memories (i.e., public events). A clinical trial of patients treated with either right unilateral or bitemporal ECT, who were compared to a healthy control group, found that memory for impersonal events was more affected than memory for self, and greater deficits were found in those patients treated with bitemporal ECT. The pattern of memory loss showed that more recent events, those closest in time to the delivery of ECT, were the most vulnerable to the ECT effects. Also, those events that were patient determined to have low salience were most vulnerable to the effects of ECT.

A neurocognitive domain that is often overlooked in both clinical and research arenas is the patient's view of his or her cognitive experience, which is commonly referred to as subjective cognitive functioning. Many elderly patients with affective disorders will complain of memory difficulties, short attention spans, and slow psychomotor speed. Although the neurocognitive functions may be intact based on formal neurocognitive testing, the patient's subjective experience needs to be considered, especially with regard to ECT. Due to the negative stigma associated with ECT, which some elderly patients refer to as the "shock," their subjective view point is a factor in the efficacy of the treatment. Prior research found that patient self-rating of neurocognitive function was related to a

depression severity self-rating scale, with higher scores on the depression scale correlating to greater subjective cognitive impairment scores. During and following an acute ECT course, patients showed significant improvement in subjective cognitive function, indicating that their memory had improved regardless of electrode placement type (bitemporal or right unilateral). The change in self-evaluation of neurocognitive functions was correlated with improvement in mood, and was also related to the degree of retrograde amnesia.

OTHER NEUROSTIMULATION THERAPIES

Although ECT is a highly effective treatment for major affective disorders and other severe treatment-resistant psychiatric conditions, its use is limited due to high relapse rates after the acute phase and associated adverse cognitive effects. In order to remedy the negative effects of ECT and to increase the delivery of efficacious treatments, other neurostimulation modalities are being developed as antidepressant therapies. These neurostimulation modalities include transcranial direct current stimulation, vagus nerve stimulation, rapid transcranial magnetic stimulation, magnetic seizure therapy, and deep brain stimulation.

Transcranial Direct Current Stimulation

Transcranial direct current stimulation (tDCS) applies a weak direct current (1 to 2 mA) with scalp electrodes. Studies suggest that anodal stimulation increases cortical excitability while cathodal stimulation increases cortical inhibition. It is thought that tDCS has variable effects on long term potentiation (LTP) or long term depression (LTD) depending on how it is delivered. As a result, this tool has been applied for a wide array of studies investigating neuroplasticity and cognitive neuroscience. Generally, tDCS is well tolerated and has the potential to alter cortical activity beyond they stimulation session. Therapeutic research has focused on depression, stroke rehabilitation, cognitive remediation, and more recently studies of dementia. Contemporary work suggests that clinical outcomes with tDCS may be enhanced by coupling it with cognitive remediation, antidepressants, or other concurrent treatments.

Vagus Nerve Stimulation

Vagus nerve stimulation (VNS) was approved by the FDA in 2005 as an adjunctive antidepressant treatment for patients with treatment-resistant depression. VNS involves implanting a device similar to a pacemaker that produces brief, intermittent electrical stimulation to the vagus nerve. This neurostimulation modality was investigated in two large-scale, randomized, controlled clinical trials. The first, an open-label trial, found VNS to be safe and tolerable, producing limited side effects grouped into

two categories, surgery related and stimulation related. These side effects were transient and resolved over time; even those related to stimulation lessened over time and many patients reported substantial adaptation to side effects such as increased cough and hoarseness during active stimulation.

In terms of efficacy, the second trial, double masked and sham controlled, found no difference between active and sham VNS during the acute phase. However, during the long-term open-label phase in which all patients received active treatment, depression severity decreased as measured by both clinician and patient reports, and modest response (29.8 percent) and remission (17.1 percent) rates were found. Although VNS has shown some benefit, it remains unclear how to adequately provide dosing. In the initial study, the majority of the patients received high-dose VNS, whereas in the second study, VNS doses were lower.

Of significance, there were no negative cognitive side effects found and, conversely, patients showed minimal improvement in the cognitive domains of psychomotor speed and executive functions. However, this improvement was hypothesized to be related to the improvement in depression as opposed to directly related to VNS. Nonetheless, VNS could be an option for geriatric patients with treatment-resistant depression who have not benefited from other available antidepressant therapies and who for any medical reasons are unable to undergo ECT.

Rapid Transcranial Magnetic Stimulation

Rapid (or repetitive) transcranial magnetic stimulation (rTMS) is a noninvasive neurostimulation technique that applies alternating magnetic currents, which then produce electrical current in cortical areas. rTMS has been under significant investigation as a treatment for major affective disorders and other neuropsychiatric illnesses. A large randomized, controlled clinical trial comparing active and sham rTMS to treat unipolar major depressive disorder during the acute phase (6 weeks) found no statistically significant difference between groups; however, active rTMS did produce clinically beneficial response and remission rates. The patients in the trial were actively taking concomitant pharmacotherapy and were treated for 6 weeks. Those who did not respond to the acute phase were offered open-label active treatment for an additional 6 weeks, and those who responded were naturalistically followed to monitor the long-term rTMS effects. While this study did not specifically address safety and efficacy in a geriatric population, elderly patients were included in the study and those data are expected to be analyzed.

In a separate study, investigators assessed the use of open-label rTMS in 18 geriatric patients (mean age: 61.2, range: 55 to 75). These patients were diagnosed with moderate to severe unipolar major depressive disorder, and many of them were resistant to polypharmacy. All patients

tolerated rTMS treatment, with side effects limited to mild headaches and scalp discomfort. Overall, there was significant improvement in global functioning and symptoms of depression and anxiety. However, the study found that the presence of general medical comorbidities and acute onset of depression decreased the therapeutic response of rTMS.

The use of rTMS is attractive to many clinicians as it has been shown to be safe and well tolerated. The main side effects reported include temporary headaches and scalp pain at the site of stimulation. As rTMS has been investigated for more than 20 years, safety guidelines have been generated by expert scientists to guide clinical decision making regarding rTMS treatment parameters. A limitation of using rTMS in a geriatric sample is the presence of cortical atrophy in the prefrontal cortex (the usual site of stimulation). Cortical atrophy is inversely related to treatment outcome with rTMS and has been found to be a predictor of nonresponse. In 2008, the FDA-approved rTMS for treating adult patients with unipolar major depressive disorder for whom one antidepressant treatment has failed to work.

Magnetic Seizure Therapy

Magnetic seizure therapy (MST) is a neurostimulation therapy currently being studied that utilizes rTMS at high frequencies (i.e., 50 to 100 Hz) to induce therapeutic seizures. The goal of MST is to focally induce therapeutic seizures, containing the cortical spread of the seizure, in order to maximize efficacy while limiting adverse effects. Initial research in primate and human models found MST to be safe and well tolerated with evidence of limited negative effects. An initial trial conducted in ten humans who each received two MST treatments within an acute course of ECT found that MST, relative to the ECT treatments, resulted in faster time to achieve orientation and generation of more words on a test of verbal fluency. To date, there have been two randomized, controlled clinical trials of MST in the treatment of severe mood disorders. One trial has been completed and one trial is ongoing. In the first trial, 20 patients with unipolar or bipolar major depressive disorder were randomized to receive focal MST, with the magnetic stimulating coil placed over the frontal cortex, or nonfocal MST, with the coil placed over the vertex. The results found the treatment to be modestly efficacious with response and remission rates of 50 and 15 percent, respectively. Of benefit, MST showed limited cognitive effects in the domain of retrograde amnesia for autobiographical memories. Also, there were no adverse effects in the domains of global cognitive functioning, verbal and visual anterograde learning and memory, or time to orientation. Patients also reported subjective improvement in cognitive functioning.

The second randomized trial will provide further insight into the efficacy of MST by evaluating high-dose MST (delivered at 100 Hz).

Preliminary studies in nonhuman primates and humans found high-dose MST to be safe and tolerable and the current trial will comprehensively evaluate the efficacy and cognitive effects. Although not initially targeted for geriatric patients, MST could have a role in future algorithms given its limited adverse cognitive effects. Thus, geriatric patients who may be more susceptible to the negative cognitive effects of ECT may be able to receive MST and benefit from therapeutic seizures coupled with limited cognitive sequelae.

Deep Brain Stimulation

Deep brain stimulation involves the surgical implantation of a pacemaker-like device that sends continuous electrical stimulation to a specifically targeted region in the brain. Deep brain stimulation has been safely used with beneficial results in patients with severe movement disorders such as Parkinson disease. The procedure is considered invasive, but safe, as the surgery takes place while the patient is awake and the electrode leads are placed directly in cortical tissue.

There has been recent interest in using deep brain stimulation to treat severe affective disorders based on initial anecdotal observations that patients with movement disorders appeared brighter during the course of treatment. A small open-label pilot study of six patients (age range: 37 to 59 years) treated with deep brain stimulation found that four patients responded (i.e., at least 50 percent decrease in depression severity) and two showed no response. Neurocognitive testing found that deep brain stimulation had no adverse effects and in turn many patients showed improvement in visuomotor functioning and verbal fluency. Aside from the development of local infections from the postsurgical implantation of the connector leads, which resolved with antibiotic treatment, no other adverse events were reported. To remedy the risk of infection, the surgical procedures were modified to implant the stimulating generator and the electrodes in one surgery session. A recent 6-month, naturalistic study of 54 patients treated with deep brain stimulation for Parkinson disease demonstrated improvement in motor and mood symptoms. Further, baseline, psychiatric comorbidities did not have a differential effect on outcome in this sample. The use of deep brain stimulation in treating psychiatric illnesses warrants further investigation based on the preliminary optimistic response, positive neurocognitive effects, and limited adverse effects.

FUTURE DIRECTIONS

Algorithm development is a crucial future step to optimize the application of ECT and neuromodulatory interventions in the elderly. This work will aid clinicians in sequential treatments or complex regiments with

multimodal approaches. Further work to identify risk factors for neurocognitive side effects and minimizing this burden for patients will improve outcomes. Optimal continuation and maintenance treatment is also still poorly understood.

With the advent of newer somatic therapies such as tDCS, rTMS and MST, additional research is warranted to understand their effects in geriatric populations. Research thus far has found these neurostimulation therapies to be cognitively benign, and possibly cognitively enhancing with promising clinical efficacy in relatively younger cohorts, and this will have significant therapeutic implications when treating elderly patients, especially those with pre-existing cognitive deficits. Magnetic seizure therapy in particular, though presently in developmental stages, could be a new frontier in convulsive therapies and psychiatric practice through its proposed mechanism of action that facilitates therapeutic seizure induction coupled with little neurocognitive effects.

With newer neurostimulation and convulsive therapies added to the psychiatric therapeutic armamentarium, future directions will need to begin to address the issue of developing high-caliber treatment algorithms tailored to the individual geriatric patient. This could involve utilizing different neurostimulation modalities at different treatment courses. For example, patients who benefited from acute ECT may receive continuation TMS to prolong the period of remission. Also, the combination of neurostimulation modalities with pharmacotherapy requires the understanding of how to refine that administration in order to enhance the clinical efficacy, particularly in elderly patients who are prescribed multiple medications. The goal of these treatment algorithms should focus on defining the optimum delivery of somatic therapies that maximize therapeutic benefits and minimize unnecessary medications and adverse reactions. In addition, these evidence-based algorithms for geriatric patients should underscore the importance of neurocognitive assessments and effects when determining clinical management with somatic and multimodal therapies. These scientific advances in geriatric psychiatry will contribute to the continued evolution of novel and advanced somatic therapies.

57.4g Psychosocial Factors in Psychotherapy of the Elderly

JOEL I. SADAVOY, M.D., AND VIRGINIA WESSON, M.D.

DEFINITION

The term *psychosocial,* as used here, refers to social and environmental elements in an individual's life that interact with and affect the individual's mental health and intrapsychic processes. Such elements may be

conceptualized at two levels: The intermediate level of factors arising within the immediate environs of the patient (e.g., friendship or family relations) and the more macro level of society and cultural norms (i.e., societal attitudes, culture, and ethnicity). Historical knowledge can be an important factor in creating an accurate clinical context for the patient's symptoms. While history obviously is not changeable, it can inform therapy by providing context for decision making. For example, for the oldest-old, key life decisions such as whether to marry or have children may have been heavily influenced by the experience of major wars, local conflicts, or worldwide economic depression. In turn, such decisions can strongly affect the degree to which an individual will age successfully. The aging demographic continues to evolve as elders live longer. In the last census in 2010 there were 53,000 centenarians in the United States with similar increases in number of individuals living to extreme old age in other industrialized countries. It is still too early to fully understand the psychosocial implications of living to extreme old age, such as the impact of outliving most of one's family and age cohort.

RELATIONSHIPS

The passage of time leads to major change in a patient's social network. In youth, time is often viewed as an ally, an opportunity for growth, and a time when new interpersonal roles and novel social partners are preferred. In old age, time is no longer an ally, eroding many life achievements and increasing the preference for emotionally close social relationships. Perhaps most profound are the changes associated with loss of relationships through death or other factors.

There is a convincing body of research in support of the concept that better social relations is related to better health and longer life in the elderly and its absence is a risk factor for psychiatric disorders, particularly depression, and stress-related physical illnesses and disability. What is less clear in the literature on social relations is which elements are most critical, for example, social support, social network, social integration, or social participation. The majority of data support the concept that elders who are part of what have been termed more socially endowed, diverse or resourceful networks have better mental health. Such networks are characterized by a greater number and variety of social ties, with whom the individual is intensely involved. It is also unclear whether all relationships confer health benefits. It may be that social relationships with friends and confidantes (the so-called discretionary or non-kin relationships) have a greater effect on mental health than relationships with kin, particularly children. There remains some debate as to whether it is the nature of the network itself or whether it is the individual's perception of and satisfaction with support that is the most important protective factor. Both seem to be important factors and should be taken into account when evaluating

individual patients. It seems fairly clear that beyond the nature of the network, the presence of negative interactions is a source of stress while perceived positive relations buffer stress. Hence, it is perhaps not surprising that strong social support helps to buffer depression, and married adults are at lower risk of depression than unmarried or widowed adults. There is an ongoing debate over the elimination of the bereavement exclusion criterion from a diagnosis of depression in the Diagnostic and Statistical Manual V. A recent study, for example, has found a high rate of significant depressive symptoms in bereaved elders who lost their spouse (although major depressive disorder was not associated with bereavement). It is estimated that one in six men and almost half of women over the age of 65 are widowed, and of these about a third will experience complicated bereavement, increasing their risk of depression and associated morbidity and mortality. Moreover, even uncomplicated bereavement can be associated with depressive symptoms which, while they may not reach threshold criteria for a diagnosis of major depression, nevertheless also may impair function and increases their risk of medical comorbidity and mortality. However, psychosocial resources including religious and spiritual belief, and practice, social and family support and Erikson's concept of vital involvement expressed in commitment to life tasks are moderating or protective factors which might be modifiable and enhanced by therapy.

Bereavement, while almost always difficult, may also be a release from an oppressive relationship, liberating the remaining spouse to resume old pursuits or take on new roles and responsibilities. For example, one spouse spoke eagerly about her ability to return to the academic research and teaching she had relinquished due to the demands of providing care to her ailing spouse.

During care of the elderly, as with younger adult patients, it is important to make no assumptions about the significance of loss but rather to explore the specific meaning of loss to each patient. It is important, too, to be aware that the bereaved spouse may need time and energy to develop new roles and relationships and they may struggle with how to identify themselves beyond being a spouse and partner. Other social changes may emerge that are supportive following bereavements. For example, widowed older women receive more help from friends than married women while widowed older men are the most likely to receive support adjusting to practical and emotional changes following the loss of their spouse.

Beyond bereavement, marital relationships in old age also are changed by physical or cognitive impairment, and shifting patterns of dominance and responsibility. For example, the basic nurturing role previously carried out by a loving wife may now fall into the unaccustomed hands of her husband in the face of her decline with Alzheimer disease. He experiences not only loss, but also the need to offer comfort and care, behavior and

feelings with which he has always been awkward. Guilt, resentment, and some anger sometimes emerge as a consequence. Conversely, the physical or mental decline of one spouse may elicit kindness and nurturing late in life that was absent in earlier years. For example, a haughty, narcissistic wife became "chastened" by her awareness of her own decline. While she agonized over her own losses, she also realized that the husband she previously demeaned and devalued was now her greatest ally. He welcomed the new role and the respect he began to feel from her, revealing a nurturing, loving side she had never seen before.

Sociocultural trends in relationships will impact the aging process. For example, in North America there has been a trend, especially among well-educated, high socioeconomic groups, to delay child-bearing in favor of focusing on career and financial advancement, only to find that fertility has been significantly reduced. This in turn often leads to inadvertent and unwanted childlessness and deep late-life regrets. In addition, greater participation of women in the workforce may preclude them from taking on the more traditional role of caregiver and further contribute to the relative lack of children able to support aging parents. Cultural patterns of marriage have also changed. Japan's almost universal marriage tradition stood in contrast to patterns in Europe where marrying at a later age or not marrying has been much more common. Interestingly, however, Japanese women are increasingly delaying marriage and childbirth, with a high percentage of the unmarried expressing the intention to never marry. This inevitably leads to a dramatically lower birthrate. The result will be a growing cohort of childless elders in many societies. Childlessness would seem to disadvantage individuals as they age but research suggests that childless individuals compensate for not having the support of children by strengthening relationships with friends and collateral kin such as siblings, nieces, and nephews. Nevertheless, in times of increased need for support in old age, childless elders are left without adequate levels of care. Women are more likely to be childless than men and childless elders of both sexes are much more likely to live alone or in institutions and have fewer face-to-face contacts than their peers who have children. However, interestingly there appears to be little difference in psychological well-being between childless seniors and those who are parents.

A social safety net can mitigate social pressures associated with old age. For example, in the United States social insurance provides the financial resources to allow many single elders to live alone. Similarly, housing alternatives for seniors including congregate living, supportive housing, and community-based social welfare services reduce isolation and dependency on others. However, it is not only practical support that is crucial to the mental well-being of elders. Rather, for many, it is the presence of true confidants that is key to warding off demoralization and depression. In this regard, informal care networks may be equally or more

relevant.

Despite enhanced social support, elders, especially women, without supportive families often face an emotionally impoverished old age. This is particularly true if governments erroneously assume that families will care for elders. Childless elders or those emotionally or geographically distant from their children will obviously be disproportionately disadvantaged by such policies and more likely to be alone. Clearly these issues have a central effect on the focus of psychotherapy. Problem-solving or interpersonal psychotherapy approaches for isolated elders will construct and address a different array of problems and issues than for elders who have strong support structures, such as the management of issues of abandonment or deficits in intimacy.

The nature of intimacy similarly shifts, often in the direction of distance and isolation. The equal partnership between married spouses may shift to a caregiver–care recipient relationship with consequent loss of mutuality and intimacy. Friendships, easily maintained during younger, more active years, often become much more difficult to sustain, especially in the face of physical impairments. Driving is more of a challenge, evening and night travel more fearsome, and gathering places less welcoming and accommodating. Healthy and active elders are more able to maintain equitable friendships where both friends can contribute equally. More frail elders receive more than they give, becoming the so-called "overbenefited" in their friendships. Equitable friendships or relationships in which elders (women) give more than they receive lead to higher morale than in overbenefited women. Interestingly, older men seem to establish more equitable relationships than women.

Affiliation and intimacy seem to be more important to women than to men, although such data should be approached with caution as there have been few studies on the needs of men for intimacy in old age. Some work has shown that, when compared to married men and married and widowed women, widowed men less often have relatives living close by and are less likely to be members of community organizations but may be no more likely to describe themselves as lonely. The data on the importance of intimacy have not been well verified for all cultural groups. For example, there's some evidence that black women place more importance on functional aid (as opposed to intimate affiliation) than do white women. Studies of Japanese elders have demonstrated an association between social support and self-rated health and mortality, results that were also noted in studies in Sweden and Finland.

Friendships are more than just emotionally supportive. Data suggest that the existence of a close friend and to a lesser extent kinship contacts increase the likelihood of maintaining functional independence.

The pattern and meaning of change in friendship networks in old age are different for men and women. For example, married men may derive

much of their self-esteem from their career and family and value friendships significantly less than married women. In old age, men may establish increased casual friendships but there is little indication of increased close relationships and overall data suggest that men (in contrast to women) decline in many measures of friendship. After retirement, men may establish casual friendships but turn to their spouses for personal meaning and self-worth previously derived from their work. With the death of a spouse, married men may be particularly vulnerable to isolation because of their relative lack of friendships and other community connections developed earlier in life. In addition, their spouse may have been their primary or only confidante and may also have been their link to the community. Married women may be relatively protected in bereavement because they are more likely to have other confidantes, both relatives and friends, and belong to community organizations. As a result, they have the opportunity to find other meaningful roles and relationships that may mitigate the loss of their spouse. However, for both men and women, social support from family or friends can only go so far. It is more difficult to lessen the internal loneliness that stems from the loss of the person who is often the spouse's most significant attachment figure and companion. Indeed, other relationships may not be able to alleviate that loneliness and the loss of the life partner must be mourned and therapy may provide an important venue for working through. While loneliness is a natural human experience it may not be easy to reliably measure using standard instruments. Why is this? While lack of social contact and support are key antecedents that can lead to loneliness, it is not equivalent to social isolation. Social isolation is an objective state and more easily identified and quantified while loneliness is an internal dysphoric and unpleasant experience which is related to the experience of deficiencies in social relationships; for example the feeling, right or wrong, that while there may be many people around to talk to nobody truly understands. This is a common expression of loneliness among elders such as those who are caring for a spouse with dementia. There are a number of loneliness measures both direct (self-report of loneliness) and indirect (measuring factors associated with loneliness without using the word itself to avoid the problem of stigma of self-identification) which yield different results. For example, a direct question revealed greater prevalence of loneliness among elderly women while an indirect questionnaire showed greater incidence among elderly men.

Illness and other age-related events like bereavement take their toll on friendship networks. These networks become depleted although the number of contacts may be less important than their quality. The maintenance of fewer emotionally meaningful relationships may provide sufficient social connectedness and protection against loneliness. Nonetheless, even for naturally outgoing personalities, the avenues for

establishing and maintaining new friendships are often blocked. One outcome is the erosion of relationships in which the old person's history, accomplishments, desires, and ambitions are known by his or her friends. Increasingly, aging fragments and isolates. Data on adaptation in the oldest-old are not consistent. The oldest-old, in contrast to the young-old, often become overburdened by illness and frailty, and even previously adaptive personality types with strong positive self-assessments often cannot successfully adjust to their disabilities. Some data indicate that subjective well-being can be sustained through positive self-referential attitudes. Results of these changes include physical distance from longstanding friendships and often, although not invariably, reduced frequency of contacts, which increase feelings of aloneness and create reliance on more casual opportunistic relationships such as with neighbors. While certainly not universal, this process of change contributes to creating a special context imposed by old age on the therapeutic process. Old patients, often through no fault of their own and despite their efforts, may present with a burden of aloneness. This is especially true for those who are unmarried or bereaved. This can create in therapists the anxious sense that they must be more than a treater, responding to an unspoken request for friendship and becoming for the patient the only place and person to offer a safe, intimate emotional haven. The therapist may find these challenges to be somewhat daunting as they may stir up the therapist's own fears about illness, incapacity, and death. The therapist may feel overwhelmed and worry about being engulfed by the patient's helplessness and dependency. In response, the therapist may distance themselves from or reject the patient, labelling them as chronically ill, beyond help and incapable of change. The reverse reaction may also occur in the therapist who wishes to halt or turn back the aging process. In this situation, the therapist may see therapy as life sustaining or even lifesaving. As a result, they may avoid termination rather than face the inevitability of the patient's and, perhaps, their own death.

Blanket rules about friendship and its impact in old age are inadvisable since the nature of friendships differs for each person depending on his or her psychological makeup. People differ in their need for, as well as their capacity to have, friends; their ability to maintain them; the nature and intensity of their friendships; their ability to do without them; and their standards for with whom they allow intimate confiding relationships. For example, Donald Winnicott suggests that those who never fully invested in friendships earlier in life may be better able to "make do" in old age with more superficial acquaintances without experiencing aloneness. Such individuals may be more invested in activities and personal expressions of creativity that are not dependent on contact with others (i.e., a well-developed capacity for self-soothing and self-sustenance). The implication for psychotherapy is that therapists are most effective when they explore in

depth with patients the nature of their friendship networks, their satisfaction with the level of intimacy and support, and strategies either for mourning lost relationships that cannot be replaced or for ways of enhancing their friendship networks to fulfill their needs. Many patients do not volunteer such information in therapy or may not be aware of their needs; hence, it must be elicited and explored actively. No specific psychotherapeutic techniques have been developed for dealing with these issues, but by extrapolation from other work (for example, on depression), interpersonal psychotherapy, cognitive-behavioral approaches, problem-solving therapy, or perhaps reminiscence therapy may be effective tools.

Assessing social isolation includes evaluating ease of relating to others; feeling of isolation from others; extent of sharing feelings with a significant other; connecting with others when needed; feelings of engagement with others; and feelings of aloneness and friendlessness.

Beyond friendship, sexual and other physical intimacy may diminish or disappear from the life of the old person—no one to touch or be touched by. The literature suggests that sexuality among the elderly can remain vibrant and pleasurable although the determinants of sexual activity are varied and may change over time. For example in one large study positive determinants of sexual activity included a positive attitude toward sexuality, sexual debut before age 20, having a very happy relationship and a physically and mentally healthy partner, good global health and mental health, being married/cohabiting, and drinking alcohol more than three times a week. While true as an isolated fact, the data also must be seen in the full psychosocial context, in which the elderly over a certain age are often widowed and without partners and with limited opportunity to form new close bonds. Lack of a suitable partner is the key predictor of sexual activity among women. One study found that 82 percent of residents of subsidized independent-living facilities had not had intimate sexual contact in the past year, although many had at least one experience of hugging or other touching. Hence, for example, intimate touching may become the domain of the medical encounter during physical examination or the nonsexual hugging of children, grandchildren, or friends. Physical isolation becomes especially evident in retirement or nursing homes or other institutions where predominantly old women live in an unusually gender-homogenous environment. Whatever sexual or intimate interest remains is put in cold storage, often forever. Having acknowledged this reality, it is also true that sexual activity and pleasure vary dramatically, often directly associated with the availability of sexual opportunities in relationships. Psychotherapists and other caregivers need to be sharply aware of the patient's needs and reactions under these circumstances, elicit the impact on the patient, and incorporate the realities into the treatment, either working toward change or to acceptance. The therapist must also be aware of countertransference reactions in this area. Unresolved conflicts over

parental sexuality may lead the therapist to avoid any discussion of sexuality or to regard the older client as asexual. As in all psychotherapies, the therapist must monitor their reactions to the patient through active self-examination. By bringing these reactions into awareness, the therapist can minimize their potential to have detrimental effects on the therapy and, instead, use them to better understand the patient.

The psychosocial phenomenon of loss of intimate relationships in old age may have special impact on the form of the psychotherapeutic relationship. Therapists are often and easily experienced by the isolated patient as a wished-for substitute for the lost relationship. Therapists may feel alone with the patient in their depleted world as well as uncomfortable pressures to adopt the roles or behaviors of friend, confidant, protector, advisor, or advocate. The therapist who identifies too closely with the patient's problems may be immobilized by pity or sadness that impairs their ability to empathize with or promote change in the patient. On the other hand, the therapist may shrink away from the patient's sadness, thereby increasing rather than easing the client's isolation and grief.

While old age is a time of substantial change and requires great adaptability, satisfactions may still abound. However, they tend to be encountered within a narrower frame, focused more on family relationships and very close friendships. For many, the loss or unavailability of friendships/relationships promotes a kind of centripetal emotional force that draws some elderly persons into their families and somewhat away from other relationships particularly when faced with the challenges of failing health. The loss of confiding relationships may be especially clinically relevant, since some research suggest that these relationships are protective against depressive disorder. Effective psychotherapy and environmental interventions that support the patient's need for new relationships can counter some of the effects of loss of confidants. While attention to relationships during therapy is important regardless of the patient's age, it is especially necessary with elders. Assessment and intervention must elicit not only the presence of instrumentally supportive relationships, but also which of them are sustaining of self-esteem and maintenance of identity.

The increasing importance of family relationships with advancing age adds an element to the psychotherapy of older adults not found as prominently among younger adult patients. Therapists often must take into account age-induced dependency issues in families and the conflicts these issues engender, such as forced intimacy and caregiving situations with adult children. For example, conflicts arise over the different perceptions of need that the elderly parent has. Children may be overly anxious and protective, aging parents inappropriately resistive of needed help or exaggerating of their helplessness. While family assistance and caring are crucial supports for the aging person, the therapist must be wary of

assuming that family can substitute for friends. Indeed, friendship interaction is positively correlated with self-esteem, while kinship interaction is not. Whatever the pattern, the psychotherapist of the elderly must take the family system into account, sometimes involving the other family members directly in the therapy or helping the elderly person develop appropriate interpersonal patterns of interaction. Flexibility of psychotherapeutic technique and interventions is essential. The usual adult–therapist stance broadens when treating the elderly as psychosocial issues associated with frailty, dependency, and relational shifts impinge often rendering individual assessment and focal intervention inadequate. Impelled by these realities, the therapist often must combine overt roles of advocate, intermediary, and educator with the more traditional psychotherapeutic roles and interventions. Sometimes this means reaching out actively to families, social agencies, or medical caregivers, roles that are often unaccustomed for psychotherapists. While therapists need to be flexibly supportive, they also need to examine their motivations when intervening on their patients' behalf. Transference- and countertransference-induced forces can lead therapists to inappropriately cross therapeutic boundaries, unwittingly adopting the idealized roles of adult–child or spouse seemingly in response to real psychosocial needs, but actually impelled by dimly understood or unconscious dynamic forces in the therapeutic relationship. Therapists dealing with relationship changes in aged patients also must be prepared to deal with their own feelings of loss, grief, fear, and loneliness and wishes to idealize, dominate, or avoid painful psychological issues that may be generated during treatment of the psychosocial stresses of old age.

ROLE CHANGES

Occupational role changes impose relatively unique challenges on the elderly. This group is almost universally forced to give up important sources of self-esteem, creative activity, social networks, and the organizing effects of job expectations. The importance of work is exemplified by the finding that nonemployed older women have lower self-esteem. Reactions to retirement differ. Retirement may be eagerly anticipated and handled well, especially among those who used to be called blue-collar workers and those with the resources, resilience, and creativity to use newfound leisure time in a satisfying way. Others, such as some professionals, often avoid retirement, and may find the loss of their occupational roles very difficult. Either way, the psychotherapist must be keenly aware of the centrality that work-related roles play in structuring life and the changes to this structure imposed by aging. These factors are especially relevant in the so-called young-old, 65 to 75 years, who are more likely to have freshly encountered the issues of occupational role change. For example, an emotionally distant marital relationship may have been quite stable and acceptable when work

substituted for unavailable marital closeness. After retirement the emptiness of this form of relationship becomes much more evident and can lead to depressive re-evaluation of life and choices. While difficult, this is also a time of therapeutic opportunity. Since retreat into work-related defenses is no longer possible, patients are forced to confront themselves and re-examine their long-held beliefs about others, especially their spouses.

Here, examining with patients the sources of their feelings both longstanding, deriving from early, perhaps unconscious developmental factors and more immediate, for example, associated with distorted modes of perception and thoughts about a partner who seems to want to care but is constantly rebuffed, is important. In the more advanced years, these issues generally recede, either adapted to and worked through or overwhelmed by other more pressing issues. However, when fresh, the psychosocial pressures of occupational role change, especially when combined with other events, such as spousal bereavement, often emerge as states of vulnerability, fearfulness, and impaired capacity to seek new, alternative sources of gratification.

Beyond its function as a source of personal gratification and self-esteem, the workplace serves an important social function. For example, one of the important considerations in retiring for women is the finding that they tend to give up work-related relationships after retirement. Working may have disrupted other familial and social roles and may not have allowed time for employed women to nurture or even maintain other relationships. In retirement, women may feel disconnected and that they have no role or purpose in life, particularly as other relationships may no longer be active. Hence, retirement creates a more impoverished social life for women, increasing their vulnerability to emotional reactions that accompany lost relationships.

As implied already, parenting roles may change dramatically in old age. For example, well-established patterns of parental dominance and reliance by children on a strong authoritative parent often suddenly reverse as parents become more frail and dependent. Conflict, guilt, or fear may invade a previously stable system. Particularly vulnerable are family systems whose members adapted to earlier conflicts by establishing distance, for example, children moving away from the pressures created by demanding, unreasonable, critical parents. In such circumstances, the increasing needs of aging parents may impose pressures on children to care for parents for whom they have had longstanding conflicted feelings. The psychotherapist must be careful to examine and understand the parent–child system and beware of taking stereotyped approaches to the aging parents, since the patterns of parental role changes are quite varied. For example, frailty and fear of being alone and incapacitated often leads elderly patients to complain about the inattentiveness of adult children.

Taken at face value, the psychosocial needs of the patient often are indisputable. However, the pattern of the family members' reactions to the patients' needs are rooted in the long history of their relationships with each other. One daughter found herself trapped providing care to her aging parents and subjected to a pattern of mistreatment well established earlier in her life. She found visits to her parents' home very difficult but, if she didn't go, her mother would attempt repeatedly to contact her and berate her when a visit eventually occurred. The daughter chose to go regularly to forestall intrusions and having to cope with her mother's disapproval and agitation. Her sense of obligation toward her parents kept her involved in a situation where she felt that there was little or nothing she could do to bring about positive change for herself or her parents. Another child spoke about her sadness at what she saw as the "changing of the guard" meaning she was now caring for the people who previously cared for her. To be effective, the therapist must be sensitive to the emotional forces that are preventing the family from adapting to the new, age-induced needs of the parent.

Many elders, mostly women, become caregivers to a spouse who develops dementia. They are subject to an array of stressors that lead to what has been termed caregiver burden. Burden is associated with disproportionate rates of both psychiatric and physical morbidity. Psychosocial factors as well as personal characteristics impact the resilience of caregivers and their capacity to manage this new and generally unwelcome new role. As with other stressors of old age social support and engagement are strong modifiers of burden as are the availability of instrumental support such as homecare, respite care, and easy access to professional support. These factors are often modifiable elements in treatment of caregiver burden when incorporated into management of caregivers. However, beyond these instrumental psychosocial factors, management of caregivers must be integrated with therapeutic interventions to strengthen adaptive, coping skills, and self-efficacy together with enhancing skills for management of dementia behaviors. It has been shown that fully integrated comprehensive approaches to caregivers which incorporate skills training, problem solving training, instrumental psychosocial support, and psychotherapeutic principles can be effective in enhancing key caregiver capacities.

SOCIETAL ATTITUDES AND RESPONSES

Biases about aging and the aged abound, and the older individual is confronted with them. Some of the North American perspectives on aging are quite negative—for example, the elderly are perceived as no longer productive and therefore marginal to mainstream life or, because of frailty, imposing undue economic burdens on overstretched pension and public support systems. As a result, there may be a tendency to dismiss the

problems of the elderly or a reluctance to provide help. The effective psychotherapist of the elderly incorporates these societally engendered issues into the therapy, recognizing with the patient the nature and impact of the messages, and working on appropriate responses. In this role, the therapist can help to buffer the sometimes harsh messages the old person hears daily about those in his or her age group. A particular issue is the difference between the patient's self-perception—more youthful, involved, and competent—and the perception of younger adults who can only see and react to the apparently universal aging appearance—lost skin turgor, decreased muscle mass, gray hair, and postural change. In other words, the older person's external and age-related life issues obscure the underlying depth of feeling and identity and can delay a more complete and deeper understanding by the young of the truer self-perceptions held by the older individual. Older patients in psychotherapy often feel both misunderstood by society at large and ashamed of themselves for their diminished capability and resultant helplessness, loss of purpose or role in life, or the burden they may feel they impose on others. In the presence of shame, individuals may fear new social situations and avoid them. The therapist will be most effective if these issues are articulated and explored with aging patients, helping them counter societally induced loss of self-esteem and feelings of alienation by confronting distortions and developing techniques to defend against inappropriate stereotyping by those around them.

ECONOMIC AND ENVIRONMENTAL FACTORS

For many, old age is a time of economic and environmental change. Retirement and the many difficulties sometimes imposed by living on fixed incomes, social security, or supplements provided by children can induce real or fantasized anxiety and preoccupation about financial security. These factors can influence psychotherapy in a number of ways, for example, inducing envious transferential feelings in patients or guilty countertransference in therapists.

Financial restrictions, often real, but sometimes imagined, lead to restricted social activity, feelings of isolation, humiliation, and shame, as well as uncertainty and fear of the future. Like advancing frailty or bereavement, economic difficulties must be actively dealt with in psychotherapy. This involves determining with patients their actual financial situation, separating distortions from reality, uncovering latent meanings about financial security, and then introducing both practical approaches to coping and interpretive understanding of the underlying meaning of the situation to patients.

Living accommodation is another important psychosocial variable that often changes in old age. The key element that induces psychological stress associated with moving to a new setting in old age is that it is generally a forced move, precipitated by physical or cognitive decline, economic

factors, or isolation. Even more than death, the specter of abandonment to an impersonal chronic care facility is most feared by the elderly. The prospect of such a move provokes various forms of abandonment anxiety, including the knowledge that this probably will be their last abode before death. This emotional reaction becomes more acute for married couples when the move necessitates separation of the partners and placement in different settings appropriate to each one's care needs. Moving to a long-term care facility also may generate internal conflicts associated with forced interaction with other elderly residents. Emotional responses may occur for a variety of reasons. For example, aged patients routinely express their anxiety at being confronted with the pain and disability of their age-peers. In them, they see mirrored their own future and become afraid. These feelings can be powerful motivators, preventing patients from accepting realistic moves to settings where they can receive needed care. Pressing a reluctant, frail patient to accept needed help in an institution can pose ethical dilemmas for the therapist. Not the least of these is the reality that many or most of these institutions are barely adequate to the task of satisfying the needs of their residents. Inevitably, no matter what the setting, the new resident entering long-term care will encounter severe psychosocial stressors, including some degree of loss of individual identity, regimentation to the institutional routines, and loss of privacy. Confronting these realities can be difficult not only for the patient, but also for the sensitive therapist who is only too aware of the limitations of the resources that they must rely upon.

The psychotherapist of an aged patient facing environmental dislocation will be most effective if they can uncover the patient's fears and anxieties—abandonment and loneliness, shame, infirmity, pain, or death—and work toward both realistic appraisal of the future and development of skills to combat the specific feared outcome of the environmental transition.

ETHNOCULTURAL ISSUES

Culture, ethnicity, and race have a profound impact on aging, which must be understood and dealt with by psychotherapists, especially when practicing in geographical areas made up of diverse communities. For example, elders among racial/ethnic minorities are less socially engaged with reduced access to social groups and non–church-related activities. This appears to be associated with greater vulnerability to less robust recovery from illness and mortality. Recent data suggest that racial/ethnic minority residents of long-term care facilities are less socially engaged than white residents although nursing home residents in general have low levels of social engagement.

Depending on the specific community, the presence of mental illness may carry with it a profound stigma that stops both patients and their

families from seeking care. These traditional cultural values are likely to be more evident in less acculturated members of ethnocultural communities. The therapist must be careful to evaluate the level of acculturation of a given patient and avoid stereotypical presumptions about cultural values, for example, assumptions about family support and filial piety.

When patients from minority ethnocultural communities do seek care, they often come with socioculturally sanctioned feelings of shame at their inability to cope with their emotional problems. Compounding the more universal problematic aspects of aging, aging members of ethnocultural communities also must deal with barriers to mental health care imposed by language- and immigration-related features, such as the feelings associated with leaving their homeland, unanticipated family conflicts, loss of status, or inaccessible spiritual support. Often, newly arrived or even well-established, but poorly integrated, aged immigrants are carrying a heavy burden of isolation, for example, unfamiliar with how to travel beyond their neighborhood, unduly reliant on often overburdened family members, feeling like aliens when they may have expected to feel like respected elders, encountering racist attitudes, or struggling with inadequate finances. While perhaps self-evident, it is crucial to the establishment of an effective therapeutic alliance for psychotherapists to convey to the patient that they are sensitive to these issues by enquiring about them in an empathic, caring, and specific manner. Therapists must be aware of the influences of their own culture on their choices, assumptions and prejudices, guard against cultural superiority and be willing to adopt an attitude of cultural humility and flexibility in adjusting their practice to accommodate cultural concerns. Most important is the overt demonstration to patients that the therapist recognizes them as individuals who will not be stereotyped by virtue of their culture, ethnicity, or race.

Therapeutic approaches and technique are influenced by cultural factors. Traditional cultural perspectives on aging and mental health forge the individual's view of the determinants of mental health and in turn the acceptability of and trust in therapeutic interventions. To be effective, the therapist must suspend preformed assumptions about the elder's background and culture and explore in an open, inquiring manner how cultural values influence explanations for symptoms and illnesses, diagnosis, and treatment. Therapists need to evaluate the degree to which culturally determined communication patterns affect therapy and adapt accordingly. These factors include four forms of communication patterns: (1) proxemics, the study of the perception and use of personal space (e.g., Anglos are more distant, while Latinos, Black Americans, and the French want much closer stances); (2) kinesics, the study of bodily movements—for example, facial expression or eye contact (e.g., among some Asians smiling is often an expression of embarrassment rather than mirth, and smiling may be seen by them as a sign of weakness rather than

friendliness); (3) paralanguage, which refers to vocal cues such as loudness of voice or inflections, and is easily misinterpreted (e.g., loud, rambunctious behavior is common in some groups such as Americans but is easily misunderstood as aggressive in low-volume cultures such as Japanese); and (4) high-low context communication, which refers to overt, intellectualized communication (low context) versus subtle or hidden communication rooted more in situations or internalized in the person. High-context communication is exemplified by how a mildly spoken "yes" can actually mean "no" when spoken by a Filipina challenged by her superior. In this context her "yes" is the expression of someone who is afraid to contradict her superior.

Once the patient's cultural perspectives are understood, the therapist's task becomes one of synthesizing this understanding and helping the patient integrate his or her traditional views with Western medical concepts (e.g., integrating the patient's view that he or she is suffering because of failure to honor ancestors with Western concepts of guilt). The successful culturally competent psychotherapist will be able to translate the patient's metaphors and belief systems, understanding both their concrete and symbolic meaning. For example, understanding that because physical symptoms are acceptable while mental symptoms are not, the patient may only feel able to convey distress in physical terms such as, "I have no energy," "My heart is uncomfortable or heavy," and so on.

Decision making in many cultures is group not individually based, as is more common in Western culture. It is necessary to therapeutic success that the therapist recognizes the importance of family hierarchy in decision making in some cultures and maintain an authentic stance of nonjudgmental collaborator with both patient and family.

An example of cultural knowledge that can be essential to the psychotherapy of a traditional, elder Native American, for example, is the centrality to the Native American of sacred tribal land. Tribal land usually refers to that which is occupied by an individual's tribe prior to their resettlement. Being torn away from traditional lands was a universal experience for Native Americans, disrupting many aspects of basic culturally based practices. For example, most religious ceremonies, culture, and custom revolve around tribal lands. Clearly, this form of dislocation, even though it occurred long ago, has had a profound effect on the personal identity of individuals, their sense of belonging in the world, their feeling of trust of those who are in power, and their sense of belonging within the wider society.

Of course, no one can hope to know all about every culture, but one basic ingredient is recognition that the elderly patient struggles with many culturally determined issues and conflicts that they may feel they have no right to speak about openly. For example, among groups who experience racism, elders may feel uncertain about how safe it is to reveal their anger

about white dominance and may view the treating doctor as a symbol of the very oppression and loss that they suffered in the past. Early in the therapy, therefore, it is useful to clearly indicate acceptance of the patient's uncertainty and, where appropriate, actively open such issues for discussion. This can be reinforced in the first assessment when the therapist can ask about the patient's feelings about traditional beliefs, experiences with the mainstream including racism, the difference between their private thoughts and their public beliefs, and their sense of belonging in society and in the therapy.

Psychiatrists and other therapists will be most effective if they are able to take a truly inquiring attitude with the patient and to be open to the patient's explicit attempts to educate them. In so doing, the therapist must also take care that the patient is not taking refuge in cultural differences to explain away all emotional reactions. It is important to carefully distinguish between patients' reluctance to reflect on and talk about themselves and true difficulties with expression. Having said this, it is also true that patients who speak a language fluently do not always use that language effectively for emotional expression. Patients may not be able to fully express their emotional state in English if it is their second language and can only convey the true meaning when they revert to their language of origin. This sometimes is relevant especially in the early stages of dementia if language skills begin to decline slightly.

Another important cultural competence of the therapist is the ability to accurately gauge the degree of closeness or distance required by the patient. The willingness or ability of individual patients to delve into important areas such as sexuality or interpersonal conflict with family members is often colored by feelings of shame and humiliation and prohibition against discussing such matters beyond the family, some of which are culturally determined. It may be helpful to preface inquiry into these areas by first acknowledging with patients their potential sensitivity and asking how they feel about exploring such issues. In other words, it is important to address the underlying culturally determined resistance that the patient may bring to the therapy before attempting to get to the substance itself.

The effective therapist treating patients from another culture will have the capacity to match the nature of the therapy to the level of belief and sophistication about Western methods that the patient holds. For example, the idea that there are social and interpersonal origins for feeling is not universally held around the world. Moreover, the implication that early life experience affects later life development may pose culturally determined problems in the therapy.

Factors associated with immigration may have special relevance to psychotherapy. For example, often hidden, but of great psychological importance, especially in refugee groups, are histories of severe deprivation

and trauma associated with war, political oppression, or famine. Because psychological trauma is a function of life experience, the prevalence of psychological trauma in the elderly will vary based on the life experiences of particular aged cohorts, for example, those who lived in times of political oppression, war or deprivation versus those who lived in relative peace and tranquility. One recent Canadian study for example found that 11.1 percent of the older adult patients presented with posttraumatic stress symptoms but less than 2 percent met DSM-IV criteria for full Posttraumatic Stress Disorder. The data are clear that late-life effects of earlier adult trauma endure, but their presence must be actively sought out by the therapist, as patients frequently keep silent about their experiences and their persisting effects.

SPIRITUAL ISSUES

Frequently omitted from psychotherapy inquiry, spiritual issues may play a profound role in the lives of many elderly patients. Religious or philosophical beliefs often are a source of great comfort in enabling appropriate acceptance of change, facing aloneness, or confronting death. Aging patients may return to religion in later years, both as a source of comfort and as a social resource. Some suggest that isolated older adults may benefit from becoming more involved in religious activity. While attending to spirituality and religious needs may be important it is often not addressed in psychotherapy and use of pastoral counseling is limited. Psychotherapy will be more acceptable to the patient and often more effective when it is carried out with a carefully elicited understanding of the patient's beliefs and attempts to use the strengths inherent in the patient's faith as an ally in treatment. However, the therapist must take care to deal with religion from the patient's perspective, not their own.

FUTURE DIRECTIONS

Regardless of the type of psychotherapy employed, the therapist of the aged patient must understand, acknowledge, and incorporate into the treatment the array of psychosocial factors that form the context of the patient's problems. The complex set of factors taken together is the matrix of the patient's life within which he or she will be supported or failed. In psychodynamics terms, this matrix may be viewed as the holding environment, the adult version of that which is provided by an infant's parents. As with children, when the holding environment fails in its supportive and enhancing functions, the individual comes under psychological stress. It is the person in his or her environment that is reflected in the environment within the person. Psychotherapists will be most helpful and effective when they work simultaneously with the external and internal worlds of the elderly patient.

57.4h Individual Psychotherapy

JOEL I. SADAVOY, M.D., AND LAWRENCE W. LAZARUS, M.D.

INTRODUCTION

Psychotherapy for the elderly has evolved in step with the evolution of general adult psychotherapy. Any debate over whether psychotherapy is as effective for the elderly as it is for younger patients is now largely resolved. The data are clear from an array of outcome studies and meta-analyses that most forms of psychotherapy are demonstrably effective in elders treated for depression and anxiety. However, as with psychotherapy in general adult populations, there are few evidence-based guidelines that help the clinician determine which form of psychotherapy will work for a given patient. Some suggest that elders prefer shorter-term therapies although clinical experience indicates that there remains wide variation in what elders want and expect from therapy. Hence, therapists will be most effective if they have an array of techniques to choose from and determine on a case-by-case basis the specific form of therapy to be used.

Overall meta-analytic reviews of randomized controlled trials (RCTs) of various psychotherapies for elders have confirmed that the psychotherapies are generally effective. Overall effect sizes derived from meta-analytic studies of psychotherapy in older adults range from 0.63 to 0.78 with higher values for specific interventions such as 0.85 for 7 studies of cognitive therapy and 1.05 for 8 studies of reminiscence therapy compared to no intervention or placebo. Life review (LR) is a more systematic technique of reminiscence (R) and data indicate it is more effective. In life review therapy for depression in older persons, the effect size is more than twice that of reminiscence (LR-ES 1.28 vs. R-ES 0.52) and four times greater when well-being is measured (LR-ES 1.02 vs. R-ES 0.24).

Because of the complexity of the challenges of late life that impact on the adaptation of elders and their vulnerability to emotional disturbance and disorders, individual psychotherapy often needs to integrate other interventions into the therapeutic process. In addition to manualized models of psychotherapy in elders, models that incorporate combinations of therapy may be necessary to address the complex factors affecting elders' adaptation. For example, social support sometimes mediated through the use of simple technology like the telephone and psychoeducational models have shown positive synergistic effects with psychotherapy on depression outcome and systematic telephone-based psychotherapy has been effective in reducing distress in aging dementia caregivers.

Psychotherapies are effective treatments for depression in late life and may sometimes be considered as a first-line intervention. Studies comparing the efficacy of various individual therapeutic approaches for

depression in geriatric outpatients (e.g., cognitive-behavioral, interpersonal, problem solving, reminiscence and life review, and psychodynamic psychotherapy) have not yet been able to demonstrate the superior efficacy of one approach over another. At the Palo-Alto V.A., for example, a comparison of cognitive, behavioral, and brief psychodynamic therapy for depressed elderly outpatients found comparable remission ratios (53 percent had remitted after about 18 sessions). At 2-year follow-up, 77 percent of those whose depression had initially remitted were still depression free. The majority of patients who did not respond to the initial treatment remained depressed at the 2-year follow-up despite continued treatment. An important variable limiting reliable generalizability of the effectiveness in depression of the most well-researched psychotherapies in the elderly, cognitive-behavioral therapy (CBT) and problem-solving therapy (PST), is the fact that these studies have generally been conducted on young-old cohorts which are well white and well educated.

A recent meta-analysis of evidence-based psychosocial therapies for anxiety revealed support for CBT, cognitive therapy, relaxation training, and supportive therapy both for self-reported as well as diagnosed anxiety in older adults at posttreatment. One comprehensive analysis reported an overall mean effect size for treatment versus no treatment or placebo control of 0.55 just above the median (0.5), providing some although not robust support for psychological treatment of late-life anxiety.

Strongest support is for CBT for generalized anxiety disorder (GAD) but is weaker for subjective anxiety, where relaxation training has demonstrated more efficacy especially when practiced long term.

For more severely depressed outpatients, a combination of psychotherapy with an antidepressant may be more effective than either alone although many elders prefer psychotherapy over medication, Interpersonal psychotherapy (IPT), for example, has shown effectiveness in enhancing social adjustment when used in combination with an antidepressant. Even here, however, initially positive research outcomes have been called into question by more recent data. One problem in interpreting the data is that the variables of psychotherapy such as frequency of intervention, is not always standardized from one study to another limiting generalizability of specific studies.

Age-related brain changes probably affect the response of elders to psychotherapy although empirical data are modest. For example, reduced bilateral cortical thickness may be a marker of individuals at higher risk for poor response to psychotherapy.

In this section, the authors review the history of, and theoretical basis for, psychotherapy with the elderly, give brief descriptions of various therapies with illustrative clinical vignettes and suggestions for future research.

HISTORY

Modern psychotherapy began with Sigmund Freud's attempt to construct a universal model of understanding human behavior. In the prebiological era of psychiatric treatment, psychoanalytic theory formed the basis for most psychotherapeutic interventions. Unfortunately, Freud held a particularly gloomy, but highly influential, view of the potential for psychoanalytic treatment of patients over the age of 50. He believed that there was too much material to be dealt with and that the elderly had inelastic mental processes and hence were not educable. These ideas produced inordinate pessimism about the potential for psychological change in elderly adults. As the psychotherapies matured and began to be applied to a broader range of patients, therapists came to recognize that age per se does not preclude therapeutic change. Indeed, in the 1950s and 1960s several analysts wrote enthusiastically of their positive experiences in treating elderly patients. In retrospect, this enthusiasm resulted from treatment of generally vigorous elderly patients who were good candidates for analytically oriented psychotherapy.

THEORETICAL ISSUES

Effective psychotherapy, at a minimum, appears to require a strong, early, working alliance regardless of which specific psychotherapy technique is used. The working alliance is commonly understood to be agreement on the goals and tasks of therapy in the context of a positive affective bond between patient and therapist. Elders, not unlike younger patients, vary in their expectations and understanding of psychotherapy. They often come to psychotherapy with general wishes to feel better but uncertain what to expect. As with younger patients, the alliance in psychotherapy is enhanced when: the therapist steps back with the patient to inquire about the nature and form of the problems; helps the patient define agreed upon goals for therapy and articulates them clearly such as reduction of anxiety symptoms or improved relationship with a significant other; there is a personal bond between therapist and patient, in which the patient views their therapist as caring, understanding, and knowledgeable; both patient and therapist agree on the means to achieve goals.

Alliance is further strengthened when the therapist implicitly or explicitly conveys to the patient their understanding and knowledge of the age-related tasks and challenges facing the patient. There are many models for framing this understanding, depending on the type of therapy being used, but at the root, each model makes use of common themes now understood to underpin the adaptional challenges of those negotiating the geriatric phase of life.

A major developmental task of aging is finding restitution for the inevitable biopsychosocial losses associated with this stage of the life cycle.

Therefore, loss is one of the most prominent issues discussed by elderly patients. For many, it is the cumulative effect of multiple repeated losses, before sufficient time has passed for mourning and resolution, that is so devastating. The older person struggles to maintain ego integrity and a sense of purpose in life at a phase of the life cycle often characterized by diminishing coping resources, increasing self-doubt, and the onslaught of assaults and challenges to self-esteem and a positive self-image. The magnitude of an elderly person's reaction to a loss depends, to some degree, on the amount of pride and emotional investment in the lost function. Beyond lowered self-esteem, elderly adults experience life changes that can damage their sense of security and safety. For some, the world becomes uninviting and dangerous, particularly if they have encountered real events such as falls, personal attack, or inaccessible help at a time of need.

Perhaps counterintuitively, fear of death is not as prominent in the elderly as in younger adults and hence is not a major theme in geriatric psychotherapy. Clinical experience suggests that other fears especially focused on health concerns, incapacitation, memory loss, pain, abandonment, and helplessness are more evident. For example, in one psychotherapy-study cohort of seniors over age 60, reasons for seeking treatment were depression related to interpersonal relationships, health conditions, grief/loss, finances, housing and challenges due to executive dysfunction.

Self-worth, security, and independence depend in part on the individual's ability to maintain physical capacities. Beyond obvious challenges posed by physical illness or decline, impairment of important psychological functions becomes pronounced when frailty or illness forces restricted function and imposes a new, different, and often unacceptable self-image and personal identity.

Psychological adaptiveness in old age varies widely. Vulnerability to states of depleted self-esteem, insecurity, fear, or anxiety is heightened when an individual cannot adapt flexibly and is too wedded to maintaining or retrieving that which must be relinquished. Problems of psychological adaptation and diminished self-esteem occur in late life because of such factors as overdependence on social or work roles, overemphasis on the maintenance of control and mastery in all situations, and unresolved problems with self-esteem arising from earlier developmental stages. Difficulties with self-esteem may be rooted in maladaptive, unmodified beliefs; unconscious issues such as dependency conflicts; or interpersonally generated psychological reactions like unresolved grief.

The majority of elderly persons adapt quite well to the challenges imposed by negative societal stereotypes about aging and the losses noted above that threaten to erode self-esteem. Several psychological self-protective mechanisms help to maintain a positive self-image, such as

focusing on past successes, discounting messages that do not fit with lifelong self-concepts, refusing to apply general myths and misconceptions about aging to the self, and choosing to interact with those who provide pleasurable self-esteem enhancing experiences. Some selectively screen out unwanted perceptions such as those that challenge impaired cognitive abilities. While often adaptive and self-protective, such selectivity may also distort reality and promote maladaptive denial.

GENERAL TECHNIQUES

In the initial interview, the psychiatrist explores the major reason the patient has come for the interview and is active and empathic in exploring patient and family resistance to therapy. The patient and family are asked to bring with them all currently used prescription and over the counter medications. Psychotherapy with the elderly can only be successful if it is integrated with effective management of relevant somatic factors affecting adaptation and emotional responses. Hence, careful attention is paid to previously overlooked medical problems and medication adverse effects that may contribute to current psychiatric signs and symptoms.

The elderly patient is usually interviewed individually before important information and concerns are obtained from the family with the consent of competent patients. Elderly patients respond positively to the therapist's listening, empathic, and encouraging attitude. Some patients like to sit close to the therapist and may welcome such expressions of spontaneous warmth as a natural touch on the patient's arm. However, the therapist evaluates each patient's sensitivity about intimacy and does not assume that familiarity is welcome just because the patient is old. Inquiring about how the patient has successfully coped with adversity in the past helps to recall effective coping strategies and offers hope that current stresses and loses can be similarly overcome.

Psychologically less sophisticated patients, who are accustomed to talking about their physical complaints when visiting a physician, initially may feel more at ease if the therapist begins with a medically oriented focus. The therapist may then shift the focus to psychological and social problems.

In general, the therapist of the elderly patient is more active, engaging, supportive, and flexible than with younger patients. The therapist is knowledgeable about the normative, age-related changes that occur in the psychological, cognitive-intellectual, and social life of older people; geriatric medicine; psychopharmacotherapy; family therapy; and community resources. In both office and hospital settings, it is especially useful to work with a mental health colleague, such as a social worker, who is knowledgeable about family therapy and community resources. Patients must feel that they have obtained something from the initial interview (e.g., empathic understanding; hopefulness) to increase the likelihood that they

will return for subsequent sessions. Telephone reminders to selected patients or family members in advance of the next appointment impart the therapist's interest and improve patient compliance. Elderly patients, particularly the frail and dependent, may hesitate to express any negative reactions or doubts about therapy. The therapist might wonder out loud whether the patient may find it difficult, for a variety of reasons, to return for a second visit. Such exploration increases the likelihood that therapy will continue.

Realistic, explicit treatment goals are negotiated with the patient and, as appropriate, family. If treatment goals are overly ambitious, both patient and therapist may experience frustration and disappointment. Many elderly patients, whether consciously or unconsciously, have a specific treatment goal in mind, which once accomplished, leads them to terminate treatment.

SUPPORTIVE PSYCHOTHERAPY

More frail patients, such as those who are cognitively impaired or chronically ill, may require such psychotherapeutic techniques as support of healthier defense mechanisms, ventilation, advice, help with acceptance of diminished capacities, and increased dependency needs. Rather than trying to achieve intrapsychic change, the therapist strives to improve and refine the environment to the particular needs of the patient. For example, the therapist may help the family to arrange a more caring, nurturing environment and assist them to become better caregivers.

The patient's life history and psychodynamics (obtained from the patient or family members) enables the therapist to institute specific supportive therapeutic strategies.

An elderly woman with progressive cognitive impairment and lifelong personality traits of dependency and passivity is anxious and depressed about entering a nursing home. She may adapt well to the home if assigned to a roommate who is nurturing and protective.

Alvin Goldfarb has described a brief, supportive therapy technique for institutionalized, cognitively impaired patients. The therapist improves patients' foundering self-esteem, sense of control, and safety by permitting them to develop an apparent special relationship with the therapist, who is perceived as benevolent and powerful. The patients believe they have some control over the benevolent physician. This is accomplished in small, subtle ways. For example, the physician may elicit the patients' preferences for frequency of sessions, daily timetables or diet, then in a realistic or symbolic way the therapist acquiesces to the patient's wishes while maintaining a quiet caution about being perceived as being unduly manipulative.

INTERPERSONAL PSYCHOTHERAPY

There are not a lot of data supporting the efficacy of IPT in elders. However, what there suggests it is useful as either a primary intervention for depression and possibly as an adjunct to antidepressants although this latter data are inconsistent.

Nevertheless, older adults often have to cope with loss of friends and family, to adapt existing social skills to changing life circumstances and to resolve conflict with significant others, especially adult children. Hence, a therapy that helps the older patient cope with and resolve interpersonal problems would seem well suited to elderly patients. Recent cross-sectional study data in elders confirmed that loneliness is a significant risk factor for depression in both men and women although especially so for women. Interestingly and perhaps counterintuitively, social network size was not associated with risk of depression, although this is consistent with other findings, that is, it is the level of perceived intimacy and social support that is most critical rather than the overall size of the social network.

IPT is a time-limited (usually 16 weeks), manualized psychotherapy that focuses on one or two interpersonal problems, such as the death of a family member. It has been adapted and studied in the acute, continuation, and maintenance treatment of late-life depression.

In a series of controlled studies at the University of Pittsburgh, 79 percent of elderly outpatients with major depression who were treated in the acute and continuation phases with a combination of IPT and nortriptyline achieved full remission. Over the subsequent 3 years, 80 percent of the patients with recurrent major depression who had remitted and who continued on combined treatment, compared with 10 percent who received placebo, were still in remission.

LIFE REVIEW OR REMINISCENCE THERAPY

There is considerable empirical support from many RCTs of the efficacy of individual life review and reminiscence therapy for the treatment of depression, compared to no treatment control groups although support for group intervention is not strong. Along similar lines there is some evidence that autobiographical memory practice can reduce symptoms of depression when compared with "usual care."

Reminiscence is characterized by the progressive return of memories of past experiences, especially those that were meaningful and conflictual. It is theorized that reviewing the past helps the patient find greater meaning in the present. To varying degrees, elderly patients in therapy reminisce about the past, search for meaning in their life, and strive for resolution of past interpersonal and intrapsychic conflicts. Life review therapy is the therapeutic promotion of reminiscence by systematically enhancing this reminiscing process making it more conscious and deliberate. The therapist

may guide the process by encouraging the patient to write or tape an autobiography. Techniques include reunions with family and friends and looking through memorabilia such as scrapbooks or picture albums. This technique has been reported to resolve old problems, increase tolerance of conflict, relieve guilt and fears, and enhance self-esteem, creativity, generosity, and acceptance of the present.

Some authors have cautioned about possible negative consequences of encouraging life review, particularly for a depressed patient with obsessive tendencies or life histories filled with multiple misdeeds not amenable to a positive review. Evoking memories in patients who have suffered massive trauma or whose lives have been seriously affected by deprivation, overwhelming abandonments or humiliation will be emotionally challenging for patients and therapeutic technique is directed to providing an environment of safety and trust so that the evoked emotion can be contained modulated and perhaps reframed to enhance self-acceptance.

COGNITIVE-BEHAVIORAL THERAPY

The elderly are a heterogeneous population. There is no consensus on how much adaptation is necessary in CBT technique for elders. However, it is probable that when frailty, sensory impairment, or cognitive decline is present, therapy will be facilitated if some adaptations are employed. For example, with some elders the therapist is often more active with a focus on here-and-now issues. The pace of therapy is sometimes slower than with younger adults, and when appropriate, the therapeutic alliance may be enhanced by permitting the patient to adopt a senior, teaching role with the younger therapist. To compensate for specific deficits such as hearing loss or cognitive slowing, information may be presented in different modalities, such as written material or taped sessions for the patient to take home. Homework has been found to be feasible with many elders and helpful to the process including use of formal thought records. With older patients, material may have to be reviewed more often and termination is often managed gradually rather than abruptly.

There is some evidence to suggest that CBT is most effective for older outpatients with mild–moderate depression who are relatively healthy with high motivation for treatment and absence of a personality disorder. These characteristics are not unlike those of candidates for psychodynamic therapy and IPT.

PROBLEM-SOLVING THERAPY

Four RCTs investigated the effectiveness of problem-solving therapy for older adults. Three found that problem-solving therapy was better than other therapies and better than no treatment although not all trials are positive. There is some indication that PST is especially useful for depression associated with executive dysfunction where problem solving

and decision making may be particularly impaired. A large comparative trial of PST and supportive therapy found that the more structured and focused intervention of PST versus a less structured supportive method was more effective for treating late-life depression associated with executive dysfunction.

PST has been adopted for use in a variety of disorders and elderly populations with demonstrated effectiveness. It has been shown to be effective in reducing symptoms of poststroke apathy compared to placebo, late-life major depression compared to supportive therapy and reminiscence therapy, minor depression and dysthymia compared with paroxetine and placebo, vision-related quality of life in patients with macular degeneration.

PST is a brief solution-focused intervention that draws on methods commonly employed in other modes of structured therapy such as CBT or IPT, that is, direction and coaching, hierarchical lists created, homework assigned, relating problems encountered to evoked emotions, situational analysis of antecedents and precipitants for the problem and patient-generated solutions guided by the therapist are core to the method. Problems can range from major adverse life events, such as bereavement or illness, to everyday coping such as transportation, banking, or shopping. Once a problem is identified and its determinants are specified, a brief list of the pros and cons of potential but realistic solutions is generated by the patient and therapist taking into account the focal nature of the therapy and the time constraints of the brief format. Patients with mild cognitive impairment can utilize PST if they retain sufficient cognitive capacity to absorb the method and retain key elements from one session to the next. They may require additional supportive strategies, such as written notes, memory devices, environmental adaptations, and caregiver involvement.

PST may be most effective when delivered face to face either individually or in group formats but other acceptable and feasible methods of PST delivery have been shown to be effective for harder to reach patients, such as Internet-based therapy for depressed home-care elders. Improvement in quality of life and a reduction in anxiety symptoms have been demonstrated through use of videophone in hospice caregivers.

PST has been widely adopted for use with informal caregivers of those with dementia improving coping skills, self-efficacy, and depression. Frontline workers dealing with patients with dementia and their families in the community are often overwhelmed by the complexity of problems they must address during relatively short interventions. When professional workers in the community are trained in PST it has been shown that, compared to a control group of caregivers in standard care, PST training helps them organize their approach to complex problems. This in turn appears to enhance their ability to help caregivers, thereby significantly improving the capacity of caregivers on key measures of function and

emotion such as coping, mastery, and competence while significantly reducing emotion-oriented coping, burden, and stress.

BRIEF (TIME-LIMITED) PSYCHODYNAMIC PSYCHOTHERAPY

Brief, or time-limited, psychodynamic therapy can be considered for elderly patients with clearly defined, age-related problems that can be expected to resolve within a brief period of psychotherapy, such as an adjustment disorder, unresolved grief reaction, or new-onset anxiety disorder. Setting a time limit at the beginning reinforces the patients' confidence in their ability to resolve problems within a circumscribed period of time, focuses and accelerates the therapeutic process, diminishes fear of dependency, and accommodates limited financial resources. Brief therapy uses the therapist's psychodynamic understanding of the patient and the patient's transference to clarify and help resolve the patient's emotional reactions to a current life stress.

In a pilot study of the process and outcome of brief psychodynamic psychotherapy of patients with an adjustment disorder with depressed mood, the women showed greater improvement and were more active and assertive than the men who tended to become more dependent on the therapist. The patients used the therapist to validate competency and normalcy, which helped to support and restore feelings of mastery and self-esteem. Symptomatic improvement often exceeded the achievement of insight or self-understanding.

INSIGHT-ORIENTED PSYCHOTHERAPY

While studies of dynamic psychodynamic therapies are relatively sparse in number, several RCTs of psychodynamic therapy (including brief dynamic therapy) for older adults have shown that it is an effective treatment for depression comparable to other forms of therapy such as CBT in one head-to-head trial. Overall, data suggest that about 70 percent of people who had received dynamic psychotherapies were in remission at 2-year follow-up, broadly consistent with meta-analytic data on the overall efficacy of psychotherapy in elders. A rich array of both earlier and recent literature describing successful clinical cases of psychotherapy with the elderly, convincingly support empirical data and the position that, for appropriately selected cases, age per se does not interfere with the effectiveness of psychodynamic therapy including psychoanalysis.

The selection of patients and the basic approach to insight-oriented therapy for older patients who are physically and cognitively intact is largely the same as that for younger patients. Appropriate patients have the ability to form a therapeutic alliance, the capacity for introspection and to mourn loses and the motivation for change. Older patients may be particularly suited for this therapy given their appreciation of the finitude of life, increased tendency toward introspection, and a more philosophical

view of themselves and life.

During longer-term psychotherapy, the condition and circumstances of the older patient evolve and change. The development of physical illness may require medical referral, collaboration with family members, or advocacy on behalf of the patient for community and other support services. Such active intrusions into the patient's real-life problems are not commonly dealt with by psychodynamic therapists, but when treating elderly patients, techniques often need to be adapted to their changing needs. Therapists are most effective when they learn to integrate different therapeutic modalities while maintaining a psychodynamic focus on the therapeutic relationship, the transference, and the goal of inner conflict resolution. Indeed, the necessity to effectively integrate different modalities of treatment is one of the hallmarks of the therapist's flexibility necessary to treat and manage the evolving therapeutic issues of elderly patients.

CLINICAL ISSUES

Indications for Individual Psychotherapy

Elderly adults are a heterogeneous population. The continuum ranges from the normative or healthy older patient whose overall functioning is retained to the frail elderly patient. Five categories are normative elderly; normative elderly in crises; independent frail elderly; dependent, physically frail elderly; and dependent, cognitively impaired, frail elderly. Indications for various modalities of individual therapy are strongly influenced by the position of the patient on the normative-frail continuum. Moreover, because capacities change over time, therapeutic approaches for a given patient may also need to change.

With advancing age, crisis is frequently the stimulus for seeking out psychiatric care, often initiated by a family member. A small qualitative study found that common reasons for elders seeking psychotherapy included depression related to interpersonal relationships, health conditions, grief/loss, finances, housing and challenges due to executive dysfunction, that is mild cognitive dysfunction.

Individual therapy during crisis focuses on mourning for lost important relationships or personal capacities and working through conflicts over separation, redirecting energy to more realistic goals, redefining relationships especially with regard to accepting appropriate dependency and reestablishing or developing appropriate strategies to enhance mastery, sense of control, and self-esteem. Family education about ways of helping the impaired elder is of critical importance. Psychotherapy during crisis is often integrated with medication and environmental therapies. Problem-solving techniques, brief IPT, and CBT are useful approaches during the crises, although longer-term supportive or psychodynamically oriented therapy may evolve.

Behavioral techniques using operant behavioral conditioning have been applied to a wide range of target symptoms in chronically ill elderly patients, including incontinence, pain, insomnia, wandering, socially inappropriate behaviors, reduced level of activity and participation, toileting, bathing, and feeding. Environmental cues are manipulated to increase, decrease, or shape behaviors. These techniques are useful for institutionalized and frail elderly patients to reduce the excess disability that often accompanies dementia. An ABC approach to behavioral management of disturbed behavior may be useful. This technique includes accurate neuropsychological evaluation; defining specific measurable and observable behavior for modification; determining the antecedents (A) to the onset of the disturbed behavior and systematically recording them; recording the type, frequency, and duration of the baseline (B) conditions; tailoring a treatment program (A&B) to alter the behavior, which includes caregiver counseling, introduction of reinforcing, and extinguishing techniques, that is, consequences (C); instituting environmental changes and psychotherapy to assist caregivers; and program evaluation. A major deficiency of behavioral interventions is their labor intensiveness and the need to maintain the program. Once the interventions are withdrawn, behaviors tend to return to pretreatment levels in these institutionalized patients. Cognitive-behavioral interventions in long-term care settings, while often effective when introduced by a consultant, generally fail if the consultant leaves. Front-line staff in these settings usually lack the training to sustain sophisticated cognitive-behavioral programs on their own.

Various forms of individual psychotherapy have shown therapeutic value for states of bereavement. Bereavement can lead to chronic states sometimes called complicated or prolonged grief, which is characterized by persistence of acute grief symptoms complicated by cognitive emotional and behavioral symptoms. Complicated grief is common, found in 9 percent of bereaved older women. Psychotherapeutic interventions are particularly effective for bereavement complications such as chronicity, depression, or anxiety disorders. Most interventions include some education, support, attention to the relationship with the deceased before death and as it has changed since, and supportive assurances of "normality" for bereaved individuals who need to be reminded that their feelings and experiences are not deviant or abnormal. Complicated grief therapy (CGT) has structured this process and includes grief monitoring, imaginal and situational revisiting (promoting memory and using aids such as pictures or situations), imaginal conversations, building personal emotional and instrumental supports, defining and planning personal aspirations and opportunities for self-care and promoting positive emotions. RCT data suggest that, when compared to IPT, CGT may be highly effective for the elderly.

Psychotherapy of various types has been recommended for the

treatment of anxiety disorders. Preliminary data suggest that CBT can be quite effective in older patients with panic disorder, and may thus be considered as an alternative to pharmacological treatment for selected patients or as an adjunct to pharmacological treatments when patients have behavioral symptoms that can be targeted.

Psychotherapy has shown some value in the management of elderly patients struggling with alcohol abuse. Inclusion of cognitive-behavioral training that addresses themes of self-advocacy, self-esteem, and relapse prevention may aid recovery.

Individual psychotherapy is often helpful in the treatment of sexual dysfunction. For example, premature ejaculation usually responds readily to sex education, reassurance, and sex therapy techniques practiced at home alone or with a cooperative partner.

Limitations

Elderly adults are underrepresented in psychiatric outpatient clinics (2 to 4 percent of patients seen) and even more so in private psychiatric practice. Older patients are often not referred for therapy possibly because primary care physicians are not fully aware of its effectiveness in the age group. Overall a minority (25 percent in one study) of depressed elders receive psychotherapy but, even of these, only one-third got ongoing consistent therapy. Young-old, more highly educated elders are more likely to receive psychotherapy.

The application of psychotherapy, therefore, appears to be limited by the willingness of practitioners, both psychiatric and primary care, to use it for elderly patients. Completion of a series of regular therapy sessions, whether short or long term, is often limited by practical considerations such as difficulties with insurance and personal finances, transportation, or weather.

Raised in an era when shame was associated with psychiatric problems and treatment, some elderly persons feel embarrassed and indignant when their physician or family suggests consultation with a psychiatrist. Many elderly persons, as well as health professionals, believe that depression and anxiety are expected concomitants of aging or routinely attribute abnormal psychological states to physical illness. The symptoms themselves, such as depression, apathy, and hopelessness, prevent older persons from seeking treatment. Patients whose ethnoracial backgrounds differ markedly from that of their therapist may have quite different notions and expectations about a visit to a psychiatrist. Many cultures view mental disorder as shameful. Individuals may fear damage to their families' reputations. For example, elderly patients from some ethnic backgrounds have expressed fear that their grandchildren may be less marriageable if there is mental illness in the family. Beyond cultural barriers, other access barriers limit care for these groups including language incompatibilities, lack of

knowledge of where to obtain psychiatric services, economic issues, a tendency to seek care only after a crisis, and fragmented, difficult-to-access, mental health care services.

Adult children of an aging parent may minimize the parent's psychiatric symptoms, be ambivalent about assuming a parenting role, and may share their parent's negative attitudes toward psychiatry. All these barriers result in impaired access to care, poor compliance with medication and psychotherapy and a high dropout rate.

Strategies to overcome these formidable barriers in the very first session include active exploration of patient and family resistances to treatment, discussion of how ethnic differences between therapist and patient can interfere with treatment, ambivalent and negative attitudes about psychotropic medication, and by encouraging the patient to share reactions to the first session. If the therapist intuitively suspects the patient is resistant to treatment, active inquiry about problems that may interfere with subsequent sessions such as shame or practical issues like transportation, are explored. It is important that the patient feels that something has been achieved in the very first session. In this way the seeds of the therapeutic alliance are planted with both the patient and family in the initial visits. Even for the very impaired depressed patient bereft with hopelessness, conveying hope and a willingness to help can facilitate the beginning of a therapeutic relationship.

Complications

Whatever the form of psychotherapy, the course may be complicated by issues of transference and countertransference. The patient's feelings about therapy will be influenced by education, socioeconomic status, culture, and ethnicity that can restrict or enhance the impact of treatment.

Transference is age independent (of both patient and therapist), the determinants stemming from the timeless unconscious. However, developmental theory expands the traditional perspectives by demonstrating that the transference derives not only from significant infantile experience, but also from internalized objects encountered in adult life, for example, a spouse or a child.

While there are no age-specific transferences, the psychodynamic impact of life experiences during old age may increase the emergence of certain forms. For example, frailty leads to dependency conflicts and fears of abandonment, emotions that can easily evoke parental transference reactions toward the health professional derived from reactivation of the patients' need for a protector (parental figure). This form of transference emerges readily in dependent, institutionalized patients, even when psychotherapeutic contact is relatively brief and intermittent. Bereavement, especially of a spouse, or other loss (e.g., sexual capacity) may lead to an eroticized spousal transference to the therapist in which the

patient unconsciously relates to the therapist as an erotic love object who becomes a fantasy substitute for the lost object.

Reverse transference describes a phenomenon of geriatric psychotherapy in which the patient experiences and relates to the therapist as a child and takes a parental role toward the therapist in the treatment dyad. Therapists may experience this transference interaction as demeaning or patronizing and feel uncomfortable with the seeming reversal of dominance. Young therapists may find this especially challenging. It is generally a transient phase of therapy that defensively protects the patient from deeper levels of transference-based affect associated with conflicts over dependency.

Somewhat different is filial transference, in which patients deal with the therapist as one of their own children, enacting such unconscious conflicts as rage for not fulfilling wishes for caring, or guilt derived from earlier failures in the parental role.

Countertransference responses of therapists are often intense in the treatment of elderly patients, sometimes blocking the therapist's willingness to engage the patient in individual psychotherapy. The complexity or chronicity of problems of late life may lead therapists to be unduly concerned that older patients will become dependent on them and engender in some therapists reluctance to embark on treatment for fear of the patient's dependency. Similarly, it is not uncommon for younger therapists to avoid treating elders because of their anxiety over having to deal with frailty or decline, in older patients. Uncertainty about their ability to help the older person may induce feelings of guilt or anxiety in the therapist and lead to withdrawal from or avoidance of provision of psychotherapy.

Less experienced therapists may initially doubt the applicability of their skill to elderly patients, thus reinforcing pre-existing uncertainties about the mastery of their craft. The patient's frailty sometimes induces especially strong withdrawal from using psychotherapy because therapists are unwilling to encounter and confront their own hopelessness and fears of abandonment or mortality. Some therapists withdraw because of fear of being engulfed by the patient's demands and dependency. These factors may be compounded by the added therapeutic burdens of working at a slower pace, dealing with sensory deficits and cognitive decline.

Countertransference parallels transference reactions in that therapists may develop strong urges to rescue the patient and do too much, reactions that may derive from unresolved guilt toward their own parents.

Therapists must deal within themselves with the repetitive need for therapy to focus on mourning and acceptance of loss. This is in contrast to the more hopeful perspective of ego development and mastery, which is common in psychotherapy of younger adults and easier for therapists to deal with. Treating elderly patients holds the danger that helpless anxiety

or despair may emerge in therapists who have not successfully dealt with their own issues of loss and/or advancing age or frailty.

Therapists of elderly patients are often surprised by the emergence of erotic countertransference during more intensive therapy and may recoil from or deny its presence or feel uncomfortable about aspects of the patient's sexual feelings, thereby depriving the therapy of crucial areas of work.

The sometimes overwhelming effects of cumulative life trauma are painful for therapists, who may retreat into mechanistic or formulistic approaches, inhibiting their own empathetic relatedness.

A young therapist was surprised when a difficult elderly woman complained angrily about feeling manipulated and exposed when sent home to write her life story, a technique the therapist had read was suitable for the elderly. In discussion of the case with his supervisor, it became evident that he felt overwhelmed by the patient's painful life and uncertain of what would be helpful. Rather than engaging her in an attempt to understand her feelings, he prematurely employed a cognitive intervention that made her feel infantilized and rejected.

The process of termination may mobilize the very conflicts and issues that led to therapy, such as the loss of a loved one. Nevertheless, the termination process affords another opportunity for the patient to work through conflicts about the finitude of life and relationships, feelings about abandonment and loneliness, and dependency.

In approaching termination, elderly patients need to be assured of the therapist's continued future availability should the stresses associated with advancing age precipitate regression, conflict, and decompensation. While some elderly patients terminate successfully, for many therapy is an intermittent process to be resumed as needed. The therapist can ease the patient's return to therapy by anticipating, with the patient, reasons that may inhibit reinstating therapy such as fear of disappointing the therapist and feeling ashamed because symptoms have recurred. Termination is sometimes imposed by unanticipated events, such as illness. Both patient and therapist must deal with the emotional impact. The focus of the relationship shifts from coping with life to dealing with illness and in the extreme, death.

Contraindications

There are few contraindications to psychotherapy, although the form of treatment is carefully tailored to the needs of the patient. Psychoanalytic psychotherapy is approached with caution. The therapist first ensures that the patient retains sufficient ego capacity to deal with regression during therapy, to work through adaptive mourning, and has the capacity to replace lost sources of self-esteem.

As in younger populations, CBT is indicated for the treatment of acute or chronic depressive disorders, concurrent with antidepressant

medications when indicated, and for symptoms associated with personality disorder. Mild cognitive impairment secondary to dementia is not a contraindication to CBT, although suicidal depression or severe cognitive decline requires alternative therapies.

Goals of Treatment

Psychotherapy is most effective when it is used for specific indications with defined goals. Goals are modified to fit the function, cognition, and psychological capacity of each patient. Generally, the greater the frailty, the more modest are the goals. Goals for patients able to undertake dynamic psychotherapy include psychological mastery over the past and its unresolved grief; resolution of adult and childhood sources of shame and guilt; resolution of current interpersonal conflicts, especially with spouse or adult children; working through conflicts associated with loss of self-esteem and establishing substitute sources of gratification for those that had to be relinquished; coming to terms with failure to achieve ideal aspirations; and, at the most advances level, processing and integrating unconscious conflicts experienced in the therapeutic transference relationship. Pollock has termed the creativity and energy that may be released by successful resolution of losses *mourning-liberation*.

In crisis therapy, the goal is to reestablish the patient's best premorbid level of function. Examples include acceptance of appropriate levels of dependence or controlling excess, psychologically induced morbidity.

For the more debilitated, frail, elderly patients, psychotherapy goals are often symptom-focused behavioral changes. These include focal interventions; for example, dealing with dementia-related behaviors such as aggression, excess withdrawal, agitation, or delusions. With these patients, therapy goals include strengthening the roles of family caregivers and fostering a more appropriate, supportive environment for the patient.

ETHICAL ISSUES

Frail, institutionalized elderly patients have limited capacity to use traditional psychotherapies. They are easily viewed by therapists as beyond help. In allocating scarce resources, therapists struggle with whether to expend effort on this population or reserve it for their more vigorous elderly patients. This is a difficult ethical dilemma since frail elderly patients are the most dependent, helplessly reliant on caregivers, who in turn are burdened with the role of deciding who shall or shall not receive certain forms of care.

While most forms of psychotherapy require the active participation of patients, and therefore their inherent consent, behavioral interventions may be applied to the patient externally. In using behavioral techniques with frail elderly patients, therapists are advised to exercise caution in

distinguishing between externally imposed goals of therapy, that is, a focal symptom that is troublesome to staff and the overall welfare of an often helpless patient whose ability to consent to, and participate in, setting treatment goals is limited.

Clinicians are often confronted with ethical concerns over confidentiality and the patient's decision-making capacity. Both family members and therapists may inadvertently infantilize more frail patients and override their right to participate fully in the therapeutic decision-making process. The psychotherapist must carefully evaluate a patient's ability to make decisions. Similarly, the family's right to know about the patient and participate in therapy is carefully balanced by the preeminent right of the competent elderly patient to confidentiality in the therapeutic relationship. In practice, this is often a difficult issue for therapists, especially when families are intrusive, demanding, or litigious.

FUTURE DIRECTIONS

Conclusions about the efficacy of psychotherapy have remained restricted to elderly patients motivated to participate in research who are typically healthy, community-residing Caucasians in their 60s and 70s. Studies of the efficacy of psychotherapy in other populations (e.g., minority elders, the frail medically compromised and the very old) and in other treatment settings (e.g., long-term care, hospital) may help clinicians to adapt psychotherapy to these relatively unstudied elders. Future research should study predictors of treatment outcome, including subtypes of depression, the role of medical comorbidity, and how therapist and patient characteristics influence outcome. Given the current understanding that motivation and compliance with psychotherapy are major factors governing success, it would be helpful to understand elderly persons' resistance to therapy and strategies to prevent premature termination.

57.4i Cognitive-Behavioral Therapy

ERIC GRANHOLM, PH.D., JOHN R. MCQUAID, PH.D., AND PATRICIA A. AREáN, PH.D.

DEFINITION

Considerable progress has been made in developing cognitive-behavioral therapy (CBT) interventions for use in elderly people with anxiety and depression, and researchers have recently begun to modify and evaluate newer CBT interventions for older people with psychotic disorders.

CBT is a form of psychotherapy that attempts to modify the interpretations of experiences that determine feelings and behaviors. The premise of CBT is that cognition (the process of acquiring knowledge and forming beliefs) can influence feelings and behaviors. CBT interventions help people to identify and correct thoughts and misinterpretations of experiences that are at the root of problematic behavior. Behavioral interventions (increasing rewarding activities, practicing new skills) both

improve mood and provide opportunities to test the accuracy and benefit of beliefs that may contribute to psychological symptoms and impaired functioning.

ADAPTING CBT FOR OLDER CLIENTS

When provided optimally, CBT is individualized for the specific client, regardless of age or aging-related issues. Problems and goals are identified in a collaborative manner, activities and skills are designed for the specific needs of the client, and the therapist and client continually review progress to determine whether treatment is providing the desired benefit. Clinicians should keep in mind that treatment modifications should not be made solely on the basis of a client's age, but should be made when issues related to cognitive impairment, disability and illness are present that can influence the effectiveness of treatment. These issues can occur in any age, but are particularly prevalent in older adults, especially common among those who are 75 years old or older. Therefore, before making any major accommodations, a good clinician assesses the need for making them first rather than solely making assumptions on the client's age.

Ageist Beliefs and Age-Related Challenges

One of the few age-specific modifications clinicians need to make has to do with cohort beliefs about seeking help and ageism. Older adults are less likely to seek help for mental health problems than younger adults, and have been noted to hold erroneous beliefs about aging. Cohort-related beliefs can devalue therapy (e.g., "Don't air your dirty laundry") and ageist beliefs held by both therapists and clients (e.g., "I'm too old to learn or change") can interfere with participation in therapy. Just as they can be applied to beliefs that increase psychiatric symptoms, thought-challenging interventions can also be used to modify ageist beliefs that interfere with treatment participation. Similarly, using CBT techniques to address interpersonal and behavioral challenges related to aging is also necessary, such as role playing age-relevant interpersonal situations (e.g., talking to a doctor about health concerns or eyeglasses) and practicing solving around age-specific concerns (e.g., finding transportation, coping with hearing or vision problems).

Transportation Barriers

Transportation and ambulation problems, which are more common among older clients, can further exacerbate problems with isolation and withdrawal from society. It may be necessary to provide transportation to therapy sessions or conduct therapy at convenient locations in the community. Providing treatment in the community can also reduce the stigma associated with going to a mental health clinic, which can especially

deter older clients.

Cognitive Impairment

Addressing neurocognitive impairment is another important factor to consider when designing CBT interventions for the elderly. Due to normal aging and a lifetime of comorbid factors that can impact cognition in older clients, especially those with severe mental illnesses (e.g., poor education, lack of work, physical illness, poor nutrition, poverty), cognitive functioning may be impaired to a greater extent in older clients. Simplifying and slowing down discussions, repeated practice of skills, and neurocognitive compensatory aids (e.g., reminder notes, treatment workbooks, writing down information in session, and acronyms to help with skill recall) can be used to help alleviate cognitive impairments. Given fine motor and vision difficulties that are also common in older clients, cognitive compensatory aids and educational materials should use large fonts and writing spaces. Clinicians who have worked with younger populations may need to modify their expectations about the speed at which change may take place, without assuming that older clients cannot make change.

Medical Problems

Many medical impairments increase in frequency as people age. With longer life spans, there is increased exposure to a variety of medical ailments, including cancer, heart disease, musculoskeletal disorders, and other chronic health problems. These changes in health have a number of direct and indirect effects on psychiatric symptoms and treatment. Physical suffering can directly influence mood, anxiety, and psychotic symptoms. In addition, reductions in physical health can interfere with engaging in rewarding activities, demands of health care can reduce financial resources, and sensory impairments secondary to health problems can interfere with both daily activities and interpersonal interactions. All of these problems can also interfere with participation in CBT, which emphasizes the active practice of new skills. Therefore, CBT interventions need to focus on increasing client activities within the constraints of their medical condition. In addition, cognitive interventions can be beneficial if they help clients to shift perspective from the negative aspects of illness and to focus on thinking that can improve their experience in the moment, even in the context of medical problems.

Role Changes

Aging is associated with transitions through different roles across stages of life. Some of these changes can be disruptive for people, particularly if they are unexpected or involve loss of important sources of reinforcement. For

example, retirement may be a positive experience for many, but for some it can be very disconcerting, particularly individuals who defined their worth primarily through their productivity. Other role transitions involve profound loss, such as changing from a spouse to a widow(er) or divorcee, or from a homeowner to a member of an assisted-living community. In addition, for some individuals role changes include unexpected demands of caregiving at an older age, either of a spouse, child, or grandchild, or alternatively losing independence and needing the aid of a caregiver. These role shifts can involve both changes in self-image as well as physical and emotional demands. These changes can contribute to depression by either reducing access to rewarding activities (e.g., work) or by activating beliefs the client has that can be depressogenic (e.g., "I'm unproductive and useless"). They can exacerbate anxiety symptoms as individuals face uncertainty and increased perceived risk (e.g., "my wife handled the finances, how can I manage without her?").

When clients are facing such role changes, CBT can be particularly beneficial. On the pragmatic side, behavioral exercises such as scheduling, information gathering, and contacting support resources can help patients more effectively navigate the role change. Cognitive interventions can address depressogenic thoughts, challenge beliefs that are inconsistent with the new role, and generate thoughts that are likely to improve functioning. These efforts can work in service of modifying schema that are less beneficial in the new role (e.g., seeing one's value as connected to productivity; feeling dependent on others) to a schema that is more functional given the realities of the situation (e.g., seeing one's self as innately valuable; remembering that new skills can be learned).

Interpersonal Events

Older adults are vulnerable to changes in their relationships that can have important implications for their mood and functioning. Deaths of spouses, other family members, friends, and acquaintances can both provoke grief and represent loss of important social supports. Interpersonal relationships can end through other means as well, including adult children moving away from home or the patient leaving the work environment. In addition, changes in relationships associated with aging, such as having a child become a caregiver of the older person or needing to become a caregiver of an older person, can strain those relationships.

Issues of loss, isolation, and improving social support, leisure activities, and interpersonal communication skills, therefore, are even more important for older clients. Again, the combination of behavioral activities, such as communicating with supports or developing new activities that can increase positive contacts, as well as thought challenging to reduce cognitions that exacerbate the pain associated with interpersonal events can be important themes in CBT for the elderly.

Culture and Age Cohorts

Broadly defined, culture provides the context that guides the development of beliefs and expectations. That context changes over time. Among geriatric populations, different age groups have different expectations. The oldest members of society, having lived through the Great Depression and World War II, grew up with different cultural expectations than their children, who were born during and after World War II and came of age during the 1950s and 1960s. It is important for therapists to assess each person's developmental history with a focus on understanding the beliefs and values that arose from that history. This assessment can then help in developing interventions that address unhelpful thoughts and behaviors while supporting the core values of the client. In addition, the assessment is critical to prevent clinicians from relying on general assumptions about a particular age cohort, but rather to have an understanding of how the experiences shaped the person with whom they are working.

In reviewing the domains above, two major themes arise: *Loss* (of health, role, loved ones, finances) and *danger* of further losses in these domains. Loss tends to be associated with risk for depression, and perceived danger with risk for anxiety. Treatment for older individuals in particular needs to address coping with such losses in a constructive manner, helping clients differentiate between likely and unlikely threats, and identifying coping strategies for upcoming risks.

Traditional CBT emphasizes change orientation, attempting to change how one acts and thinks to improve mood. However, emphasizing change alone can be limited in effectiveness and potentially invalidating of the client, if the therapist does not also acknowledge the unchangeable nature of some challenges in the older person's life. Some CBT experts refer to this as "the healthy management of reality." From this perspective, the role of CBT is to help clients accurately understand the challenges they face, and then when appropriate modify their actions and thoughts so they can live a meaningful and rewarding life within the context of those challenges. Recent models that have derived from CBT and incorporate acceptance and mindfulness approaches (including dialectical behavior therapy, acceptance and commitment therapy, and mindfulness-based cognitive therapy) all emphasize both skills in change as well as acceptance of unchangeable realities.

TECHNIQUES

Stages of CBT

In general, CBT can be framed in three stages. The first stage is assessment and initial treatment and includes definition of clients' current problems and goals, education about the model of treatment, establishment of a collaborative relationship, and agreement on a treatment plan. In addition,

the therapist begins to develop a case formulation. The formulation is a model that attempts to explain the current difficulties in terms of a schema (an organizing set of deeply held beliefs that define the client's perception of self and determine the information that the client attends to, remembers, and recalls, and how that information is interpreted). One goal of this phase is to instill hope that improvement can occur, if possible through the client experiencing some symptom relief secondary to an initial exercise or homework assignment. The middle stage of therapy focuses on skills acquisition, with the primary goal of the client learning to implement CBT interventions independently. The final stage, relapse prevention and termination, emphasizes consolidation of skills, problem-solving obstacles to skill use, identifying potential risks for symptom exacerbation, and developing a plan to apply learned skills in the case of symptom recurrence.

Assessment and Initial Treatment

CBT emphasizes objective measurement of constructs whenever possible, and this begins in the assessment phase. When working with older clients, this will include assessing not only symptom severity, but also the resources available and the challenges faced, and then trying to define all these factors in objective terms. Number of supports, income relative to expenses, health limitations, and caregiver responsibilities are all-important aspects to assess. In addition, standardized measurement of symptoms provides a baseline to assess progress in treatment. In particular, the use of measures with normative data for older populations (such as the Geriatric Depression Scale) is important because several symptoms of depression and anxiety (e.g., sleep changes, reduced energy, memory, and concentration difficulties) can occur in older populations independent of depressive symptoms, and therefore measures need to account for these potential confounds.

As noted above, a key goal of the initial assessment is the development of a case formulation. A case formulation provides a framework for choosing interventions that match the specific needs of the client. Case formulation is particularly important when dealing with special populations such as older adults because it guides both the assessment and the treatment. A well-defined case formulation increases the likelihood that areas such as those reviewed above are addressed and incorporated into treatment.

Juanita was a 69-year-old divorced, unemployed Mexican American woman, who supported herself on her Social Security benefits. She lived in a one-bedroom apartment. Due to her daughter having been arrested for drug possession, she was serving as guardian of her 5-year-old grandson. She presented with the following concerns:

1. Depressed mood: Juanita reported daily crying, anhedonia, increased appetite and weight gain, feeling tired "all the time," feelings of guilt and shame, and thoughts of death.

2. Anxiety symptoms: Juanita met criteria for generalized anxiety disorder. She reported constant excessive daily worry about both major stressors (her daughter's legal troubles; financial stress) as well as other factors (her children, her friends, safety).
3. Daughter's arrest and custody of grandson: Her daughter had been arrested approximately 1 year prior to treatment, leading to Juanita receiving custody of her grandson. Her grandson frequently cried at night for his mother, and Juanita felt overwhelmed by trying to provide for his care. Her daughter was incarcerated several hours from where Juanita lived, preventing visitation.
4. Health problems: Juanita had type II diabetes. She had difficulty managing her symptoms in part due to anxiety about checking her glucose levels. Juanita was obese and worried that her diabetes would progress and lead to amputation of her foot.
5. Social isolation: Although Juanita had family and friends in the area, she rarely contacted them or answered her phone.

In the intake interview, Juanita stated, "I tried to be a good mother, but I failed. And now I'm going to fail my grandson." When discussing goals, Juanita stated that her greatest concern was her daughter's and grandson's futures. In discussing this goal in terms of what Juanita could influence, she agreed that she would like to provide a safe and loving environment for her grandson, and to be a support for her daughter. These goals required her taking several actions around caring for herself, including:

1. Reconnect with family and friends to increase pleasant activities and get help with caring for her grandson
2. Improve her diabetes care and reduce weight so that she could be physically better able to care for her grandson
3. Generate additional income by re-establishing her home-based business sewing traditional dance dresses for a local dance studio
4. Make arrangements to visit her daughter in prison with her grandson on a regular schedule

In this case, several of the described factors that are associated with depression and anxiety in older people were apparent. Juanita had clear medical problems that limited her activities, she had limited resources, and she was isolated from supports (albeit by her own actions). She also experienced a clear loss (her daughter being incarcerated) and a demanding role change (becoming caregiver to her grandson). In the context of the meaning of these events ("I failed"), it is not surprising for her to be experiencing depressive symptoms. Of particular note, her anxiety and depressive symptoms were exacerbating both her health problems (interfering with diabetes management) and interpersonal functioning (avoiding supports).

In reviewing the goals, the initial theme expressed by Juanita was a desire to care for others. However, the therapist was concerned that without taking care of Juanita's own issues, she would be unable to achieve her goals. Therefore, the therapist helped focus on self-care in terms of necessary preparation for her goal of caring for others. In this case, the proposed formulation identified a potential core belief held by Juanita of "I am undeserving; I need to care for others to get love." Rather than directly challenging this initially, the therapist first worked with strategies to achieve the goals Juanita had identified. Over the course of therapy, an additional goal of schema change (moving from "I'm undeserving and need to care for others to get love" to "I am a good and deserving person who loves to care for others") was instituted, but initially therapy focused on engaging Juanita in treatment so that she could gain some symptom improvement before taking on the more difficult tasks of acceptance and schema change.

In working with the therapist, these general goals of providing for her grandson were translated into more specific goals that could meet her goals and be beneficial to her in terms of improving her mood and functioning.

Middle Stage Interventions

Although the interventions in this stage of therapy are generally divided into behavioral and cognitive interventions, they frequently have cognitive and behavioral aspects. Behavioral interventions can lead to changes in cognition (e.g., doing an activity and finding out it is more enjoyable than predicted), while cognitive interventions can be useful in helping patients to do behavioral interventions (e.g., challenging the belief that one has to "feel" like doing something before doing it). Research has shown that cognitive or behavioral exercises lead to change in both cognition and behavior. In general, interventions focus initially on assessing baseline thoughts and activities and their relationship to mood and other outcomes. Clients then learn change strategies and coping skills in this stage of therapy, and assess whether these skills are effective in improving outcomes.

Psychoeducation. This initial assessment of thoughts and activities and their relationship to mood and other outcomes provides an opportunity to introduce the cognitive model and the idea that thoughts influence feelings and behaviors. The groundwork for future cognitive work is laid by using the client's own experience to illustrate how thoughts might be interfering with their goals by producing unwanted moods and behaviors. With all clients, but particularly with older clients with cognitive impairments, it is helpful to draw on a pad or marker board or use a handout to illustrate associations between thoughts, feelings, and behaviors, as shown in Figure 57.4i–1.

Depending on individual client needs, it may also be important to provide education about symptoms associated with specific diagnoses, the action of medications, medication adherence strategies (especially in the context of memory impairments), and complementary interactions between medication and psychotherapy treatments. It is often useful in this context to provide education about the vulnerability-stress-coping model of mental illness, focusing on the interaction of biological vulnerabilities, stress triggers, and coping strengths in symptom exacerbation or relapse. Finally, depending on the individual client, it may be essential to provide education about triggers and signs of crisis and develop a safety plan for prevention of suicide or relapse/hospitalization.

FIGURE 57.4i–1. Generic cognitive model illustrating relationships between unhelpful (*top*) and helpful (*bottom*) thoughts, feelings, and behaviors.

Behavioral Interventions. Behavioral interventions in CBT for mood disorders tend to emphasize activities that increase positive affect, gather evidence to challenge unhelpful beliefs, or both. Initial interventions can solely consist of activity tracking (e.g., recording a baseline of all activities that a person is doing throughout the day). Activity scheduling is simply identifying one or more activities that clients may find rewarding and planning it into their day. Keys to successful activity planning are generating multiple options, working with the clients to identify choices they believe they can complete, and problem solving potential obstacles to the activity. In addition, tracking mood levels before and after the activity can help clients notice whether there is any benefit. In the elderly, medical problems can significantly limit motility and activity and older clients can have beliefs (e.g., "But, I've been doing it this way for years") that make

changing routines can be particularly challenging. However, activities do not have to involve strenuous physical activity to enhance mood or alter cognitions, and most clients can manage some change in routine if care is taken to address on interfering cognitions and problem solve around limitations.

A variant on activity scheduling is pleasure predicting. This is a useful technique when clients doubt that they will enjoy an activity. In addition to rating mood before and after the exercise, clients are asked before they do the activity to predict how much they will enjoy it. Comparing the predicted outcome with the actual outcome helps challenge the belief "I won't enjoy it" and helps to highlight the tendency to underestimate the benefit of negative events.

For anxiety disorders, behavioral interventions include gradated exposure, which involves engaging in feared activities in an organized fashion. Using principles of systematic desensitization, clients break down a feared activity (e.g., shopping in a store) into specific steps that are arranged from least anxiety provoking to most (e.g., shopping in a large grocery store early when no one else is there versus shopping in a small crowded shop at the busiest time of the day). Clients practice doing less anxiety-provoking tasks first until their anxiety level is reduced, and then move on to the next task. Clients both become less physiologically reactive to the feared situation, as well as develop more helpful cognitions (e.g., "I can handle this.").

Clients in anxiety treatment can also be taught a variety of relaxation techniques, such as progressive muscle relaxation or breathing retraining, to facilitate management of their anxiety symptoms. The limited research available suggests that relaxation alone can be as effective as CBT for reducing anxiety symptoms in older clients. Recommendations specific to late-life anxiety include (1) ensuring that sufficient time is devoted to learning relaxation training skills, (2) emphasizing in vivo rather than imaginal exposure exercises, and (3) de-emphasizing more abstract cognitive restructuring techniques (e.g., directly disputing dysfunctional thoughts).

A related exercise that has been incorporated into both anxiety and depression treatment, and to some extent acceptance interventions for psychosis, is mindfulness meditation. Mindfulness is defined as paying attention in a purposeful way, in the moment, nonjudgmentally. Clients are taught to allocate their attention to a particular stimulus (e.g., their breath), and to just notice this. As distractions arise (e.g., internal thoughts, external sounds), clients learn to just notice these, as well as their own reaction to them. They then return attention to the task at hand. Mindfulness is a particularly useful skill in depression and anxiety for helping clients learn to observe their thoughts. When people can notice their thoughts, they can then question the accuracy of them and do not

need to act on those thoughts.

Juanita had stopped communicating with other family members, even though this had been a rewarding activity in the past. Therefore, therapy focused on this as an opportunity for behavioral activation.

Therapist: One thing you told me is that you used to enjoy time with your son and his family. Why don't we work on arranging some time with them?

J: Okay.

T: Okay, so what day and time do you think makes sense?

J: Well, my son works, so it would be best on the weekend, maybe in the afternoon.

T: How do you usually arrange to get together?

J: I just call him up and tell him I'm coming over.

T: Is there anything stopping you now?

J: I just don't want to be around people. I just feel like I'll bring everyone down. That would just make things worse.

T: Remember, part of the goal is to test beliefs like that. Would you be willing to go visit and then write down your evidence as to whether you brought everyone down and things got worse?

J: Okay.

This example highlights several important skills: Activity planning (spending time with the family), identifying obstacles (thoughts about her response), and challenging thoughts (gathering evidence from the experience).

Cognitive Interventions. One of the key skills that clients learn is thought challenging. The key steps to thought challenging are:

1. Noticing clients' thoughts and identifying their effect on mood and behavior
2. Learning to test the helpfulness and/or accuracy of those thoughts
3. Generating a new, more accurate or useful thought
4. Examining the effect of the new thought on mood and behavior to determine if it is an improvement

For some clients, the initial task of noticing thoughts is challenging. For clients who have difficulty even noticing their thoughts, a form such as the automatic thoughts checklist can be helpful. This is a list of thoughts associated with depression. Clients read through the list and check those that they experience. Once clients can recognize their thoughts, there are a variety of forms for teaching clients to examine and change them. With older clients a straightforward model, such as the "3C's" form, can be useful, because it is a simple model (Table 57.4i–1). Clients are initially taught to write down thoughts in the "catch it" column and the relationship to their mood in the "check it" column, as well as any errors or problems with the thought. Once clients can recognize their cognitions, they learn strategies to question and challenge thoughts that are unhelpful. Strategies include identifying common unhelpful thoughts (e.g., all-or-nothing thinking, predicting the future) and examining evidence both in support of

the unhelpful thought and in contradiction to it. Throughout these exercises, clients are taught to determine the effectiveness of these efforts by rating changes in their mood (Table 57.4i–2).

Table 57.4i–1.
3C's Homework Form

Catch-It, Check-It, Change-It (3C's) Worksheet	
Situation: What was happening? Where and when?	**Feelings:** How was I feeling at the time? **Actions:** What was I doing?
CATCH IT: What was I thinking in this situation? What went through my mind? Which thought best explains how I was feeling and what I was doing?	
CHECK IT: Check to see if the thought is accurate by listing the evidence for and against the 'Catch It' thought. Also, check to see if the thought is a mistake in thinking.	

FOR	AGAINST	MISTAKES IN THINKING
		(Check any that apply) ► All or nothing ► Mind reading ► Fortune telling ► Jumping to conclusions ► Catastrophizing ► Emotional reasoning

CHANGE IT: What would be a more accurate and helpful thought? If there was mistake in thinking or if the thought was inaccurate, develop a more helpful thought based on the evidence you listed.

Many people, including therapists and older people themselves, hold unhelpful beliefs about the older adults. These can include thoughts such as, "Older people can't learn/change," "Others do not want to be around older people," "Older people are a burden," or "Older people don't have much to give." Beliefs about managing suffering ("Don't air your dirty laundry") or about therapy ("Therapy is for crazy people") can also interfere with the acceptability of treatment. Therapists need to attend to both of these sets of beliefs, both in how therapy is initially presented and in the course of the actual treatment.

Table 57.4i–2.
Common Types of Unhelpful Thinking

All or nothing	Viewing situations in terms of absolutes: "I am a complete failure"
Selective attention	Attending to negative information and/or ignoring positive information (e.g., noticing health problems and ignoring supportive family members)
Shoulds	Holding rigid rules and expectations; refusing to accept realities outside one's control: "I should be able to do all the things I used to do."
Emotional reasoning	Judging a situation based on one's emotional response, rather than objective evidence: "I was feeling anxious; therefore, I must have looked foolish."
Mind reading	Making assumptions about others' perceptions: "They think I'm too old."

Predicting the future/probability estimation errors	Overestimating the likelihood of a negative event: "I know that I will fall and break my hip if I go to the store."
Catastrophizing	Underestimating one's ability to cope with a negative event: "I can't stand it if I get sick."
Overresponsibility	Feeling guilt for situations outside of one's control: "It is my fault my grandchildren are unhappy."

Mike was a 75-year-old retired, gay identified white male whose long-time partner and husband had died approximately 2 years before initiating treatment. He was referred for care by a close friend who was concerned that he was still grieving the death of his husband and had become isolated.

Mike had grown up in a traditional Christian family on a farm in a small Midwest town, the middle of three siblings (an older brother and younger sister). He reports having a loving mother and distant father, but feeling separated from his parents and siblings when he developed awareness that he was homosexual. He joined the Navy in part to "escape" small town life. Mike had served as a Navy corpsman including deployment on an aircraft carrier during the Vietnam War. He had no direct combat exposure, but was involved in caring for wounded aboard the ship.

Mike found his role rewarding and served in the military approximately 15 years. However, he ended up leaving the military prior to retirement because rumors of his sexual orientation were beginning to spread among his unit. Upon leaving the military he attended a state university in a large city and obtained his bachelor's degree and teaching credential, and had a successful career as a middle school teacher.

Mike had very limited dating or sexual experience prior to or during his military service, fearing consequences for his career. However, while in school he was active in the gay community of his city, dating frequently. He also reports drinking heavily at this time. He met his partner, Bill, and reports that within a year they had developed a committed relationship. Bill was approximately 10 years older than Mike, and Mike describes him as a partner as well as a mentor helping him navigate the "gay scene." Over the next 10 years with Bill's support he was able to disclose his sexual orientation to his parents and siblings, and his brother and sister in particular were supportive and developed a close bond. His parents were initially "disappointed" but eventually "came around."

Mike reported that his relationship with Bill was marred by several periods of heavy drinking during which Mike had anonymous sexual encounters with other men. When Bill found out about these incidents, they had a series of arguments and confrontations that led to Mike attending Alcoholics Anonymous (AA). While they maintained their relationship and married when gay marriage was legalized, and Mike remained sober for the following 30 years, Bill would frequently remind Mike of his infidelities and criticize him.

Approximately 10 years prior to the initiation of CBT, Bill had developed a neurodegenerative disease that quickly limited his physical functioning, and left him bed-ridden for the last 4 years of his life. Mike served as his primary caretaker throughout his decline, retiring from his job as a teacher to take care of Bill. During this time, as Bill developed symptoms of dementia, he would continue to recall Mike's earlier infidelities and remind him of how he had hurt Bill in the past.

When initially presenting for treatment, Mike shared that since Bill had died he continued to feel both extreme sadness at the loss and guilt about his previous behavior. However, he also reported anger at Bill's inability to forgive him, which in turn led to additional guilt. In addition, he reported having "no purpose" now that Bill had passed. Although he and Bill had a large network of friends, he was not interacting with any. While he was still attending AA, he no longer took leadership roles in the organization, sponsored other members or participated in social events. He only spoke to his brother and sister when they called, and had taken to screening their calls to avoid them.

At the beginning of therapy Mike was meeting criteria for major depression, including daily sad mood, anhedonia, decreased energy, pervasive guilt, poor appetite, insomnia, and thoughts of death (he denied suicidal ideation, plan or intent, but thought that the world would be better off without him). He stated he was irritable at AA meetings, and took benign comments as

criticisms directed at him. He also reported he had not cleared out any of Bill's belongings, and that he criticized himself for this as well.

Therapy focused on three areas: Acknowledging the loss of Bill, developing goals for Mike that were consistent with his values, and increasing his engagement with people who cared about him. Based on his history, the therapist developed a case formulation that focused on the core belief "I'm defective." This manifest in secondary assumptions of "I deserve to be punished" and "I can never be forgiven for the harm I've done." This in turn led him to be both very self-critical and to interpret those around him as being critical as well.

In the course of therapy, Mike learned to examine his thoughts, and the relationship between thoughts, actions, and feelings. As an example, he stated that one of his goals was to start cleaning up his home, including donating most of Bill's clothes to charity. However, in session Mike reported that he had been unable to donate the clothes and got upset when he thought about it. The therapist helped Mike to examine his thoughts using the 3C's form: In reviewing the thoughts, Mike was guided in identifying thinking errors, in this case, "should" thoughts. He was then guided through questioning the assumptions underlying the thoughts, to generate alternative, more helpful thoughts:

Therapist: What do you tell yourself when you looked at Bill's clothes?
Mike: If I get rid of them, I'm being unfaithful. I'm betraying him.
T: When you say that, what emotions come up?
M: Shame, guilt . . . and some anger
T: I can see where the shame and guilt come from; how does that thought lead to anger?
M: I get angry at myself for even wanting to give away his clothes. I shouldn't want to.
T: I see. You're telling yourself there's something wrong with you if you want to give his clothes away; "I shouldn't want to do this." So what would be a more helpful thing to say to yourself?
M: I don't know.
T: Well, what is the reason you want to give away the clothes? Is it because you didn't love Bill?
M: No! It's just that it is so hard to see those reminders. I think it would help me move forward.
T: Do you think that Bill would not want you to move on?
M: No, he told me that he wanted me to be happy after he was gone, or at least he did when he wasn't upset with me.
T: So it sounds like the "should" thought is not true; there are good reasons for wanting to give the clothes away, and it makes sense to want to do so. What would be a more helpful thing to say?
M: Maybe that it's ok to give the clothes away; it is doing something for others, and Bill would like that.
T: And what's your evidence that this is true?
M: Well, he told me to move on when he was gone, and he did like donating stuff to charity.
T: Anything else? If the roles were reversed, what would you want Bill to do, if you were gone and your stuff caused him pain?
M: Oh, I'd want him to donate it. I wouldn't want him to hold onto it.
T: So what might be a more useful thing to tell yourself?
M: He'd be ok with me giving his stuff away, because it would be helping others
T: On a scale of 0 to 100, how much do you believe that's true?
M: I would say about an 80; we had talked about this.
T: When you say that to yourself, what happens to your emotions?
Mike: They get better.

In this example, the therapist asked questions to guide Mike in questioning his assumptions, and to notice evidence that alternative thoughts may be true. The therapist then helped Mike formulate a more helpful thought, and tested its usefulness by asking how it affected his feelings, using the 3C's form.

Situation	Catch it	Check it	Change it
Deciding on what to do with Bill's things	"If I get rid of his clothes I'm betraying him" "I shouldn't want to give his things away"	Emotions: Shame (90) Guilt (90) Anger (60)	"Giving away Bill's clothes would be helping others, and he'd like that." Emotions: Shame (20), Guilt (20) Anger (30)

Socratic Questioning and Techniques for Getting at Thoughts. Also called "guided discovery," the overall purpose of Socratic questioning is to challenge accuracy and completeness of thinking. These are open-ended questions phrased so people rarely respond with a "yes" or "no." It is important that the tone of the discussion remain collaborative, and the therapist not betray judgment of the client's interpretations. Socratic questioning may be used at almost any stage of therapy, and may be particularly useful when resistance is detected. There are several different categories of Socratic questioning, defined below with examples:

CONCEPTUAL CLARIFICATION QUESTIONS. These are basic "tell me more" questions that encourage deeper thinking:

- *What exactly does this mean?*
- *How does this relate to what we have been talking about?*
- *What is the nature of . . . ?*
- *What do we already know about this?*
- *Can you give me an example?*
- *Are you saying . . . or . . . ?*

PROBING ASSUMPTIONS. These are directed at uncovering assumptions underlying beliefs. This can be particularly helpful for identifying underlying core schema.

- *You seem to be assuming . . . ?*
- *How did you choose those assumptions?*
- *Please explain why/how . . . ?*
- *How can you verify or disprove that assumption?*
- *What would happen if . . . ?*
- *What would it mean about you if . . . ?*
- *Do you agree or disagree with . . . ?*

PROBING RATIONALE, REASONS, AND EVIDENCE. These uncover reasoning in arguments.

- *Why is that happening?*
- *How do you know this?*
- *Why do you think X causes Y . . . ?*
- *Are these reasons good enough?*
- *Would it stand up in court?*
- *How might it be refuted?*
- *What evidence is there to support what you are saying (or an alternative)?*
- *When did you first decide this was happening?*

QUESTIONING VIEWPOINTS AND PERSPECTIVES. Most arguments are given from a particular position. Show that there are other, equally valid viewpoints.

- *Another way of looking at this is . . . ; does this seem reasonable?*
- *Is there an alternative way of looking at this?*
- *What is the difference between . . . and . . . ?*
- *Why is it better than . . . ?*
- *What are the strengths and weaknesses of . . . ?*
- *How are . . . and . . . similar/different?*
- *What if you compared . . . and . . . ?*
- *How could you look at this another way?*

PROBING IMPLICATIONS AND CONSEQUENCES. The argument given may have logical implications that can be forecast. Do these make sense? Are they desirable?

- *Is . . . a helpful thought? Is . . . helping you reach your goal?*
- *How does this thought affect how you feel or what you do?*
- *Then what would happen?*
- *What are the consequences of that assumption?*
- *What are the implications of . . . ?*
- *How does . . . affect . . . ?*
- *Why is . . . important?*

Mindfulness and Acceptance-Based Interventions. These interventions can be particularly helpful in helping clients to observe their thoughts and emotions, and to also tolerate distressing situations. Key exercises include body scans (where the client learns to notice each part of the body in order, in a nonjudgmental way) and breath-focused meditation (paying attention to breathing without trying to change it). Clients then learn to use the skills of nonjudgmental observation practiced in these exercises in attending to experiences in their everyday life.

Schema Change. CBT also addresses schema, defined as core beliefs and associated cognitive biases that are held by people. Common core beliefs in mood disorders focus on achievement ("I am worthless unless I am productive") or affiliation ("I am unlovable"), while in anxiety disorders they focus on vulnerability ("I can't cope; I am insufficient"). Due to the stigma and multiple failure experiences associated with severe mental illness, people with schizophrenia may have both types of core beliefs. In paranoia, core beliefs may also focus on persecution as an explanation for failure ("poor me") or as a deserved punishment ("bad me"). Schema change involves the other treatment techniques previously defined. In addition, the hypothesized schema is reviewed with the client. The costs

and benefits of the schema are discussed in the context of the current problems and goals, and an alternative schema is derived that is more functional for clients while still being consistent with their values.

Mike frequently expressed the thought "I'm a screw up; I'm not good enough." His therapist noted that Mike seemed to believe that there was something inherently flawed or defective about himself and he deserved to be punished. Mike agreed with this. He noted that intellectually, he knew he was trying to be a good person, but emotionally he always felt there was something innately "broken" about him. Via guided discovery, Mike tied this sense of himself as flawed to struggling with his sexual orientation as a young man, as well as his infidelities with Bill and Bill's lasting anger about them. The therapist suggested to Mike that he consider another perspective; what would the people in his life say they valued most about him—Would they focus on his flaws or his gifts? Mike was able to share that his family and friends had all said how much they respected the love and dedication with which he cared for Bill. He also still received cards from former students sharing how important he had been to them as a teacher. In addition, although Bill frequently criticized him, Bill also was very loving and appreciative. In fact, most of the time, they were very loving toward each other, and Mike realized he tended to focus on the negative times. Finally, Mike and his therapist reflected on the strength and commitment it took to have stayed sober for 30 years, and the support he had provided to others in AA, particularly younger gay men struggling with their own sexual orientation.

Mike was willing to consider a more helpful view of himself, and came up with an alternative self-statement; "I am a caring guy." He developed some new secondary assumptions; "I've done things that I'm ashamed of, but I have worked hard to acknowledge my mistakes and make amends" and "I've been a good influence in a lot of lives."

While Mike agreed that these statements were true, he stated "they don't feel true." Therefore, assignments were designed where Mike would act as if the new formulation was true, and see how it worked for him. This included increasing his contacts with family members and friends, and behaving like he deserved to be happy (e.g., doing enjoyable things). He found contacting people hard initially, but he was greeted with enthusiasm. As he started joining friends for activities, his mood started to improve and he found it easier to act on tasks around the house. He still would miss Bill, but now had more support to cope and friends who expressed understanding about his loss.

Termination and Relapse Prevention. As clients achieve symptom improvement and functional gains, the emphasis of CBT shifts to preparing for termination. Treatment emphasizes clients developing their own interventions and experiencing mastery of skills. In addition, the therapist helps the client identify both persistent problems that need to be managed as well as potential future problems, and then identify the skills that can be used to address those problems. Particularly for older clients, termination can be stressful if they have lost other relationships recently. Therapists need to emphasize the goal of the client developing skills, and the importance of independent practice to adequately learn the skills. However, it is also helpful to schedule follow-up "booster" sessions. This both provides the client with some sense of support and allows a chance to problem solve difficulties in implementation of relapse prevention plans.

Modifications for Psychosis

Psychosis is the most expensive mental disorder to treat, with

hospitalization costs accounting for the majority of expenditures. The cost of care for psychosis patients over 65 years old is even higher than for patients aged 30 to 64. Best practice guidelines and nationalized healthcare systems recommend or mandate that CBT be delivered to consumers with schizophrenia as part of a comprehensive treatment program. For example, CBT is among the recommendations made by the American Psychiatric Association, Department of Veterans Affairs, and the Schizophrenia Patient Outcomes Research Team (PORT), a project sponsored by the National Institute of Mental Health to develop evidence-based treatment guidelines for schizophrenia in the United States. PORT client survey findings, however, indicate poor conformance with this recommendation, especially for older people with psychotic disorders. Providers with expertise in delivering these interventions for older people with psychosis are very much needed.

In principle, all of the stages and techniques of CBT discussed above can be applied to the treatment of older people with psychosis, with some modifications but not fundamental differences. All of the techniques discussed above are appropriate for the treatment of the multiple problems faced by consumers with psychotic disorders. In this section, a brief discussion of the vulnerability-stress model and the general cognitive model of schizophrenia is provided, followed by descriptions of specific CBT interventions applied to psychosis, negative symptoms and poor functioning in older people with schizophrenia.

Cognitive Model of Schizophrenia. In the context of the vulnerability-stress-coping model of schizophrenia, personal enduring vulnerability traits, like cognitive and neurobiological dysfunction, interact with environmental stressors and coping responses to contribute to symptom formation. Neurocognitive deficits exacerbated by stress hyperreactivity can lead to decompensation and the emergence of delusional beliefs and hallucinations, as well as diminished capacity to accurately evaluate anomalous beliefs. People with psychosis, like healthy individuals, have great difficulty distancing themselves from their highly charged beliefs, but also have the added problem of insufficient cognitive resources available to evaluate and correct them. Rigid thinking, perseveration, cognitive biases, impaired abstract reasoning and memory, and cognitive distortions can play an important role in the development of delusional beliefs by leading to exaggerated appraisals of negative life events that become highly charged delusional belief systems.

In addition, multiple failure experiences due to cognitive deficits, odd behavior, and social withdrawal can lead to dysfunctional performance beliefs and social aversion attitudes (e.g., “I am inferior,” “Why bother; I will fail,” “If you can’t do something well, why do it at all?” and “People are against me”), which can exacerbate maladaptive behaviors, such as social

withdrawal and suspicious avoidance. In the context of generic cognitive model applied to schizophrenia, dysfunctional attitudes like these may contribute to negative symptoms and poor functioning. Negative appraisals about one's self and one's ability to perform goal-directed tasks contribute to passivity and avoidance of productive activities, as a defense against anticipated failure and negative evaluations by others. This avoidance and lack of effort manifests as diminished motivation (avolition-apathy), loss of pleasure (anhedonia-asociality), impoverished speech (alogia), and blunted affect. CBT can be used to address and challenge beliefs about psychotic symptoms, social aversion attitudes, and defeatist performance beliefs, including expectancies ("It won't be fun"), self-efficacy beliefs ("I always fail"), and anomalous beliefs ("Spirits will harm me") that interfere with functioning. In addition, by including behavioral interventions, such as social skills training, skills deficits that can also interfere with social functioning can be addressed. By challenging self-defeating beliefs that interfere with skill performance while addressing skill capacity, people are more likely to engage in functional behaviors and use the skills they have.

Psychoeducation for Psychosis. Education is a key component in helping clients with psychotic symptoms make sense of their experiences. Psychoeducation is best accomplished as a two-way process, whereby the clients themselves come up with psychological explanations of their symptoms using guided discovery with inclusion of information from the therapist only where necessary. It is typically helpful to review the history and symptoms at the onset of psychotic illness in the context of the initial stressors that may have triggered it, using reflections like, "So, with all these stressors going on, including your father's death, you suddenly began hearing this voice, and tried to make sense of it." Further, "Given that it seemed that nothing else could explain where this voice was coming from, I can see why you decided it was your father talking." Comments like this emphasize both that data were gathered that led to a conclusion about the source of the voice (an empirical approach) and that there were life events that contributed to the experience. This can set the stage for gathering evidence that might dispute these long-held conclusions, as well as identifying potential relapse triggers for relapse prevention plans. It can be challenging to review the first episode in older clients, when the first episode was often more than 30 years ago. Collateral informants and record reviews can be helpful here, but the most important information is the evidence and context recalled by the client. In older clients, reviewing the impact of recent losses and bereavement (and sometimes anticipated losses or illness of loved ones) on symptom exacerbation can be useful to illustrate the impact of stress on symptoms. In the context of the vulnerability-stress model, it is often useful to focus on "normalization," that involves presenting the idea that any individual is vulnerable to

experiencing psychotic symptoms if exposed to certain circumstances and sufficient stresses (e.g., sleep deprivation, unusual severe stressors, or substance abuse). This "normalization" discussion can serve to reduce stigma associated with severe mental illness. The focus on normalization and open questions and reflections directed at an honest understanding of how the client arrived at delusional beliefs often facilitates rapport and builds a trusting relationship. Time and patience are needed in this process, as trust can be slow to develop with some clients (e.g., with paranoia).

FIGURE 57.4i–2. Generic cognitive model applied to psychosis.

Clients are introduced to the general concepts of CBT, including the relationship between thoughts, behaviors, and feelings (cognitive model). Multimedia presentation of information can help compensate for neurocognitive impairment associated with both psychotic illness and aging. For example, drawing figures, like the one below, on a pad (or handout) for clients to take home can help compensate for cognitive impairment (Fig. 57.4i–2).

This example helps to illustrate the importance of interpretations or thoughts about experiences, such as auditory hallucinations. It is important to stress that it is not the voice itself that leads to unwanted feelings or behaviors, but the thought about the voice. It is more distressing to think Satan is making threatening demands (Satan is a powerful, controlling, external agent) than to think voices are due to brain changes caused by illness. If the interpretation is that voices are due to illness (no power to

harm, controllable, internal origin), then fear, helplessness, and risk of self-harm can be reduced. The core belief ("I deserve punishment") is provided in Figure 57.4i–2 to illustrate the importance of developing a formulation about highly charged beliefs that drive interpretations. It is typically not useful to complicate the model by including this aspect in the psychoeducation process early in therapy, although it may be added later.

Behavioral Interventions. Behavioral activation, pleasure predicting, and relaxation training techniques described above are all relevant to the older client with psychosis, and these techniques are used in essentially the same way. In addition, an important treatment target for older people with schizophrenia or other psychotic disorders is to improve communication skills and psychosocial interactions (e.g., asking someone to share a leisure activity; making positive requests for support from friends, family or professionals; expressing anger and assertiveness). The predominant therapeutic technique used to improve communication skills is the behavioral role play. Role plays are also useful for generating thoughts that can interfere with adaptive social interaction (e.g., "He thinks I'm dumb"; "He won't want to talk to me"; "He wants something from me"). These thoughts can then be targeted for change using thought challenging interventions (e.g., the 3C's). Low self-efficacy and defeatist performance beliefs ("I will forget what to say"; "I will mess it up") can also be identified by using scaling techniques, where the therapist asks clients to rate their expectations for success in the role play on a scale of 1 to 10 before practicing and again rate performance after practice. The therapist can then compare these ratings to point out how people perform better than they think they will (pre-post ratings almost always increase), so clients can raise expectations for success to increase the likelihood that they will use the skills in the real world. In this way, the role play itself can serve as a behavioral experiment to test out defeatist beliefs. By teaching new social skills, while changing the defeatist thoughts that interfere with skill performance, negative symptoms and functioning can improve.

Role plays can focus on a number of topics. Clients are more motivated to learn skills when role play topics are linked to the client's personal goals (e.g., role playing how to ask someone to coffee, if the client's goal is to make a friend). Expressing positive and negative feelings and making a positive request can be emphasized to improve assertive, nonaggressive, clear, and comfortable sharing of feelings in social interactions. Improving everyday leisure activities and psychosocial functioning are common role play topics for these skills (e.g., asking a roommate to change his or her behavior; asking someone to go to the movies). Another common focus of role plays is on identifying warning signs of psychotic symptom exacerbation and practicing reporting these to the doctor. It is sometimes useful to make a video recording of role plays and play back the recording

in session. With the help of the therapist, clients critique the strengths and weaknesses of their own performance, according to a list of key skills displayed on a handout or poster board (e.g., eye contact, speech volume). Clients sometimes have little insight into the impact of their negative symptoms (e.g., low voice volume, poor eye contact, blunted affect) on their social skills until watching themselves on video. The group therapy setting is ideal for role plays. Members with better skills model for others, and this leads both to a sense of mastery for the skilled client and an increased perception that the skill is learnable for the unskilled client. Clients can sometimes accept feedback better from peers than from therapists, and situations played between group members are more similar to in vivo experiences than role plays between therapist and patient.

Given the loss and isolation experienced by older clients, one important focus is to help clients to recognize and identify support persons in their lives. Older clients with psychosis often have a difficult time recognizing that some people in their life truly are support persons, such as health care providers, board-and-care workers, and peers. Often, clients believe that only family or relatives can act as support persons. Because many older clients with schizophrenia no longer have connections with their family or relatives, it becomes increasingly important to identify support persons and help clients to recognize that many others in their life outside of family can act as supports.

Cognitive Interventions. Thought-challenging interventions (e.g., using the 3C's) for clients with psychosis are delivered in essentially the same way as for clients with depression or anxiety. Clients are introduced to the general concepts of CBT, including the relationship between thoughts, actions, and emotion (generic cognitive model); identifying automatic thoughts; and challenging unhelpful thoughts by examining evidence for beliefs and mistakes in thinking (e.g., jumping to conclusions, mind reading, all-or-none thinking). Through in-session discussion and homework assignments, clients are taught to identify thoughts; identify relationships between thoughts, feelings, and behaviors; and identify mistakes in thinking. Thought records are used to elucidate the relationship between situational triggers (e.g., people speaking outside the client's room) and thoughts (e.g., "They've come to hurt me") and subsequent changes in feelings (e.g., fear) or behaviors (e.g., isolation, aggression) in response to thoughts. Thoughts that lead to distressing feelings or maladaptive behaviors are labeled as "unhelpful," and are examined for accuracy. Socratic questioning is used to help clients examine the logic of beliefs and generate more adaptive alternatives to mistakes in thinking or thoughts without sufficient evidence. The primary thoughts targeted are typically beliefs about voices (e.g., "My voices are from an external being," "My voices have power to harm me," "My voices cannot be

controlled"), beliefs about daily events that clients use as evidence to confirm delusions ("That person on the bus was part of the conspiracy"), and dysfunctional performance beliefs (e.g., "Why bother, I will fail," "I am too sick") that interfere with adaptive functioning.

Using the 3C's technique for thought challenging is particularly helpful to compensate for neurocognitive impairment that is common in older clients with severe mental illness. The 3C's technique simplifies learning and serves as a mnemonic device to help clients remember and use cognitive techniques in everyday life. Table 57.4i–3 shows examples of a 3C's thought record for beliefs about psychosis. Thought records like this are completed both in session and as homework assignments. Situational antecedents are typically first linked to the feelings and behaviors that arise in them. This is done to emphasize that clients need to use these unwanted feelings and behaviors as an alert or "red flag" reminder to examine their thinking ("Catch it"). Once the thought linked to the feeling or behavior is identified and written down, possible mistakes in thinking are identified and the evidence for and against the thought is reviewed ("Check it"). If the thought does not "check out" (e.g., there is evidence the thought is unhelpful), it is replaced in favor of a more balanced, more helpful thought ("Change it"). The group setting can facilitate thought challenging, because other members are often better able to notice delusional thinking and articulate logical flaws, contrary evidence, and alternative thoughts than the client, who has an emotional conviction attached to the inaccurate thought.

To gather evidence to evaluate thoughts, behavioral experiments are conducted inside and outside of sessions (homework). For example, one common belief is that a voice is from an external agent that is omnipotent (e.g., the voice of God or the Devil). A behavioral experiment to test this belief might involve training clients in distraction techniques to stop or quiet hallucinations, such as humming, listening to music, shadowing what the voices say, watching TV, or counting. If clients can control the voices to any extent using these techniques (in session if hallucinations are triggered or at home for homework), this is discussed as evidence against the omnipotence of the voices. How can simply humming or turning on the TV control God or Satan? The following therapist–client interaction illustrates a behavioral experiment.

Pat had been experiencing some paranoia that was causing her to isolate at home.

P: I'm really confused because I had so many coincidences happen that I was writing them down. Then my friends will say, "Are you taking your medication?" when I tell them about what's been happening. But then they can't deny that there are so many of them and it is really weird. And then it becomes so weird that mathematically it would be like getting hit by lightning two or three times. It's just that the odds are such long shots that all this would be happening. Then I start thinking that I must be under some kind of mind control and it's preplanned because the odds of this happening couldn't possibly be this strong. So

this has been difficult. This is confusing.

T: What kinds of things have been coincidences in the past few weeks?

P: Just like a matter of 2 days. What I'm thinking about or what I'm doing, the next thing I'll see it in print and or it will be said on the TV. Whatever I'm thinking about, one thing or another after another. Just like, I was thinking about hermaphrodites and people who are male and female and I open my book and it's right there. Talking about androgynous people, male and female people as I was just thinking it, and then several conversations like that came up. What I was talking about or what I was thinking happened right then and there, at that moment, and I keep trying to ignore it 'cause people have said something about free associating or something like that, too much. It just got to be too much of it happening. Either I'm at some really strong path with God or I'm under some kind of mind control. I don't know which.

T: How does that impact your life? How does it get in the way of you obtaining your goals?

P: When I feel my mind controlled, for me, I end up deciding not to move at all. Like the only way is to contain it. Like it's a disease, infection. I just feel diseased, like I have an infection. Like nobody should be near me.

T: Because we might catch it?

P: Yeah or something like that.

T: So we could catch the coincidence disease?

P: Yeah.

T: What would happen to us?

P: You'd be in the same situation.

T: Which is?

P: Being controlled.

T: So we would feel the same ways you're feeling. Well, are you feeling that way right now?

P: Yeah, pretty much.

T: What if I came and sat next to you? Can we try this out and see if I catch what you've got? How about it?

P: I don't think you would know right away.

T: How long would it take me to know?

P: Just until you start noticing those types of coincidences all happening to you.

T: How long would it take me to know?

P: I don't really know.

T: Approximately?

P: I don't know. I'm just guessing how all this works.

T: Well, would you mind? I mean because you're going to be in therapy for several months. So do you think it could happen during that time?

P: Yeah.

The therapist sat next to Pat for the next 2 months and revisited the idea weekly that the "coincidence disease" was contagious. Over time, Pat continued to notice coincidences, but the inferred controlling nature of these occurrences decreased over time, in part, because her conviction in the belief that it was a disease diminished. This is an example of thought chaining—if others don't catch it, maybe it is not a disease, and if I don't have a disease, then the cause of coincidences is not a controlling disease. As conviction in this delusional belief diminished, Pat was willing to try more activities outside the home, which provided additional opportunities for behavioral experiments to test out possible causes of coincidences, with a focus on generating alternative hypotheses.

Table 57.4i–3.
Example of 3C's Thought Record for Beliefs about Psychosis

	Catch It (What's the Thought Going	Change It (What's a More

Situation	Feelings/Behaviors (Consequences of Thoughts)	Through Your Mind?)	Check It (Mistakes In Thinking and Evidence Against the Thought)	Helpful and Accurate Thought?)
On the bus people looking at me	Afraid; angry; Left-got off	"They want to hurt me."	Mind reading; jumping to conclusions; just looking at me doesn't mean they want to hurt me; maybe they think I look like a friend or someone they know; maybe they think I'm attractive	"There are lots of reasons people would look at me on the bus."
While going to fill out a job application, voices say: "You can't do anything right"; "Nobody would ever hire you"	Sad; hopeless; went home; did not apply for the job	"The voices are right; I could never get a job."	All-or-none thinking; predicting the future; the voices have been wrong before; I used to have a job	"Maybe the voices are wrong; I can check it out if I try and see if I get hired."

The following case example illustrates how cognitive-behavioral interventions can be used to address command hallucinations, paranoia, and medication adherence.

Mark is a 61-year-old unmarried Caucasian male who was unemployed and taking an art class at a local community college. He served in the US Army for 6 years from ages 18 to 24, but had not worked since his discharge from active duty. He was not in combat and denied trauma (was trained in a logistics/support role). He was medically discharged from the military for Psychosis NOS and received some Veteran's benefits income. He received care from the local VA facility, including antipsychotic medication, and was diagnosed with schizophrenia, paranoid type.

He lived in a group home in a financially depressed area of his city. He had several psychiatric hospitalizations, often stemming from physical altercations, including assaulting an individual he thought was going to hurt the pastor of his church. He was arrested but not charged in this assault. He reported frequently hearing voices, including command hallucinations, especially when he forgot to take his medications, and ascribed these assaults to the voices ("The voices tell me to stop bad people from hurting other people"). He also experienced difficulty with paranoid ideation, reporting he often thought people were watching and talking about him on public transportation and at his group home.

Mark had a strong identity as an artist, and pursued art consistently for many years since leaving the military. He sculpts using clay in his bedroom, and showed his therapist pictures of his sculptures. However, he reported that the limited space in his room prevented him from working on his art consistently. He also recognized that when his symptoms increased, it interfered with his working on his art. Therefore, the consumer and therapist developed goals increase his opportunity to practice art and better manage his hallucinations and paranoia by learning cognitive-behavioral strategies and improving his medication adherence.

Treatment involved using the 3Cs and behavioral experiments to examine thoughts about the omniscience of his command hallucinations (e.g., "They know who will hurt my friends") and medications (e.g., "It's no big deal if I forget my meds"). For example, he would Catch thoughts about the omniscience of his voices ("They can tell who has evil in them"), Check the evidence against the thought ("They were wrong about the guy they said would hurt my pastor") and the consequences ("I get arrested when I listen to them"), and Change the thought to be more realistic and helpful ("Maybe the voices are wrong"). After his conviction about the

omniscience of the voices was reduced, he was more willing to ignore them and not comply with their commands to protect others in order to test whether they their threats would come true. By not complying, he was conducting a behavioral experiment that produced further evidence that he did not have to do what they say to protect himself or others. He also reported that his voices were from "good spirits; maybe angels" who would warn him about "people with evil in them." The fact that he thought the voices were benevolent and might protect him from harm contributed to poor medication adherence, because he did not want to take medications that quieted or eliminated the voices that he perceived as helpful. The therapist used Socratic questioning to challenge these beliefs about the voices as a benevolent and omniscient external agent:

T: You mentioned that you have noticed that the medications can make the voices go away, right?
M : Yes, I have noticed that.
T: That makes me a little confused, though. How can something you put in your body—medications that change your brain chemistry—make angels or something outside of your body stop talking?
M: Well, I'm not sure but it does.
T: But does it make sense that a chemical inside you could change an angel or some kind of powerful supernatural spirit? How does that work?
M: I don't know but I get nervous when it's been a while since the voice has given me any warnings or told me who to watch out for.
T: I can see how you might want to stop taking the medication for a couple days when you get nervous about that, so the voices might come back, but does it make sense that medications would make angels or spirits come and go. What if the voice isn't from an angel or spirit? What if it is from inside you and not an outside spirit? That would help explain why changing your brain chemistry can stop it. What do you think about that possibility?
M: Well, that part adds up, I guess, but I'm just not sure.
T: And we already discovered that the voices are not always correct about who is dangerous. That also makes me think the voices are from you rather than an angel, because people are more likely to be wrong about things than angels. We all make mistakes, but angels probably don't.

CLINICAL ISSUES

CBT and Medications

The use of CBT forms one part of a package of care that often includes the use of medications, where relevant and appropriate, as well as other services (e.g., case management, vocational rehabilitation, couples/family therapy). This is particularly true for psychosis. For depression, meta-analyses of CBT compared to antidepressants indicate that effects are similar (d = 0.35), and that response to CBT among older adults is similar to effects seen in younger adults. A recent meta-analysis including head-to-head comparisons of antidepressants and CBT in older adults found no differences between treatments, but the authors conclude the number and quality of studies was too low to make definitive conclusions. For late life GAD, results are further mixed. Some studies indicate that CBT is as effective as antidepressant medications for late life GAD, but others contend that CBT is not an effective treatment at all. Although older adults report a preference for talk therapies over medications, the two are often prescribed together. This generally has meant that cognitive therapy is used

alongside medication in a synergistic way, such that CBT improves medication adherence and medication controls acute symptoms that might interfere with CBT. It is recommended that, if the CBT therapist is not the psychiatrist, a two-way release of information be obtained from each client in order to facilitate continuity of care and communication.

Individual versus Group Format

There are several advantages to using these interventions in a group format. Groups are widely used in mental health clinics (increasing the likelihood that these interventions will be acceptable to such sites); treatment can be provided for a greater number of clients in groups than could be accomplished in individual sessions; groups can impact social support systems and allow practice of communication skills; groups provide a shared identity with others (i.e., healing power of connections with others, "me too" and "not alone" influences); confronting or observing others in groups may provide better insight into one's own symptoms and skills deficits; and groups can provide social reinforcement for change. One important difference between group and individual CBT formats is that groups tend to emphasize skills training over detailed case formulation. There is less time in groups to fully explore the unique content and history of each client's presenting concerns in developing a formulation. There is also greater flexibility to tailor therapy to the individual needs of the client in individual therapy.

Goal-Setting Challenges

Setting goals for therapy with older clients who have been ill for decades can present unique challenges encountered less frequently with more recent onset clients. Particularly for older clients who have had a chronic or recurrent course of a disorder, there may be low expectations for treatment success. Information-processing biases also often lead to a focus on failures and ignoring past achievements. By acknowledging a goal, older clients must accept the risk of yet another failure. This risk assessment is often exaggerated into risk of symptom exacerbation and rehospitalization. For patients with psychosis in particular, by this stage of illness, older people have also been informed that they have a severe, chronic brain disease with little hope of recovery. Older clients have had much less exposure to modern recovery and psychosocial rehabilitation models that have only recently begun to transform health care systems to focus more on strengths and hope for functional achievement. Hopelessness in providers can be passed on to older chronic clients. While not as potentially profound as with psychosis, other depressive and anxiety disorders that have followed a chronic course can also facilitate hopelessness for change.

These factors can create challenges for eliciting a goal for therapy.

Setting a treatment goal may require patience and many sessions. Cognitive therapy tools can be used to address dysfunctional performance beliefs, negative expectancies, and ignoring the positive and other attributional styles that can lead to hopelessness and reluctance to set a meaningful goal. Older clients may also initially offer a goal that they have learned providers want to hear (e.g., "I want to take my medications more regularly"), rather than a more personally meaningful goal. Goals may need to be revised as more meaningful goals emerge. It may be useful to ask clients to recall a time when they were functioning better in the past or imagine a time years in the future when they are much better and ask about daily behaviors. Ask, "What would you be doing if you weren't feeling this way?" This can stimulate a helpful discussion about desired, meaningful functional behaviors (relationships, volunteer work, leisure activities). The key is to get a personally meaningful goal.

We have found it most helpful to focus on specific, functional behavioral goals (increasing socialization, relationships, leisure activities, living skills to promote independent housing, school, work/volunteering) chosen by clients. Emotional or symptom goals (e.g., "I want to stop being sad" or "I don't want to hear voices") are less helpful, unless framed in terms of their impact on functional behaviors. For example, one can ask, "How would you know you weren't sad anymore? What would you be doing?" The response is often something like, "I would be getting up and doing more things." The therapist can then ask what things, and frame the functional behavior as the goal (e.g., doing things with friends, taking a class). Goals should also be specific and stated as attainable behaviors. For example, the therapist can ask, "How will you know the goal has been achieved? What will you be doing differently each day if you achieve the goal?" The therapist's goal is to help older clients set meaningful, realistic, attainable, specific goals stated in terms of functional behaviors.

Importance of Homework

One goal of CBT is to provide skills that generalize and are used by the client outside therapy in everyday life. To that end, treatment should include both skill practice in sessions as well as homework assignments. In-session practice is a crucial means by which clients understand the sometimes difficult concepts in this intervention. Homework assignments are crucial for generalizing these skills to the "real world," but homework adherence can sometimes be challenging. The term "at-home practice" is often used, rather than "homework," to emphasize the importance of practice outside of sessions and to reduce the negative connotation associated with "homework" assignments back in school days. Adherence to at-home assignments can vary considerably between clients. Older clients in particular may have expectations that the active treatment factor in therapy is disclosure rather than practice, and this can interfere with

willingness to complete outside assignments. To facilitate homework completion, the therapist guides, instructs, and explains the rationale for completing home activities, and activities are practiced in session. The therapist goes over several examples, so that clients can more easily do the remainder of the assignment at home. An analogy with learning to play a musical instrument can be used to stress the importance of practicing skills (e.g., "Just like learning to play the guitar: If you only practice when you are at your music lesson, you won't learn songs as fast as if you practice in between lessons"). Principles of operant conditioning are also used to facilitate homework completion (e.g., positive attention and praise to those who complete homework). The therapist makes clear to clients that homework completion is expected and failure to complete assignments is the topic of thorough problem solving to help the client do a better job next time. The authors have had success in obtaining 80 percent homework completion in 80 percent of older clients with schizophrenia in their CBT for psychosis groups. Previous research with other populations has shown that CBT incorporating homework assignments helps clients improve about 60 percent more than those in treatment without homework.

Indications

CBT treatment targets may change as people age. There is evidence that CBT is efficacious for a range of disorders in older adults, including depressive disorders, and psychosis. In addition, while there are a number of pharmacologic treatment options available, clients often desire psychotherapy options. Aging in people with schizophrenia is typically associated with improvement in positive symptoms and reduced hospitalization, whereas approximately 60 percent of older people with schizophrenia still reside in assisted care settings (e.g., board-and-care homes). Although positive symptoms in these older clients with severe mental illness may often be fairly well controlled through pharmacological treatment, these clients still have negative symptoms and severe psychosocial functioning deficits, which are important treatment targets of CBT in older people with psychosis.

Contraindications

A number of factors may interfere with psychotherapy overall. For all older adult clients, it is important to assess the possible causes of many psychological symptoms, such as fatigue, appetite, and sleep disturbance, because medical comorbidity and normal age-related changes may contribute. Comorbidities, such as substance abuse and medical illness, may interfere with attendance in CBT. This barrier can be overcome by conducting therapy in the client's home or senior center in the neighborhood or in the presence of a caregiver, or by finding a resource for

transportation. In addition, CBT interventions can include comorbidities as treatment targets (e.g., reducing substance use through harm reduction techniques, improving health status through addressing obstacles to treatment adherence). Poor insight (awareness of having a mental illness that requires treatment) is prevalent in some psychotic disorders and predicts poor course of illness and functioning. There is also some evidence that insight moderates treatment outcome in CBT for psychosis. Severe disorganization in psychotic clients presents a number of challenges to the logical, hypothesis-testing process of cognitive therapy, but some of these clients succeed despite thought disorder, and there are no clear data on the impact of this potential barrier. The authors have found that disorganization frequently fluctuates, as well, so a more behavioral intervention focus can be used until clients are more able to communicate more linearly. Neurocognitive impairment is often assumed to interfere with CBT, but this assumption may not always be accurate. Progressive dementia will likely interfere with CBT and neurocognitive impairment does predict poorer outcome in serious mental illness, in general, as well as treatment outcome in psychosocial interventions. However, there is no evidence that neurocognitive impairment reduces the benefit of CBT in serious mental illness relative to standard pharmacological care alone. That is, even participants with moderately severe neurocognitive impairment show added benefit from receiving CBT plus pharmacotherapy, relative to receiving only pharmacotherapy. With little clear evidence about which clients will and won't benefit from CBT, the authors recommend that willing clients be given a chance to succeed. The biggest barrier to success is provider hopelessness; clients who are never referred for CBT because they are thought to be too old or too impaired in some way can never succeed.

Cognitive Therapy versus Cognitive Remediation

Two broad categories of cognitive interventions have been developed: Cognitive remediation, which focuses on rehabilitation of specific cognitive functions (e.g., memory, attention), and CBT, which trains participants to use metacognitive strategies to identify and challenge unhelpful or inaccurate thoughts. These areas of intervention have several factors in common and may lie on a continuum from more "molecular" to more "molar" cognitive rehabilitation approaches, but they are often incorrectly equated. At one end, cognitive remediation targets specific problems of neurocognitive processing, and at the other end, CBT targets more global cognitive constructs, such as thinking and self-concept. Clients with severe mental illness typically have neurocognitive impairment and may benefit from cognitive remediation interventions and/or medications that attempt to improve neurocognition. Combining these interventions may enhance outcome in CBT, but cognitive remediation is not cognitive therapy.

RESEARCH AND EVALUATION

Depression

Recent studies indicate that CBT is as effective as pharmacotherapy for treatment of major depression. A meta-analysis of treatments for late-life depressive disorders found that pharmacotherapy and psychotherapy (most often, CBT) were similarly effective in terms of symptom reduction. There is currently little evidence of differential effectiveness of pharmacotherapy versus psychotherapy in the treatment of major depression and related mood disorders, and therefore recommendations for treatment should be based on factors such as patient preference and possible medical implications. In particular, older clients may have more difficulty with side effects of medications or have concerns about interactions with other medications, making CBT a particularly appropriate option. Finally, treatment preference studies overwhelming suggest that older adults prefer talk therapies over medications, so these treatments should be accessible in settings that serve older adults.

Anxiety

There are fewer well-designed studies available of CBT for late-life anxiety disorders, especially trials comparing CBT with pharmacotherapy for late-life anxiety disorders, and the combination of medication and psychotherapy has not yet been formally tested in an adequate clinical trial. Most randomized, controlled trials have compared CBT to other psychotherapies or control conditions, and most have examined generalized anxiety disorder or else have enrolled clients with a range of anxiety diagnoses without differentiating between them. The minimal amount of available evidence does suggest, however, that medications, particularly selective serotonin reuptake inhibitors, appear to be more effective than psychotherapy as an acute treatment for late-life anxiety disorders. In general, results of psychotherapy trials also suggest that CBT has some benefit, although clients do not on average reach a symptom-free status. CBT is superior to wait list and usual care, and not significantly different from other active treatments such as relaxation alone or supportive therapy. Cognitive-behavioral interventions that include relaxation training appear to be more effective than those without. For older individuals who refuse to take medications or for whom they are contraindicated, relaxation training may be the most effective component of a behavioral treatment, but direct comparisons have not been conducted. At this point, there is need for better controlled trials of CBT for specific anxiety disorders, and in particular trials that compare CBT with pharmacotherapy as well as trials examining combined pharmacotherapy and psychotherapy, especially in older clients. Nonetheless, the current literature indicates that CBT is a potentially useful approach for older

clients with anxiety disorders.

Schizophrenia

Only a handful of studies have examined any form of psychotherapy interventions for older people with schizophrenia. Over 50 clinical trials of CBT for psychosis have been conducted with middle-aged and younger people with schizophrenia. These clinical trials found significant improvements in hallucinations and delusions (typically the primary treatment target), community functioning, negative symptoms, social anxiety, and mood. Available clinical trials, however, have concentrated on the adult population up to 65, so their generalizability to older groups needs to be considered cautiously. The authors developed, manualized, and are conducting randomized, clinical trials of a novel psychosocial rehabilitation intervention called cognitive-behavioral social skills training (CBSST) in older people with schizophrenia (mean age 58). CBSST combines techniques from both CBT and social skills training to target the multidimensional deficits that contribute to disability in aging people with schizophrenia. In two separate clinical trials, the authors have found significant improvements in social skills and community functioning in CBSST relative to standard care and relative to a goal-focused supportive contact control group, and these gains in functioning were maintained at 1-year post-treatment follow-up. Based on the evidence for the efficacy of CBSST for older people with schizophrenia, CBSST is registered in the National Registry of Evidence-based Programs and Practices of the Substance Abuse and Mental Health Services Administration (nrepp.samhsa.gov).

57.4j Family Intervention and Therapy with Older Adults

CAROL ANN PODGORSKI, PH.D., LAUREN N. DECAPORALE-RYAN, PH.D., ANN ELIZABETH CORNELL, PSY.D., AND DEBORAH A. KING, PH.D.

INTRODUCTION AND DEFINITION

Over the past decade demographic trends have altered the composition of the older adult population in substantive ways. The older adult profile began to change in 2011, when the Baby Boom generation, currently one-quarter of the US population, began to turn 65. Demographers report that older adults are now more diverse in some meaningful ways. Older adults are now comprised of two generational cohorts—the "traditionalists" born before 1946, and the "Baby Boomers" born between 1946 and 1964. These groups differ in terms of experiences, values, attitudes, and preferences. The Baby Boom generation is likely to have families that are more geographically dispersed; experienced more divorces; had fewer biological children; amassed more blended families; and are increasingly living in multi-generational households. Baby Boomers are more likely to be healthier, but with the increased longevity of "the traditionalists," 70 percent of those over 65 have functional limitations. Similar to previous generations, their needs are met predominantly by informal supports consisting of families and friends.

The infiltration of Baby Boomers into the over-65 population has also triggered shifts in health care preferences and in relationships with medical professionals. This information-seeking, authority-challenging generation was instrumental in forming and shaping the movement toward consumer-directed health care. In addition, the newest older adults are more accepting of the notion of "mental health" and less resistant to seeking mental health care. Thus, the demand for mental health services among older adults is increasing, and the nature of the older adult patient–mental health clinician relationship will continue to evolve to reflect multiple generational influences.

Other changes in health care delivery approaches have increased the need for clinicians to hone their skills for working with families. The Patient Protection and Affordable Care Act, passed in 2010, has placed a greater emphasis on integrated care through establishment of federally qualified patient-centered medical homes. According to the Agency for Healthcare Research and Quality, "integrated behavioral health care" is the care a patient experiences as a result of a team of primary care and behavioral health clinicians, working together with patients and families, using a systematic and cost-effective approach to provide patient-centered care for a defined population. Another widely adopted health care practice affecting health care delivery is the emergence of patient- and family--centered care. In 2012, influential organizations, including the Institute of Medicine and The Joint Commission, adopted patient-centered care as a fundamental aim toward enhancing quality of care. An outgrowth of patient-centered care has been the emergence of family-centered care. The primary goal of patient- and family-centered care is to promote patients and families as active participants in care and decision making by treating

them with respect and dignity; sharing complete and unbiased information in ways that are useful and affirming; and encouraging their participation and collaboration. Inherent in these principles is the need for clinicians to be skilled in building and navigating relationships within families, as well as among families and health and social service providers. The adoption of integrated health care and patient- and family-centered care have created a shift in health care delivery from *serving* patients to *partnering* with patients and families.

Older adults today often have modified extended families as byproducts of single-parenthood, multiple marriages, and blended families. While families may span great geographical distances, they nevertheless remain able to mobilize support between and among elders, adult offspring, and other family members as needed. When elders do not have relatives nearby, they often form intimate social bonds with friends, neighbors, or others who are not related by blood or legal ties. Thus, an appropriate definition of the aging "family" must be flexibly inclusive.

Family intervention and family therapy are not one and the same. Family intervention is the process of bringing together two or more family members to address problems causing distress or impairing function. In late-life families, family intervention involves educating about the unique medical and psychosocial challenges of aging and their effects on the older adult and family. Family intervention also may involve facilitating communication among family members regarding age-related concerns, but it does not involve intentionally changing the way a family functions. In contrast, family therapy is an intervention that brings family members together to alter the family structure or functioning, thus facilitating adaptation to the challenges of aging. Family therapy is considered when assessment reveals problems in the family's pattern of organizing itself or interacting in response to age-related concerns, and when family members explicitly agree to engage in a deliberate process of change. The decision to engage in family therapy typically reflects an acknowledgment that the family's natural adaptive capabilities are overwhelmed by the nature or intensity of challenges or perhaps that the family does not have the knowledge or skills necessary to deal with the situation at hand.

HISTORY

Family therapy with older adults has its roots in two distinct but overlapping theoretical approaches to the understanding of human behavior. First, family systems theory maintains that the family functions as a network of interconnected elements so that change in any one individual's status or behavior will affect that of others in the family. Accordingly, there is a natural tendency for the family system to attempt to maintain balance or homeostasis. Second, family life cycle theory views the family system as moving as a unit through time, encountering both

predictable, normative transitions and unique, family-specific challenges. Life events such as a change in health or functional status, loss of a loved one, or remarriage of a parent, challenges the family's natural homeostatic mechanisms and requires a dynamic process of adaptation in order to reestablish equilibrium. The clinician working with aging families interprets the behavioral or emotional problems of an older adult as indications that the family system is struggling with transitions or crises associated with the life cycle stage. The therapist's task is to help family members organize or reorganize their resources and family roles in a manner consistent with the life cycle challenge they are confronting.

Although much of family developmental and systems theories has focused on the first half of the family life cycle, more recent depictions consider the structural and cultural heterogeneity of aging families. Life cycle theorists now consider late-life families as being comprised of blended families, families with single parents or grandparents raising children, and families of gay, lesbian, and transgendered individuals. Moreover, life cycle theories have started to include description and differentiation of developmental tasks during the second half of life, including adjustment to retirement, attainment of grandparenthood, coping with loss and illness, and passing on family legacy. Recent theoretical accounts also address stages of family reorganization when its elders decline due to progressive illnesses. One such account contends that adult children undergo predictable stages of denial, gradual acceptance, and eventual assumption of power over their parents' affairs. Such new models help therapists frame interventions that are appropriate to the tasks associated with a family's needs for adaptation.

THEORETICAL ISSUES

A variety of specific approaches to family intervention and therapy with older adults have their foundations in systemic and life cycle themes. The contextual approach emphasizes family ethics and seeks to help families balance the intergenerational "ledger" so that patterns of caregiving are congruent with the family's history and resources. The developmental-interactional model categorizes late-life family problems as situational, transitional, or chronic, integrating life cycle and structural-strategic approaches to help the family frame solutions to the problems in a manner consistent with their unique history and style. Recent approaches to grief therapy combine elements of family systemic, symbolic interactional, and narrative approaches to facilitate family storytelling, or "meaning making," thus strengthening family ties among the living as well as helping families redefine their relationships with those who have died. Cognitive behavioral therapy approaches, such as problem-solving therapy, are increasingly being used with older adult couples, caregivers, and families alike.

Strength-Vulnerability Model of Health and Illness

The strength-vulnerability model postulates that the mental health of individual family members is determined over time by the interaction of individual and family life cycle processes. Although not empirically validated, this clinical approach builds on systemic and life cycle theories, as well as research linking health outcomes to a variety of personality and psychosocial factors. Specifically, the model focuses on strengths and vulnerabilities at the level of the individual older adult (e.g., biological health, personal themes, and individual life history) as these interact with health-enhancing and risk factors at the larger levels of family and other social systems (e.g., family events, themes, relational processes).

According to this theory, attachment and caregiving form the bond of affection between family members that must be present as a foundation for the development of other interpersonal processes in the family. Communication is the development of shared meaning between family members. This process includes sharing important themes and content, as well as constructive communication of affect. Shared problem solving is the ability to develop solutions to problems and carry them out cooperatively. Implicitly or explicitly, this process involves the delineation of family roles as they pertain to decision making and authority. Mutuality involves a long-term commitment to the relationship and the dynamic ability to reinvent the relationship over time in the face of life cycle transitions. These processes are thought to develop sequentially in families, so that some element of attachment and caregiving is necessary for effective communication. Likewise, some effective communication is needed to successfully and collaboratively solve problems. Finally, effective problem solving is a prerequisite to the ability to reorganize and reinvent family relationships with mutual understanding through periods of crisis and life change. The epigenetic pattern is actually circular and dynamic, involving periodic reworking of various relational abilities, rather than being a linear progression through a series of discrete stages. Thus, if late-life transitions and crises are met with successful mutuality, attachment and caregiving will take a new and strengthened form. With unsatisfactory resolution of change, the bedrock of attachment and caregiving will be undermined.

TECHNIQUES

Family therapists are tasked with developing interventions that are congruent with the family's stages of relational and life cycle development. Thus, a detailed family assessment is the foundation upon which family interventions are developed.

Assessment

During the initial sessions, the therapist evaluates the family's unique

strengths and vulnerabilities, including at a minimum the following key points which can be easily remembered using the acronym LIFE: **Life cycle transitions** faced by the family and by individual family members—for example, raising children, job demands, financial stressors, retirement, grandparenthood, loss of spouse, or onset of chronic or degenerative illness; **Individual roles** assumed by family members—for example, caregiver, breadwinner, matriarch or patriarch, and scapegoat; **Family relational processes**—that is, the quality of attachment or caregiving bonds, communication, and problem solving; and **Ethnic or cultural factors**, including spiritual beliefs and practices impacting the family's functioning.

Levels of Intervention

The family assessment determines whether the intervention will most appropriately be psychoeducational, with a focus on providing information pertinent to a problem or illness, or therapeutic, with a goal of changing the family's structure and quality of relational functioning. Several levels of therapy are considered, each reflecting work at successively deeper strata of family relational functioning. These levels serve as general guidelines for considering the type and intensity of treatment appropriate for a particular family.

Level One: Psychoeducational Intervention and Community Referral. Families who exhibit solid attachment bonds, open communication, and good problem-solving skills do not require ongoing therapy but, rather, benefit from brief education regarding a specific late-life issue. For example, when elders develop new medical disorders, such as Alzheimer disease, families benefit from information specific to the disorder and its management as well as referral to community agencies and support groups. Families can usually organize themselves for effective problem solving regarding the care and support of the older adult. Despite their potential benefit, only a small percentage of families avail themselves of these resources. In the case of chronic, deteriorating illnesses, however, the family may benefit from brief, intermittent contact with the therapist at those transition points when the disease worsens or they acknowledge readiness to face the next challenge. Such families typically do not require regular, ongoing professional support.

Level Two: Restoring Effective Problem Solving. Families often have solid, positive bonds of attachment with good communication skills and histories of effective problem solving, yet they temporarily are overwhelmed by the intensity and unfamiliarity of a late-life problem, such as severe illness, functional decline, or the approaching death of a previously capable family member. In these cases, effective problem solving

may be temporarily stymied because of paralyzing grief reactions or sudden disequilibrium in the previously stable family structure. The family may need to reorganize lines of authority and decision making to bring them into accordance with the demands of a later-life transition. For example, families typically go through a natural transition during which the younger generation gradually assumes more of a role in an elder's affairs. This reciprocal process requires not only commitment and involvement on the part of the younger family members, but also willingness on the part of the elders to allow this transition to occur without becoming overly demanding, resentful, or needy. Therapists recognize that the history of parental authority and caregiving continues to influence intergenerational dynamics well beyond the actual parenting years.

One common example of family difficulty at this level is when an elderly matriarch or patriarch experiences a decline in health or cognitive capacity, throwing the surviving family members into a state of disequilibrium. The spouse and adult offspring in this situation are unaccustomed to assuming decision-making authority and typically need assistance in reorganizing family roles. After receiving clear and direct information about the status of the elder, reflecting on the meaning that they as well as the elder assign to this situation, and having an opportunity to grieve these changes, adaptive adult children at this level of relational development can often mobilize their resources to solve family problems.

Level Three: Improving Patterns of Communication. Some families who care deeply about each other and have solid bonds of attachment communicate little about serious problems. Some may have a history of arguments and resentment stemming from past crises. Some family rules prohibit the exchange of certain emotions or information. Others have been able to function with little overt communication in earlier stages of the life cycle, because they were not confronted with major loss or illness. When faced with challenges of aging, they have difficulty developing a common understanding of the problem and thus cannot work collaboratively to find and carry out solutions. Families at this level benefit from active modeling of open, positive communication. Basic communication techniques, such as active or reflective listening, can greatly benefit these families, as can clear and consistent modeling of how to talk openly but respectfully about the challenges before them.

QUESTIONS FOR THE PATIENT

Communication and Problem Solving. How is information about important events shared in your family? Who typically participates in making decisions? Is one person responsible for making a final decision? Is anyone excluded from important family decisions? How do family members resolve conflict when it occurs?

Family Roles and Expectations. What role does the older adult play in the family? Who are the individuals responsible for caring for the older adult? Who if anyone is primarily responsible for providing care? Does anyone live with the older adult? How much time in person, on the phone or otherwise is each person able to contribute to the older adult's care? Who if anyone is responsible for helping the older adult with his/her activities of daily living (ADLs)/instrumental activities of daily living (IADSs)? Are you aware of local resources that may be able to help the older adult? What have your experiences with the medical system been like in the past? What are your expectations for the older adults care? What do you know about his/her end-of-life wishes? (if the older adult is unable to express these himself/herself).

Level Four: Improving Bonds of Attachment and Caregiving. Families with negative, weak, or ambivalent bonds of attachment typically have a history of conflict, marginal functioning, or insufficient nurturance between family members. In some cases, adult children who were abused or neglected as children struggle to take care of the one they perceive as a former abuser. Such families are at risk for elder abuse, and some may require referral to professional caregivers or long-term care facilities. In many instances, however, techniques including family life review or contextual family therapy interventions can be used to induce empathy for the older adult's position, thereby decreasing negativity, increasing feelings of safety, and making it possible to forge more positive bonds of affection between the generations.

Family life review is the process of bringing multiple generations together to weave a coherent intergenerational family story. Typically, this process is facilitated by constructing a family genogram, which is a graphic, multigenerational picture (family tree) that encapsulates family history, structure, and relationships over time. The therapist encourages the family to begin with the story of the elders' families of origin, gradually working down through the themes and experiences of subsequent generations. Learning about the elders' upbringing, cultural context, and early family circumstances often gives younger family members a different, more empathic perspective. Some offspring or grandchildren then can establish more mature "adult-to-adult" relationships with their elders, rather than continuing to relate solely from the vantage point of children whose needs for nurturance and care were unmet.

CLINICAL ISSUES

Clinical Applications across Health Care Settings

The strength-vulnerability model of health and illness is an appropriate framework to use for conceptualizing and delivering patient- and family-

centered care to families with older adults in multiple therapeutic contexts. Applications of this model across health care settings in which mental health clinicians practice are described here.

Outpatient Psychiatry

The majority of older adults with behavioral health symptoms receive mental health services through some type of outpatient setting. Outpatient services are provided in a variety of settings, including private practices, community mental health centers, hospital-based clinics, or programs embedded within nonprofit organizations. Geriatric specialty clinics offer a range of services including psychotherapy, social work, and case management which can help to support the work of mental health clinicians. Many older adults gain access to psychiatry through consultation models that exist in some integrated care settings. In this model, primary care physicians and psychiatrists are colocated, and physicians are able to consult with a psychiatrist onsite, or they can refer patients within the practice to see the psychiatrist for an evaluation and treatment recommendations. Occasionally, independent living communities may help organize or provide access to psychiatric services for residents. In any type of an outpatient setting, psychiatry can play an important role in assessing and identifying family, social, contextual, environmental, and physiological factors that can support or exacerbate the patient's mental health issues.

In any outpatient setting, clinicians should focus on: conducting a comprehensive evaluation of mood, cognition and functional capacity, paying particular attention to issues that may impair the patient's ability to perform ADLs or IADLs; gather information about the patient's social support network including family, friends, and community resources; provide psychoeducation on the identified mental health issue and how such issues may impact the older adult's ability to care for themselves; identify potential barriers to treatment including financial resources, transportation, housing, and access to health care; and gather information about the older adult's physical health and collaborate with the patient's physician or other members of the health care team. As with any population, there are challenges involved when treating older adults in an outpatient setting. The most salient issue is the constraint of time. Completing a comprehensive evaluation that includes an assessment of family history and function within a 30-minute intake poses a formidable challenge. The medical comorbidities with which many older adults present often add to the complexity of the assessment and treatment planning processes.

Mrs. D was an 89-year-old, white, widowed female of Italian descent, referred to an older adult outpatient specialty clinic for symptoms of depression and anxiety. She reported a long history of depression and anxiety and estimated that her current symptoms began 6 months ago when

her family decided she could no longer live alone after she gave herself food poisoning. This incident made the family realize how difficult it was for the patient to complete her ADLs due to arthritic pain, decreased mobility and stamina, and an unstable gait.

The patient's family consisted of her four daughters, three of whom lived locally. Each of the daughters contacted the psychiatrist separately to provide information about the patient's mental and physical health. During the intake, which two of the daughters attended, the patient was irritable and expressed her concerns about her eldest daughter's ability to care for her properly. The daughters argued openly about the patient's needs until one daughter left. As the psychiatrist gathered more information it was clear that this family had deep emotional wounds that negatively impacted all of their relationships. The daughters felt "burnt out" and stated that they cared for their mother "out of obligation, not love." Two of the daughters reported having been physically and emotionally abused by the patient.

Based on the strength-vulnerability model, this family is best described as having negative, weak and ambivalent bonds of attachment (Level 4). Communication and, therefore, problem solving were ineffective. They were unable to make decisions as a group and each wanted to be in a position of authority. Working on the hypothesis that the family needed to work on a family life review to encourage more positive family communication, the psychiatrist referred the patient and her family for family therapy. Meanwhile, the psychiatrist took active steps to create opportunities for positive communication and problem solving. The patient and her daughters were asked to create a list of activities with which the patient would require assistance, and the degree to which she would need assistance. The psychiatrist provided guidance regarding the ADLs and IADLs to consider. Family members were encouraged to review the list and to decide which type of help each was able to provide. An information system including the patient's needs, medical status, and psychological status was devised and shared with all family members on a biweekly basis. The combination of these interventions helped the family learn how to communicate and problem solve more effectively while working with a counselor to improve the overall quality of the attachment bonds.

Inpatient Medicine Service

Over 40 percent of older patients seen in the emergency department are admitted to the hospital. These patients not only face physiological problems but also suffer psychosocially, which is even more likely if diagnosed with chronic medical conditions. Estimates suggest that nearly 75 percent of older adults who enter the hospital functionally independent will leave requiring support with ADLs. The need for adequate discharge planning and improved long-term disposition is dependent upon assessment of their holistic needs, including functional status, cognitive capacity, mood, and social network/support. Though hospitalists are often relied upon to conduct such assessments, their time is limited and many have not been trained extensively in the unique needs of geriatric patients or in psychiatric interview techniques. Psychiatry can play a supportive role in acute medical settings by offering consultation to the medical team and to patients and their families, thereby ensuring a safe transition from hospital to home or an alternate placement. In addition to this consultative role, psychiatrists offer valuable help to patients coping with biopsychosocial changes and transitions.

To do this work most effectively, it is important to utilize a patient- and family-centered approach that recognizes the older adult as an activated patient who wishes to participate in the development of treatment and discharge plans. Psychiatry supports the patient and family by recognizing

the patient's preferences, helping them to make informed decisions, listening to their concerns and questions, providing them with education about the mind–body connection in the context of acute medical illness, and informing them of available resources. In an acute medical setting, psychiatrists can anticipate conducting a comprehensive assessment of mood, cognition, and functional capacity, paying attention to the illness story and changes that have occurred as result of hospitalization; evaluating patient's social supports and availability of caregiving; providing consultation on medication management of symptoms, including labile mood, poor appetite, and insomnia and identifying resources to address other patient and family needs.

Conducting a comprehensive assessment with an older adult in the medical setting is similar to the health assessments psychiatrists conduct with adult patients, but requires additional detailed attention to the functional capacity of the patient as outlined in Recommended Questions for the Patient.

RECOMMENDED QUESTIONS FOR THE PATIENT

Personal/Social Functioning

Where do you currently live? Where will you go after discharge? Where do you hope to go? Is there anything you (patient/family) worry about regarding discharge? Is there anything about the physical layout of your home that concerns you? Prior to your hospitalization, did you require help with ADLs/IADLs (specify each)? How does your illness limit you in your ability to engage in routine activities? Who has helped you in the past when you've become ill? Who will help when you go home? Are you the caregiver to a loved one (and, if yes, who will help you care for them now)? Have you experienced any other transitions or changes recently? Do you have transportation needs?

Experience of Past and Present Illness

Have you recently been hospitalized? What caused you to become sick enough to return to the hospital? Why were you readmitted? What could have been done differently before you left the hospital last time? What has gotten in the way of you taking care of yourself? What needs to happen while you are here/before you are discharged so that you remain healthy? How well do you follow medical recommendations? What gets in the way of taking care of yourself?

Psychiatry is also often tasked with providing psychoeducation to the treatment team, patient, and family. It is well established that a patient's physical functioning, number of comorbid medical conditions, and history of depressive episodes can result in comorbid mood and anxiety disorders in late life. When patients and families receive adequate information it

serves to validate the experienced change in mood, normalizes the experience of lability, acknowledges the mind–body connection, explains the anticipated recovery from changes in personality and mood, and provides patients and families with hope for improved quality of life following illness.

Clinicians can also provide supportive listening, paying attention to the patient and family experience of illness, the subsequent loss of function and independence, and fears of death. Through dialogue, the consultant can identify whether the development of improved coping skills and implementation of relaxation techniques at the bedside would be beneficial. The family draws support from acknowledgment that they are also impacted by the hospitalization. Caregivers are described as "invisible patients," as their needs are often not assessed or addressed in health care. They report that hospitalization causes disruptions to their everyday routines, distress, and difficulty meeting their own personal needs. Caregivers are often elderly themselves and require assistance with their own care in order to best serve the patient. Consideration for caregiver burden, burnout, risk of elder abuse, and determination of the family's capacity to provide care are essential components of a discharge plan.

Mr. B was a 76-year-old man of Jamaican descent. He was hospitalized following a stroke, suffering from dysarthric speech and changes in mobility. His wife of 47 years reported that their youngest daughter, who lived with them, had been admitted to the same hospital that week for management of congestive heart failure. Their six other children expressed concern about their mother's capacity to care for both her husband and daughter post discharge.

The patient was very tearful throughout his hospitalization. Mrs. B was increasingly distressed by the patient's continued dysarthric speech, which was exacerbated by his tearfulness. She wanted to know what was "wrong" with him, articulating that he had never suffered from such a labile mood and expressing uncertainty of how best to support him. Though the Medicine service recognized the patient's symptoms as common following a stroke, they did not have adequate time to address Mr. or Mrs. B's distress or understand it fully. The Medicine service felt strongly that a supportive consult from Psychiatry would be best suited to meet the patient's and family's needs and made a referral.

A psychiatry resident met Mr. B, asking questions about his medical experience. Mr. B expressed regret that he had not been a more spiritual man, noting that his survival would not have been possible without religious intervention. His wife frequently nodded her head, saying little except to occasionally repeat what Mr. B had said when concerned the resident had not understood him. Amidst the couple's sobbing the resident asked, "How much do you understand about why you feel this way?" Again, Mr. B noted religious reasoning. The resident was able to validate the family's tie to spirituality while simultaneously providing psychoeducation about the mind–body connection and impact of stroke on mood.

Mr. B heard this information and asked if he would always be a burden on his wife in the aftermath of this acute event. By then one of their sons had arrived and inquired about what types of care his father would likely require. Though occupational therapy had evaluated the patient, the family had not yet heard the results. The resident reviewed the results, noting areas in which the patient would require full assistance. He was then able to facilitate a conversation focused on problem solving, helping Mr. and Mrs. B identify their personal wishes for his recovery and the ways in which this would be facilitated best. At the close of the visit, the resident ensured that Mr. and Mrs. B were given resources regarding therapeutic services, including support groups and respite services for Mrs. B. The referring provider was given recommendations for medication management of symptoms, which had already been shared

with the family.

In this case, Psychiatry identified what the family understood about the patient's health and mood, and provided education on both topics. The family learned new coping strategies and received referrals to appropriate services both in the hospital and out. Through these interventions, Psychiatry supported Medicine, completed tasks that would have otherwise been the responsibility of the hospitalist and may not have been addressed as thoroughly. Psychiatry's efforts enabled the patient to become active in his own recovery and his family to become participants in discharge planning. Psychiatry helped Medicine transition the patient safely home, reduced the likelihood of readmission, and increased patient–family satisfaction.

Long-Term Care

While the number and variety of housing and residential care options for older adults have evolved to include retirement communities and assisted living facilities, this proliferation has not obviated the need for traditional long-term care facilities or nursing homes. Among the 1.5 million long-term care residents in the United States, 80 percent have one or more psychiatric diagnoses. Since the 1990s, nursing homes have absorbed increasing numbers of older adults with severe mental illness and serious behavioral problems and, hence, the prevalence of mental illnesses in long-term care populations is likely to rise. Despite the high prevalence of mental disorders in this population, less than one-fifth of nursing home residents with psychiatric diagnoses receive mental health treatment. In facilities that do provide mental health services, psychiatrists typically work in one of two models—as consultants or as members of multidisciplinary teams. At present, the consultant model is used more widely, and psychiatrists are most often consulted to address behavioral manifestations associated with adjustment issues, disease and infirmity, and dementia. A survey of geriatric psychiatrists in the United States found that the most common treatment recommendations in long-term care included psychiatric medications followed by changes in the general medical regimen, staff support interventions, medical diagnostic testing, behavioral interventions, staff training, individual or group psychotherapy, and family psychotherapy. These data suggest that geriatric psychiatrists tend not to rely solely on pharmacotherapy, but instead recommend a more diverse range of interventions in accordance with evidence-based practices. In some facilities psychiatry is the discipline responsible for intervening with family issues, especially conflicts between staff and families; in others, disciplines such as social workers, marriage and family therapists, and mental health counselors are available to serve in this role. Since 40 percent of long-term care residents generally reside with family prior to placement, family involvement after admission is commonplace. Additionally, long-term care placement is a significant life cycle event for older adult families that often triggers the manifestation of a spectrum of family dynamics.

Maria was a 47-year-old Caucasian woman of Italian-American descent and daughter of her 83-year-old father and nursing home resident. Her father, Mr. F., lived in the facility for 6 months following a discharge from the hospital following a stroke that left him with limited function on his left side. Prior to the stroke Mr. F. had lived in the in-law apartment attached to the home where Maria lives with her husband and son. Mr. F. moved into the apartment reluctantly 2 years ago following his wife's death. He did not want to leave his home, his church, or the diner in his neighborhood where he met "the guys" for coffee a couple of times a week. Mr. F. had been well known in the community "in the day" because he owned and operated a popular barbershop for many years. Maria ultimately persuaded him to move so that she could help him more and he would be near family. He continued to grieve the loss of his wife, and spent most of his time watching baseball games and old movies and helping his daughter with her garden. His health was stable for a while despite hypertension and high cholesterol, but Maria began to become concerned about when he started to lose his appetite, appeared noticeably thinner, and started to become a bit withdrawn. Shortly thereafter Mr. F. had a stroke, was hospitalized and then went to a rehab facility for 2 months. He recovered some function while in rehab but not enough to be able to return home safely.

Mr. F. did not resist moving into a nursing home as he believed he would never be "home" again anyway. After a month or so of adjusting to his recent physical limitations, he began to eat dinner in the dining room. Being a "ya gotta do what ya gotta do kind of man" the nursing staff and therapists from rehab liked him. He was quiet but friendly and very compliant in therapy. He met a couple of the other residents on the unit, began to watch baseball with another resident, and occasionally played cards or checkers when invited. The nursing home staff was pleased with his adjustment to the facility.

Maria was not as pleased. She didn't understand why he was not getting stronger. She repeatedly advocated for rehab services for her father at least 4 days per week. The social worker overheard Maria commenting to another visitor that "they were giving up on him." The social worker did her best to validate Maria's feelings while explaining that her father was receiving as much rehab as he could tolerate. Maria felt better after speaking with the social worker and continued to advocate for more rehab now that "the social worker said that she agreed with her."

Maria was also displeased with the food her father was served. She was concerned about his cholesterol and feared that he could have another stroke. She questioned his dietician about the menu choices he recommended. She advocated for fresh fruits and vegetables and talked about how important gardening had always been to him. She questioned the physician about alternative medicine and use of herbal supplements to reduce his risk of stroke. She decided to back down on that fight and took matters into her own hand by supplementing his diet with lots of green, leafy vegetables from her garden.

At the time of the 6-month family meeting the nurse manager opened by reporting that Mr. F. was doing really well, that he had developed a few friendships on the unit, that his mood had improved, and then declared, "We are all fond of him and I think he is happy here." Maria became agitated and started to voice other complaints. She asked if his bed could be moved because the sun glare obstructed his view of the TV. The nurse responded politely that she had discussed this with Mr. F. and he said that he preferred it the way it is because he did not wish to give up his view of the outdoors. This upset Maria because she felt that her father no longer needed her to advocate for him.

OPPORTUNITIES FOR INTERVENTION WITH MARIA

Provide Education

- To assure her that the meals meet nutritional standards
- To address her questions about herbal supplements
- To explain about the potential effects of green, leafy vegetables on clotting when blood thinners are involved

Improve Communication

- Develop and deliver "team" messages as a way to reinforce that all team members understand and can explain the plan of care

- Respect the delicate balance between allowing Maria to be "the expert" of her father and assuring her that the staff have relationships with him and are getting to know him also

Create Collaborative Team Meeting Formats

- Avoid "Team shares information–Family shares concerns" hierarchy
- Allow Maria an opportunity to add items to the agenda
- Come prepared with answers to questions Maria typically asks

Provide Maria With Opportunities To Be A Partner In Care

- Assure Maria that she maintains a special role in her father's life
- Encourage her to bring in sauce or other foods her father used to enjoy
- Show Maria how her contributions have shaped her father's plan of care or the way in which care is delivered

Palliative Care Service

Current research demonstrates that patients with advanced, life-threatening illness benefit from care that addresses their psychosocial needs, including loss, grief, quality of life, and suicidal ideation. Though rates of depression are as high as 58 percent in this population, psychiatric needs often go unrecognized or untreated. Lack of treatment is partially the result of limited availability of psychiatry consultation and clinicians' perceptions of their insufficient competence to meet the needs of this population.

Patients and families facing terminal illness are often seeking improved quality of life and maximum comfort. Psychiatry can support a patient–family-centered experience that enhances shared decision making about end-of-life decisions, honors patient preferences regarding place of care, and recognizes caregiver fatigue. Families require continued education not only about the disease process, but also about palliative care treatment options. Though palliative care teams are equipped to have these conversations, the dialogue can sometimes come as a surprise to families, and clinicians in psychiatry and medicine can continuously assess the family's readiness for palliative interventions. Additionally, psychiatry is uniquely positioned to help address family conflicts that may arise with respect to different perceptions around end-of-life options, and to help families transition from their in-hospital experience to post-loss bereavement experience and provide grief counseling.

Ms. P was a 67-year-old, Asian American when she presented to the hospital. Widowed for over a decade before, and suffering from amotivation and anhedonia, she had paid little attention to her own health and not modified her diet despite medical recommendations. She lived with her daughter and grandson and followed her grandson's dietary habits, eating largely sweet snacks and carbohydrates that were easy for her daughter to cook. The patient had suffered from uncontrolled diabetes for several years, episodes of gastroparesis, and chronic kidney disease. Upon hospital admission she was diagnosed with end-stage kidney disease and there was discussion of starting dialysis; alternatively, they noted that without dialysis, Ms. P would likely

die. In the interim, palliative care was monitoring the patient's medication management of pain, and had started a PCA. Ms. P was quiet whenever members of the medical team entered her room, as was her daughter; however, her daughter shared her preferences quite openly outside of the hospital room, adamant that her mother should receive dialysis.

Psychiatry was consulted to enhance communication between mother and daughter, and to help the team better assess Ms. P's interest in dialysis. Knowing that Ms. P and her daughter remained silent in front of the team, the psychiatrist recommended that a family meeting take place to include psychiatry, medicine, and palliative care. In doing so, the team was able to model (and subsequently encourage) effective communication. The psychiatrist demonstrated use of open-ended questions, facilitating a conversation that prompted participation from all team members, Ms. P, and her daughter. Ms. P eventually articulated that she was not interested in living a life that required intensive medical care and wanted to be with her husband. Her daughter was tearful but able to verbally accept her mother's choice. Palliative care was then able to provide insight about expectations of the disease process. With this information, the psychiatrist then invited Ms. P to consider other personal preferences and wishes. The psychiatrist supported further dialogue between mother and daughter. At conclusion of the conversation, Ms. P expressed gratitude that she might die with dignity, and was happy to know that she could live her remaining days at home with supportive services and her daughter and grandson nearby.

When Ms. P died a few weeks later, her daughter mailed a letter of thanks to the palliative care team and psychiatrist. She explained the value she perceived in preparing her for the future, avoiding treatment her mother viewed as futile, and improving their communication. She lamented the fact that a family meeting had not occurred sooner in her mother's care, wondering if the last decade of their relationship might have been different. She shared that she previously found her mother's quiet, stoic nature to be one of avoidance rather than resilience, and that the family meeting helped her view her mother more positively. She concluded that in giving her mother dignity at the end of her life, the psychiatrist had reduced the family's experience of guilt and grief.

Indications

Family therapy is most commonly used in older adults when the presenting problem is one in which the patient's distress or capacity for problem solving is rooted in a relational context. Family therapy is also indicated when the clinical situation at hand could likely be resolved with brief, solution-focused interventions that are designed to address specific therapeutic goals. Most serious mental health problems of older adults are more successfully addressed when family members are involved in the treatment. Although caution and clinical judgment must be exercised as to the type and timing of family interventions, substantial evidence indicates that psychiatric problems worsen or resolve less completely when conflictual or chaotic family environments are not addressed in the treatment. A major developmental task that families face throughout the life course is finding a balance between supporting individual members to be competent and independent while at the same time remaining connected to and part of the family as a whole. Families are often confronted with this challenge as they encounter life cycle transitions such as the birth of a child, marriage, retirement, an aging parent, or the loss of a loved one.

Limitations

Older adults are most likely to share psychiatric complaints with their primary care physician, and even then their report of symptoms is often in the form of somatic concerns. It is therefore quite difficult to reach aging families and implement therapeutic interventions without flexibility, integration, and collaboration. Though family therapy is most commonly provided by marriage and family therapists, social workers, and clinical psychologists with specialty training in family psychology, making referrals to family therapists is not always straightforward as requirements for licensure differ by state and availability of clinicians is often limited. Reimbursement for family therapy services varies by payer, type of mental health provider, setting, and state. Psychiatrists face similar barriers in the implementation of this work. In addition to complexities regarding access, a major limitation is the pervasive attitude among clinicians that potential for change in late-life families is negligible.

Contraindications

Family therapy with older adult clients is contraindicated if a patient's insight or capacity to change is impeded by cognitive impairment, paranoia, or active substance abuse. Conjoint family therapy is typically contraindicated in situations that involve extreme anger on the part of any involved family member or situations in which an assessment has indicated that therapy may increase the likelihood of abuse or other harm. Additionally, it is important to be mindful of the setting in which therapeutic interventions are being applied. For example, in an inpatient medical setting where an episode of care is brief, longstanding transgressions and disagreements are unlikely to be resolved. It is contraindicated to initiate exploration of such work without a plan for follow-up after a hospital discharge, or if a referral for outpatient care is not yet established.

Goals of Treatment

Family therapy interventions are used to reduce clinical symptoms that impact the individual and the family system. As noted, such interventions can be utilized to improve function by effectively changing the family's structure, patterns of interaction, problem-solving abilities, capacity for empathy and understanding, communication skills, and sometimes the meaning that a family ascribes to a certain event or situation. In the context of current health care reform, addressing a family's response to medical illness, death and dying, and the aging process is critical. The cases presented in this chapter provide examples of the multiple layers of family dynamics that accompany the transitions older adult families often confront.

ETHICAL ISSUES

Providing treatment to older adult families at critical times in an elder's life is embedded within layers of complexities. The settings in which the care is provided often introduce additional ethical considerations that may interfere with the provision of optimal patient- and family-centered care. Some ethical issues that clinicians are likely to encounter are discussed here.

End-of-Life Care

Patients, families, and care teams encounter difficult life-and-death decisions, which address medical decision-making, comfort management, and emotional and spiritual well-being. Though formal documents and legal statutes in the United States emphasize the importance of individual autonomy and independent decision making, research suggests that older adults want family members involved in end-of-life decisions. Those suffering from chronic and terminal illness may experience cognitive changes that impede their ability to make decisions independently and benefit from familial support. Despite this, research indicates that older adults and their children often disagree on key factors about end of life. Clinicians can support patients and families by facilitating open dialogue about end-of-life preferences, especially when patients still have capacity to share their wishes.

Clinicians further assist families to make decisions collectively by addressing the family's relational dynamics and life cycle considerations. Such conversations may occur rapidly in acute medical situations that require immediate decision making, or more slowly at the outset of a chronic illness. In some instances, family members express concern that they do not support their loved one's preferences regarding the use of life-sustaining measures. Such scenarios may require development or enhancement of families' natural problem-solving abilities, modeling of adaptive communication, or grief work. In such situations, clinicians are challenged to balance the patient's needs while acknowledging the larger family experience.

Capacity and Decision Making

Decisional capacity refers to a person's ability to make his or her own decisions in a variety of contexts including those related to health care. The issue of consent or refusal of treatment arises regularly when working with older adults, particularly in the inpatient setting. Some have argued that the medical conditions older adults face can contribute to feelings of helplessness, thus rendering these patients more open to the undue influence of others. Though clinical methods are available to assist with assessing capacity, this determination is made amidst multiple contextual

factors. Psychiatrists are thoroughly trained to assess capacity, but it is important to not only determine the patient's ability to understand and reason, but also to ascertain a sense of the patient's values prior to the onset of illness. Such evaluations and subsequent information sharing with the patient attempt to honor patient autonomy and appropriate family inclusion. It is important to understand shared versus conflicting values held by the patient and family, and the risk of conflict and potential coercion when values and wishes do not align. Further, if a patient is deemed "incompetent," clinicians also consider whether the surrogate decision-maker is acting with the patient's values and best interest in mind.

Cultural Considerations

Each generation of older adults gives rise to a unique set of values, beliefs, and family dynamics. These factors impact how older adults and families interact with the health care system and can play an important role in treatment decisions and outcomes. As increasing numbers of Baby Boomers reach the age of 65, it is important for clinicians to recognize the different social and demographic characteristics that define this unique cohort. Individuals in this group tend to be more educated than their predecessors, have more access to health care information, hold higher and more specific expectations of the health care system, and have a tendency to challenge authority. Baby Boomers are more open to receiving mental health services than previous generations. Despite these overarching themes, Baby Boomers comprise a heterogeneous group. Thus, careful evaluation and treatment planning are fundamental to providing care that honors and respects these elders and their families.

In addition to generational considerations, US Census data indicate that the fastest growing segment within the over-65 population is Latinos. There is a need for practice guidelines addressing the feasibility and acceptability of family therapy approaches with this population.

Elder Abuse, Neglect, and Exploitation

Elder mistreatment, including abuse and neglect, is a public health problem of significant concern. Estimates indicate that over 500,000 older adults in the United States alone are the victims of abuse or neglect. Community-based studies indicate that between 7 and 10 individuals over the age of 65 experienced abuse in the prior year, with the majority of abusers being family members. Older adults who are cognitively or functionally impaired are at higher risk for abuse, and some who experience severe disability are unable to report maltreatment. Elder abuse is one of the strongest predictors of long-term care placement. Advanced age, female gender, being in a spousal relationship, African-American race, living with others, physical and economical dependency on caregivers,

isolation, intergenerational conflict, alcoholism, and mental illness have all been associated with increased risk of abuse. Additionally, published reports suggest that family members who perceive a high level of caregiver burden, have a history of their own mental health needs, or have a history of substance abuse, may be more likely to engage in abusive behaviors, particularly when seeking compliance from the patient.

Clinicians must be alert to the needs of patients and their caregivers. It is helpful to look for signs of abuse or neglect, including repeated, unexplained bruises or injuries, malnutrition, fearfulness around particular family members, or, in the case of elders who are being financially exploited, a discrepancy between their ability to pay for personal commodities and their reported level of income. Clinicians can reduce the risk of abuse by conducting thorough assessments of caregiver burnout and by attending to the caregivers' experience of an aging relative. Family therapy is recommended to mediate conflicts that might give rise to mistreatment, but more research is needed to understand the treatment techniques that are most effective.

The majority of states now have mandatory reporting laws for elder abuse, as well as state or county-funded protective service programs for older adults who have been abused or are at risk. Practitioners are responsible for knowing state reporting laws. Although estimates indicate that one-third of actual cases of child abuse are reported, some studies estimate that only 1 in 14 cases of elder abuse is reported. Older adults are often reluctant to disclose the problem for fear of retaliation from the abusive family member. Further limitations to the frequency of reporting are thought to be related to the professional's fear of offending the patient or family.

RESEARCH AND EVALUATION

Despite the growing knowledge base on family systems and life cycle approaches to the treatment of older adults, evidence of the utility of these methods remains sparse. Controlled outcome studies are needed to confirm the general effectiveness of systemic family therapy with older adults and to clarify which approaches are applicable to the range of problems confronting families in later life. In contrast to the paucity of outcome studies of family systemic approaches to therapy, there are numerous studies of the effectiveness of psychoeducational interventions and cognitive-behavioral psychotherapies that are focused on family caregivers of older adults. Many of the most promising advances in the field are rooted in ecosystemic interventions that are delivered outside of the traditional health care practitioner's office. These interventions have been demonstrated to have positive effects on such outcomes as caregiver burden, depression, subjective well-being, knowledge and skills, and physical health, as well as on the level of symptoms expressed by the older

adult receiving care. At present, research on caregiving, elder abuse, and end-of-life care remain the most fertile areas for investigation of family therapy approaches.

57.4k Group Therapy

KENNETH M. SCHWARTZ, M.D., AND MOLYN LESZCZ, M.D.

DEFINITION

Contemporary group therapy practice of the psychogeriatric population has expanded significantly as noted in earlier editions of this chapter. Relevant models of new applications are emerging steadily to meet the increasing needs of elderly patients with complex medical and mental health issues, although evaluation and research have yet to keep pace with these clinical developments. Foci of intervention include the aging-related losses of interpersonal, emotional, social, physical and cognitive capacities. The group therapies provide demonstrably effective treatment achieved through improving social support and engagement while enhancing individual patient and family member coping capacities and skills. Group therapy is provided in ambulatory, hospital, and institutional settings and ideally should also be available in community and primary care settings. In all instances the group leader's belief in the continued potential for growth and change in later life is of overarching importance: it is at the heart of clinical effectiveness.

HISTORY

The roots of group therapy can be traced back to the work of social workers in a variety of settings for seniors including homes for the aged, community centers, and mental institutions in the earlier part of the 20th century, providing group interventions combining activity and social treatments, emphasizing instruction, inspiration, and social support. In the following decades, interest in psychodynamic group approaches with elderly gained prominence as Maurice Linden, an American psychiatrist and pioneering group therapist, wrote a series of transformative articles on the topic. His early conclusions that group therapy provided psychotic and "senile" institutionalized patients opportunities for resocialization, happiness and some self-sufficiency have stood the test of time. The approach was well tolerated by patients, satisfying to staff, and economical. Group therapy has since broadened its reach with the provision of treatment in acute care settings, day hospitals, ambulatory, and community settings. Accompanying this has been a shift in the emphasis from the powerful and caring leader to interpersonal models emphasizing the importance of relationships between group members in healing and change. As well, not only are psychotherapeutic interventions routinely integrated with pharmacotherapy, but the recognition of the limits of singular models has encouraged integration within group psychotherapy itself, synthesizing the benefits of cognitive-behavioral, dynamic, and developmental models. As is

common in the field of group therapy, practitioners continue to respond to emerging clinical need with diverse populations with renewed emphasis on creating evidence-based models of intervention that are applied and then evaluated.

Current models include (1) verbal groups for the cognitively intact which include groups for burdened caregivers; (2) verbal groups for the cognitively impaired, including cognitive stimulation, resocialization, remotivation, and reality orientation groups; (3) activity- and creativity-centered groups, including dance movement, drama, music, art, and poetry groups; (4) a variety of time-limited homogeneous groups addressing issues such as retirement, bereavement, and medical illness; and (5) self-help and advocacy groups.

THEORETICAL ISSUES

Elderly individuals cover a large range, from baby boomers to centenarians, with an increasing diverse range of diagnoses and abilities. The need for more effective psychological treatments will become more, not less important, as the aging population becomes more psychologically sophisticated, having utilized psychotherapy at earlier stages of life.

The themes encountered in geriatric group therapy include reactions to loss, both developmental and traumatic, and to decline, with the resultant discontinuity with a prior, more valued sense of self. Consequently, themes revolve around issues of maintaining dignity, increased need for help and dependency, changing roles and/or conflictual relationships with adult children and mourning of losses of spouse and/or health.

Depression is a major public health concern because it is associated with high prevalence, morbidity, chronicity and health care cost, and affects both the cognitively intact and cognitively impaired elderly. Loneliness and the lack of social support are profound risk factors in depression. Group therapy provides opportunities to grieve losses and to re-engage with interests and relationships. It provides real relatedness alongside the acquisition of skills needed to generate continuing social integration beyond treatment. Because the experience of relatedness generated in the group is the result of the members' own actions, feelings of dependence may be reduced and feelings of personal competence may be increased. Enhanced social support produces a primary effect of improved well-being and a secondary, stress-buffering effect, which is particularly important for the elderly in light of the likelihood of further losses in the future. Higher levels of social support predict a significantly superior clinical course in the treatment of depression.

Often group members experience shame at having lost their prior sense of self, viewing the current incompetent mental and/or physical replacement to which they must adjust as bad or defective. In group, they can be assisted to learn that their presumed defect is merely human and

that other members also struggle with similar thoughts and feelings. The sharing of painful and secreted concerns can reduce the shame and stigmatization that isolate the individual. Through the therapeutic mechanism of altruism, members help one another, simultaneously raising self-esteem for both the receiver and provider of support. Realistic hope can similarly be nurtured countering feelings of demoralization and despair. Hope is malleable and can evolve with support to focus on wishes and aspirations even in the face of decline, loss, and limited time. The social milieu of the group, with members at different points along a developmental continuum can restore hope and also provide members with an opportunity to relate to, share with, and care about others dealing with similar challenges.

In a day hospital program for depression, each week typically saw the arrival of one to two new members and the impending departure of senior members. The group therapists determined that the task of introducing the integrated group therapy and orienting new members into the group would enhance the independence of senior members. Mr. Y, an 80-year-old widower, enthusiastically seized the opportunity to orient the new members to the group. He began by saying that he recalled his own start in the program 16 weeks before and how scared he was at starting something new. Another member commented that it was quite normal to feel apprehensive and discouraged starting out, adding how initially Mr. Y was so withdrawn and lacking in energy that he could barely get out of bed, never mind begin and contribute to the group as he was now doing. A third member recounted how he also benefited and encouraged the newcomers to give the group time to help them also get better. Although Mr. Y was sad at the prospect of being discharged from this very supportive and accepting environment, he would continue in follow-up sessions that he was confident would help him stay free from depression as he was leaving with many new skills and ideas that he had learned through therapy. In response to a question from a new member asking what he was leaving with, Mr. Y described a restored sense of confidence and usefulness, the capacity to challenge his tendency to withdraw, and a new set of skills that helped him better understand himself and others leading to improved relationships with his children.

A metatheoretical synthesis of dynamic and developmental approaches along with cognitive-behavioral approaches into a seamless whole emerges from the recognition that effective psychotherapy is facilitated by understanding of the individual's private, subjective experience residing beneath more manifest interpersonal behavior, bridging emotional insight of oneself and others with skill acquisition. In all instances the overarching goal is to increase each group member's sense of self-efficacy. Restoring a sense of personal effectiveness and the recognition of cause and effect in one's life is essential. This integrative model emphasizes the individual's sense of agency, as opposed to viewing oneself as a victim, of his or her own relational world. It combines interpersonal feedback within the here-and-now of the group and the processing of extra-group events and assigned homework, adding an intensity and immediacy that enlivens cognitive and behavioral approaches. Behavioral activation and skills training build atop this. Allied with these more traditional and recent approaches are mindfulness-based cognitive therapy groups and dialectical behavior

therapy aimed at increasing reflective capacity, reducing reactivity and enhancing skills in regulating negative emotions. Adapted for older adults, these approaches also focus on teaching skills to enhance openness to new experience and in creating meaning over the course of life. Problem-solving therapy is a structured approach that is derived from cognitive-behavioral principles and teaches older individuals to address problems by systematically examining and finding solutions to problems, without depth exploration. Life review approaches encourage reflection on historical material or reminiscences, either spontaneously produced or actively elicited by the therapists that is in turn explored and linked to the group member's current life and relationship. Past accomplishments and areas of competence and pride are highlighted to help restore feelings of worth, status, and competence through the articulation of past successes as the declaration of one's credentials. Members are encouraged to respond to the reminiscences of others and to explore their own emotional response to the material presented at the level of the here-and-now. Incorporating the patient's reminiscing about an earlier, more robust sense of self not only creates opportunities for psychological restoration by recollection of the past, but also sets the stage for contemporary employment of these valued elements of the self. The examination of actual models of group therapy described in the literature underscores this integrative process regardless of the specific noted designation of the intervention.

The elderly's awareness of the limits imposed by aging, loss, and decline focuses attention on existential issues regarding death, meaning in life, and personal responsibility. Group therapy should support exploration of these concerns with a view to facilitating members' meaningful engagement with life. The event of death obviously ends life, but the idea of death can vitalize life by focusing attention on both reducing regrets of things undone or unsaid and living life before time runs out.

Mrs. S, an 84-year-old woman in a group spoke of "how at memorials people often joked or were blocked from expressing their emotions." She contrasted this with the group which allowed members to share their vulnerability. Another member commented he used to think vulnerability was bad or was now a sign of weakness. Mrs. S agreed and went on to say she was once afraid of aging but was now helped by believing she was still growing because "I no longer get so angry and I can now approach my children to talk. I'm having the best time of my life, but I'm still sad. Why? I don't want my life to end as I've never had this in my life before."

Combined pharmacotherapy and psychotherapy are progressively employed in the acute, maintenance, and continuation phases of treatment. Combining drug and psychosocial therapies demands that attention be paid to the meaning each treatment has to the individual while being cognizant of the risks of devaluing one modality or the other. For example, a medication group where participants are encouraged to discuss their shame and fears associated with taking antidepressant medications can lead to

sustaining durable treatment responses, reducing subsequent affective morbidity, chronic psychosocial invalidism, and poor adherence to medical treatment. The universality of the group, that is, the realization that other group members taking medications may suffer from similar fears or shame coupled with the increased awareness that others benefit from these medications often leads to hope and improved acceptance of the use of medication.

Activity- and creativity-centered groups (e.g., dance, movement, pottery, music, or drama) encourage social engagement through shared participation in a pleasurable activity that may rekindle a connection with the previous sense of self through the use of the creative process. Group activities elicit feelings of pleasure and mastery; challenge self-denigrating and constrictive distortions that individuals may have about themselves; and counter the trend toward homogenization. Although the focus in the group is on a physical activity, integrating a psychodynamic appreciation to the meaning of the activity groups amplifies the use of the physical activity to promote social interchange. This has been demonstrated to assist in role transition, acceptance of loss in body function and integration of new goals, interests, and meaning in life.

Groups for caregivers are used widely in response to the increasing number of frail or cognitively impaired individuals being cared for in the community by their families. Increasing longevity is a challenge for both society and family members generally unprepared with little knowledge and few skills to deal with their loved one's physical and especially cognitive decline associated with dementia. These caregivers are often highly stressed, isolated, overwhelmed, and have an increased risk of psychological, physical, and financial problems, yet they remain the key resource to the implementation of any interventions for the identified patient. Groups may provide an opportunity for working through feelings of loss and abandonment, as well as anger at the burdens imposed on the caregiver. Attention to the process of the giving and receiving of mutual care within the actual groups provides a direct opportunity to address self-management and self-care issues. Education, social support, and skills training all may be integrated in these groups. Using simulation of challenging caregiver scenarios is also being applied to good effect in facilitating direct application of specific and relevant coping skills. Growing attention to individuals with mild cognitive impairment is evident in groups that provide psychoeducation, support, and coping strategies for couples with the objective of reducing anxiety, aligning expectations, and jointly coping while reducing marital stress.

Admittedly, cognitive impairment makes it more difficult to process new information, relate to what others are experiencing and participate in a group environment. Nonetheless, cognitive stimulation, resocialization, remotivation, and reality orientation groups for the more cognitively

impaired elderly play a significant role in institutional and community settings. Wellness group models teach skills, such as relaxation, guided imagery, and deep breathing, with the objective of fostering in members a sense of personal integrity and dignity to reduce the emotional distress that may underlie agitation and behavioral disruption. Members' sense of who they are within their environment is consistently validated. Interpersonal engagement with the present may be achieved through the structure and content of the group. Group interventions employ maximal multisensory stimulation in the form of sound, sight, and even pleasant aromas so that cognitively impaired individuals maximize opportunities for engagement with their environment and the retention of their cognitive and social abilities through sensory stimulation and reinforcement. Multisensory stimulation focuses on realigning sensory stimulus imbalance with gentle and humane exposure to language, sound, visual smell, texture, and touch stimuli: complex cognitive capacity is not required.

Group models are also developing outside of traditional venues. A group music intervention using percussion instruments with familiar music may lead to reduction of anxiety and agitated behaviors of those with dementia and to alleviate the burden of nursing caregivers in institutional settings. Telephone group therapy increases access for those unable to attend therapy sessions due to infirmity or distance. Technological advances and growing individual competence with technology will expand the reach of group therapies, as reflected in the growth of Internet support groups. Internet-based psychotherapeutic support group intervention for family caregivers of individuals with neurodegenerative illnesses already demonstrate the feasibility of such groups to benefit members with the reduction of caregiver stresses.

TECHNIQUES

Technical expertise in the application of the group therapies is surpassed in importance only by the therapist's posture of respect, hopefulness, genuine warmth, and empathy. Study after study has reiterated the findings that effective group therapy is predicated upon a strong sense of group cohesion and the leader's capacity for both receptive (understanding) and expressive (communicative) empathy. Beyond the relationship between member and leader, successful treatment hinges on the establishment of group cohesion. Modifications of therapy approaches are sometimes necessary for group work with the elderly in order to achieve and maintain cohesion. These include the use of cognitive reframing, supportive techniques, and practical arrangements for problems in hearing, vision, mobility, and other disabilities. Nonetheless, cohesion may be difficult to achieve with demoralized, withdrawn, and self- or other-devaluing patients. The therapist needs to be mindful that cohesion emerges both from the emotional bond shared by group members and the group's effectiveness

with its designated tasks. Therapist interventions follow from the understanding of the tasks and goals of the therapy. The rationale for the group and the therapist's intervention should be transparent and clear. Co-therapy may be useful in providing an appropriate level of focus and activation, continuity during therapist absences, and the added opportunity to address countertransferential reactions through co-therapy discussion and the co-constructed space for thinking. Within institutional settings, co-therapy also facilitates transmission of information between the group and other institutional care providers to ensure maximum treatment integration and reduce institutional resistances to the group interventions.

Attention must be paid to the maintenance of group norms and group integrity, which may be challenged by patient or institutional resistances. Patient resistance may be difficult to discern or be interwoven with illness or realistic reliance on others for transportation services. In institutional settings, an alliance between the group therapist and administration is essential. The group therapy inevitably reflects the culture and norms of the larger milieu in which it is embedded. The principle of isomorphy notes that important concerns, values, and fears are transmitted throughout the institutional system and gain expression at every level from patient to leader to group to ward to institution. Hence, an opportunity for dialogue and interchange between all the stakeholders in the treatment environment is invaluable, while striving to ensure appropriate privacy and confidentiality within the circle of care.

A key aspect of this is to ensure that group sessions in institutional settings are scheduled in an accessible location without conflict with other scheduled activities. Active outreach including the arrangement of portering may be required to promote regular attendance. Groups for the elderly may often be held at midday in ambulatory settings and may be contiguous with lunch, to encourage opportunities for social interaction around mealtime. In institutional settings and day hospital programs, the treatment frame is also affected by the fact that group members will often have involvement with one another outside of the group. Opportunities for engagement and interaction outside of the group can be employed as part of the prescription of behavioral interventions and to facilitate homework. In all instances, a group norm should be established that protects the confidentiality of the group members and encompasses extra-group contact within the treatment frame.

Therapy groups generally consist of 6 to 10 patients, but activity groups or groups for depressed or frail populations may be larger and benefit from the increased energy in the room. Duration of sessions is shaped by members' capacities and may vary from 30 minutes daily for cognitively impaired patients to 75 minutes weekly for more cognitively intact patients. Many group formats are ongoing, but the majority of cognitive-behavioral groups and groups for burdened caregivers are closed and time limited,

lasting from 6 to 20 sessions. The limits of briefer treatments are being recognized, and treatments are often extended to include follow-up sessions that meet at a reduced frequency, but over a longer period of time, to extend treatment into maintenance and continuation phases. It is not uncommon in some settings to see members attend a monthly maintenance phase meeting for many years or for group participants to continue to meet informally after the group sessions end.

The ideal treatment setting will offer an array of group therapy options, phasing and tailoring interventions to patient requirements with graded levels of intensity and depth. The therapy should be experienced as a self-esteem–enhancing and sustaining experience and a nonfailure experience for each member. Therapist activity must focus on promoting group interaction in ways that maintains the dignity of participants. The therapist should achieve a balance between support and expression and may need to intervene with active prompting, reinforcement, reframing, and modulation of emotional intensity, emphasizing the invitation for what is desired rather than the rebuke for what is not. An important therapeutic task is the empathic confrontation of projective defenses and resistances to engagement that isolate individuals and undermine group cohesion. The therapist may need to be quite active in reinforcing progroup or procohesion exchanges, bolstering patient feelings of worth and belonging. It is essential not to permit depressive affect to overwhelm the group as the depressed elderly are particularly prone to the effect of demoralization. Patients and therapists must understand that demoralization is a state—it is a specific emotional reaction and not an obligatory trait of aging.

Mrs. X, an 86-year-old widow, was a member of a group designed to help people adjust to living in a nursing home. Initially, frightened by her belief that a nursing home was a place where one went to die, she was pleased that the group members, some of whom had been in the home for years, reassured her that one could still have a good quality of life. She suffered from chronic depression and a history of unsatisfactory interpersonal relationships due to a perceived lack of attention, including from her son. Mrs. X entered the group unaware of how her responses when upset would offend other residents and staff leading them to stay away. With the group's help, she became aware of the consequences of her responses both inside and outside the group. Following the group's encouragement, she was able to appropriately invite her son to visit. That visit and subsequent visits went well and her mood and her adjustment improved.

An outbreak of viral illness then necessitated the cancellation of two group meetings. Upon resumption, Mrs. X was weepy as she complained about the lack of attention offered by her son and staff during the outbreak. Other group members shared their demoralization during this period. One group member, however, wondered if Mrs. X and other group members were more demoralized because of the break and enforced isolation of some of the ill members. Mrs. X then wondered if she was particularly affected because of her sensitivity to interpersonal rejection, as previously pointed out to her. The group acknowledged Mrs. X's increased insight and her affect brightened in conjunction with the other group members.

Self-psychology makes a valuable contribution in psychodynamic group approaches by virtue of the understanding it provides about the inner

world of the individual and the consequences of loss of self-object and self-sustaining relationships, capacities, and functions. Empathic awareness of the impact of loss and decline as experienced subjectively may diminish the risk of unwitting collusion with patient demoralization or engagement in negative interpersonal cycles of criticism and rejection. Without this perspective, the patient's narcissistic defences of devaluation, externalization, or self-inflation may recruit hostile and damaging feedback. The group may be used constructively in a self-sustaining mode by providing mirroring, idealized, adversarial, or twinning self-object transferences, thereby creating an opportunity for each member of the group to feel a valued member within a group of peers. This in turn may promote a restoration of a prior, more cohesive sense of self.

Life review and reminiscing techniques employ the naturally occurring process of patients' recollections and review of their lives. It can serve as a vehicle for making meaning of one's life viewing it as valuable and of consequence; and aid in resolving old conflicts and accepting losses. When used in a group format it also creates a sense of social identification among group members. Reminiscing can be used as a main treatment focus or to stimulate cohesion in beginning groups as an introductory exercise. Reminiscing can be spontaneous or prescribed in a series of sessions, following a chronological life course sequence. Either milestoning, which emphasizes only positive events, can be utilized, or the review process can be comprehensive and autobiographical, providing an opportunity for mourning, conflict resolution, and acceptance. Encouraging a focus on the past is not without risk. Facilitating the group members' return to dialogue within the here-and-now of the group, eliciting feedback and interaction, ensures that morbid self-absorption, preoccupation with painful memories or regrets, and guilt do not exacerbate the individual's withdrawal from the group or adherence to the past as a way of avoiding engagement with the present.

Aging often involves a shift from primary control and autonomy in which one effects change in the environment to deal with obstructions to one's needs and potentials, to secondary control in which one's beliefs and attitudes must be realigned to address these obstructions, for example, decreased mobility and access to social engagement and opportunities. Failing to do so may generate profound difficulties with self-criticism and beliefs about one's incompetence. Effective modification of thoughts and behaviors plays a major role in addressing the lack of perceived control. Therapists can challenge the "evidence" that patients have to support their fears. While recognizing age-related limitations of time and energy, the belief that their remaining life will be one of unhappiness and despair can be challenged, often through the countervailing experience in the here-and-now of the group. In turn, the behavioral responses employed to cope with change to life situations can also be evaluated for their effectiveness, and by

these means positive adjustment can be promoted and successful aging and an improved mood can be resumed.

Mr. Z, an 82-year-old widower in group in a retirement home, described his apparent decline. He first thought using a cane was a sign of getting old. Still not feeling old, he soon was told that for safety reasons he needed a walker. He imagined everyone he encountered was feeling sorry for him. Months later, and now in a wheelchair, he was struggling with not feeling sorry for himself. A co-member also in a wheelchair commented on similar struggles, particularly in light of having earlier led an active life. A third member encouraged both to look at what they could still do to help others who could not see or remember as well as them. Mr. Z gratefully received this feedback as one of his worries was whether he could still be useful and of value at his stage of life in an institutional setting.

Cognitive-behavioral therapy emphasizes conscious cognition and learning and adapts behavioral strategies and the cognitive therapy model to the group setting, affording opportunities for the acquisition of cognitive and behavioral skills. Cognitive therapy addresses the patient's problems with dysfunctional thinking patterns that reinforce negative cognitions and beliefs about the self. Behavioral approaches focus on remediating the patient's reduction of environmental or social reinforcement that results from his or her withdrawal, diminished interpersonal skills, or increase in adverse life events.

This approach emphasizes the teaching of skills with a consistent focus on patients assuming responsibility, crediting themselves for improvements, and stimulating a sense of mastery. Larger problems are deconstructed into smaller, more manageable components. Therapeutic strategies include challenging the patient's processes of generalizing, catastrophizing, magnifying, and black-and-white thinking. Patients are helped to examine evidence for and against their beliefs and by finding alternative explanations for their negative thoughts; reattribute meaning to events; schedule activities with the assertion of pleasurable activities and affects; utilize time meaningfully; and challenge both the discarding of positive options and the failure to take credit for partial positive gains. Patients may be taught to log the relationship between mood and either pleasurable or aversive experiences and to increase the frequency of pleasure-focused activities. Thought record logs, modified for use with the elderly, have been developed by Larry Thompson and colleagues. The Daily Record of Unhelpful Thoughts (DRUTS) facilitates this recording and review process. Active commitment to the assigned homework impacts directly on the outcome of therapy and may require input and support from family members. Behavioral prescription may be quite explicit and includes modeling, role play, didactic sessions, psychoeducation, behavioral exposure to anxiety stimuli, and the review of homework with the provision of feedback about each group member's efforts in using prescribed skills to re-engage with pleasurable experiences.

In a day hospital for depression, Mrs. A, a 78-year-old widow, commented upon entry to the group that she was depressed and that "the group will not help me." Other members of the cognitive-behavior group suggested a thought record could improve Mrs. M's mood. Group members then assisted Mrs. A in finding evidence that did not support her thoughts. In a later session focused on creating personal action plans, Mrs. A observed she had withdrawn from her friends, was not returning phone calls and was declining offers to socialize. Encouraged by the other group members, she decided on the action plan of returning a phone call to a friend. In the next session, she reported that she was able to complete the action plan of phoning the friend who was happy to hear from her that her mood improved as a result. Having achieved this success and seeing the effect on her mood, Mrs. A decided that she would call a friend several times a week.

Cognitive-behavioral therapy groups are quite structured and follow a predictable format of a check-in, homework review, summary, assignment of new homework, and discussion of anticipated obstructions to completion of the homework. It does require a baseline of cognitive capacity and in most instances respecting the impact of slower cognitive processing with greater respect paid to pacing, appropriate repetition, and reinforcement allows them to benefit. The group setting is ideal for this model, linking together mutual support, modeling, and the collaborative challenging of common cognitive and behavioral contributions to distress and depression. Early studies that showed that individual cognitive-behavioral therapy was superior to group cognitive-behavioral therapy likely reflect the inadequate attention to the impact of working with group process, an important consideration, even in highly structured groups.

Groups for cognitively impaired patients focus on patient engagement, with the structure of the group activity employing multiple modes of cognitive stimulation. Interpersonal and group processes are generally not addressed. These groups employ a broad range of sensory and cognitive stimuli to activate and engage patients, with consistent reinforcement and validation provided by the leader(s). The therapist should be guided by the principle of conferring meaning to every patient communication rather than dismissing these expressions as irrelevant. Cognitive exercises; activity and word games; life review; discussions; participation in arts and crafts; pleasant aromas; music; baking; guided imagery; relaxation; and physical exercise are components of these groups. What links all such groups is the moment-to-moment focus on esteem-enhancing patient engagement with the world around them. Groups of 6 to 10 participants work well. The group should be small enough that each member actively participates. Future growth in these approaches is likely, reflecting the growing role and positive effects of nonpharmacological interventions for dementia recommended in contemporary practice guidelines.

Group therapy interventions for caregivers work best when they integrate a variety of techniques which are structured and intense; require active involvement of caregivers, include education, support and respite; promote knowledge transfers, skill building and competency; and are

combined with individual support.

CLINICAL ISSUES

Indications

The choice of a group modality for the elderly may take into consideration both practical issues, such as the availability of various group types, along with affordable and convenient transportation, and patient issues, such as the type and extent of psychiatric illness and/or cognitive impairment.

Group therapy may be used as an adjunct to pharmacotherapy, individual treatment or as an independent treatment. With respect to selection criteria, structured groups, especially those that are more homogeneous in terms of membership, ego functioning, and cognitive capacities and not age alone are more effective than unstructured groups. There is a potential for poorer treatment outcomes in groups that lack either focus or appreciation for the potential to amplify depression by intensifying affects related to illness and death beyond some members' capacity. As with all treatments, therapeutic success is enhanced by the linking of patient goals and abilities to the tasks and techniques of the treatment. Mixing cognitively impaired and intact patients together is likely to jeopardize cohesion and group effectiveness by generating a wish among members to disidentify and withdraw from the more impaired participants.

Although pregroup preparation has not been extensively researched with the elderly, the evidence for its usefulness in other patient populations is quite substantial. Pretherapy preparation outlining the group treatment's goals and methods demystifies an otherwise anxiety-provoking situation, normalizes and destigmatizes treatment, helps to establish a therapeutic alliance, and sets group norms regarding regular attendance, confidentiality, and extra-group socialization. This process may increase group therapy tenure and task adherence and foster patient hopefulness. Role play or simulations may be utilized to induct the patient into the therapy role.

A written summary of the group therapy logistics, norms, tasks, and expectations may be useful to supplement the preparation interview. Pregroup preparation should also explore treatment resistances. Identification of ego-syntonic character difficulties, in particular narcissistic pathology or interpersonally alienating behaviors, may be useful in containing behaviors that can result in early peer rejection from the group.

Dropout rates in group therapy in general range between 10 and 50 percent in younger adults and are likely the same with the elderly. The likelihood of premature termination from treatment increases with increasing severity of depression, comorbid physical illness, and comorbid characterological difficulties of devaluation and externalization.

Burdened caregivers are a notably vulnerable group. Limits in health care resources coupled with the an aging population has resulted in the common situation of caregivers routinely providing at home the kind of care that in a previous generation was provided by professionals. Caregiver stress emerges from strain around safety, managing patient problematic behavior, self-care, social support, and personal emotional well-being. Caring for the cognitively impaired individual generates greater psychological strain and burden than caring for the medically ill. Family caregivers are often disproportionately vulnerable to both psychological and medical illness.

Contraindications

In general, individuals who require acute and active management because they are in crisis, suicidal, actively abusing substances, or acutely psychotic do not do well in general groups. Severe cognitive or sensory impairment or medical illness that obstructs the individual's engagement with the group enterprise may also require exclusion from group therapy. Some contraindications are relative and can be remedied by employing groups that are homogeneous for that condition. A program that has very few dropouts or therapy failures likely has set the bar for entry too high and may be missing opportunities to treat some patients who could benefit.

Goals

Notwithstanding the range of group formats described, consensus exists regarding realistic goals of treatment. Although obviously shaped by particular patient needs, in general, the goals of treatment include: reduction of symptomatic disturbance; reduction of isolation; restoration of interpersonal skills and engagement within a social network; correction of psychological distortions and cognitive beliefs; restoration of self-esteem; improved cognitive function; acquisition of problem-solving and coping skills; grieving and adaptation to loss; and realistic acceptance of one's needs and limitations with effective use of available resources. In institutional settings, group therapy may provide a forum to deal with the imposed inhibition of personal autonomy associated with routine, regulation, and restricted opportunity, thereby enhancing quality of life by addressing the dissonance between the individual's wishes and the imposed environment. At other times, addressing interpersonal tensions between residents may be the focus of treatment. A men's group may have particular value in institutional settings in which men are in a minority and feel isolated and particularly distant from former pursuits and interests.

Objectives of groups for burdened caregivers include education about the illness process and specific ways of providing care with the acquisition of strategies for dealing with disruptive behavior and problem-solving and

stress reduction skills. Working through loss and grief and facilitating appropriate disengagement that may lead to more realistic decisions about placement are also important objectives. Additional areas of focus include legitimizing the needs of the caregiver and promoting self-care, working through anger and guilt, and addressing relationships with health care professionals. These objectives may be integrated or addressed in a series of modules emphasizing important aspects sequentially.

Groups for the cognitively impaired aim to reduce excess disability and foster more appropriate social behavior and social functioning, thereby optimizing quality of life. Groups that emphasize creative expression aim to restore a sense of competence and mastery through the activity, be it art, drama, sculpting, or dance. Wellness and exercise groups aim to maintain patient well-being through physical activity and stress reduction provided in the context of a social milieu.

ETHICAL ISSUES

Proper patient selection and preparation and competent therapist functioning contribute to an environment that is generally well tolerated and experienced by participants as respectful and helpful. There is growing awareness of the differential impact group therapists can achieve, even when applying the same model of intervention. The interplay of therapist attributes and models of care may result in wide differences in impact.

Ethical care demands the therapist commit to ongoing training, evaluation of one's clinical impact and supervision or consultation. The ending of group may be resisted because of the important social support and self-restorative experience offered by the group and because it provides a sense of stability and consistency in the face of the participant's many life changes. This necessitates an active focus on the transfer of skills gained in treatment into the external world, recognizing that treatment is a bridge and not a destination. Therapeutic groups must be well integrated collaboratively into the overall milieu in which the individual resides. Alterations in the frame of group therapy required within institutional settings, along with other factors that contribute to a higher likelihood of extra-group contact both occurring and even being endorsed, warrants special attention to issues of confidentiality. Extra-group contact and the risk of subsequent subgrouping may be managed by diminishing secretiveness around the extra-group relationships and actively bringing them to the attention of the group.

Societal stereotypes of aging often lead to barriers hindering the elderly from being referred and appropriately treated. For too many, the idea of aging stirs up feelings of loss and deterioration, chronic medical illness and challenges the wish the public has for beauty and remaining young. As a result, attention to therapist countertransference and reactions to the clinical work is particularly important in the practice of group

psychotherapy. Realistic expectations guard against such negative countertransference as denial, hopelessness, and therapeutic despair. A reflective capacity for self-examination is particularly important in working with the elderly because of potential issues of identification with patients, filial countertransference, and avoidance of the issue of sexuality. Ageist beliefs in group members, such as aging inevitably being associated with senility, depression, illness, or being too old to change, when present, must be identified and worked through.

Group therapy is compatible with clinically indicated pharmacotherapy or individual therapy. Its concurrent use is complementary and not antagonistic. However, collaboration between treatment providers is the critical, at times neglected component of effective conjoint therapy.

An additional important ethical concern relates to the removal of barriers to access of care that are rooted in ethnic and cultural patient factors. The concept of cultural competence is gaining prominence in the field of mental health as an important variable influencing treatment effectiveness. Cultural competence relates to the therapist's appreciation for and understanding of the patient's specific cultural context regarding illness, aging, mental health, family relationships, and, of course, treatment. The ideal group therapy will be provided in the primary language of the participants and in accessible settings within the specific communities. Recognition of cross-cultural factors may require attention to the culturally resonant translation of therapy models.

RESEARCH AND EVALUATION

Substantial evidence has emerged documenting the effectiveness of the range of group therapies with the elderly. Meta-analysis of group psychotherapy studies for those over age 55 suffering from a variety of disorders such as depression, anxiety, and dementia document the average effect size for pre–post-studies was quite similar to those of younger adults and adolescents. Older adults who received group treatment were more improved compared to those who received no treatment or a control treatment, and the results seemed to be enduring. The young-old were more likely to benefit, but those with an average age over 76 still reported significant improvements over the course of therapy. Although group interventions for both functional and organic problems demonstrated a significant improvement at posttreatment, the treatments for functional and psychosocial disorders were more effective than treatments for organic problems, such as dementia. However, more group therapy research outcome studies are required as the number of groups providing adequate posttreatment follow-up data is limited.

Reviews underscore that conceptually sound and clinically relevant group approaches appear to be equally effective, equivalent to individual therapy, and significantly superior to no treatment in the area of geriatric

depression. Meta-analysis in this area documents the most effective and most robust evidence for cognitive-behavioral therapy groups compared to waiting-list controls. Dynamic group therapy approaches appear equivalent; however, further research studies evaluating the benefits of psychodynamic and interpersonal therapies in geriatric depression are required. The current evidence is most clear for mild or moderate depression, but even for severe depression group therapy may play an important role, allied with pharmacotherapy, in the acute, maintenance, and continuation phases of treatment. Combined pharmacotherapy and psychotherapy confer the best protection against depression and relapse and improve social adjustment in the longer term while improving medication compliance in the near term as well. Comparative trials of maintenance-phase group with individual therapy or pharmacotherapy or guided self-help groups are required.

A review of relevant treatment studies for depression in long-term care suggest that both group and individual psychotherapies hold promise in being efficacious with various kinds of residents, from those closer to a full mental capacity and relatively robust physical health, to residents with significant cognitive impairment or physical frailty. The evidence suggests that behavioral approaches that decrease pleasant events and cognitive approaches that challenge distorted cognitions both through increased self-esteem and self-mastery are effective, as are interpersonal therapies that address relationship issues or reminiscence or life-review approaches that seek to re-establish meaning in life.

Meta-analysis of psychosocial interventions in geriatric depression note that psychosocial interventions, where group psychotherapy is particularly prominent, demonstrate a significant effect size relative to placebo or no treatment comparisons. Positive outcome correlates with the degree of interpersonal engagement in the sense of interpersonal competence and effectiveness experienced by members of the group.

A meta-analysis of group cognitive-behavioral psychotherapy for subclinical depression in the elderly demonstrates statistically significant but modest reductions in depressive symptoms posttreatment compared with waiting-list controls. However this is not maintained at follow-up. Therefore, there is a need for more research to investigate the different outcome measures on the effect sizes, as the baseline scores in this population are relatively small, and the expected level of change for any intervention is at best modest.

Group interventions for individuals with anxiety disorders are effective, as significant improvements with worry, anxiety, and quality of life emerge posttreatment and endure 1-year follow-up. Mindfulness-based cognitive therapy groups show significant improvements in reported anxiety, ruminative thoughts, sleep problems, and decreased depressive symptoms. The use of dialectical behavior therapy as an augmentation strategy of

antidepressant medication is successfully used to treat chronic depression and personality disorders. Adapted for older adults, the approach focuses on teaching skills to enhance openness to new experience and in creating meaning over the course of life. Chronicity of symptoms may reduce treatment benefit and demand a longer treatment. Mild cognitive impairment may warrant modification of therapy technique, but does not preclude a positive response.

Group cognitive-behavioral therapy alone is efficacious in reducing comorbid anxiety and depression in the elderly and gains are maintained for at least 3 months. An integrative group therapy model combining a more structured cognitive-behavioral therapy with more process-oriented interpersonal therapy for depression and anxiety in later-life shows statistically significant changes in pre- and postgroup scores on several outcome measures for anxiety and depression and quality of life.

A review of two randomized clinical trials using Standard Dialectical Behavior Therapy (DBT) skills training groups as an augmentation strategy of antidepressant medication to treat chronic depression and personality disorders in the elderly demonstrates significant advantages for decreasing remission rates for medication and DBT compared to medication alone in the treatment of chronic depression. As well, DBT plus medication demonstrates superiority compared to medication alone in decreasing interpersonal sensitivity and interpersonal aggression at posttreatment and 6-month follow-up in a sample of elderly adults with comorbid depression and personality disorder. Research is underway to explore the effectiveness of the DBT model that has been modified to better meet the needs of the elderly.

A systematic review of the literature of group and individual cognitive interventions programs for individuals with mild cognitive impairment of the amnestic type demonstrate equal efficacy of both training formats. Statistically significant improvements after either treatment are obtained on objective memory and on subjective measures of memory, quality of life, or mood. It is suggested for further research to combine group and individual approaches as both approaches have unique benefits.

A group program for patients with mild cognitive impairment and their significant others based on cognitive-behavior principles combined with psychoeducational and cognitive rehabilitation elements incorporates slight adjustments in the CBT method because of cognitive impairments of patients. Pre- and posttreatment scales demonstrate that compared to a waiting-list control group, the group treatment helps patients to be better able to accept their illness, with the female patients especially showing a decrease in helplessness cognitions. No changes on subjective measures of general well-being or distress were experienced. It is suggested that efficacy of this developing group intervention may be enhanced by tailoring the content to patients sharing particular pertinent characteristics and by

incorporating more sex-specific themes and training.

Groups for burdened caregivers generally demonstrate that participants are very satisfied with the group experience. Complexities in the measurement of subjective and objective burden, coupled with the likely progressive deterioration of the care recipient may confound other outcome measures. The acquisition of knowledge is easy to measure and demonstrate successfully. Reductions in burden are harder to demonstrate. Both professional- and peer-led groups show significant effects with the former tending to emphasize the provision of information and problem solving and the latter emphasizing peer support and networking. The best results emerge from integrative interventions that employ a broad focus, recognizing that there are multiple domains of concern for caregivers. This is consistent with a summary of the reviews of the caregiver intervention literature that demonstrates that more recent intervention studies are more effective when they employ combined interventions that target both the caregiver and patient.

A pilot study of evidence-based interventions for family caregivers of individuals with behavioral and psychological symptoms of dementia demonstrates improvements in carers' self-perception of competence, significant reductions in emotion-focused coping, enhanced mastery and reduced burden. Carers with more compromised baselines benefited most from the intervention comprised of three integrated components: group psychotherapy, problem-solving techniques, and skill acquisition for specific current challenging interactions in caregiving. Systematic use of standardized patients to role play the spouse or parent with dementia is employed. Limitations of the study include lack of a control group of carers and no outcome measures of care recipients.

FUTURE DIRECTIONS

An ever-increasing need for effective and meaningful group therapy interventions for the elderly and their families can be anticipated. Challenges and opportunities that lie ahead include creating models of intervention that are culturally accessible to a heterogeneous population of seniors. The field will also need to develop and test interventions for mood disorders that address common comorbid conditions including anxiety, substance abuse, personality disorders, and, of course, cognitive impairment. In allied fashion, integrative group interventions for the treatment and management of patients with dementia and their families, both together and separately, will need to be developed. Groups for caregivers, both family and professional, of older adults with late-life psychiatric and medical illness and behavioral and psychological symptoms of dementia also need to be developed. In all domains, greater efforts will need to be made in the training of group therapists as theory is linked to practice to empirical evaluation of the therapy.

57.4l Counseling and Support Needs of Dementia Caregivers

LIAT AYALON, PH.D., AND PATRICIA A. AREáN, PH.D.

INTRODUCTION AND DEFINITION OF CAREGIVING

What does caregiving mean? According to Webster's online addition, a *caregiver* is someone, either family member or provider, who has responsibility for meeting the physical and psychological needs of an infant, child, or dependent adult. While anyone may assume the function of

caregiver, primary caregivers are individuals who help the patient with at least one instrumental activity of daily living, such as bathing, eating, dressing, or getting to appointments, or a person who supervises a disabled patient. Two types of primary caregivers exist: *Formal caregivers,* individuals who are paid to meet the physical and psychological needs of patients, and *informal caregivers,* individuals who provide those needs voluntarily. This usually involves family members and friends. Although the reasons for assuming these responsibilities vary between the two types of caregivers, the burden of caring for a demented person is still high for both types of caregivers. Currently, informal caregivers are the majority of the caregiving population. Less than 10 percent of all older adults received their care solely from paid carers. In 2012, more than 15 million informal caregivers provided care to individuals with AD and other dementias. This care has a tremendous economic value mounting to $216 billion and 17.5 billion hours of care. Given the increase in life span, the decrease in childbirth, the entrance of women into the workforce, the high divorce rate, and the popularity of the nuclear family system, it is expected that formal long-term care alternatives will become more popular in future years.

Who is most likely to be a caregiver? According to the Behavioral Risk Factor Surveillance Survey, 62 percent of all informal caregivers are women. According to Kaycee M. Sink and colleagues, caregivers are on average 64 years old and largely female (72 percent) and nearly half of caregivers are spouses. About two-thirds of caregivers also work outside the home in addition to their caregiving duties. According to the National Alliance for Caregiving (NAC/AARP), 30 percent of all caregivers also cared for children younger than 18 and thus, are torn between caring for an older relative and younger children.

Researchers found no demographic differences between caregivers of individuals with dementia and those with milder cognitive impairments. Most caregivers of dementia patients care for people with Alzheimer disease, although a fair number also care for people with Lewy body disease, frontotemporal dementia, and vascular dementia. Each of these illnesses poses a unique set of problems for caregivers. Alzheimer disease is typically characterized initially by memory impairments, but as the illness progresses, can result in personality and behavioral changes that may be upsetting to caregivers. Lewy body disease shares this same course but is coupled with physical disability related to tremors and unusual hallucinations that many caregivers find hard to understand and manage. Frontotemporal dementia is particularly vexing, as patients who develop this illness tend to be younger and physically healthy (men in their 50s), and while their memory remains intact for a long time in the course of the illness, behaviorally these patients become impulsive, inappropriate, and highly agitated. These disorders are not mutually exclusive. A person with Alzheimer disease may also have vascular disease; a person with Lewy body

disease may also develop frontotemporal dementia. The more complicated the dementing illness in the patient, the more caregivers have to contend with. Because Alzheimer disease is the most common dementia afflicting older people, caregivers of Alzheimer disease have received the most attention, with the majority of research focused on informal caregiving.

The Mental Health Consequences of Caregiving

Caregivers are generally at greater risk for mental health and health problems than noncaregivers. Those caring for older adults with dementia tend to present with more negative emotional consequences compared with those who care for older adults who do not suffer from dementia. The most common mental health consequences of caring for a dementia patient are depression, anxiety, and a condition called *burnout*. These three conditions are often lumped together under the term *caregiver distress*. Studies find mixed results as to which condition is most common. It is largely believed that depression is the most common mental health consequence of caregiving. The Aging, Demographics and Memory Study (ADAMS) found that as many as 44 percent of the caregivers of people with dementia were depressed, but only 27 percent of the caregivers of older adults with cognitive impairment but no dementia indicated depressive symptoms. Others have shown that as many as 40 percent of caregivers of older adults with Alzheimer disease are depressed, but only 5 percent of noncaregivers report depressive symptoms and meet the clinically significant cutoff of depression.

It is important to note that burnout is not necessarily the same condition as depression or anxiety, but these conditions do co-occur. According to Schulz, caregivers of dementia patients are particularly vulnerable to burnout, a psychological and physical state of exhaustion resulting from excessive and prolonged stress. Caregivers who are family members are particularly vulnerable to burnout, and many speculate that this emotional consequence to caregiving explains why 90 percent of elder abuse is committed by family members. Stress and burnout are not one and the same. People under stress can generally feel hopeful about the future, and when no longer in the stressful situation they begin to feel like their normal selves. Burnout is far more severe and is characterized by frustration; feeling powerless and hopeless; feeling drained of emotional energy; becoming detached from others, which results in withdrawal and isolation; and feeling trapped, irritable, and sad.

Caregiver distress, be it depression, anxiety, or burnout, does not necessarily remit after caregiving responsibilities end. According to Carol S. Aneshensel and colleagues, caregivers who are less distressed before the death of the care recipient tend to have better mental health outcomes, whereas caregivers with significant emotional distress while caregiving tend to become even more depressed after the loss of the care recipient.

Caregiver burden before death tends to increase the odds of becoming depressed; self-esteem and emotional support tend to have protective roles.

The Effects of Caregiving on Physical Health

In addition to mental health consequences, there is a notable increase for poor health outcomes in caregivers. Compared with caregivers to older adults without dementia, caregivers to older adults with dementia are more likely to say that caregiving worsens their health. Some researchers speculate that poor health outcomes are the result of poor health care behaviors; caregivers generally do not have sufficient time to attend to their own medical appointments, and therefore potentially preventable health problems arise, such as hypertension and heart disease. Recent research also suggests that the stress related to caregiving may also influence health outcomes. Brent T. Mausbach and colleagues found that an exaggerated plasma norepinephrine response in caregivers is linked to an increased allostatic load related to cardiovascular disease. These researchers have also associated caregiver stress to reduced immune cell ss2-receptor sensitivity and increased D-dimer marker of hypercoagulability. Roland von Känel and colleagues have also found that caregiver distress is associated with increased frailty, affecting interleukin-6, C-reactive protein, and D-dimer. Janice Kiecolt-Glaser and colleagues found that caregiver distress has a direct effect on immune function through increases in the pro-inflammatory cytokine interleukin-6. Taken together, these studies suggest that morbidity and mortality related to caregiving have a physical basis, and that beyond mental health consequences, caregiving distress has significant and direct impacts on health.

HISTORY AND THEORETICAL ISSUES

Attention to the needs of informal caregivers has been increasing over the past three decades. This is primarily due to the changing demographics and the realization that caregiving to older adults with dementia carries substantial economic, emotional, physical, and relational tolls. Several theoretical models have been offered to account for the negative effects associated with caregiving. Most theoretical models explain caregivers' burden, depression, and ill health by proposing a relationship between primary stressors such as the older adult's functional or cognitive impairment and the caregiver's outcomes. This relationship is thought to be mediated through the amount of informal support provided by the caregiver and the use of formal support.

TECHNIQUES FOR PREVENTING AND MANAGING CAREGIVER DISTRESS

Intervention models are often based on the above-detailed conceptualization of caregiver distress, and many are multicomponent

models that address several risk factors, including education about the dementing illness, emotional support, information about resources, and counseling in the form of skills training, anger management, and mood management. The most widely studied interventions are skills-training classes, educational interventions, and support groups. Interventions that are administered over a long period of time and target the entire family are considered particularly effective.

Skills-Training Classes

There is considerable evidence in support of the efficacy of structured classes aimed at educating caregivers in stress management, anger management, and self-care. These interventions typically are multicomponent, in that they teach caregivers about the causes of dementia, explain the reasons for behaviors they will see in the care recipient, and provide them with strategies for managing their anger, mood, and burden. Most of these interventions are behaviorally focused; they teach caregivers how to refocus their understanding of the care recipient's behavior, make use of stress-reduction strategies like meditation and relaxation training, increase pleasant activities, and find opportunities to take a break from their caregiving responsibilities. The success of these interventions is very well documented. According to Mary Mittelman and colleagues, interventions aimed at mediating the factors related to caregiver distress (coping, appraisals, support) have significant effects on distress even 4 years after treatment. Interventions aimed at anger management and burnout are also effective. According to David Coon and colleagues, anger management and skills-building interventions have positive impacts on caregiver appraisal and self-efficacy.

Skills-training classes appear to be effective across ethnic groups. According to one study, a multicomponent intervention that targets stress management and self-care strategies was better than education and support alone in Caucasian, Hispanic, and African-American caregivers. Caregivers with low-pretreatment self-efficacy seemed to respond better to these interventions than those with high self-efficacy, although across groups, everyone experienced benefit from these skills-building groups. One of the largest studies of caregiver treatment is the REACH trial, a study of 167 caregiver–recipient dyads, which found that coping and stress management classes were far more effective in managing caregiver depression and burden, than interventions focused solely on how to manage behavior related to dementia. These findings were robust for 2 years after caregivers participated in the coping skills interventions. The REACH trial has also shown to improve self-reported health status.

Education and Support Groups

Research shows that even minimal education classes that focus on caregiver-coping strategies and information about dementia have benefit for caregivers in mitigating distress. In one study, a minimal information control condition was compared to a skills-building program for African-American and Caucasian caregivers. The Caucasian caregivers benefited from the information control condition better than the skills-building condition, indicating that even the provision of information about dementia and caregiving can have substantial benefit to caregivers. Robert Woods and colleagues compared a mental health nursing program to support caregivers to community educational programs and found that community educational programs were as effective in reducing caregiver distress as the more intensive nursing program.

CLINICAL ISSUES

Indications

Not everyone who cares for a demented person feels the experience is a negative one. Some people, while experiencing some stress, are able to cope well with the role of caregiver. Spouse caregivers are more likely to report depressive symptoms, greater financial and physical burden, and lower psychological well-being. This is only partially accounted for by the fact that spouse caregivers also provide more hours of care. Compared with men, women caregivers are more likely to report depressive symptoms. Those caring for older adults with frontotemporal dementia are more likely to report distress and strain compared with caregivers of older adults with Alzheimer disease. Other studies have shown that certain ethnic groups cope better with caregiving than others; for instance, Hispanic and Black caregivers are more likely to report high levels of burden compared with White and Asian caregivers. A number of caregiver characteristics seems to be related to whether or not the caregiver will be distressed by his or her responsibilities. The most notable and well-studied characteristics related to the development or prevention of caregiver distress are the caregiver's culture, coping style, social support, and formal support; relationship between the caregiver and care recipient; and, finally, characteristics of the care recipient. While each of these factors contributes to distress, most researchers agree that these factors interact with one another, and no one factor alone contributes to caregiver distress.

Limitations

One of the most complicated aspects of treatment for distress is access to these effective interventions. Several studies show that caregivers rarely feel they have time to devote to their own well-being. A number of studies have been done to see if telemedicine-type of support could benefit caregivers. The studies have largely been mixed, indicating that simple

telephonic support does not result in as good outcomes as in-person group support. However, a study of 299 caregivers receiving a multimedia caregiver intervention over the Internet found that Internet interventions of this nature provided a low-cost, convenient, and effective means of overcoming caregiver distress, as well as being flexible enough to tailor the intervention to the needs of the caregivers. Further, web-based support combined with in-person caregiving groups appeared to have a substantial impact on depression in 225 caregivers. Finally, Sara Anne Smith and Paul Bell studied a CD-ROM plus printed material intervention for rural caregivers, and found this intervention to result in greater use of available support services, use of behavioral interventions to manage care-recipient aberrant behavior, and reductions in distress. Research of this nature is beginning to show that access to effective psychosocial interventions is possible for caregivers. However, a recent systematic review found only low levels of support for the efficacy of Internet-based supportive interventions.

Mrs. Y was a 56-year-old Caucasian woman whose husband of 30 years was diagnosed with Alzheimer disease 3 years ago. Over the years, Mr. Y had become increasingly forgetful and impulsive, often leaving food on the stove to burn, walking to the corner store and becoming lost, and buying expensive items that the family did not need. In the last year, Mr. Y bought two new cars and three high-definition televisions, despite the fact that he already owned a 2-year-old car in good condition and the Y did not watch television. Since Mr. Y's dementia became more apparent, he had to stop working, and Mrs. Y, as a consequence, also had to cut back on her working hours to accommodate Mr. Y's needs. In addition to Mr. Y's forgetfulness and impulsivity, his sleep patterns also became disturbed, and he often woke at night and wandered around the house, which disturbed Mrs. Y's sleep.

Mr. and Mrs. Y had two children, both of whom lived in different states; thus, Mrs. Y had to cope with caregiving demands on her own. As a result of a part-time job and an increasing worry that leaving Mr. Y at home alone would result in either a fire in the home or more unnecessary excursions to car dealers and electronics stores, Mrs. Y became quite distressed and experienced several colds and flus that she was not able to care for. One such illness resulted in a case of pneumonia, and it was at this point in time that Mrs. Y came to the attention of the clinical team.

Although Mr. Y had ongoing neurology appointments in a prestigious university hospital, it was clear that Mrs. Y had not made use of the resources available to her through this service. Her reason for not attending the support groups, working with the social worker to link her to respite care, and making use of community resources was her lack of time between taking care of Mr. Y and her work to help support them financially. While in the hospital, the team social worker visited Mrs. Y to talk to her about the importance of making use of available services and the need to care for herself first, so that she could then better care for Mr. Y. From this discussion, it was clear that Mrs. Y had become depressed and burnt out. Not only was she suffering physically from her caregiving responsibilities, but she was also feeling less interested in usual activities, had lost her appetite, had begun feeling hopeless and helpless, had trouble concentrating at work, and wished she or her husband would die. This last symptom left her feeling incredibly guilty; she loved her husband, and although forgetful and impulsive, he remained a loving companion to her. She was also clearly resentful toward her children; when she entered the hospital, her daughter had reluctantly flown in from her home to care for Mr. Y, and had made it clear she would only stay until Mrs. Y returned from the hospital.

A clinical team began to work on reducing Mrs. Y's caregiver distress in the following way. First, the social worker began to make arrangements for Mr. Y to attend a day treatment program that would provide services within the Y's financial means. Mr. Y's schedule would be mapped to Mrs. Y's work schedule, so that she would not have to worry about Mr. Y being

home alone. Temporary evening respite care was also arranged while Mrs. Y recovered from her pneumonia. This respite care eventually was reduced to 1 day a week so that Mrs. Y could have time for herself and attend a skills-building class for dementia caregivers. Mrs. Y was reluctant to join the class—in fact, she only attended intermittently; however, she did make use of the neurology department's online caregiver support program, in conjunction with the occasional classes, and reported that she found the website helpful.

Six months after her hospitalization for pneumonia, Mrs. Y was feeling both physically and emotionally better. She still struggled with her husband's increasing dementia, but had become more active, reengaged with friends, and was more productive at work. One year after her hospitalization, Mr. Y was moved to an assisted-living facility because of his rapidly deteriorating condition. Mrs. Y then joined a caregiver support group, as she missed her husband and was dealing with guilt related to assisted-living facility placement. This group was particularly useful to Mrs. Y in helping her see this placement as a necessary step in her and Mr. Y's health, gave her strategies for making her visits to Mr. Y pleasant, and reinforced her need to remain connected to her friends.

Goals of Interventions

Given the diverse nature of the various caregiving interventions, potential goals for treatment are also diverse. Goals may include increasing knowledge about dementia, improving the caregiver's coping skills with problem behaviors, reducing caregiver burden, depression or anxiety, increasing well-being, reducing the care recipient's problem behaviors or increasing social support. The exact intervention goals should determine the intervention offered.

ETHICAL ISSUES

Caregivers of older adults with dementia face multiple ethical challenges. As the disease progresses, dementia caregivers have to make decisions about various treatment options, end-of-life care, and participation in drug trials. Some of these issues are likely to surface, during treatment, as a source of great distress and agony to some dementia caregivers. A different ethical issue that should be addressed by researchers is the amount of burden put upon dementia caregivers, who often accompany their loved ones during drug trials and as a result become secondary participants in dementia research.

RESEARCH AND EVALUATION

Successful interventions exist, with the majority of caregiving interventions including both a supportive and an educational component. Longer interventions tend to be more effective than shorter ones. More attention should be placed on clinically significant interventions, rather than merely statistically significant ones. There is also increasing interest in establishing consensus on outcome measures for caregivers' interventions. In the past, access to interventions was complicated by the fact that caregivers, who rarely feel they have time to attend classes, were not likely to take the time to attend these sessions. Recent research suggests that interventions can be successfully delivered over the telephone and Internet. However, these

interventions may not meet the need for social support so often present among caregivers of older adults with dementia and their efficacy should be further examined.

▲ 57.5 Financial Issues in the Delivery of Geriatric Psychiatric Care

STEVE KOH, M.D., AND HELEN H. KYOMEN, M.D.

INTRODUCTION

Financing medical care in the United States is often complex and involves multiple factors. This is especially true for the aging population where complications for providing care are confounded by multiple economic concerns. Despite the passage and implementation of the Patient Protection and Affordable Care Act (PPACA) in 2010, universal health care is not yet a reality and health care cost continues to be a significant percentage of total personal and governmental expenditures. Mental health care continues to suffer from a complicated interplay between federal, state, county, and private payers and consumer demands. Even with the passage of the Mental Health Parity Act (MHPA) and subsequent Mental Health Parity and Addiction Equity Act (MHPAEA), mental health care is often carved out from general health care coverage and patients suffer from inadequate financial support. Older adults with fixed incomes are reliant

on social security and government health care coverage. Many individuals become care givers to loved ones with chronic illnesses, placing additional financial burden on the household. Economic factors such as payment mechanisms and funding sources are key determinants of access to geriatric psychiatric care and health care delivery services, and the actions of providers.

Since the 1990s, both the government and industry have sharpened their focus on health care expenditures and it has become more and more clear that cost effective health care cannot ignore comorbid mental illness. Now widely recognized as a cost multiplier when present as a comorbid condition, the need for improved mental health treatment to achieve better outcomes have been reported by multiple sources. While not perfect, recent changes to the health care system and increased attention to cost savings, outcome measures and population-based medicine allows for innovative models of care. These developments highlight the relationship between patients, providers, and larger systems crucial in providing the best care for older adults.

This chapter will give a brief overview of current demographic trends, the historical background and updates on the Medicare and Medicaid system, out-of-pocket health care costs to older adults, and changes brought on by MHPAEA and PPACA. It will conclude with a discussion of potential future directions for the mental health care of older adults.

DEMOGRAPHIC TRENDS AND THE COST OF HEALTH CARE FOR OLDER ADULTS

Rational planning for mental health care services for the future requires an understanding of the magnitude and diversity of the projected growth patterns in the elderly population in the United States. Furthermore, the differences between sexes and ethnic groups are important to note as there continues to be significant financial resource differences between them. In the mid-1950s, only 1 of every 11 Americans was older than the age of 65. In each of the last several decades, the proportion of elderly has grown substantially. By 2000, there were more than 35 million people older than the age 65, constituting approximately 12 percent of the American population. Since then, the growth of the baby boomers has contributed to more than 76 million adults over the age of 55 in 2010. By 2030, this number will increase to 112 million, accounting for about 30 percent of the total population. By 2050, it is projected that there will be 88.5 million individuals over the age of 65. This is not unique to the United States. The United Nations estimates that by 2050, 21 percent of the total global population will be above the age of 60. Additionally, the number of oldest-old adults (85 years of age and above) continues to increase. It is expected that by 2040, 14.6 million Americans will be among the oldest-old.

The differences in the number of older men versus women will have important economic consequences. The economic effects of lower

educational levels, traditional work roles, and income discrimination experienced by women in young and middle age will be exaggerated as retired women depend on pensions and social security derived from preretirement income. Currently, older women outnumber men by 25.1 million to 19.6 million. While in 2013, the ratio of older males to females was 76:100, by 2050, it is projected to increase to 87:100. This is due to continued increases in life expectancy for both sexes and improved health care. In 2013, the median income of older men was larger compared to women by $29,327 to $16,301. Older men are more likely to be married than women (72 to 46 percent) and 35 percent of women were widows. While 28 percent (12.5 million) of older adults live alone, 8.8 million are women and almost half of older women above the age of 75 live alone. Notably, many older adults continue to be the primary financial support for their household and often are responsible for the care of grandchildren who live with them.

Similarly, ethnic minorities make up a growing proportion of the older-than-65 population. In 1990, approximately 11 percent of people older than 65 in the United States were of nonwhite ethnicity (non-European descent). In 2013, 21.2 percent of older Americans were members of racial or ethnic minority, which are approximately 9.5 million individuals. This is expected to increase to 21.1 million by 2030. Currently, older African Americans make up 8.6 percent of the population while Hispanics represent 7.5 percent. It is expected that older Hispanics will become the largest ethnic minority group by 2030. Life expectancy at birth for Caucasians exceeds that of African Americans, although this gap is decreasing. In 1993, there was a 7.1-year gap. Currently it is 5.4 years for males and 3.8 years for females. This change has been due to decreases in the rates of human immunodeficiency virus, heart disease (in women), homicide, and unintentional injuries. Still, many older African-American individuals have considerably higher rates of poverty, illness, and violent deaths than Caucasian individual in the same age group. The economic and social discrimination of the chronic underprivileged associated with American minority status is exaggerated by the socioeconomic consequences of older age. In this population, accrued social and financial resources are limited; access to preventive and acute health care is poor; and the likelihood of exposure to tobacco, alcohol, other toxins, and violence is higher. In addition, barriers to governmental services such as housing, transportation, meals, and income maintenance are more likely. All of this results in a cycle of medical, economic, and social poverty that materially affects the quality of life and has a substantial impact on the provision and financing of geriatric psychiatric care for elderly minorities. Further compounding this situation is the fact that there are significant state-to-state discrepancies in ethnic minority life expectancies.

Retirement from employment has important effects on economic status,

access to health care, and insurance. Retirement reduces personal income and increases reliance on government assistance and retirement plans. Reduction in income after retirement threatens stability of social class for older people and increases the likelihood that some people will experience economic poverty for the first time, during late life. These poverty prevalence rates are noticeably higher for women and minorities. In 2012, the major sources of income for older Americans were distributed between the following: social security (86 percent), income from assets (51 percent), private pension (27 percent), government employee pensions (14 percent) and earnings (28 percent). Social security constituted more than 90 percent of beneficiaries' income. In 2013, over 4.2 million older adults were below the poverty level based on income alone. If regional variants in cost of living, noncash benefits received, and nondiscretionary expenses are taken into account (the so-called Supplemental Poverty Measure), the poverty level of older persons reaches 14.6 percent. A major contributor to this increase is high medical out-of-pocket expenses. This cost is magnified in geriatric mental health care and in long-term care, where out-of-pocket copayments, deductibles, and direct purchase of services account for a substantial component of total costs.

As long-term financial stability is questioned, many individuals are electing to delay retirement or continue to work part-time. Since the Great Recession (spanning from 2007 to 2009), the average retirement age increased. Thirteen percent of Americans continue to work past 65 years of age and 8 percent continue to work part-time. Even though median income peaks between the ages of 45 and 54, between 2012 and 2013, those above age 65 saw percentile increases in their median income. This indicates that more Americans are working into their 60s. Yet, many indicate that there is added pressure to retire despite their worry about long-term security. The single most important factor for concern about retirement is health care cost. Retirement directly affects health insurance premiums, the availability of certain insurance plans, and access to some health care delivery systems.

Overall fiscal impact on health care by the older population is undeniable. While their earnings are decreasing, health care needs of the growing older population continue to rise. The cost of health care in the United States is far greater than other industrialized nations. In 2011, the United States' health care expenditure per capita of $8,508 was about $3,000 more than the next largest health care expenditure per capita country. Older adults make up significant portion of this high cost. Almost half of all health care spending is consumed by just 5 percent of the population, and these are focused in age groups below 5 and above 65. In fact, older adults account for more than 36 percent of total health care cost. Those between 65 and 70 years of age represent 29 percent, and those above the age of 80 account for 14 percent of the top 5 percent of spenders.

Among those with Medicare–Medicaid coverage, the elderly and disabled account for more than 70 percent of Medicaid spending despite representing just 25 percent of the Medicaid population. The top five most expensive health conditions to treat are heart disease, cancer, trauma, mental disorder, and pulmonary conditions. Twenty-five percent of the US population reportedly has one of the top five chronic conditions (mood disorder, diabetes, heart disease, asthma, and hypertension). The rising Medicare and Medicaid cost can partially be explained by the aging population and mental illness accounting for a significant portion of the cost. All of this has led to attempts to restructure Medicare and social security and to even raise the retirement age in the United States.

HISTORICAL BACKGROUND

Historically, government policy has been important in shaping the status of psychiatric care for older people. During the 19th century, financial responsibility for the care of the chronically mentally ill and people with major neurocognitive disorder was transferred from local to state authorities, resulting in the replacement of asylums and almshouses by the massive state hospital systems of the first part of the 20th century. Ultimately, deinstitutionalization in areas of limited community resources resulted in the transfer of a substantial number of older people with severe and persistent mental illnesses from state hospitals to community nursing homes with sparse psychiatric resources. Beginning in approximately 1965, reimbursement for nursing home care under Medicaid effectively shifted some of the financial responsibility for this population from states alone to the states and federal government.

The introduction of Medicare and Medicaid in the mid-1960s created a private market for older adult health care. Private practitioners and institutions were reimbursed fee-for-service at market prices by these insurance programs. Adequate financial returns for hospital-based services, reinforced by the growth of commercial indemnity insurance, drove the development of for-profit hospital care, particularly in freestanding psychiatry. Simultaneously, severe limitations in reimbursement for ambulatory psychiatric services under Medicare impeded the growth of private practice interest in geriatric psychiatric care while creating imbalanced incentives for the use of hospital resources. Federal-level sensitivity to these new expenditures and social concerns about inappropriate care led to the nursing home reform provisions of the latter part of the 1980s and to the formulation and implementation of a set of guidelines for the use of psychiatric interventions in that environment. The health care cost reform of the last generation has similarly reshaped geriatric psychiatric service delivery. In the recent past, Medicare was more attractive than some commercial payers to hospitals and individual providers. Nonpsychiatrist mental health specialists, newly eligible for

participation in Medicare and other payment programs, created the availability of a greater diversity of providers, with psychotherapeutic services much more broadly available to the elderly.

However, as the population ages and health care cost continues to rise, models to decrease expenditures, increase cost-sharing and improve access to care have dominated health care discussions. For geriatric mental health care, the focus has been on achieving mental health care parity, developing cost-effective, innovative programs, and providing access to care to growing population with limited providers. As will be noted later, inequality in mental health care coverage has made the treatment of mental illness in older adults difficult and the impact of MHPAEA can dramatically improve the care received by older adults. Furthermore, the impact of changes to Medicare and Medicaid by PPACA is still being examined and is likely to have a lasting effect on psychiatric care for older adults.

MEDICARE SYSTEM

The Medicare program was established in July of 1966 to provide medical care benefits for older people participating in the Social Security program. Since then, a number of modifications were made to the Medicare program, in both the Hospital Insurance program, Part A, and the Supplemental Medical Insurance program, Part B. The Medicare Prescription Drug, Improvement, and Modernization Act of 2003 provided the most extensive changes to Medicare since its initiation.

In 1972, Medicare was expanded to cover younger people with disabilities and older adults outside of social security who were willing to pay a premium. In 1973, the program was further expanded to provide medical coverage for people with end-stage renal disease. In 1997, the Balanced Budget Amendment of 1997 (BBA 1997) established Medicare Part C, or Medicare+Choice. Medicare Part C included Medicare managed care plans (such as HMOs, provider-sponsored organizations [PSOs], and preferred provider organizations [PPOs]); Medicare private, unrestricted fee-for-service plans; and medical savings accounts. In the 2003 revision, Medicare was extensively updated to include: (1) expansion and renaming of the Medicare+Choice program as Medicare Advantage; (2) prescription drug programs and benefits, including a new program called “Medicare Part D”; (3) medication therapy management programs for those with multiple chronic conditions, multiple prescriptions, and likely high drug expenses; (4) coverage of certain screening and disease management programs such as initial physical examinations and cardiovascular disease and diabetes screening; (5) changes in reimbursements to hospitals and physicians, including ongoing refinement of the prospective payment system for inpatient psychiatric care; (6) improved rural health care provisions; (7) a demonstration project for recovery audits to identify underpayments or overpayments and collect overpayments; and (8)

changes in the acquisition systems for durable medical equipment and other products to provide for a competitive bidding process. In 2013, Medicare covered more than 52 million people, or almost 17 percent of the American population. Over 83 percent of this Medicare-covered population in that year was 65 or older.

Growth in the older adult population, advances in medical technology, more extensive use of pharmaceutical treatments, and other increases in the cost of health care have contributed to the extraordinary growth in health care expenditures, both in the Medicare program and otherwise, that has occurred since the mid-1990s. Although health care costs have continued to grow in recent years, especially among the elderly, various efforts to contain Medicare costs have been successful in slowing health care inflation rates. Each of these changes has profoundly affected access to appropriate psychiatric care for older people, and each has impacted the scope and configuration of geriatric mental health specialty care. Aggregate Medicare cost reductions have resulted from decreases in reimbursement levels of hospital and physician providers, increased requirements for out-of-pocket payments by Medicare beneficiaries, and substantial shifts from indemnity insurance to managed care. In addition, as part of the Deficit Reduction Act of 2005, the Centers for Medicare and Medicaid Services (CMS) (replacement agency for the Health Care Finance Administration) has been allowed, starting in 2008, to begin adjusting payments for "never events." "Never events" are "serious and costly errors in the provision of health care services that should never happen" and include hospital-acquired infections, death or serious disability related to a medication error, and death associated with falling while being cared for in a health care facility. "Never events" lead to increased health care costs due to the need to treat the consequences of the error. Additional Medicare cost reduction has been attributed to the Affordable Care Act (ACA) of 2010 and sequestration, which started in 2013. Still, Medicare spending represented 20 percent of national health spending in 2013 and grew 3.4 percent to about $586 billion, but was a slowdown from a growth of 4.0 percent in 2012. This slowdown was thought to be due largely to slower enrollment growth and impacts of the ACA and sequestration.

Medicare was designed to provide coverage for the treatment of acute conditions, and this has been the primary orientation of the program over the years. Medicare had not covered most preventive and pharmaceutical services since the program's inception. The 2003 law provided for some change in this focus with coverage of some preventive services and the addition of pharmaceutical benefits. Long-term care and dental services continue to be excluded from traditional indemnity Medicare. Other services, including mental health care, had been subject to limitations in payment and substantial copayments. However, the Wellstone-Domenici Mental Health Parity and Addiction Equity Act of 2008, enacted into law

on October 3, 2008 and effective for most health insurance plans on January 1, 2010, was designed to change this. This law required that group health plans (with over 50 employees that offer both medical/surgical and mental health/substance-use benefits) provide coverage for treatments of mental health/substance-use disorders that is no more restrictive than the coverage for treatments of medical/surgical conditions. Equity coverage is applied to financial requirements as well as treatment limitations. Format guidance and rule-making as to how this law is implemented continues to evolve.

The Medicare program, in summary, has several components: Hospital Insurance, or Part A, covers inpatient care, limited home care, skilled nursing facility care, and hospice services. Part B, the Supplemental Medical Insurance program, covers services provided by physicians and other professional providers, durable medical equipment, ambulatory medical laboratory tests, some outpatient hospital care, and group therapy services of psychiatric hospitals and comprehensive outpatient rehabilitation facilities. Part C includes Medicare-managed care plans (such as HMOs, patient safety organizations [PSOs], and PPOs); Medicare private, unrestricted fee-for-service plans; and medical savings accounts. Under Medicare Part D, effective starting January 1, 2006, Medicare beneficiaries have been eligible to obtain prescription drug coverage by enrolling in a private prescription drug plan or in an HMO or other plan that accepts Medicare capitation payment and offers a drug benefit.

Hospital Insurance (Part A)

Americans older than age 65 who participate in the Social Security program are entitled to Part A Medicare coverage. The Part A Hospital Insurance Trust Fund is supported by social security payroll taxes paid by employers, employees, and the self-employed. In 2013, 52.3 million people had Medicare coverage, and the Hospital Insurance Trust Fund had assets of $280.5 billion.

Medicare coverage for inpatient care is limited to relatively brief inpatient stays, presumably for the stabilization of acute symptoms. Part A provides coverage for episodes, which are time-limited “spells” of illness. A spell is an episode of inpatient care that starts with hospital admission and ends after the first period of 60 consecutive days outside the hospital after hospital discharge. If a person is discharged and readmitted numerous times during a given episode of illness and has not been out of hospital for 60 or more consecutive days, he or she is considered to have remained within the same “spell.” For treatment of any condition in a general hospital, there is no limit on the number of spells or days covered within an individual’s lifetime. However, no more than 150 inpatient days are covered during each episode.

The first 60 days of each spell are fully paid after a deductible equal to

the average cost of 1 day of hospitalization has been met. The next 30 inpatient days are paid at the same rate less a 25 percent copayment. The last 60 days of covered hospitalization requires a 50 percent copayment. Days 91 to 150 are identified as "lifetime reserve days." Medicare pays for those days during any single spell of illness but only once in a beneficiary's lifetime. For example, if a patient requires five hospitalizations totaling 110 days without a period of discharge of at least 60 days, he or she would have 40 days of remaining coverage in his or her lifetime for future episodes that lasted more than 90 days. Individuals may save these days for future hospitalizations and use other resources to pay for any part of the costs of days 91 to 150.

At the time that Medicare was first signed into law, there were large populations of older adult patients in state psychiatric hospitals. Federal legislators feared at that time that the enactment of Medicare would shift the burden of care for that population from state-supported resources to acute care facilities reimbursed with federal monies. As a consequence, Medicare coverage for inpatient treatment in freestanding psychiatric hospitals was limited to a total of 190 days over the course of a person's lifetime. The law provides that if an individual becomes eligible for Medicare during the course of a psychiatric hospitalization, the Medicare intermediary may deem that less than the full 150 days allocated for that spell of illness will be covered. Given improvements in treatment and increased life expectancy, this limitation can easily create undue hardship and compromised continuity of care. For example, a person with a recurrent major affective disorder who experiences several depressive episodes requiring inpatient care after age 65 could easily exhaust the lifetime freestanding psychiatric hospital benefit.

Part A provides coverage for nonacute services, including skilled nursing facility care if these services are used briefly and for "remediable" conditions. For a beneficiary to obtain benefits for skilled nursing facility care, he or she must have been hospitalized for at least 3 consecutive days for an acute condition, and skilled nursing facility admission must follow within 30 days of hospital discharge. Medicare may fully cover up to 20 days and partially cover days 21 to 100 of skilled nursing facility care for each episode of illness. Similarly, coverage for home health services is limited to care for acute and remediable conditions.

From 1966 until 1983, Medicare Part A paid for hospital care using a retrospective cost-based reimbursement system. This system compensated providers on a fee-for-service basis for all of those costs deemed allowable under Medicare without an incentive for utilization management. In 1982, after years of rapid and sustained growth in Medicare expenditures for inpatient care, the Reagan administration signed into law the Tax Equity and Fiscal Responsibility Act (TEFRA). TEFRA created incentives to reduce hospital payments by setting targets for operating costs, and it provided

supplemental payments for compliance with specified objectives. Reimbursement was transitioned from a retrospective cost-based approach to a payment system designed to reflect patient mix, geographic location, and training costs. This TEFRA mandated system is known as the prospective payment system.

The prospective payment system established by TEFRA uses diagnosis-related groups to classify patients who require similar care into 23 major diagnostic categories and assigns each Medicare patient discharge to one of 468 diagnostic groups. These groups are derived from principal and secondary diagnoses; procedures rendered; and, to a lesser degree, age, sex, complications, and discharge status. The diagnosis-related group system was revolutionary in creating a "case-based" approach to reimbursement. Under the prospective payment system, hospitals are paid a fixed amount for each case according to the corresponding diagnosis-related group regardless of the resources that are consumed during the hospitalization. If patients require extraordinary resources or extremely prolonged hospital stays, Medicare classifies the patient as an "outlier" and provides additional payment to the hospital, although at a per diem rate considerably below actual costs. This set of conditions creates an incentive for hospitals to provide efficient care and create an infrastructure of ambulatory services that can shorten or substitute for hospitalization.

Fourteen of the original diagnosis-related groups applied to the treatment of psychiatric disorders. Several studies had indicated that, although diagnosis-related groups are modestly effective in predicting use for medical and surgical diagnoses, their ability to predict use for psychiatric diagnoses is poor. Accordingly, the Health Care Finance Administration, the federal agency responsible at that time for Medicare/Medicaid fiscal management, exempted freestanding psychiatric hospitals and distinct psychiatric units in general hospitals from the diagnosis-related group system until a fairer system could be ascertained. On November 15, 2004, a newly designed Medicare prospective payment system for inpatient psychiatric services with updated psychiatric diagnosis-related groups was established by the CMS. Under this new system, a federal per diem rate was established, providing for adjustments for changes in the hospital market basket index, age, comorbidities, and psychiatric diagnosis. In this system, 15 psychiatry-related diagnosis-related groups were established, with weights ranging from 22 percent above average for diagnosis-related group 424 ("Operating Room Procedure with Principal Diagnosis of Mental Illness") to 12 percent below average for diagnosis-related group 523 ("Alcohol/Drug Abuse or Dependence without Rehabilitation Therapy and without Complications and Comorbidities").

Until the new prospective payment system for inpatient psychiatric services was initiated, freestanding psychiatric hospitals and psychiatric

units in general hospitals were reimbursed retrospectively by Medicare. Ever since TEFRA was implemented in 1983, payment for treatment in psychiatric units had been capped at a rate established for each facility based on use during its first fiscal year of operation after October 1, 1983. Until 1998, if the actual cost of care per case was greater than the capped rate, the hospital absorbed the loss. However, if the cost was less than the capped rate, a small incentive payment was retained by the hospital. The Balanced Budget Act (BBA) 1997 modified and limited these reimbursements by establishing differential caps, with or without wage adjustment, and also provided less generous bonus and relief payments for prospective payment system–exempt facilities. The Balanced Budget Refinement Act of 1999 (BBRA 1999) addressed some of the flawed policy and excessive payment reductions resulting from BBA 1997. The BBRA 1999 allowed for wage adjustments at the 75th percentile limit established by the BBA 1997 for prospective payment system–exempt facilities that received their first Medicare payment before October 1, 1997, and also increased bonus payments for psychiatric hospitals. The BBRA 1999 also stipulated that a new Medicare prospective payment system for inpatient psychiatric services was to be initiated by April 1, 2004. The final rule establishing the prospective payment system for inpatient psychiatric facilities was published on November 15, 2004, in the Federal Register. The main features are the following:

1. A base per diem prospective payment system rate of $575.95 was determined in 2004, effective for the first payment period from April 2004 through June 2005. Subsequent payment periods, starting on July 1 of each year, had adjustments to the base rate determined by estimated changes in the hospital market basket index. In addition, the base rate was further adjusted at the patient level for age, comorbidities, and psychiatric diagnoses. For patients 65 years of age and older, payments increased by 10 to 17 percent. In 2015, the base per diem rate was $728.31.
2. There were adjustments to increase payments for services provided to patients with one or more of 17 designated comorbid conditions, as well as adjustments for psychiatric diagnoses (one of 15 psychiatry-related diagnosis-related groups mentioned previously). Rates were also adjusted to reflect area wage differences, rural location, and the presence of teaching programs.
3. Rates were 19 to 31 percent higher for the initial day of admission, depending on whether the inpatient facility had or was a psychiatric unit in an acute care hospital with a qualifying emergency department. There were smaller adjustments for subsequent days until the 10th day, when these auxiliary payments ended and adjustments to decrease payment below the base per diem rate from 1 to 5 percent would occur through the

21st day. After the 21st day, the rate would be 8 percent less than the base per diem rate. The payment system also included "outlier payments" for hospitalizations resulting in significantly higher costs.

4. Once the cost of an admission exceeded a designated threshold (initially $4,200) above the diagnosis-related group payment, Medicare paid part of the additional costs from an outlier pool of funds equal to 2 percent of the estimated total payments for inpatient psychiatric care. Of note, the payment system did not offer adjustments for disproportionate share status, patient gender, and distinct units, although these elements were all considered by CMS.

Supplemental Medical Insurance (Part B)

Medicare Part B is a medical insurance program that is voluntary and requires a monthly premium payment ($104.90 in 2015) for participation. Approximately 97 percent of Medicare Part A beneficiaries also participate in the Part B program. Part B is supported by the Supplementary Medical Insurance Trust Fund, which includes general revenues from the Treasury, as well as premiums. Premiums cover approximately 25 percent of the total cost of the program. Part B benefits are subjected to an annual deductible ($147 in 2015) as well as a 20 percent copayment. Since enactment of the MHPAEA, group health plans and health insurance issuers are required to ensure that financial requirements (such as copays, deductibles) and treatment limitations (such as visit limits) applicable to mental health or substance use disorder benefits are no more restrictive than the predominant requirements or limitations applied to substantially all medical/surgical benefits. MHPAEA supplements prior provisions under the MHPA, which required parity with respect to aggregate lifetime and annual dollar limits for mental health benefits.

From 1984, when TEFRA and prospective payment were initiated, until 1992, the rate of growth of Medicare physician costs was more than double the rate of growth for inpatient hospital costs. Policy analysts attributed this growth to uncontrolled price escalation and substantial increases in the number and intensity of services consumed. In 1989, inflation in physician-related costs and mounting evidence that physicians' behaviors in treating complex medical illnesses were influenced by the high prices of the procedures they performed led to a sweeping reform of Medicare Part B through the Omnibus Budget Reconciliation Act of 1989 (OBRA-89).

OBRA-89 created standards for expenditures and procedure volumes in an attempt to bring the total cost of physicians' services under control. The law required the secretary of the U.S. Department of Health and Human Services (HHS) to identify specific volume performance standard growth rates for surgical, primary care, and nonsurgical nonprimary care services at the beginning of each fiscal year. These standards must be related to medical inflation and changes in the size of the Medicare population as well

as to changes in service volume and intensity. At the end of each year, the secretary must compare actual growth and expenditures with this volume performance standard and determine any changes in fee schedules for the following year.

OBRA-89 also created a national uniform Medicare fee schedule to replace local methods that were traditionally used by intermediaries to set fees for each procedure and for each provider. In 1992, a Resource Based Relative Value Scale (RBRVS) was developed to determine relative values of approximately 7,000 physician procedures and services. In this scale, the relative value of each of these services is derived from three components: Work, practice, and malpractice expenses, and the opportunity costs of postgraduate specialty training required. The proportion of each component in determining the relative value is based on a weighted average of specialty-specific practice expense and malpractice data. In an effort to change provider behavior and reduce incentives to perform highly reimbursed technical procedures, the work component is derived from estimates of the time intensity and stress associated with delivery of the procedure. Approximately 60 percent of the value of each fee is adjusted for local costs. The product of each relative value and a monetary conversion factor determine the fee for each service.

OBRA-89 was a landmark for behavioral health in its provision for direct reimbursement of services provided by psychologists and social workers. It also set criteria for nonphysician providers regarding consultation with a physician. Nonphysician providers must document that a patient has been informed that consultation with the patient's primary care physician (PCP) is desirable for the PCP to evaluate medical conditions that could contribute to a patient's well-being. The provider must also document any written or verbal communications with the PCP about treatment unless the patient specifically prohibits such contact. The law does not require consultation with a psychiatrist. The law stipulates that reimbursement of services provided by psychiatric nurses and other therapists requires direct physician supervision.

In general, direct patient contact is required for any reimbursable service. Consultation or other services rendered by telephone and renewals of prescriptions that do not include direct evaluation of a clinical condition are not reimbursable. Medicare Part B allows billing for services required to obtain clinical information from relatives or close associates of unreliable or uncommunicative patients. Family counseling services are reimbursable only when their purpose is to facilitate patient care.

There are two ways in which providers may participate in Part B of the Medicare program:

1. A provider may accept assignment and agree to accept the applicable Medicare fee as payment in full. Medicare's fiscal intermediary pays the

provider the approved amount less copayment and deductible directly. The provider is legally required to bill the patient directly for the copayment and the deductible.

2. A provider may choose not to accept assignment. Providers who do not accept assignment may charge patients up to 115 percent of the approved Medicare fee. Medicare reimbursement for providers who do not participate in Medicare Part B is limited to 95 percent of the approved fee less deductibles and copayment. The provider may then bill the patient directly for the balance of charges up to the 115 percent limit.

All providers must accept assignment from Medicare beneficiaries who also participate in the Medicaid program. Assignment must be accepted for all Medicare recipients who are at or below the federal poverty level regardless of whether they have Medicaid as a secondary payer. In an increasing number of states, medical licensure authorities and insurance commissions require that all physicians who participate in the Medicare program accept assignment for patients seen within that state.

Medicare Risk in Managed Care

Since the early 1970s, Medicare has encouraged older Americans to enroll in capitated health plans. Since that time, HMOs have been able to contract directly with Medicare. Between 1985 and 1997, Medicare payments to risk-contracting HMOs for aged and disabled beneficiaries were based on adjusted actuarial estimates of the per capita cost of such services incurred in a beneficiary's county of residence, using adjusted average per capita cost (AAPCC) methods. The AAPCC had been based on the individual's county of residence, age, and sex and whether a patient is covered by Medicaid, lives at home or in an institution, and works or is retired or disabled. These county per capita payment rates, adjusted for the average beneficiary, have been published annually as the County Rate Book.

HMOs, although allowed to earn "normal profit margins," must use savings above a predetermined rate to provide extra services for elderly members. For many years, to penetrate a local market, HMOs frequently waived premiums and offered to include usually uncovered services in the benefit package to induce enrollment. Unlike traditional Medicare, HMOs allow access to primary care and other preventive services in the absence of a primary diagnosis. In addition, managed care plans usually have provided coverage for some portion of outpatient pharmaceutical costs.

The nature of HMO risk-contracting with Medicare provides an incentive for HMOs to market to healthy older adult populations who are likely to consume services valued at considerably less than the 95 percent of AAPCC criterion used to set capitation rates. Indeed, healthy populations, even if older than 65 years, yield substantially greater profit margins for HMOs, leaving sicker, more disabled people to be cared for via

direct payments from CMS in the traditional Medicare program. Several studies have indicated that capitated plans generally enroll healthier and less costly beneficiary populations than those who remain in fee-for-service Medicare. In one study, in the 6 months preceding enrollment, new members of capitated plans had health care costs that were 35 percent lower than the average costs of patients in traditional fee-for-service Medicare. Some plans profit through marketing to "younger older adults" (people aged 65 to 70) in settings in which there is a greater likelihood of health and independence. Studies indicate that Medicare has overpaid some capitated plans by 5 to 20 percent because selection factors resulted in enrollees with better health, on average.

To reduce financial incentives rewarding the enrollment of healthy persons and to pay more fairly for the care of frailer populations, the BBA 1997 required Medicare to link payments to HMOs to the health status of their beneficiaries by the beginning of the year 2000. In this system, frail enrollees are eligible for higher payments than healthier cohorts are. This should encourage plans to discontinue avoiding the enrollment of more chronically ill populations and to bring a broader base of the general older adult population into managed care. In enacting Medicare Part C in 1997 to create Medicare+Choice, a new methodology was introduced to pay organizations that enter into Medicare Part C contracts. The equivalent of the County Rate Book is based on the greatest of three amounts: (1) a new blended payment rate based on a calculation method combining local and national rates in setting county rates, (2) a new minimum specified rate amount (e.g., $367 per month per enrollee in 1998), or (3) an amount that is based on a 2 percent increase over the prior year's rates, with the 1997 County Rate Book serving as the baseline.

The percentage of beneficiaries enrolled in Medicare managed care increased steadily into the 1990s. Whereas only 3.6 percent of older Americans were enrolled in HMOs in 1990, this proportion increased to 10 percent in 1996 and to more than 15 percent in 1998. Since 2001, enrollment has been declining due to the departure of many health insurance programs from the Medicare managed care market due to reimbursement rates that are increasingly inadequate to cover medical utilization costs. The Medicare+Choice program, a major component of the BBA 1997, renamed in 2004 to Medicare Advantage, is the Medicare managed care component. It is designed to make it easier for various kinds of organizations, including PSOs and PPOs, to become participants in Medicare managed care. Medicare Advantage has been organized to encourage greater competition among health plans enrolling Medicare beneficiaries.

Managed care plans caring for Medicare recipients have applied the same paradigms to behavioral health care that they have used for their younger commercial populations. Many of these plans, perhaps a majority,

"carve out" the behavioral health benefit and capitate the risk for these services to managed care organization (MCO) vendors. Most of the MCOs are large for-profit entities that function as psychiatric and substance abuse insurers in numerous markets regionally and nationally. MCOs generally establish local networks of ambulatory and inpatient providers; establish fee-for-service pricing with those providers; provide medical management, care management, utilization review, and credentialing functions; and also pay claims. These MCO systems are generally very effective in reducing inpatient use. This effectiveness allows them to negotiate significantly discounted prices for services and to limit the size of available networks, thereby reducing the management effort required to control service use.

A review of the credentialing and procedure manuals for a group of the largest MCOs nationally found virtually no mention of requirements for specialty training or expertise in the care of older adults or for special consideration of medical comorbidity or frailty. There were no requirements for services to be sited at locations in which older adults reside or where access to care may be facilitated for frail or disabled people. This review suggests that the current model for delivery of managed behavioral health services to older adult Medicare beneficiaries is unlikely to reflect recent advances in behavioral neuroscience. Similarly, many carve-out programs exclude or limit comprehensive assessment, neuropsychological testing, and other routine components of major neurocognitive disorder evaluation.

A number of not-for-profit entities have developed the capacity to be included in full-risk agreements with their medical and surgical colleagues. This has allowed an emergence of a new model of behavioral health care, carving in services while locating providers on site or adjacent to primary care delivery. These programs are serving considerably smaller populations than most MCOs, and differences in actual outcomes have yet to be demonstrated.

Managed care continues to be a priority in Medicare policy. However, reductions in payments to managed care entities by Medicare coupled with complex paperwork requirements have prompted many managed care plans to leave the Medicare program in recent years. The tension between the financial effects of the BBA 1997 and BBRA 1999 laws and government efforts through the 2003 Medicare Advantage provisions to attract beneficiaries to managed care plans is likely to persist over the course of the coming years.

Insurance Coverage Supplementing Medicare

More than 90 percent of older Medicare beneficiaries have supplemental Medicare coverage for service costs not covered by Medicare directly. These supplemental coverages include employer or union-sponsored retiree health plans, Medigap policies, Medicare+Choice/Medicare Advantage,

and dual Medicaid–Medicare coverage.

In July 1991, Congress enacted mandatory federal Medigap standardization requirements as part of the OBRA of 1990 (OBRA-90). It provided requirements for 10 basic policies. All of these policies must include payment of the Medicare Part A hospital and Part B provider coinsurances. In addition, all policies must pay any applicable 50 percent copayment for outpatient psychiatric services. More comprehensive policies may elect to cover deductibles, skilled nursing facility coinsurance, outpatient prescription pharmaceuticals, and preventive in-home services. Medigap regulations provide incentives for the use of PPOs by Medicare recipients. This allows insurers to offer lower premiums to members who agree to use a PPO for all of their care. An increasing number of states have authorized insurers to offer this option.

The Medicare Prescription Drug, Improvement, and Modernization Act of 2003 impacts Medigap policies that have a drug benefit. People currently enrolled in a Medigap plan without a drug benefit are not affected. However, those who have a Medigap policy with drug benefits have two choices: (1) They may keep their current Medigap plan with drug benefits. However, if they later decide to enroll in a Medicare Part D plan, a late enrollment penalty may be charged if the Medigap policy is not equivalent to Medicare Part D. (2) They may enroll in a Medicare Part D plan. Those who choose to do this can either enroll in another Medigap plan without drug coverage to cover Medicare's cost sharing for other services or keep their current Medigap plan but drop its drug benefits and pay a lower premium. People who reach age 65 after January 1, 2006, are able to enroll in Medigap policies without drug benefits. After January 1, 2006, people were not able to purchase a supplemental policy to help offset their deductibles and copayment for drug policies. Regarding employer-sponsored retiree plans, the government pays 28 percent of the costs that companies incur for each retiree, to encourage companies to maintain their drug coverage for retirees; this amounted to between $250 and $5,000 per retiree in 2006.

On April 16, 2015, the Medicare Access and CHIP Reauthorization Act of 2015 (MACRA) was authorized. Among various actions, this replaced the Sustainable Growth Rate formula (never actually put into action due to multiple short-term Congressional "patches" since 2002). Starting in 2020, it will affect insurance coverage supplementing Medicare by decreasing funding to supplemental Medicare plans, reducing "first dollar" coverage of supplemental Medigap plans.

MEDICAID SYSTEM

Enacted in 1965 as a social insurance program to pay for the medical care of Americans with limited financial means, Medicaid is funded through a combination of federal and state matching funds. To receive these

matching funds, states must provide a basic benefit package, including hospital, physician, and nursing facility services, as well as a wide range of supportive services. The program allows states to impose restrictions on the services that they fund and on the level of reimbursement. Medicaid is a means-tested and needs-based program thus, an individual must meet certain criteria to be eligible. The eligibility varies widely from state to state, but the most important criteria are poverty and financial resources. With PPACA, the eligibility was increased to 133 percent of poverty line. The federal government is required to pay for the cost of Medicaid expansion at 100 percent rate till 2016, 95 percent in 2017, 94 percent in 2018, 93 percent in 2019, and 90 percent starting in 2020 and thereafter. Medicaid expansion does not apply nationwide, as states are able to reject the PPACA Medicaid expansion. Therefore, as of this writing, Medicaid coverage continues to depend on the state.

For older Americans with mental illness, Medicaid is important in two ways. First, it is the most important payer for long-term care services. The nursing home is an important site of care for older adults with severe and persistent mental illness, including major neurocognitive disorder, schizophrenia, and depression associated with medical illness and disability. Deinstitutionalization from state facilities shifted the financial burden of care for many people with these diagnoses from the states (in state hospitals) to cost sharing with the federal government via its partial support of Medicaid. The nursing home reform provisions of the OBRA of 1987 (OBRA-87) require preadmission screening for nursing home applicants to determine if active psychiatric illness is present. If active treatment for an identified psychiatric disorder cannot be provided appropriately in the nursing home, alternative referral for this care is mandated. Nursing homes must demonstrate efforts to provide appropriate care for behaviorally disturbed people, and appropriate training in management of difficult behaviors is required of all staff members of long-term care facilities participating in the Medicaid program. Currently, Medicaid continues to be the major coverage option for long-term services and supports. Its scope is broader than Medicare and encompasses services delivered in hospitals, institutions, home, and communities. As Americans continue to age, it is estimated that over 70 percent of those above the age of 65 will need long-term services and those above the age of 85 are four times more likely to need long-term services. In 2013, 51 percent of the estimated cost of $310 billion for long-term services was covered by Medicaid (19 percent was out-of-pocket). The second area of importance is the dual Medicare–Medicaid eligible patients. These are individuals who not only meet eligibility criteria for Medicare but also Medicaid (often due to financial hardship or disability). Currently, 8.3 million Americans meet this dual eligibility and 62 percent of Medicaid expenditure or about $91.8 billion were for long-term care. 4.6 million are low-income seniors. With

the expansion of Medicaid, it is expected that this number will increase. The 2015 dual eligible standards based on percentage of federal poverty level amounts to $1,001 for individuals and $1,348 for couples/families with slightly higher rates for Alaska and Hawaii. Asset limits are $7,280 and $10,930, respectively. Even with Medicaid expansion, the dual eligible individuals do not constitute the majority of the Medicaid population. However, they account for over 70 percent of Medicaid spending.

OUT-OF-POCKET COST

As discussed above, maintaining one's health is the single most expensive cost during old age. Despite governmental support in the form of Medicare and Medicaid, many older Americans bear out-of-pocket costs in health care. Part of the cost is due to the simple fact that increases in federal budget and growth in Medicare spending has prompted political and policy interest in raising cost-sharing obligations of older adults. Out-of-pocket costs can include the following: monthly premiums for physician services under Medicare, prescription drug coverage under Medicare, custodial long-term care services and supports, routine dental care (including dentures), routine vision care or eyeglasses, and hearing exams and aids. To cover these expenses, many opt to get supplemental insurance to cover the cost not covered or only partially covered by Medicare (Medigap, employer or union-sponsored retiree coverage or employer-sponsored insurance for those who are still working). Those who cannot obtain supplemental insurance due to the high cost and are below the federal poverty level can receive Medicaid supplements. However, even with Medicaid expansion under PPACA, some older adults with low income do not qualify for Medicaid due to their saved assets. Although there have been measurable reductions in recent years in per capita out-of-pocket Medicare beneficiary spending due to the growth of managed care and cost containment measures, the effects of out-of-pocket payments on older adults, particularly those with limited resources, continues to be problematic.

Recent studies give some estimates of out-of-pocket expenses for health care. In 2010, Medicare beneficiaries spent $4,734. Premiums and supplemental insurance accounts for about 42 percent, and of the remaining, long-term facility costs are the highest accounting for about 18 percent. This is followed by medical providers/supplies (14 percent), prescription drugs (11 percent) and dental care (6 percent). The cost rises with age and there are notable differences between men and women as they approach and pass age 85. For women, who pay more out-of-pocket expenses then men, the difference can be attributed to rising long-term care cost. Chronic illness such as Alzheimer disease and Parkinson disease that are associated with aging have profound impacts on rising health care cost ($8,305 and $5,841 respectively). Additionally, the out-of-pocket cost

can increase with those with mental illness requiring more Medicare-covered services, as well. As noted in the Mental Health Parity section, coverage of mental health treatment is not equitable, hence older adults with chronic mental health issues requiring frequent or long psychiatric hospitalizations can face catastrophic costs when obtaining adequate treatment.

Since Medicare and Medicaid do not cover different levels of long-term care, privately paid long-term insurance plans are available and add to additional personal cost. Prescription drug continues to be the fastest-growing segment of health care cost for older Americans. To help with this, by 2020, PPACA will close Medicare Part D's "donut hole" and will reduce the cost by an average of $2,000 per year. Furthermore, PPACA restructures Medicare Part B and D premiums to reduce cost for those in low-income brackets and increase contributions from the wealthy. These measures, as well as coverage of preventative care, may work to decrease overall out-of-pocket costs.

MENTAL HEALTH PARITY

A significant financial barrier to mental health care has been inequality of coverage of mental treatment by insurers. There has been a long history of benefit inequality between mental health and general health. Historically, the inequality was shown by higher mental health insurance premiums, limitations on mental health care coverage, and carving out mental health care from general health insurance. Importantly for older adults, lack of mental health care parity in Medicare meant that outpatient mental health treatment services required up to a 50 percent copayment while general care required just 20 percent. This posed significant barriers for older Americans to access mental health care.

While President Kennedy's administration first required Federal Employees Health Benefits Program (FEHBP) to cover psychiatric illness at the same level as general medical care, by 1975, even FEHBP scaled back on mental health coverage. Efforts in the 1980s to improve private insurance benefits were largely driven by individual states and no consistent parity level care or financial coverage existed. The MHPA originated during President Clinton's administration in context of his ultimately failed health care reform. By the time it was passed in 1996 as an amendment to the Veterans Affairs, Housing and Urban Development legislation, it just provided mental health parity for annual and lifetime dollar limits for group plans with 50 or more employees. It did not apply to annual hospitalization day or visit limits nor alcohol/substance treatments. Most health plans found loop holes to circumvent the law and restrictions were placed on psychiatric hospitalization days and outpatient visits. They also put larger emphasis on cost sharing. Despite its limitations, MHPA pushed the agenda toward mental health parity.

After significant work, in 2008, MHPAEA was passed to address the loopholes present in the MHPA. It underwent the implementation stage and became effective on April 5, 2010. It became applicable beginning or after July 1, 2010. MHPAEA requires that if an employer offers behavioral health coverage, it must be equal to those for general medical/surgical benefits. It continues to prohibit use of annual and lifetime dollar limits for mental health benefits and now includes addiction benefits. While the law is applicable to all US employers with more than 50 employees, it does not mandate employers to provide mental health and substance abuse benefits and does not extend to individual insurance market. MHPAEA does allow individual states to impose stricter parity requirements. Importantly, it also mandates that health plans that provide out-of-network coverage for medical/surgical benefits also provide equal mental health benefits. After the implementation of MHPAEA, Medicare payment liability limitations were gradually reduced and by 2014, 100 percent limitation was in effect. Thus, just like other medical treatments, mental health treatment had cost sharing of 20 percent. As of this writing, the implementation of mental health parity continues to be played out on the ground level. The law did not create any funding or mechanism to monitor, enforce or implement parity at the local level. This forces many psychiatrists and patients to continue advocating and working toward mental health parity. Therefore, it is important for mental health providers and organizations to closely monitor the continued carving-out mental health benefits to third parties so that the coverage is at parity. Also, the process of carving-in mild to moderate mental illness to primary care must be evaluated to ensure that adequate, high-quality mental health care is being delivered in medical homes.

PATIENT PROTECTION AND AFFORDABLE CARE ACT

Since the passage of the Medicare and Medicaid in 1965, the most significant health care reform legislation in America is the PPACA. Its overarching goals are to increase the quality and affordability of health insurance, lower uninsured rates and reduce overall costs of health care. After its passage, it successfully underwent challenges in court on individual mandate and federal subsidies mechanisms and is currently the law of the land. PPACA's numerous provisions started to take effect in 2010 and has a rollout period to last till 2020. Since its passage, by 2015, Centers for Disease Control and Prevention reported 11.4 million fewer Americans without insurance and polls indicated a decrease in the percentage of uninsured from 18 to 11.4 percent. While it is outside the scope of this chapter to give an overview of all provisions, several, as it pertains to care for older Americans, are worth noting.

For older Americans with mental illness, keeping out-of-pocket health care cost low, ensuring mental health parity, helping low-income

individuals, and ensuring adequate coverage of mental health treatments are important. PPACA works on several levels to help achieve these goals. First, the law prohibits insurers from denying coverage due to pre-existing conditions and sets minimum standards for health insurance policy. As most states have set certain mental health coverage as a minimum standard at parity level, PPACA works to ensure that mental illness treatment is adequately covered. The law also makes significant changes to the health insurance market by creating exchanges which allow individuals and employers to compare policies and prices of insurance. This along with sliding scale mechanisms for low-income individuals and families (between 100 and 400 percent of federal poverty level) allows for a more affordable and robust insurance market. Additionally, Medicaid eligibility has been dramatically increased. Now individuals and families with incomes up to 133 percent of federal poverty level qualify. This expansion of Medicaid is arguably the single most important aspect of the law, which has worked to decrease the number of uninsured in America. Furthermore, PPACA made several important reforms to Medicare. The reimbursement model has been restructured from fee-for-service to bundled payments. This encouraged cost savings at point of care. It also created Independent Payment Advisory Board to help reduce cost and created several measures to monitor for and control Medicare fraud and abuse. PPACA also improves preventative care coverage, which will be very important to improve the lives of older adults by potentially screening for and possibly preventing chronic diseases earlier. As mentioned earlier, it also closes out the "donut hole" in Medicare Part D. By 2020, this will be closed out and reduce prescription cost by an average of $2,000 per year. Mechanisms of PPACA can help serve older Americans with mental illness by improving outreach and education, improving care transitions, creating Medicare–Medicaid Coordination Office, and encouraging innovation.

It is generally hoped that PPACA will help offset the cost of health care in several ways. Its provisions will help reduce the number of bankruptcies due to medical care costs. Not only is medical cost the leading reason for personal bankruptcies, it also forces individuals to be locked into a job solely for health insurance coverage. PPACA is expected to reduce Medicare and Medicaid spending and thus leading to overall cost savings. Another facet of the law is to encourage new models of care delivery, one in which long-term, health care quality and health information transparency is encouraged. Innovative models like medical homes and accountable care organizations (ACOs) are just some examples being tested in the market now. These are largely designed to integrate health care providers to provide comprehensive care to the patient and to measure, report, and improve on quality of care. It also attempts to increase access for medically underserved populations. Access challenges is a complex problem and involves not only financial access but also provider access. Addressing the

critical shortage of primary care services and providers, PPACA expands community health centers and invests in public health programs. Finally, it creates new Medicaid options to promote community-based care and care giver support for those requiring long-term care.

Mental health treatment is not provided in isolation. Research and statistics argue that mental illness' impact on overall health cannot be overstated. It is integral to health and without it, true health care reform is not possible. As Americans continue to age and the impact of chronic mental illness grows, it is hoped that PPACA will have lasting positive changes on health care outcome and cost.

CURRENT AND FUTURE DIRECTION

As of this writing, the financial implications and impact on geriatric psychiatric care is actively evolving. MHPAEA and PPACA have made significant changes to the insurance market (private and public) and their impact will be felt for years to come. The growth of the older adult population will continue to be a major challenge faced by health care policy makers and providers. Without continued innovation and change, older adults will continue to consume health care services at an unsustainable rate. The recent emphasis on cost reduction in service delivery, while technology advances and the size of the frail older population grows at an unprecedented rate, has created conflict, threatening stability and coherence in the humanistic, scientific, and economic spheres. Advances in behavioral neuroscience and in particular, geriatric psychiatry, can improve quality of life, while extending life spans and improving the economic productivity of the fastest-growing segment of the population. Despite some concerns, there are ample opportunities for geriatric psychiatrists to get involved and to take on leadership roles.

Some immediate impact from MHPAEA and PPACA has to do with improving the inequality in mental health care coverage and treatment. Before this legislation, among employer-sponsored health insurance, 2 percent excluded mental health benefits and 7 percent excluded substance use benefits; rates were much higher in individual insurance markets. By the inclusion of mental health and substance abuse services as one of ten required components of Essential Health Benefit, PPACA supports the parity regulation from MHPAEA. While this does not mean that all Americans will benefit from increased parity level access to mental health care, it significantly increases the number of patients who are able to seek care. This poses challenges to geriatric psychiatrists as there simply are not enough providers to take on the increase in volume of work. Additionally, the growing emphasis on quality outcome measures begs the question of how to adequately represent quality geriatric psychiatric care when chronic mental illness follows a different time course and expected outcomes. The push to integrate mental health with general health also

challenges the traditional geriatric psychiatry practice model. Geriatric psychiatrists must be more transparent and collaborative with their primary care colleagues and expanding mental health providers (such as mid-level providers like physician assistants and nurse practitioners, therapists and peer specialists).

Strategic goals that underlie the continuing health care reform initiatives that will impact how geriatric psychiatry will be practiced are the triple aim of better care, affordable care, and better health for populations. By leveraging technological and medical advances, geriatric mental health care is well suited to achieve these goals. Some emerging models that will impact geriatric psychiatry in the future are ACOs, integrated care, patient-centered medical homes, and population health. All of these models attempt to provide cost-effective, best quality care not only to the individual, but to large populations. The Center for Medicare and Medicaid Services defines ACOs as groups of doctors, hospitals, and other health care providers who come together voluntarily to give coordinated high quality care to Medicare patients. One of the goals is to provide coordinated care to the chronically ill. It benefits within the Medicare program by sharing the cost savings. Integrated care is one response to the often disjointed and uncoordinated health care being delivered. World Health Organization defines it as a concept that brings together inputs, delivery, management and organization of services related to diagnosis, treatment, care, rehabilitation, and health promotion. The integration model then is designed to improve the overall access, quality, and efficiency of care delivery. One of its outcome goals is to achieve improved patient satisfaction as well. The patient-centered medical home is a model developed by PCPs where a health care provider leads a team centered on comprehensive and continuous care of an individual with the goal of maximizing health outcomes. It embraces the whole person orientation, care coordination by a personal physician, and emphasizes quality and safety. Finally, population health focus is an approach that tries to improve large patient populations by reducing health disparities, influencing social determinants of health, and developing strategies to have specialized but hard to find providers focused on certain diagnosis or patient subgroups. Population health management endeavors to focus interventions to specific patients and to avoid worse outcomes in the future. By focusing specialists, like geriatric psychiatrists, to complicated patients as identified within a patient registry and/or within a large organization, it seeks to maximize the impact of the specialist. The overall result would be identification and prevention of potentially high-cost patients.

Mental health care has been and will continue to be intimately related to financial aspects of health care delivery models. MHPAEA and PPACA have fundamentally changed the way in which Medicare, Medicaid, private insurance, and out-of-pocket cost impact mental health care of older

Americans. As of this writing, the full consequences of these landmark legislations are unknown, but it is hoped that they will improve the well-being of patients. For geriatric psychiatrists, participation and acquiring leadership roles in new models of care will be crucial to effectively provide treatment for the increasing number of older adults.

57.6a Psychiatric Aspects of Long-term Care

ABHILASH K. DESAI, M.D., AND GEORGE T. GROSSBERG, M.D.

The prevention and treatment of psychiatric disorders is a critical

component of comprehensive, state-of-the-science care for all individuals who live in long-term care facilities. Psychiatric disorders in long-term care residents are prevalent and complex; have heterogeneous etiologies, clinical presentations, and treatment outcomes; and are the subject of extensive research. Early and comprehensive management of psychiatric disorders has the potential not only to promote the dignity, well-being, and safety of residents in long-term care facilities but also to improve the quality of life of their caregivers and reduce the costs to society by preventing visits to emergency departments and hospitalizations.

At least 20 percent of older adults will spend their last years in a long-term care facility, and another 40 percent will have a short stay in a skilled nursing facility for rehabilitation (subacute care) after hospitalization for acute care. Long-term care facilities primarily include nursing homes and assisted living homes but can also include the many certified family homes and group homes that provide care to older adults who are unable to live independently due to disabling physical and/or psychiatric problems. More than 3 million individuals in the United States live in long-term care facilities, with 1.5 million of them in approximately 16,000 nursing homes. This number of 3 million is expected to double by 2030. The proportion of residents older than 85 has increased dramatically in the last decade and currently comprises the largest age group (37.1 percent). Residents in nursing homes and assisted living homes have grown progressively more debilitated, requiring more assistance with basic activities of daily living, such as bathing, grooming, and toileting. A growing number of residents are younger, having experienced stroke, traumatic brain injury, or other disabling neuropsychiatric disorders. Adults who have developmental disability (especially intellectual disability, Down syndrome, cerebral palsy, autism spectrum disorder) are also living longer and often live their last years in a long-term care facility.

More than 90 percent of the long-term care population at some point will experience clinically significant psychiatric symptoms. (Table 57.6a–1shows the prevalence of common psychiatric disorders in the long-term care population.) Thus, psychiatric care is a core component of the day-to-day care of most of the residents in long-term care facilities. The long-term care population is not only primarily older adults who have substantial disability but also those who have considerable cognitive impairment and/or medical burden, making the availability of mental health professionals (psychiatrists, psychiatric nurse practitioners and physician assistants, psychologists, and licensed counselors) who have additional training in geriatric medicine and psychiatry, key to high-quality care for this vulnerable population.

THE ROLE OF THE PSYCHIATRIST IN LONG-TERM CARE

A psychiatrist typically has the role of a clinical consultant in long-term

care, although some may serve as medical director. Psychiatrists can also play a vital role in administrative aspects of care, especially in moving the culture of the facility toward a person-centered approach and improving collaboration with primary care clinicians and pharmacists to reduce inappropriate use of medication. Psychiatrists can play a key role in educating and training the staff to understand behavioral symptoms of major neurocognitive disorders, in handling psychiatric emergencies, and in helping the facility develop policies and procedures regarding when to transfer a resident to a local emergency department for treatment in an acute inpatient psychiatric unit. The authors recommend adhering to the American Medical Directors Association's clinical practice guidelines on delirium, acute problematic behavior, dementia, depression, pain management, sleep disorders, and transitions to other care. Psychiatrists trained in geriatrics (e.g., geriatric psychiatrists, psychiatrists who have completed training for nursing home medical directors provided by the American Medical Directors Association) can also play the role of the facility medical director or codirector. Many residents and their family members are reluctant to accept psychiatric help due to perceived stigma. Psychiatrists can play a crucial role in alleviating such concerns by being available for informal meetings with the resident and their family to clarify the unique expertise they provide and the great potential for psychiatric help in reducing suffering and improving quality of life of the resident. Psychiatrist's presence in monthly support groups at the facility for the residents and/or their family members may also help reduce stigma for psychiatric care.

Another role which psychiatrists can fill in long-term care is via telepsychiatry. Telepsychiatry involves providing psychiatric assessment and management remotely (typically using a two-way computer system with audio–video conferencing). Telepsychiatry can help overcome a key barrier to improving psychiatric care in long-term care facilities: lack of availability of mental health professionals with geriatric expertise, especially in rural areas. Although the benefits and risks of telepsychiatry have not been subject to rigorous research, the authors support the use of telepsychiatry for facilities that do not have a mental health consultant with geriatric expertise primarily for the goals of reducing the use of psychopharmacologic agents (especially antipsychotics, benzodiazepines, and multiple antidepressants), differentiating delirium from other psychiatric disorders, educating and supporting families, evaluating residents who have suicidal ideation, helping with decisions about palliative and end-of-life care, and educating and training the staff to implement individualized psychosocial environmental interventions.

APPROACH TO EVALUATING AND MANAGING PSYCHIATRIC SYMPTOMS AND DISORDERS

A systematic approach to evaluating and managing psychiatric disorders using evidence-based practices and interventions has the potential to reduce suffering dramatically and to prevent unnecessary visits to the emergency department and hospitalization. The authors recommend four steps to evaluating and managing psychiatric disorders in the long-term care population.

Assessment of Safety

The first step is to assess safety. The psychiatrist may need to address behaviors that pose an imminent danger to the resident or others (behavioral emergencies), such as violent or suicidal behaviors, before attempting to assess underlying psychiatric problems. Suicidal behaviors can be direct (e.g., suicidal ideas, such as voicing thoughts to cut oneself with a knife or scissors, or suicide attempt, such as attempting to strangle oneself with a cord) or indirect (e.g., refusing dialysis, refusing food or life-preserving medications such as warfarin). Completed suicides, although rare in long-term care, may be more common than in the community. If a behavioral emergency cannot be resolved, the resident may need to go to the nearest emergency department for urgent evaluation and stabilization.

Team-Based Evaluation to Identify Causes of Psychiatric Symptoms and Disorders

The second step is for a multidisciplinary team (resident, family members, primary care clinician, psychiatrist, nurse, nursing assistant, and social worker) to identify all factors that may contribute to psychiatric symptoms. Psychiatric symptoms are typically due to several specific reversible or modifiable causes. (Table 57.6a–2lists common reversible causes of psychiatric symptoms in the long-term care population.) Obtaining the resident's perspective is essential, even if the resident has significant cognitive impairment. Diagnoses listed in the long-term care resident record need to be validated as they are often incorrect. In complicated cases (e.g., presence of chronic mental illness, refractory and severe behavioral and psychological symptoms of neurocognitive disorder, concerns of abuse and neglect, and complex polypharmacy), the psychiatrist may need to consult a professional who has geriatric expertise (e.g., geriatric psychiatrist, geriatrician).

Action Plan

In the third step, the team collaboratively devises and institutes an action plan (treatment plan) that is individualized and directed at the specific target psychiatric symptoms, diagnoses and differential diagnoses identified in the second step. An action plan generally consists of a multimodal approach combining a variety of psychosocial environmental

interventions targeted at caregivers and residents to address psychiatric symptoms that are most distressing or problematic. An action plan should address all the potentially modifiable causes of psychiatric symptoms identified during evaluation. Professionals from allied fields (e.g., pharmacist, occupational therapist, physical therapist, speech therapist, recreational therapist, music therapist, activity therapist, and art therapist) and professionals who have knowledge of complementary and alternative medicine (e.g., aromatherapy, massage therapy, and horticultural therapy) can play valuable roles. Psychopharmacologic interventions may be the first line in behavioral emergencies related to violent behaviors, relapse of pre-existing psychiatric disorder (e.g., bipolar disorder), new onset of major depression, persistent and distressing psychotic symptoms, and persistent aggressive behavior. (Table 57.6a–3lists key principles of psychopharmacology with the long-term care population.)

Table 57.6a–1.
Prevalence of Common Psychiatric Disorders in Long-Term Care

Psychiatric Syndrome (Point Prevalence)	Key Example(s)	Comments
Major neurocognitive disorders (MNCD) (60–90%)	Alzheimer disease (AD) Vascular cognitive impairment (VCI) Parkinson disease dementia Dementia with Lewy bodies Frontotemporal dementia Traumatic brain injury and chronic traumatic encephalopathy Hypoxic/anoxic encephalopathy Alcohol-related dementia	Many residents have both AD and VCI. Most residents are in advanced stages of major neurocognitive disorder. Behavioral and psychological symptoms of major neurocognitive disorder are the most common reasons for psychiatric consultation. Many residents, especially in subacute care, have minor neurocognitive disorder and, when there is superimposed depression or delirium, may be misdiagnosed as having major neurocognitive disorder.
Depressive disorders (20–40%)	Depression due to MNCD, stroke, cerebrovascular disease, or another general medical condition (most common) Major depression (single episode and recurrent) Persistent depressive disorder (dysthymic	Adequate control of pain is needed to improve depression, and optimal treatment of depression is needed to improve pain for residents who have pain and depression. Drug–drug interactions between antidepressants (e.g., SSRIs[a]) and drugs used to treat medical comorbidity (e.g., tramadol, diuretics, warfarin) are common and need to be monitored. A schedule of pleasant events and physical exercise have been found to be effective in the treatment of depression.

	disorder) Adjustment disorder with depressed mood or with mixed depression and anxiety Depression due to medications	
Delirium (5–15%)	Hypoactive delirium (most common) Hyperactive delirium Mixed delirium	Delirium is especially prevalent among residents newly transferred from an acute care hospital (subacute settings in skilled nursing facilities). Subsyndromal delirium is even more common and commonly manifests with new onset of agitation and/or new onset of falls.
Psychotic disorders (5–10%)	Psychotic symptoms due to MNCD (most common) Psychotic symptoms due to Parkinson disease and dopaminergic agents used to treat Parkinson disease Schizophrenia and schizoaffective disorder	Psychotic symptoms are also common in the context of delirium. Psychotic symptoms are a common cause of persistent physical aggression. As adults who have schizophrenia and schizoaffective disorder live longer, their prevalence in long-term care is expected to rise further.
Hypomania and mania (2–5%)	Bipolar disorder (types I and II, most common) Medication-induced hypomania or mania Hypomania or mania due to stroke or another general medical condition	As adults who have bipolar disorder live longer, their prevalence in long-term care is expected to rise further. Corticosteroids are the most common cause of medication-induced hypomania or mania.
Anxiety disorders (lack of rigorous data on prevalence; clinical experience indicates high prevalence)	Anxiety symptoms and bathing phobia in the context of major neurocognitive disorder (most common) Generalized anxiety disorder Panic disorder Fear of falling	Anxiety symptoms are often comorbid with depressive symptoms. Premorbid subsyndromal generalized anxiety disorder is often exacerbated by development of a major neurocognitive disorder.
Trauma-related disorders (lack of rigorous data on prevalence; clinical experience indicates growing prevalence)	Posttraumatic stress disorder (PTSD)	War veterans, victims of abuse (physical, sexual, emotional), and victims of a motor vehicular accident should be identified at the time of admission to a long-term care facility so that investigation for presence of PTSD can be done soon after admission.

Impulse-control disorders (5–15%)	Sexually inappropriate behaviors in the context of major neurocognitive disorder (especially VCI)	Dopamine agonists (pramipexole, ropinirole [Requip], rotigotine [Neupro]) may cause impulse-control problems, including sexually inappropriate behaviors and excessive gambling or spending sprees.
Substance-use disorders (lack of rigorous data on prevalence; clinical experience indicates growing and significant prevalence)	Alcohol (most common) Tobacco Prescription opioids Benzodiazepines	Hazardous use of alcohol, tobacco, prescription opioids, and benzodiazepines that do not meet the criteria for substance-use disorder are prevalent in long-term care and should be treated vigorously. As more baby boomers enter long-term care, the prevalence of substance-use disorders (especially alcohol and marijuana) in the long-term care population is expected to grow.
Other psychiatric disorders with growing prevalence	Disorders of the sleep–wake cycle Eating disorders Intellectual disability Autism spectrum disorder Personality disorder	These disorders are often comorbid with other psychiatric disorders. They need to be identified and the treatment plan modified accordingly.

[a]SSRIs, selective serotonin reuptake inhibitors.

Table 57.6a–2. Common Reversible Causes of Psychiatric Symptoms in Long-Term Care

Cause	Key Example(s)	Potential Psychiatric Symptoms
Medications	Benzodiazepines Anticholinergics Corticosteroids Dopamine agonists	Cognitive impairment Agitation Hypomania, mania Psychotic symptoms
Physical health conditions	Pain, neuropathy, constipation, urinary tract infection, dehydration, delirium, anemia, vitamin B_{12} deficiency, vitamin D deficiency, low blood pressure due to overtreatment of hypertension	Agitation Depression Cognitive impairment
Sensory deficits	Hearing deficit Vision deficit	Depression Agitation Paranoia Visual hallucinations Cognitive impairment
Disorders of the sleep–wake cycle	Insomnia Obstructive sleep apnea Excessive daytime sleepiness REM sleep behavior disorder Restless leg syndrome	Increased or decreased sleep Nighttime agitation Cognitive impairment

Psychiatric conditions	Major neurocognitive disorders Major depression (single episode or recurrent) Generalized anxiety disorder Posttraumatic stress disorder (PTSD) Bipolar disorder Schizophrenia	Agitation/aggression Social withdrawal Insomnia Cognitive impairment Nightmares Poor food and fluid intake Delusions Hallucinations Hypomania/mania
Long-term care staff approach	Impatience Lack of empathy Overexpectation	Agitation/aggression Depression
Long-term care staff's understanding of psychiatric symptoms/disorders	Staff's opinion that the behaviors are intentional ("he can stay in bed all day, as he is 90 years old and is tired")	Agitation Depression Insomnia
Long-term care staff distress	Caregiver anxiety and depression Caregiver burnout Excessive caregiver burden (having to care for too many residents)	Agitation Depression
Negative environmental factors	Nighttime noise Low lighting Boredom Overstimulation Improper or inadequate incontinence care routines Therapeutic diet Lack of places to wander Physical restraint	Agitation Depression Anxiety Poor food and fluid intake Insomnia
Unmet needs of residents	Toileting, hunger Physical activity Spend time with nature To be productive, to be needed Spiritual needs To express and vent Freedom from restraint	Agitation Depression

Response to Treatment

The fourth step involves appropriately monitoring adverse effects of interventions as well as response to treatment so that the psychiatrist can evaluate whether to modify or continue the interventions. If the problem is not improving, the psychiatrist should discontinue the intervention. If the intervention included an antipsychotic, the psychiatrist should make systematic attempts to taper the dosage and discontinue the medication after 6 to 12 months.

DELIRIUM AND PSYCHIATRIC ASPECTS OF COMORBID MEDICAL CONDITIONS

Age above 85, presence of a neurocognitive disorder, and polypharmacy are the three most important risk factors for delirium in the long-term care

population. More than 70 percent of residents have major neurocognitive disorder, and the majority of the remaining 30 percent have minor neurocognitive disorder. Residents who have advanced stages of major neurocognitive disorder have low cognitive reserve and thus are prone to develop delirium even with mild conditions such as urinary tract infection or a new medication that has anticholinergic activity. The psychiatrist should consider acute change in mental status, that is, the sixth vital sign (pain being the fifth vital sign and heart rate, respiratory rate, temperature, and blood pressure being the first four vital signs). New onset of falls and agitation are the two most common early signs of developing delirium in long-term care populations. New onset of agitation is one of the most common reasons for psychiatric consultation, and the psychiatrist may be the first health care professional to diagnose delirium.

Table 57.6a–3.
Key Principles of Psychopharmacology in Long-term Care

1. Prescription of even a single psychopharmacologic agent is a complex decision. It should be undertaken judiciously and, in most situations, after psychosocial environmental interventions have been tried and failed.
2. Start low, go slow, and keep going. Initial doses of psychotropic drugs need to be low or, for frail residents, very low. The dose increase needs to be slower than for younger adults. Final therapeutic doses for some residents may need to be as high as those for younger adults.
3. The benefit–risk ratio for all pharmacologic agents (including psychopharmacologic drugs) is lower than that for younger adults, necessitating close monitoring for adverse effects and prompt discontinuation of the drug if adverse effects develop or if there is no therapeutic response.
4. The psychiatrist should evaluate for periodic dose reduction and discontinuation of psychotropic drugs, and documentation should include the justification for continued use of psychopharmacologic agent(s).
5. The psychiatrist should promptly reassess the benefit–risk ratio of all psychotropic drugs whenever there is significant decline in the resident's overall health and functioning or decline in renal and/or hepatic function.
6. Psychopharmacologic therapies should comply with regulatory guidelines for the use of medications in nursing homes.
7. The psychiatrist should provide residents and their surrogate decision makers optimal information regarding the risks and benefits of psychopharmacologic therapies and alternatives before initiating therapy and periodically thereafter.

There are three types of delirium: hypoactive (most common), hyperactive, and mixed. Psychotic symptoms are common during delirium and may cause the resident to become severely agitated or physically aggressive, further complicating management. The Confusion Assessment Method (CAM) is a useful tool for improving accurate diagnosis of delirium in the long-term care population. (Table 57.6a–4lists common causes of delirium in the long-term care population.) Mania can also mimic delirium. Management of delirium involves ensuring safety and identifying and treating its various causes. Judicious short-term use of atypical antipsychotics may be appropriate and necessary for the management of

severe physical aggression and psychotic symptoms in the context of delirium.

Ms. A is a 65-year-old woman who was recently transferred from a local hospital to a skilled nursing facility. She was referred for psychiatric evaluation because she was not eating, appeared depressed, and was not sleeping well. The nursing staff suspected depression. During assessment, the psychiatrist discovered that Ms. A had undergone a colonic resection for ulcerative colitis and had excessive liquid drainage from an ileostomy. During examination, Ms. A was inattentive and somewhat drowsy and had psychomotor retardation. The psychiatrist diagnosed hypoactive delirium, possibly due to disorders of fluids and electrolytes. A subsequent basic metabolic panel showed hyponatremia, elevated blood urea nitrogen and serum creatinine (higher than baseline), confirming the diagnosis. Treatment with intravenous fluids at the facility quickly brought resolution of the presenting symptoms.

Table 57.6a–4.
Common Causes of Delirium in Long-term Care

Cause	Key Example(s)	Comments
D: Drugs	Anticholinergic drugs Benzodiazepines Opioids Steroids	Drugs listed in Beers list of drugs that are inappropriate for older adults often cause cognitive impairment and delirium. Many drugs have low anticholinergic activity and, if used with other drugs that have anticholinergic activity, may increase anticholinergic load sufficient to cause delirium. Benzodiazepine withdrawal can cause delirium.
E: Embolic–thrombotic	Pulmonary emboli Deep vein thrombosis (DVT) Cerebrovascular accident (CVA)	Residents who spend a large amount of time in bed (e.g., those who have depression, those who are in pain) are at high risk of DVT and its complications. Neuroimaging may be necessary to diagnose CVA accurately.
L: Last phase of life	Residents in end-of-life state	Delirium is common in terminal stages of major neurocognitive disorder.
I: Infections	Urinary tract infection Bronchitis Pneumonia Cellulitis	Asymptomatic bacteriuria and asymptomatic pyuria are prevalent, especially among women, and often misdiagnosed as urinary tract infection. Delirium may be a more common manifestation of pneumonia than fever and cough.
R: Respiratory conditions	Acute exacerbation of chronic obstructive pulmonary disease (COPD)	Acute bronchitis is one of the common causes of exacerbation of COPD.
R: Renal conditions	Acute renal failure (ARF)	Dehydration is a common cause of ARF.
I: Intestinal conditions	Acute intestinal obstruction, including fecal impaction	Inadequate treatment of constipation often leads to intestinal obstruction.
I: Injury	Hip fracture	
U: Urologic	Urinary retention	Drugs that have anticholinergic activity are the most common cause of acute urinary retention.
M: Myocardial	Acute myocardial infarction (AMI)	Delirium may be a more common manifestation of AMI than chest discomfort.

dysfunction	Acute congestive heart failure	Laboratory tests may be the only way to diagnose dehydration accurately.
M: Metabolic	Dehydration	
	Hypothyroidism or hyperthyroidism	
	Hyponatremia	

Clinical pearl: Hypoactive delirium often presents as depression.

Malnutrition

Malnutrition is prevalent in the long-term care population. It commonly manifests as unintentional weight loss or rarely as excessive weight gain and is a common reason for psychiatric consultation. Weight loss is usually accompanied by loss of appetite (including general loss of appetite as well as loss of appetite for food offered at the facility) or refusal of food. Depression is one of the most common causes of a general loss of appetite. Medications such as cholinesterase inhibitors also can cause anorexia and weight loss. Not having someone available to assist with meals, especially in residents with neurocognitive disorders is also a common reason for weight loss in long-term care facility population. Liberalizing diets, optimizing dental health, cutting food into smaller and manageable sizes (finger foods), giving smaller portions at each meal, and increasing the availability of snacks throughout the day can help address the problem of food refusal. The psychiatrist should evaluate all residents who refuse food for depression as well as for psychotic symptoms (especially delusions of food being poisoned). For residents who have depression accompanied by loss of appetite and weight loss, the psychiatrist may consider prescribing mirtazapine (Remeron) as the antidepressant of first choice. Nutritional supplements should be given between meals rather than with meals.

The prevalence of obesity and excessive weight gain is increasing in the long-term care population. This is typically accompanied by excessive consumption of calorie-dense food. Along with sedentary lifestyle, psychopharmacologic medications (e.g., valproate [Depakote], olanzapine [Zyprexa], quetiapine [Seroquel], mirtazapine) and other pharmacologic medications (e.g., gabapentin [Neurontin]) are common causes of excessive weight gain. It may be necessary to discontinue psychopharmacologic agents that are thought to cause or contribute to weight gain and as necessary replace them with alternative psychopharmacologic agents that have lower propensity for weight gain.

Pain

Psychiatric consultation can provide valuable help in improving outcomes and quality of life of residents who are experiencing chronic pain. Depression is common, underrecognized, and undertreated in residents

who have chronic pain. Pain is one of the most common causes of agitation in residents who have major neurocognitive disorder, especially verbal agitation (e.g., yelling, screaming, verbally abusive behavior) and resisting personal care. The psychiatrist should consider pain, the fifth vital sign. Antidepressants, especially serotonin–norepinephrine reuptake inhibitors (SNRIs, such as duloxetine [Cymbalta]), can help reduce the perception of pain and improve function as well as quality of life, even in the absence of significant depression, for residents who have chronic pain. Serious adverse drug–drug interactions between psychotropic drugs and analgesics (e.g., selective serotonin reuptake inhibitors [SSRIs] and tramadol [Ultram] [increased risk of seizure and serotonin syndrome], benzodiazepines and opioids [increased risk of delirium, falls, and injury]) can be prevalent and underrecognized in the long-term care population. The psychiatrist should consider recommending a trial of scheduled acetaminophen (Tylenol) to treat agitation (especially verbal agitation) before prescribing psychopharmacologic agents. Psychiatric care should be a key component of an integrated approach to pain management for all residents who have chronic pain.

MAJOR NEUROCOGNITIVE DISORDERS (DEMENTIAS)

Evaluation and treatment of major neurocognitive disorders is one of the key aspects of psychiatric care of long-term care residents. Residents who have major neurocognitive disorder and have not had a thorough evaluation to clarify its cause(s) may need workup to rule out potentially treatable or reversible factors of cognitive decline, including thyroid dysfunction, vitamin deficiency (e.g., B_{12} deficiency), subdural hematoma, normal pressure hydrocephalus, central nervous system infection, and brain tumor. The authors recommend using the Mini-Mental State Examination (MMSE), Montreal Cognitive Assessment (MoCA), or Saint Louis University Mental Status (SLUMS) to assess residents' cognitive function. The Brief Interview for Mental Status is not as thorough as the previous three scales, although it is part of the Minimum Data Set used to assess all residents in nursing homes in the United States.

Behavioral and psychological symptoms of major neurocognitive disorders (also called behavioral and psychological symptoms of dementia [BPSD]) are a heterogeneous group of symptoms that tend to cluster into five distinct groups—depression, apathy, psychotic symptoms (delusions and hallucinations), sleep disturbance, and agitation—and are distinct from the cognitive deficits that are the hallmarks of all major neurocognitive disorders. Agitation, defined as "inappropriate verbal, vocal, or motor activity that is not explained by needs or confusion per se," can be characterized as either aggressive or nonaggressive. Aggressive behaviors can occur with or without agitation and include fighting, throwing, grabbing, destroying furniture, cursing, and screaming, whereas

nonaggressive agitated behaviors include restlessness, pacing, wandering, hoarding, repetitive questioning, inappropriate disrobing, and verbal outbursts. Agitation is best understood as an expression of a resident's efforts to communicate unmet needs. The majority of individuals who have major neurocognitive disorder (including those who have advanced major neurocognitive disorder) can speak for themselves to a much higher degree than has been recognized to date. The psychiatrist should make all efforts to understand the resident's perspective and have the treatment plan be guided by that perspective. The psychiatrist may use the Agitation Subscale of the Neuropsychiatric Inventory nursing home version (NPI-NH), Cohen Mansfield Agitation Inventory (CMAI), or Pittsburgh Agitation Scale (PAS) to evaluate the severity of agitation and to document response to treatment.

Management of major neurocognitive disorders should begin with discussion with the resident and/or the surrogate decision maker regarding potential benefits of use of cholinesterase inhibitors and memantine (Namenda). Some more capable residents (e.g., residents who have minor neurocognitive disorder due to probable Alzheimer type and highly motivated residents who have mild major neurocognitive disorder) may benefit from and often prefer interventions to slow cognitive decline. For these residents, creating and implementing an individualized brain fitness program that includes regular exercise, Mediterranean diet, cognitive and social strategies, cholinesterase inhibitors, and use of memantine in various combinations is appropriate and recommended.

Table 57.6a–5.
Psychosocial/Environmental Interventions for Neurocognitive Disorders

Psychosocial Interventions Directed Toward Caregivers		
Type of Psychosocial Environmental Intervention	**Examples**	**Practical Suggestions**
Staff education	Education about dementia Education about Parkinson disease Education about common triggers for agitation Education about adverse psychiatric effects of commonly prescribed medications	Case-based education preferred. Recording the education and making it available on website for caregivers to review on their own time. Providing work credit for caregivers who complete the education.
Staff training	Training in approach to the management of behavioral and psychological problems in long-term care residents. Training in effective communication and appropriate documentation.	Hands-on training, especially of new staff and staff with minimal experience. Video recordings of training for staff to review on their own time.
Staff support and incentives	Informal support to staff members Formal support groups for staff	During visits, psychiatrist can provide direct and situation-specific verbal support to

	members Opportunity to take on leadership role in psychiatric aspects of long-term care	caregivers. A break room for staff members where they can "chill" (massage chairs, relaxing music, yoga videos and mats).

Psychosocial Environmental Interventions Directed Toward Residents

Type of Psychosocial Environmental Intervention	Examples	Comments/Resources
Environmental	Design of physical environment that accommodates cognitive impairment and promotes emotional well-being Robust activity programming Structured routines Therapeutic gardens	www.healthdesign.org Consultation, staff education, and periodic supervision of the programs by recreational therapist Activity programs run by activity therapist Cognitive stimulation therapy (www.cstdementia.com) www.timeslips.org www.thegreenhouseproject.org
Music-based strategies	Individualized music Group music	Consultation, staff education, and periodic supervision of the programs by music therapists Availability of piano for the residents to play, music CDs, iPod, mp3 players, radio
Physical activity and exercise	Walking programs Chair yoga Tai Chi Dance exercise programs	Guidance, staff education, and periodic supervision of the programs by physical therapist Staff encouraged to make physical activity a normal part of resident's routine
Aromatherapy combined with massage therapy	Hand or foot massage with a fragrant lotion	Consultation, staff education, and periodic supervision of aromatherapy programs by certified aromatherapist Availability of common therapeutic lotions (e.g., lavender and citrus lotions) for staff to use
Animal-assisted therapy	Dogs and cats visiting	Eden Alternative programs (www.edenalt.org)
Emotional support	Support groups	Stroke support group Early-stage dementia support group
Counseling	Problem-solving therapy Reminiscence therapy Interpersonal therapy Cognitive-behavioral therapy	Facility administration encouraging licensed psychotherapist/counselor to provide psychological therapies to cognitively capable residents Internet-based self-psychotherapy for cognitively capable residents
Spiritual	Maintaining religious rituals	"Postcards to God" program

Psychosocial environmental interventions (also called nonpharmacologic interventions) are recommended as the first line of treatment of all behavioral and psychological symptoms related to major neurocognitive disorders because they are effective and the risks are minor. (Table 57.6a–5lists psychosocial environmental interventions for

neurocognitive disorder.)

The psychiatrist should institute psychopharmacologic interventions to treat agitation related to neurocognitive disorder only after thoroughly evaluating and treating all potentially treatable medical conditions and other modifiable factors and psychosocial environmental interventions have not been adequate in addressing them. Discussions should make it clear that any psychopharmacologic intervention for agitation in the context of neurocognitive disorder is off label (i.e., is not approved by the U.S. Food and Drug Administration for its treatment).

Antipsychotics are the most commonly prescribed psychopharmacologic agents for the treatment of agitation and aggression among residents who have major neurocognitive disorder, and the prevalence of use in the long-term care population is high (20 to 25 percent). There is a strong initiative from the Center for Medicare and Medicaid Services (CMS) in the United States to reduce the use of antipsychotics in the long-term care population. In addition, the United States Congress has passed legislation mandating reduction of antipsychotic use in nursing homes. This is in response to strong evidence that antipsychotics are often used inappropriately in the long-term care population (with the majority of its use being by residents who have major neurocognitive disorder) and the use of antipsychotics by individuals who have major neurocognitive disorder carries high risks of morbidity (e.g., cerebrovascular event, pneumonia, deep vein thrombosis, hip/femur fracture) and increased mortality. (Table 57.6a–6shows a stepped care approach to appropriate use of antipsychotic medications for major neurocognitive disorder.) The psychiatrist may consider prescribing short-term use of low-dose risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Seroquel), and aripiprazole (Abilify) to treat severe agitation, aggression, and psychosis with dementia in certain clinical situations (e.g., clear risk of harm to the resident or others and psychosocial environmental interventions have not been effective). Atypical antipsychotics are preferred over conventional antipsychotics (e.g., haloperidol [Haldol]), which are associated with higher risks. It is important that the psychiatrists explain to the surrogate decision maker(s) that severe psychotic symptoms and/or persistent aggression are associated with considerable emotional distress, increased mortality, falls, and hospitalization; hence, in certain situations, the use of antipsychotics may be justified. To minimize risks, the authors recommend prescribing the lowest possible dose of antipsychotics for the shortest possible time and regular monitoring of metabolic parameters when appropriate and for extrapyramidal symptoms.

Table 57.6a–6.
Approach to Appropriate Use of Antipsychotic Medications to Manage

Severe Behavioral and Psychological Symptoms of Major Neurocognitive Disorder

Step 1: Presence of at least one of the following:

- ► Persistent severe agitation and or physically aggressive behavior

or

- ► Psychotic symptom causing severe emotional distress

Step 2: Assess safety

- ► The resident poses an imminent danger to self and/or others (address safety first using following options individually or in combination: one-to-one staff monitoring; use of oral or intramuscular antipsychotic medication; transfer to Emergency Department. When safety is ensured, proceed to step 3)
- ► The resident does not pose an imminent danger to self and/or others (proceed to step 3)

Step 3: Treatment team completes a thorough evaluation to look for treatable or reversible causes of target problems

- ► Primary care clinician or psychiatric consultant completes history and examination (including pertinent neurologic and detailed mental status examination)
- ► Complete team discussion to identify treatable or reversible causes
- ► Order laboratory and other tests as necessary and results reviewed or testing not required

Step 4: Treat agitation and/or emotional distress with an individualized treatment plan and without psychopharmacologic intervention

- ► Correct identified causes of target problems
- ► Team discussion identifies and institutes individualized psychosocial environmental interventions

Step 5: Assess response to treatment

- ► Adequate improvement and/or resolution of target problems
- ► Lack of adequate response to treatment (proceed to step 6)

Step 6: Attempt trial of pharmacologic interventions other than antipsychotics

- ► Attempt trial of acetaminophen if there are no contraindications
- ► Attempt trial of citalopram (up to 20 mg/day) or escitalopram if there are no contraindications
- ► Attempt trial of low-dose trazodone if there are no contraindications
- ► Attempt trial of combination of above medications if there are no contraindications

Step 7: Assess response to treatment

- ► Adequate improvement and/or resolution of target problem(s)
- ► Lack of adequate response to treatment (proceed to step 8)

Step 8: Make decision to prescribe antipsychotic medications

- ► Obtain consent from surrogate decision maker for use of antipsychotics after adequately explaining risks and potential benefits of their use

Step 9: Attempt trial of antipsychotic medications

- ► Attempt trial with one of three atypical antipsychotics: risperidone, olanzapine, aripiprazole

Step 10: Assess response to treatment

- ► Adequate improvement and/or resolution of target problems without significant adverse effects
- ► Adequate improvement and/or resolution of target problems but associated with significant adverse effects (proceed to step 11)
- ► Lack of adequate response to treatment (proceed to step 11)

Step 11: Attempt trial of another of the three antipsychotic medications mentioned above

- ► Adequate improvement and/or resolution of target problems (proceed to step 13)
- ► Lack of adequate response to treatment (proceed to step 12)

Step 12: Team discussion (including with surrogate decision maker) regarding further care

► Decide to transfer resident to local Emergency Department for acute inpatient psychiatric treatment or to transfer resident directly to an acute inpatient psychiatric unit in a hospital (preferably a geropsychiatric unit)

► If in keeping with the residents' values and wishes, decide to switch to palliative care (with more liberal use of antipsychotics and, if necessary, short-acting benzodiazepines such as lorazepam to relieve the burden of intractable suffering, even at the cost of excessive sedation) as the resident is in severe to terminal stages of dementia and burdens of transfer to Emergency Department and hospitalization are high and potential benefits low.

Step 13: Attempt to reduce and discontinue antipsychotics after 3–6 months of stabilization

► Attempt to reduce and discontinue antipsychotic medication

Step 14: Assess response to dose reduction and discontinuation

► Lack of relapse of target symptoms

► Relapse of target symptoms (proceed to step 15)

Step 15: Reinstitute antipsychotics and attempt step 13 after 3–6 months of stabilization

Note: The psychiatrist may need to skip steps 5 and 6 if the resident who has major neurocognitive disorder has behavioral and psychological symptoms that are posing immediate danger to self and or others. In behavioral emergencies (e.g., violent behavior), immediate use of one or two doses of antipsychotic medication may be necessary to stabilize the emergency situation before stepped care approach is initiated. If, during step 3, the team concludes that the resident qualifies for end-of-life care, proceed to palliative care directly. Step 12 can be instituted at any point if there is radical change in the resident's clinical status. Collaboration with a pharmacist is encouraged at every step and in creating a facility-wide initiative to reduce inappropriate use of antipsychotics.

Among mood stabilizers, there is some support for the use of carbamazepine (Tegretol) to treat physical aggression in major neurocognitive disorder, but its use carries considerable risks, including falls, drug–drug interaction, and delirium. Valproate has been the most studied of all anticonvulsants for the treatment of behavioral and psychological symptoms of major neurocognitive disorder, but the results to date have been inconsistent or negative and its use carries considerable risks (especially falls and sedation). Hence, the authors do not recommend the use of valproate to treat behavioral and psychological symptoms of neurocognitive disorder.

SSRIs (especially citalopram [Celexa] and escitalopram [Lexapro]) and trazodone (Desyrel) are an option for the treatment of persistent agitation and aggression not responding to psychosocial environmental interventions. The psychiatrist may also consider prescribing antidepressants to treat severe emotional lability. Antidepressants, although safer than antipsychotics, carry considerable risks, including the risk of increased agitation, nausea, insomnia, and falls. The psychiatrist may consider prescribing a trial of a combination of dextromethorphan and quinidine (Nuedexta) to treat pseudobulbar affect as well as for moderate to severe agitation (off label) in the context of major neurocognitive disorder or stroke that is not responding to psychosocial environmental interventions. The psychiatrist may consider a judicious trial of

methylphenidate (Ritalin) for residents who have major neurocognitive disorder or traumatic brain injury and are experiencing severe apathy when psychosocial environmental interventions have not been effective and there are no cardiac contraindications. The use of benzodiazepines carries a high risk of serious adverse effects (especially delirium, falls, and injury) and thus should be avoided. Short-term use of low-dose short-acting benzodiazepines such as (lorazepam [Ativan] or oxazepam [Serax]) is an option for the treatment of prominent anxiety or infrequent severe agitation.

Mr. C is an 80-year-old male, married for 55 years, a retired school teacher and father of three children. He has had major neurocognitive disorder, probable Alzheimer type, for the last 8 years. Mr. C had been experiencing severe agitation and aggressive behaviors over the last several months. His wife reported that Mr. C would be "Dr. Jekyll and Mr. Hyde," at times pleasant and nice but then suddenly would "have a look of hatred" toward her and accuse her of infidelity. Mr. C had been physically aggressive toward his wife, which prompted admission to an assisted living home. At the facility, Mr. C attempted to choke a female resident, twisted the arm of a female staff member, and made several threats that he would "destroy" the place. Mr. C had also voiced paranoid thoughts that "they" (meaning the staff and residents) were trying to steal his money and belongings. Mr. C's primary care physician had done a thorough workup but found no reversible cause, so had prescribed escitalopram (10 mg daily), donepezil (Aricept), and as-needed alprazolam (Xanax). The staff had attempted various individualized psychosocial environmental interventions (e.g., take him for walks, play his favorite music in his room) but the aggressive behaviors persisted. At this point, psychiatric consultation was requested to facilitate transfer to a local acute inpatient geropsychiatric unit. After completing a thorough assessment and review of records, the psychiatrist encouraged the facility to give a trial of antipsychotics before transferring Mr. C to an acute inpatient psychiatric unit. The facility agreed. The psychiatrist recommended initiation of olanzapine 5 mg at bedtime, discontinued alprazolam, started scheduled acetaminophen as there were some reports from the staff that Mr. C occasionally complained of lower back pain, and added as needed orally dissolvable 5 mg olanzapine up to twice a day. Over the next 2 weeks, Mr. C's aggressive episodes improved modestly and the staff were able to engage him in more individualized psychosocial environmental interventions. After 4 weeks, his wife and the staff felt that Mr. C was much better, although he still had episodes of anger.

Clinical pearl: Judicious use of atypical antipsychotics may help reduce aggressive behaviors by residents who have major neurocognitive disorder and prevent transfer to the emergency department.

DEPRESSIVE DISORDERS

The prevalence of depressive disorders is high in long-term care residents. Hence, the authors recommend assessing all residents for depression within 1 month of admission to a long-term care facility and every 6 months thereafter. Residents who have a history of depression, psychiatric hospitalization, and/or antidepressant treatment have shown the strongest association with new onset of depression after admission to a long-term care facility, and thus would benefit from closer monitoring. The period of adjustment to living in long-term care can range from a few weeks to 12 months as residents cope with multiple losses, including independence,

home, privacy, possessions, and control over personal schedule. Additional challenges to living in long-term care include interaction with peers who have severe major neurocognitive disorder. High staff turnover and lack of robust activity programming may also contribute to depression.

Standardized scales recommended for assessing depression in long-term care residents include the Geriatric Depression Scale, used for residents who have mild cognitive impairment or mild dementia, and the Cornell Scale for Depression in Dementia, used for residents who have moderate to severe dementia. The Patient Health Questionnaire-9 or the Saint Louis University "AM SAD" (appetite, mood, sleep, activity, thoughts of death) may be used in place of the Geriatric Depression Scale.

Psychosocial and environmental strategies are appropriate and necessary and may be sufficient for the treatment of mild to moderate depressive disorder. Such interventions include psychotherapy, physical exercise, individualized pleasant activity schedule, bright light therapy, increasing social support, and complementary and alternative treatments such as yoga, Tai Chi, meditation, massage therapy, and aromatherapy. Psychotherapy with the long-term care population primarily involves supportive psychotherapy (including reminiscence therapy) with problem-solving strategies (especially for residents who have executive dysfunction) and/or interpersonal psychotherapy components (especially for residents coping with grief or family conflict). With more capable residents, cognitive-behavior therapy may also be appropriate. Malnutrition, dehydration, constipation, and pain are common comorbid conditions among residents who have depression and need to be optimally treated for successful outcomes.

Although rigorous studies have not consistently found antidepressants to be effective for the treatment of depressive disorders among long-term care residents, most experts and expert consensus guidelines support the use of antidepressants to treat moderate to severe depressive symptoms. The starting doses of antidepressants need to be low, but final effective doses may need to be comparable to those used by younger adults. One of the SSRIs, SNRIs, or mirtazapine is the preferred first-line treatment for depression if the psychiatrist opts for pharmacotherapy. Bupropion (Wellbutrin) and nortriptyline (Pamelor) are usually the second line of treatment. Nortriptyline may be preferred over other antidepressants to treat depression for residents who have Parkinson disease (PD). The psychiatrist should also consider prescribing pramipexole (Mirapex) to treat depression for residents who have PD; it may even be preferred over nortriptyline and other antidepressants, as it also improves motor symptoms of PD. The psychiatrist may consider prescribing short-term use of low-dose methylphenidate to treat depression with severe apathy to speed up the response to antidepressant, especially in the context of rehabilitation if the resident is not participating in physical therapy. The

psychiatrist should avoid prescribing monoamine oxidase inhibitors as well as antidepressants with high anticholinergic activity, such as amitriptyline (Elavil), imipramine (Tofranil), and doxepin (Sinequan), because of the high risk–benefit ratio. For residents who have psychotic depression, adding an atypical antipsychotic medication is recommended. For residents who have inadequate response to an antidepressant, the psychiatrist should consider adding aripiprazole or quetiapine or brexpiprazole as an adjuvant to treat moderate to severe major depressive disorder.

Mr. L is an 88-year-old widowed male, a retired construction worker living in a nursing home. He has a long history of alcohol addiction and alcoholic liver disease. Psychiatric consultation was made, as the staff felt Mr. L was depressed. The staff reported that for the last several weeks, Mr. L had been refusing to get out of bed, was not eating well, lost 15 lb, did not enjoy visits from his grandchildren, and had voiced multiple somatic complaints, including dizziness. During evaluation, the psychiatrist found out that Mr. L had had multiple recent losses: two of his children had died of heart disease in the last year, his pet dog had died 6 months ago (just before he moved into the nursing home), and 3 months ago his house was sold to pay for the nursing home. Mr. L became tearful during the interview. Workup for reversible conditions detected mild vitamin B_{12} deficiency and mild dehydration. There was no any evidence of major neurocognitive disorder, and Mr. L was open to recommendations from the psychiatrist, including antidepressants. The psychiatrist recommended vitamin B_{12} supplementation, improved intake of daily fluids, and weekly individual psychotherapy with a psychologist who visits the facility; the psychiatrist did not recommend antidepressants. Over the next 6 weeks, Mr. L showed significant improvement. He started to come out of his room, participated in activities, improved his food intake, gained 2 lb, and would look forward to visits from his grandchildren.

Clinical pearl: The psychiatrist should routinely consider recommending psychotherapy to treat depression for cognitively capable residents, and long-term care facilities should arrange with local psychotherapists to visit the facility and provide psychotherapeutic services.

PSYCHOTIC DISORDERS

Psychotic symptoms in the context of major neurocognitive disorder are the most common psychotic disorders in the long-term care population, followed by psychotic symptoms due to medication and due to general medical conditions (e.g., stroke, traumatic brain injury). Dopaminergic agents used to treat PD and corticosteroids are the two most common categories of medication that cause psychotic symptoms. Psychotic symptoms in the context of affective disorder (major depression as well as bipolar disorders), schizophrenia, schizoaffective disorder, and delusional disorder are becoming increasingly prevalent due to the aging of adults who have chronic mental illness. Psychotic symptoms may also be the initial or most disturbing manifestation of delirium. Psychotic symptoms are among the most serious complications of major neurocognitive disorder and are associated with a high degree of emotional distress and

accelerated cognitive decline. The psychiatrist should consider new onset of psychotic symptoms among long-term care residents as equivalent to delirium, with a thorough workup, including, as appropriate, neuroimaging.

Psychotic symptoms associated with major neurocognitive disorder are typically mild to moderate in severity and are best managed with psychosocial/environmental interventions. Antipsychotics have not been shown to reduce psychotic symptoms related to neurocognitive disorder, and the authors do not recommend their use unless psychotic symptoms are accompanied by severe aggression and or agitation. Management of psychotic symptoms in the context of PD is challenging, as the majority of residents who have PD have PD-related major neurocognitive disorder. Furthermore, only clozapine has been found to be effective for the treatment of psychotic symptoms in the context of PD, and the use of clozapine carries even higher morbidity and mortality risk for long-term care residents who have PD than for community-dwelling individuals who have PD due to frailty and the presence of significant cognitive impairment. The first strategy is to reduce the dosage of antiparkinsonian agents (such as Levodopa) and use psychosocial environmental interventions to manage psychotic symptoms. If psychotic symptoms are causing severe distress and agitation, the psychiatrist may consider prescribing low-dose quetiapine or aripiprazole. A new drug, pimavanserin is the only drug approved by the Food and Drug Administration for the treatment of psychotic symptoms for individuals who have PD. For residents who have neurocognitive disorder due to Lewy body disease and are experiencing psychotic symptoms, a trial of rivastigmine (Exelon) may help both cognitive and psychotic symptoms to a modest extent.

Ms. T is a 71-year-old divorced female, a homemaker and mother of one daughter and one son, who has a long history of schizophrenia. She was admitted to a nursing home after a stroke. Psychiatric consultation was requested to adjust Ms. T's antipsychotic medication, as she was refusing to participate in physical therapy and making paranoid statements. After completing a thorough evaluation, including review of records from previous psychiatric hospitalization, the psychiatrist confirmed the diagnosis of schizophrenia. Ms. T also had minor neurocognitive disorder due to cerebrovascular disease. The psychiatrist noticed that many staff members felt that Ms. T should be transferred to another facility, as they were not equipped to manage chronic mental illness. Ms. T's primary care clinician was also not comfortable managing chronic mental illness by adjusting antipsychotics. Ms. T was taking quetiapine 200 mg daily at bedtime and risperidone 0.5 mg once daily. The psychiatrist increased risperidone to 0.5 mg twice daily for the first week and then 1 mg twice daily and decreased and discontinued quetiapine over 2 weeks. Ms. T showed significant improvement in psychotic symptoms over the next 3 weeks and began to participate in physical therapy.

Clinical pearl: Individuals who have chronic mental illness such as schizophrenia or bipolar disorder are living longer, and the prevalence of these illnesses in long-term care facilities is expected to increase. The majority of facilities are not prepared to meet their needs. Psychiatric

consultants can play a key role in improving their acceptance by facility staff and help improve the staff's understanding of these illnesses and knowledge about evidence-based strategies to treat them.

DISORDERS OF THE SLEEP–WAKE CYCLE

Insomnia, excessive daytime sleepiness, and reversal of the night–day cycle are common among long-term care residents. Medications are the most common cause of disorders of the sleep–wake cycle. Restless leg syndrome (RLS) and REM sleep behavior disorder (RBD) are prevalent in the long-term care population, are often underdiagnosed, and are amenable to treatment. The primary treatment for insomnia should be psychosocial environmental interventions (e.g., reducing daytime napping, increasing physical activity and exposure to sunlight or bright light, following a regular sleep time, reducing exposure to noise and light at night). The psychiatrist may consider prescribing low-dose trazodone to treat persistent insomnia not responding to psychosocial environmental interventions. The use of hypnotics such as zolpidem (Ambien), zaleplon (Sonata), and eszopiclone (Lunesta) should be restricted to low doses for short periods of time (days to 2 weeks) (e.g., for a new resident adjusting to living in a long-term care facility and experiencing significant insomnia) due to a high risk–benefit ratio and regulatory concerns. Ramelteon (Rozerem) and surovexant (Belsomra) may also be considered for treatment of insomnia. The psychiatrist may consider prescribing low-dose clonazepam (Klonopin) and melatonin to treat RBD and may consider prescribing dopamine agonists and gabapentin enacarbil (Horizant) to treat RLS.

POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder (PTSD) is increasingly seen in the long-term care population, not only among veterans but also among civilians who have a past history of abuse or motor vehicular accident. Long-term care staff needs education to understand psychological and behavioral manifestations of past trauma and training in care practices to accommodate trauma-related challenges residents typically face. For example, male staff members should not be involved in caring for a female resident who has a history of sexual or physical abuse by a male. Physical restraints are not recommended in general but may have additional negative psychological effects on residents who have a history of abuse. The treatment of PTSD typically involves antidepressants (especially SSRIs) and, when feasible, individual psychotherapy. Short-term or as-needed use of short-acting benzodiazepines may be necessary for residents who have PTSD and are experiencing acute anxiety attacks. Low-dose prazosin (Minipress) may be appropriate for the treatment of nightmares in the context of PTSD, although long-term care residents are at higher risk than

the general population of adverse effects of prazosin, such as hypotensive effects, orthostasis, and falls.

ANXIETY DISORDERS

Generalized anxiety disorder (GAD), panic disorder, and phobias, especially bathing phobia, are prevalent in the long-term care population. Bathing phobia is also common among residents who have major neurocognitive disorder and is best managed by staff training in creative and alternative ways to maintain hygiene using strategies such as towel bathing instead of using a shower. The authors recommend the DVD "Bathing without a Battle," created by the University of North Carolina, for training all staff members in person-centered strategies to bathe residents who have advanced major neurocognitive disorder. Treatment of GAD and panic disorder typically involves antidepressants (especially SSRIs) and, when feasible, individual psychotherapy.

PSYCHIATRIC ASPECTS OF PALLIATIVE CARE

More than 25 percent of older adults currently die in a long-term care facility, and the number is expected to rise to more than 40 percent by 2030. The majority of residents have at least one life-threatening illness, and at least 50 percent of these have a life expectancy of 2 years or less. Thus, it is imperative that all these residents be offered palliative care as soon as possible after admission. Psychiatric consultants can help the staff appreciate that most residents and their family members find the goal of increasing comfort much more satisfying and reasonable than aggressive life-prolonging care. The psychiatrist can play a key role in clarifying a resident's advance care directives, especially in the context of advanced major neurocognitive disorder, where it may be difficult to predict life expectancy but the burdens of traditional medical care may still be high.

Delirium and depression are two psychiatric syndromes residents frequently experience at the end of life. Psychiatric consultants may be the first health care professional to identify the resident as in the process of dying and help initiate palliative and hospice care. During end-of-life care, it is appropriate and often necessary to prescribe benzodiazepines to manage anxiety and insomnia, morphine to manage pain and dyspnea, and atypical antipsychotics such as risperidone and olanzapine to manage psychotic symptoms associated with agitation or aggressive behavior. The use of methylphenidate to treat depression during end-of-life care has been recommended for its rapid effect but among long-term care residents, who often have advanced major neurocognitive disorder, methylphenidate may cause delirium or agitation and thus the psychiatrist should closely monitor its use. Palliative sedation may be necessary to relieve the intractable suffering some residents experience during the end stages of life.

Another common reason for referral to a psychiatrist is for evaluating

decision-making capacity. Some common clinical situations for such a referral are: a resident who has end-stage renal disease and wants to discontinue dialysis; a resident who has depression and is requesting a Do Not Resuscitate status.

57.6b Forensic Aspects

DAVID NAIMARK, M.D., KEITH A. DAVIDSON, J.D., AND ANSAR M. HAROUN, M.D.

The American Board of Psychiatry and Neurology has recognized both geriatric psychiatry and forensic psychiatry as subspecialties, each meriting their own fellowship training programs and their own subspecialty board examination. These two fields have an overlap, and this field of "forensic geropsychiatry" is growing in its knowledge base and literature. Unlike clinical geropsychiatry, which evolves slowly based on the natural progression of knowledge in the basic psychiatric sciences, forensic geropsychiatry may grow rapidly with abrupt changes, based on any new pronouncement by a court of law. Whereas geriatric psychiatry is generally defined by a demographic characteristic (that of age), forensic psychiatry is defined by its ethical duty to tell the truth. This is in contrast to the duty of clinical psychiatry, which is to be helpful to the patient. Much of forensic work within the field of geriatric psychiatry requires attention to this tension between these two competing duties, which may or may not conflict.

CRIMINAL ASPECTS OF FORENSIC GEROPSYCHIATRY

Epidemiologically, there is a relationship between criminal behavior and age, with an overrepresentation of youthful offenders and an underrepresentation of elderly offenders. In absolute terms, criminal behavior remains a primary problem of the young, but the relative rate of increase in criminality is more pronounced in the elderly. This trend may partially be accounted for by the population increase in the total number of elderly, resulting in a corresponding increase in bad behavior. There are, however, suggestions that there may be an independent increase in criminal behaviors in the elderly for other reasons. Possible explanations include the improved efficiency of law enforcement to detect crimes or new patterns of crimes (such as Internet-based crimes) that may be easier for physically disabled elders to commit. It is also useful to look at the relationship of age to subtypes of criminal behavior. One typology of criminal behavior contrasts crimes that are affective (based on emotion, impulsive) with those that are predatory (coldly calculated, premeditated). While youthful offenders are often hotheaded and at high risk for the former, the elderly are more mature, are less hotheaded, and may be at greater risk for the latter.

The expertise of a geriatric psychiatrist may be needed at several stages of a criminal proceeding. At the time of the arrest, when elder defendants are read legal rights, do they understand those rights? If not, any statements made in response to police questioning may not be admissible in a court proceeding. Older individuals (or any other persons who may be

confused, have mild cognitive impairment, or be demented) are at risk for not understanding the warnings that the arresting officers are required to state and the understanding (or lack of understanding) can change the outcome of a legal case by allowing (or disallowing) the statements or confessions. In real life, it may be difficult for a psychiatrist to separate such cases into the two boxes (did or did not understand) as many elders are in a gray zone of partial understanding. As a result, what may be relevant was whether the elder spoke to the police voluntarily or through coercion. While it may be rare for the police to coerce using physical pain, they may be tempted to coerce using psychological pressures to which the elderly may be especially susceptible (see the following discussion of undue influence). A practical problem that may arise from such possible coercion is that the elder may "confess." If the confession is voluntary, it is of course admissible, but if coerced, it may be challenged. Analysis of the voluntariness of such a confession requires knowledge not only of the behavior of those who elicited the confession (usually the police), but also of the unique strengths and frailties of the confessor, both psychological and physical.

Competency to Stand Trial

When a criminal trial starts, the court must be satisfied that the defendant is not only physically present, but also mentally present (i.e., mentally competent to stand trial). The psychiatrist may be asked to give an opinion around the cognitive status of the elder (whether there is any deficit in *understanding* the nature of the criminal proceedings), the social capacities of the elder (ability to *assist* an attorney), and the rationality of the elder (able to understand and assist in a *rational* manner). Further, the psychiatrist must opine whether any deficit is from a mental disease (making the defendant mentally incompetent) or from some other cause. An elder who cannot assist because of a hearing loss is "audiologically" incompetent, but not mentally incompetent. Problems may arise from elderly defendants who are forgetful. If this represents a mental disorder, such as a dementia of the Alzheimer type, then the defendant may postpone or even avoid trial (often a desired outcome), but if the forgetfulness represents age-related cognitive decline, then it may not qualify for a finding of mental incompetence.

JO had a clear psychotic disorder at the time of the trial. He had numerous delusions and hallucinations. Most of these concerned the fidelity of his spouse, though not all. He seemed to have a basic understanding of the trial process, with the exception of two unusual beliefs: While he could tell the evaluator that the judge oversees the trial and tells the jury the law, and the jury is the body that decides, after hearing the evidence, whether he is guilty or innocent, he also had the belief that the judge was an "interloper" and the jury members were "four-footed animals."

Is this defendant incompetent to stand trial? JO's competency to stand trial is likely to be controversial. Is his understanding of the functions of judge and jury adequate? Does it matter

if his conception of the judge and jury is irrational if he knows their function? On the other hand, perhaps he thinks their status as interloper and animals will make them perform their jobs in a severely substandard way—a way that will deprive him of due process.

Involuntary Medication to Restore Competence

If the court finds that a defendant is incompetent to stand trial, the court may seek further opinion from the psychiatrist as to whether the court may or may not order restoration of competency through involuntary medications. Such an analysis in a geriatric case may differ from a nongeriatric case, since the balancing of the defendant's interests (to be free of side effects of psychotropic medication) and the State's interests (to restore the defendant to competency for trial) may be altered. Geriatric patients may have different responses (good and bad) to medications, which must be separately analyzed in each case. In the case of the elder who may have many medical conditions complicating the side-effect profile of the intended psychotropic medication, a different conclusion may be reached than in the case of a nonelder, making it more likely that the court may reject the application for involuntary medication, thus creating a class of "permanently incompetent" persons. Up to the present time, such cases of the permanently incompetent have been rare, since most cases of trial incompetence arise from psychotic-like disorders, which mostly do respond to antipsychotic medications.

At some point in the future, as more elderly enter the criminal justice system and as more elderly are found to be incompetent to stand trial, it is likely that there will be more cases of trial incompetence from cognitive disorders (such as the dementias) rather than from the psychoses. Since some cognitive disorders are reversible and some are not, geriatric psychiatrists will increasingly be asked to separate these two subpopulations. Ultimately, there will be a large group of elderly persons who are permanently incompetent to stand trial. Permanent incompetence is potentially a problem because the Supreme Court has said that one cannot hold a person as incompetent to stand trial for more than the reasonable period of time necessary to determine whether there is a substantial probability that he or she will attain that capacity in the foreseeable future—and these individuals will not. On the other hand, such persons can be held under ordinary civil commitment laws, which would allow most of them to be committed: they have a mental illness that makes them dangerous. Still, the policy problem remains: such persons cannot be tried (since they are incompetent to stand trial), but they cannot be released (since they may repeat criminal behavior), and there is no point in confining them for treatment (since they are incurable).

Mental Health Defenses

Most criminal defendants are immediately or eventually found competent

to stand trial and during the trial may assert any one of several mental health defenses, including psychiatric excuses and/or justifications. In the movies (and hence, in the popular imagination), a common mental excuse is that of legal insanity. This requires a confession of behavioral guilt ("I did it") but an absence of moral guilt, based on some mental deficit (cognitive or volitional). Elderly defendants may specifically be at greater risk for cognitive deficits. The geriatric psychiatrist should clarify the legal standard in the jurisdiction of practice, especially noting what types of cognitive deficits represent an excusing condition. Cognitive deficits around memory ("I don't remember what I did"), while common in the elderly, are unlikely to excuse, whereas cognitive deficits in the areas of understanding are more likely to excuse. Further analysis may be required as to whether the court wants an opinion on the elder's capacity to know, to understand, or to appreciate. An elder who is having some cognitive decline is likely to first lose the capacity to appreciate, then to understand, while the ability to merely know is likely to be the last to be lost.

Restoration of Sanity

If an elder is indeed found to be legally insane, the state must make efforts to restore sanity. In the case of youthful offenders, most of the not guilty by reason of insanity acquittals are likely to be based on a severe mental illness that is treatable, usually of the psychotic type. But in the case of the elder, the acquittal may be based on a mental disorder not of the psychotic type (with a likely good response to medication), but rather of a cognitive type (which may or may not respond to medication). If the cognitive decline is medically reversible, the court should be so informed, and will order the appropriate treatment. If there is an irreversible dementia, however, this will create a problem for the court, since no punishment may be imposed (the defendant is "not guilty"). Although the defendant may be confined for treatment, he or she may not be confined in the absence of treatment. In many court cases, however, the right to treatment is extremely minimal—for example, enough to help keep people out of restraints. The fact that certain people are effectively untreatable does not mean that they cannot be confined if they are dangerous or gravely disabled. Notwithstanding this, a skillful defense attorney may argue that the elder must be treated or released, thus creating a dilemma for the court. The case of an elder being acquitted after a finding of not guilty by reason of insanity is uncommon; more common is a verdict of guilty (or not guilty). In such cases, the court must decide on a sentence.

Sentencing

In sentencing, judges are guided by many factors, including some age-related factors like the epidemiological risk of future harm (lower in the

elderly), the degree of culpability based on gullibility (the elderly may be more gullible, and hence less blameworthy), the likelihood of physical violence (lower in the elderly), and the likelihood of good compliance with medication to achieve remission of mental illness (which may be lower in medically impaired subjects, whose medical status may make tolerating psychotropic medications more difficult). Such objective factors should be noted in a presentencing report for a judge. Subjective factors (whether the elder did or did not inspire pity in the examining doctor) should ideally not be given weight, but if the doctor is temperamentally compassionate and is aware of feelings of pity that may introduce a bias, the doctor should either avoid giving an opinion (which could be invalid) or should give the opinion but clarify why the feelings may not have produced a valid opinion.

The geropsychiatrist should be aware of the possible purposes of sentencing, which can be punitive, nonpunitive, or a combination of the two. If the purpose of the sentence is punitive (to punish), it is uncommon that a court seek a psychiatric opinion, although a skillful defense attorney may argue that the very punishment that may be appropriate for a youthful offender may be cruel or unusual for an elder, who may have a reduced capacity to tolerate discomfort. If the court then moves to a less punitive sentence (perhaps some combination of restitution, incapacitation, or rehabilitation), the geropsychiatrist can offer an opinion as to the merits of any of these. Philosophical problems may arise from sentences that are "rehabilitative," since it may be argued that these are doomed to fail (since the elderly criminal may be too old to reform), or that even if rehabilitation is possible, it fails the test of cost–benefit analysis (the costs of rehabilitation perhaps should not be incurred in late life, when there will be only a short time to reap the benefits).

CIVIL ASPECTS OF FORENSIC GEROPSYCHIATRY

Civil matters, involving a dispute between parties, constitute the majority of the cases for which a forensic geropsychiatrist may be retained. There are two broad legal claims that require the assessment of a subject's mental state: (1) legal capacity, also known as decisional capacity to do a certain act (such as make a contract, create a will, give informed medical consent, or appoint an agent), and (2) undue influence, also known as coercion. Civil commitment issues, substituted decision making (i.e., living wills, advanced directives, and durable powers of attorney), elder abuse, and nursing home malpractice are additional areas for possible geropsychiatric involvement.

Decisional competence is a legal concept that concerns the ability of an individual to comprehend and manipulate the relevant information for a decision. While the doctor analyzes the decisional capacity (a dimensional construct) and forms a penultimate medical opinion, the trier of fact forms a legal judgment about competence (a binary construct), which is the

ultimate issue.

Undue influence is a legal concept where a person's free will is overcome by the excessive persuasion of another, also commonly understood as coercion. While there are a number of factors to establish a legal claim for undue influence, the geropsychiatric involvement primarily concerns determining whether a person is susceptible to undue influence.

Informed Consent

In settings of clinical work and research, informed consent is one of the cornerstones of ethical practice. The informed consent process ideally epitomizes professional ideals and protects individual rights. Often, unfortunately, the informed consent discussion morphs into a procedure done to the patient or subject (i.e., "consenting" the individual). This implies that the elder is a passive recipient of information who then acquiesces to the decision. Optimally, however, the informed consent process can provide a meaningful chance for a physician and elder to participate in a personalized discussion of risks/benefits and alternatives associated with a decision in question. In this process, the patient becomes a partner with the physician in the management of the situation, and hopefully thereby engages in authentic decision making. Common disputes leading to forensic evaluations in this area would be analysis of capacity to (1) consent to medical treatment, (2) consent to be a research subject, and (3) decide to die. In life outside of medicine, issues of decision making present themselves constantly. Unlike in the medical world, however, the rules around the need for the transactor to obtain informed consent from the transactee become markedly murkier (i.e., does a Wal-Mart employee need to obtain informed consent before he allows an elder to purchase socks?). Common disputes leading to geriatric forensic evaluations in this area would be analysis of capacity to (1) make financial decisions/contracts, (2) make a will (testamentary capacity), and (3) drive.

Over the last half-century, multiple state and federal court decisions have greatly influenced the analysis of the concept of informed consent. What the doctor must disclose is measured by two standards. The older rule, and one contained in some statutes, is that the doctor must disclose what a reasonable doctor would disclose. The newer rule is the "reasonable patient" standard: The doctor must disclose all material information that he or she could reasonably expect a patient would want to consider in determining whether to undergo the procedure. Informed consent requires not only that the patient is informed, but also that he or she have the capacity to decide and that his or her decision should be voluntary. The latter was called into question in one case: An involuntarily confined prisoner was deemed unable to consent to experimental psychosurgery because his choice would be coerced as a matter of law.

The first element of informed consent refers to "informed" and asks

whether the information from the database (regarding the specific decision in question) was transmitted to the decision maker. It does not assess the state of mind of the transactee and, as such, is a responsibility of the transactor. With inadequate or absent information, the consent would be uninformed, not informed.

The second element of informed consent addresses the "sent" (from the same root as *science*, as in knowledge) and requires the elder to have the mental capacity to understand and appreciate the information provided. The best information in the universe is useless to the elder whose cognitive plumbing is clogged to the degree that it simply can't pass through the pipes of mental functioning. It is here that the forensic evaluator will perform the analysis of decision-making capacity through a mental functioning examination. Mental status deficits, in and of themselves, do not lead to mental incapacity to make a decision. It is only when the observed defect prevents the information from penetrating into the awareness of the subject that the defect becomes relevant. Put another way, mental state defects are a "threshold test"—some decisions are complicated and require a maximally functional mental state, whereas others are simple and probably require no more than a marginally intact mental state.

The third, and perhaps most misunderstood, element of informed consent concerns the "con" part of consent (distinguishing it from assent), and requires the assessment of whether the elder was able to give a voluntary agreement to the transaction. Lack of voluntariness can be as simple as the overt threatening of an elder unless he or she agrees to a decision or as subtle as the insinuation into a susceptible elder's life to the degree that the elder becomes unduly influenced, and thereby unable to give a voluntary consent. It is important to understand that "influence" is generally construed to be acceptable, as all human beings influence each other repeatedly every day. It is only when the influence progresses to the point that the will of the elder has been substituted by another's will (generally for the purpose of extracting money or other property) that the court may declare that the influence is undue. Although there may be considerable disagreement about when undue influence may exist, there are some circumstances where undue influence likely cannot occur. These circumstances include if the elder (1) knows his or her own mind, (2) can distinguish between his or her interests and the interests of another, and (3) can distinguish a neutral disinterested assertion from an active, persuasive one. These conditions emphasize cognitive constructs (i.e., knowing and distinguishing) but seem to leave out issues of emotional knowing. If there is no emotional vulnerability leading to emotional dependence, undue influence probably cannot occur.

The three elements of informed consent clearly overlap (i.e., mental capacity is related to the ability to give voluntary consent) and the distinction is, therefore, somewhat artificial. It is helpful for clarity, though,

for the forensic evaluator to separate the elements as much as possible.

General Procedure to Assess Undue Influence

While every jurisdiction has different elements for undue influence, the legal concept can best be understood to consist of four elements: (1) vulnerability of the victim, (2) the influencer's apparent authority, (3) the actions or tactics used by the influencer, and (4) the equity of the resulting decision or action. Undue influence can be used to set aside any type of decision or action taken, including financial decisions, contracting, medical decisions and consent, and will or trust creation.

Vulnerability of the Victim. This element is the most relevant to geropsychiatric involvement because it requires a finding of at least one of the following conditions: incapacity, illness, disability, impaired cognitive function, emotional distress, isolation, or dependency.

Influencer's Apparent Authority. An influencer's apparent authority focuses primarily on the relationship between the influencer and the victim. Relationships that create an increased risk of undue influence include fiduciaries, family members, care providers, health care professionals, legal professionals, spiritual advisers, financial advisers, and experts.

Actions or Tactics Used by the Influencer. Actions and tactics focus on the bad acts undertaken by the influencer to suppress the free will of the victim. Actions and tactics include controlling necessities of life, medicine, and access to family and friends, use of affection, intimidation or coercion, initiating changes in personal or property rights, use of secrecy in making financial changes, or making changes at inappropriate times and places.

Equity of the Decision or Action. Equity is a legal concept that refers to the fairness of the result. If a person has a long history of benefitting family members under his or her will, and then suddenly changes that plan to benefit a caretaker, this could be viewed as an inequitable result under the circumstances. While equity, by itself, is not enough to establish undue influence, an apparent inequitable result can be persuasively used to help support the other elements of undue influence.

Presumption of Undue Influence. Most jurisdictions have a general presumption that undue influence exists where: (1) a confidential relationship exists between the influencer and the victim (much like the apparent authority element discussed above), (2) the influencer actively participated in the procurement of the decision or action, and (3) the influencer unduly benefitted from the decision or action taken. Where a

presumption exists, it is then the burden of the influencer to prove the absence of undue influence, which can be difficult to accomplish in most cases.

Competency to Make Medical Decisions or Consent to Be a Research Subject

While the "meat" of the medical/research capacity evaluation is the forensic interview, there are certain standardized assessment instruments that may be useful. These tools (the MacArthur Competence Assessment Tools) have been shown to have good validity and reliability in multiple populations. Included are semistructured interviews for evaluating the four aspects of decision-making capacity as described in the previous section. Recently, a new instrument for assessing decisional capacity for clinical research has been validated. The University of California, San Diego, Brief Assessment of Capacity to Consent (UBACC), a 10-item scale focusing on understanding and appreciation of information contained in a research protocol, was found to have good reliability and validity, taking less than 5 minutes to administer.

Recent research suggests that certain procedures for "enhancing" informed consent for research and treatment may be helpful. Effective interventions include corrected feedback, multiple learning trials, and well-organized simplified consent forms. Even in elderly individuals with psychotic disorders, enhanced consent procedures involving a computerized slideshow have recently been shown to improve understanding of research consent. When elderly people are incapable of deciding whether to participate in research, the question arises whether their family—or some other proxy—may consent on their behalf. The federal regulations allow a legally authorized representative (LAR) to do so, leaving the question of who may serve as an LAR to the states. Study of the state regulations shows fairly wide variability in the state statutes, with most states not weighing in on whether families may consent. The important questions that remain are whether proxies are/should be permitted to consent to research on behalf of an incompetent subject; if so, who may/should serve as available proxies and in what order; and whether there are/should be limits on when proxies may decide in the research context. Further study of these issues is warranted, as is gathering data on what is actually being done and how well it is working.

Competency to Make Decisions about Death and Dying

Over the last generation, there has been a change in societal attitudes to death and dying and this is reflected in the way in which geriatric patients may view this topic. Throughout history, life has been mostly valued and cherished, while death has been feared. The respect given to the healing professions stemmed partly from the ability of the healer to prolong life

and postpone death. But recently, scholars from both medicine and medical ethics have looked more critically at what should be valued in life, its quantity or quality? There is now a school of thought that argues that it is the quality of life that is more valuable, and that if a good enough quality of life is not possible, death should not be feared and postponed at all costs, but rather considered and possibly welcomed.

Elderly patients may raise questions about: (1) treatment refusal, (2) suicide, (3) physician-assisted suicide, and (4) euthanasia. Geriatric psychiatrists are likely to face such questions in elderly patients who approach their end of life, and may wonder how best to proceed. Is the role of the psychiatrist to ascertain the wishes (conscious or unconscious) of the patient? And promote those wishes, even if the wishes are unconventional (not to prolong life, but to shorten it)? But what if those wishes conflict with: (1) the values of the psychiatrist (who may wish to prolong life at all cost), (2) the law, which may criminalize medical behaviors such as physician-assisted suicide (or any action that even resembles that), and (3) societal pressures which may make it difficult for the psychiatrist to support the patient's decision to refuse treatment, resulting in an earlier death, and the risk of a medical malpractice law suit.

If an elderly patient indicates that she needs to make a decision to promote death or dying, the psychiatrist should take a number of clinical and forensic steps, beginning with a determination of the quality of decision making (i.e., is the decision contaminated by mental illness). If the decision to seek death is causally related to a mental disorder, then the ethical task is simple—treat the mental disorder, and reassess. The ethical task is more complex if the decision (not to promote life, but to seek death) is not related to a mental disorder (so there is no disorder to treat), and the decision is rational, suggesting the patient is competent. Under the law, competent patients are generally free to make decisions about their health status, including decisions (e.g., to refuse treatment) that may hasten death. How should the geriatric psychiatrist then proceed?

Strictly following the law (allowing the competent senior to make medical decisions, including those that may promote death) may not seem ethically right. But not following the law, by denying a competent senior the right to make medical decisions is also fraught with dangers! In such cases, where there is a clash (real or apparent) between law and ethics, the clinical geropsychiatrist should seek consultation from a forensic colleague. The forensic specialist may then advise the clinician that it is the doctrine of Informed Consent that best balances the competing demands from law, ethics, and psychiatry. The clinical psychiatrist should ensure that all three elements of informed consent are met. Since such cases have the potential for careful scrutiny by legal agencies, ethics committees, and the media, the documentation of how the elements of informed consent were met should be documented in some detail.

The elements of informed consent may take on added complexity with respect to decision making in death and dying. Much interest is now focused on the potential for abuse in the process of informing, rather than on the content of information. Previously, it was assumed that competent patients were rational and therefore blind to the framing of the information. In fact, one of the defining criteria of rationality is that a rational person is blind to such framing (the way the information is presented). It is now believed that most individuals are not blind to framing effects, but improperly biased by them. This may create a situation where a patient is properly fully informed (in the legal sense), but disinformed in the psychological sense.

A doctor is required to inform the patient of the risks of a medical treatment. The doctor has the choice of framing the information in positive terms ("75 percent probability of success") or in the alternative ("25 percent probability of failure"). The two pieces of information are mathematically equivalent, and a rational agent should be indifferent to how the information is presented. But most patients process these two pieces of information differently, and are likely to reach differing conclusions depending on the presenting frame.

An ethical doctor should inform the patient of the choices open to the patient, and to the risks associated with the choices. If the doctor presents the patient with a forced choice (simplifying the treatment decision to one of two), and if one option leads to certainty, while the other option has an uncertain outcome (most medical treatments do not offer any guarantee of success), the patient may make a medical decision based not on the merits of the case, but on the risk preference of the patient. Most humans are risk-averse (are more comfortable with outcomes that are certain), rather than risk-seeking (taking a gamble on a decision that has an uncertain outcome). The doctor may inform the patient of possible intervention in one of two ways: either emphasizing the advantages (benefits) of participating in the intervention, or emphasizing the disadvantages (risks and costs) of not participating. The two informing processes are logically equivalent, but produce different outcomes. Most patients are likely to be more swayed by the doctor who emphasizes the disadvantages of not participating in the intervention, and therefore are more likely to consent.

Another new area of interest is the distinction between a threat and an offer. Informed "consent" based on a threat is clearly not a valid consent, because it was not given on a voluntary basis. But what if the doctor denies making a threat (which invalidates the consent), but reframes it as an offer (which does not invalidate the consent). For example, if a doctor says to a senior patient: "I wish to inform you of your medical choices; if you seek treatment, you will exhaust your finances, soon become poor, a burden on your children, and they will hate you . . . but if you refuse treatment, you will die an earlier death, with dignity, with your financial assets preserved,

which you can pass on to your children, who will cherish you and your memory . . ."

If the senior makes a medical decision (to refuse treatment), was that decision voluntary, or was it subtly coerced, by a threat pretending to be an offer? Some philosophers argue the distinction is based on whether the proposed outcome (in this case death with dignity) makes the patient better off, or worse off than they are now. But in such cases, this is unclear, a value judgment, and not a medical judgment.

Competency to Make Financial Decisions or Contract

From a legal perspective, some forms of competency have a higher threshold to meet than other forms of competency. For example, competency to make financial decisions or contract is one of the highest levels of legal competency because it requires more mental cognition and reasoning abilities than capacity to make a will (also called testamentary capacity). In fact, in most jurisdictions across the United States a person can lack the capacity to make financial decisions or contract (such as individuals under a guardianship or conservatorship proceeding), but still have the necessary legal capacity to make a will.

Competency to make a financial decision or contract is usually questioned while the patient is alive (in contrast to testamentary capacity, which is often retrospectively questioned when the elder is deceased) and often occurs in the context of a dispute involving an elder's right to give money to a person of his or her choosing, particularly when a suspicion exists that the elder is being financially exploited.

Generally, to be found legally competent to make financial decisions or contract, the subject must be able to understand and appreciate, to the extent applicable (1) the rights, duties, and responsibilities created by or affected by the decision, (2) the probable consequences of the decision, and (3) the significant risks, benefits, and reasonable alternatives involved in the decision. In contrast to testamentary capacity (discussed in more detail below), this standard is vastly different and requires more mental functioning.

A financial decision or contract can also be overturned based on the legal concept of undue influence. In this context, undue influence focuses more on the actions of the wrongdoer and looks to mental functioning only to determine if the subject is susceptible to undue influence. A person can be susceptible to undue influence, but still have the requisite legal mental capacity to make a financial decision or contract. At times, undue influence can be an easier claim to prove in court as the mental functioning aspect is not as stringent and makes up only one of four elements to prove undue influence (the four elements being: (1) vulnerability of the victim, (2) apparent authority of the wrongdoer, (3) actions and tactics of the wrongdoer, and (4) equity of the result).

Diane is an 85-year-old female, who has always been independent, and refuses to talk about her finances with her only daughter, Tina Smith. Tina lives in San Francisco, while Diane lives in Los Angeles. Diane owns the home she lives in as well as three other homes on the same block, which she rents out to various tenants. One of Diane's neighbors, Ned Riley, is a handyman who has helped her repair her properties and various other odd jobs throughout the past 10 years. Diane's mental functioning has slowly declined and she has started having troubling walking. Ned and his wife, Brenda, starting assisting Diane with grocery shopping, taking her to medical appointments, and obtaining her prescription medicine. After several months, Brenda takes over Diane's checkbook and starts paying her bills. Brenda writes all the checks by hand, and then has Diane signs the checks. After 10 months of assisting Diane, Ned and Brenda create a corporation and enter into a contract between Diane and the new corporation to "buy" Diane's three rental properties by paying a $1,000 down payment and agreeing to make payments of $1,000 per month. They set a total purchase price for all three properties at $300,000. Each rental property is worth over $250,000, making this sale arrangement a below-market bargain for Ned and Brenda. After the initial down payment, no other payments are made and all rental income goes directly to Ned and Brenda. After a year of this arrangement, Diane runs low on funds and cannot pay for her prescriptions, which is the first time Diane mentions her finances to her daughter. Tina hires a lawyer and discovers the "sale" arrangement as well as the neighbors' actions with Diane's checkbook.

In this scenario there are two possible claims to set aside the "sale" of the real properties to the sham corporation created by the wrongdoers, Ned and Brenda. The first claim is the lack of capacity to contract, which can be evaluated using the elements pertaining to competency to make a decision. While the above facts do not provide enough details to fully evaluate capacity, the mere fact that the properties were sold at a substantial discount suggests there were problems with Diane understanding the consequences of that decision.

In addition, these facts are typical of the pattern of behavior found in many undue influence claims. The neighbors started by being helpful and slowly took over more and more jobs for Diane. Such actions built trust and goodwill with Diane. Over time, the neighbors used that trusting relationship to convince Diane to enter into a bargain sale of the properties. The first step in evaluating an undue influence claim is to determine Diane's susceptibility to undue influence. Add to that the action and tactics of the neighbors, their position of trust with Diane and the inequity of the result, and the undue influence claim is further established. Capacity and undue influence are separate claims that can be evaluated at the same time, but one claim can succeed where the other fails, or they both can be established where the facts are sufficient to prove both.

Competency to Make a Will

Testamentary capacity has two components. First, the testator must understand what he or she is doing in making a will; the nature and extent of his or her property; and the "natural objects of his or her bounty"—that is, his or her relation to living descendants, spouse, and parents, and others whose interests are affected by the will. Most jurisdictions require evidence of a mental defect that has a direct correlation to the individual's ability to understand one of these three elements. A series of eccentric or odd behaviors will not, by itself, establish a lack of capacity under this standard. A mental defect, however, such as impaired cognitive functioning that directly affects an individual's ability to understand the natural objects of his bounty, would qualify as a lack of capacity under this standard.

Second, the person must not suffer from a mental disorder that involves delusions or hallucinations that have an effect on the particular bequest. In both of these, the mental health evaluator is typically called upon to make

judgments after the fact (some lawyers have evaluations at the time of the will to try to avoid later disputes about testamentary capacity).

The "insane delusion" standard is hard to meet: The delusion must be extreme and the individual must cling to the delusion in the face of uncontroverted contrary facts. For example, a belief that one's family no longer loves one would not be an insane delusion even if it is untrue and not well grounded in evidence: It *could* be true. By contrast, a belief that one's family is trying to kill one with ray guns would be an insane delusion. Or, a belief that one's child is the product of adultery, and not really one's child, will typically not be an insane delusion. A belief that the child has been taken over by aliens, and is not really one's child, would. The delusion must also affect the bequest. If the individual has another independent (sane) reason for the bequest, then the delusion does not vitiate his or her testamentary capacity.

Mr. Jones was an unmarried 75-year-old male with three children. One year prior to his death, he began exhibiting strange behavior. He would repeatedly visit his neighbors and offer to buy all of the furniture in their home even though the furniture was never for sale. Mr. Jones would also make crank calls to local pizza parlors. Over the course of 12 months he refused to let any family members or friends into his home, and would send gifts through the mail that typically consisted of a whole fish or raw meat. Mr. Jones was never diagnosed with any form of dementia or mental defect causing cognitive impairment. Upon his death, Mr. Jones' will was discovered. The will was created 6 months before Mr. Jones' death and he left his entire estate to his church. Did Mr. Jones have legal capacity to create his Will?

Mr. Jones likely had the requisite legal capacity to make his will. The law in this area presumes that decedents have capacity until proven otherwise. Here, there is no evidence of a mental defect. Even though Mr. Jones exhibited eccentric and strange behavior prior to his death, he lacked any mental defect that would directly affect his ability to understand the objects of his bounty, the fact that he was creating a will, and the general nature of his property.

Undue influence is commonly used in attempts to overturn a decedent's will. The elements (1) vulnerability of the victim, (2) apparent authority of the wrongdoer, (3) actions and tactics of the wrongdoer, and (4) equity of the result are the same as using undue influence to overturn a decision or contract.

It is usually the case that lessened capacity makes a subject more susceptible to undue influence. While the lessened capacity may not be enough to prove a lack of capacity, it could provide support of a successful undue influence claim provided the other elements of undue influence are present. In the example above, there are no facts to support the other elements of undue influence, but if a wrongdoer was present and exerting pressure on Bob Jones' decision to leave all his assets to his church, then there could be a claim for undue influence.

Roger is a wealthy business executive, age 83. Roger is married to Jenny, age 81 and they have two daughters, Wendy and Sally. For the past 20 years, Sally has worked in Roger's business where she oversees all of his finances. Roger was advised to start gifting some of his assets to

his children and grandchildren so he would not be subject to estate tax on his death. He instructed Sally to prepare checks of $10,000 each to Wendy, Wendy's two children, Sally, Sally's one child, and Sally's husband. Wendy became enraged when she learned that Sally's husband received a $10,000 check, but her husband did not. A few weeks after the checks were written, Roger died. Wendy then went to Jenny and told her that Sally is stealing money, cannot be trusted with the funds, and that Sally is trying to take Jenny's assets. Jenny becomes alarmed and immediately fires Sally from the business. She cuts off all communications with Sally. Wendy then moves Jenny into her home to care for her. Wendy is given a power of attorney to manage the finances, and Wendy begins overseeing the family business. Jenny then creates a new will, leaving all assets to Wendy and disinheriting Sally (all previous wills gave everything equally to the two daughters, Wendy and Sally). Sally attempts to talk to her mother, but Wendy refuses to let them speak and refuses Sally entry to her home to see Jenny. During this time Wendy continually tells Jenny that Sally is trying to be nice to her so that she can steal more money. Jenny dies and Wendy believes she is entitled to everything.

Was Jenny unduly influenced to create her will leaving everything to Wendy? The first question is whether Jenny was susceptible to undue influence. Here, there are signs that she may indeed be susceptible due to the death of her husband, her age, and her actions in so readily believing Wendy's wild claims. The first step in evaluating this claim would be to investigate Jenny's medical records to determine her level of mental functioning. But Jenny need only have a weakened mental state, not a complete lack of capacity, because the remaining elements focus on the actions of Wendy. Wendy had apparent authority over Jenny both as a trusted daughter and as an agent under Jenny's durable power of attorney. Wendy used suspicious tactics in keeping Jenny secluded and refusing to allow Sally to see Jenny. The resulting will was unlike any past will, where the estate was divided equally. This example also highlights the "poisoning of the mind" that occurs when an elder is secluded and manipulated by a single child. In this example, undue influence is present and the will can be set aside based on this claim.

Competency to Drive

Generally, geriatric psychiatry training does not provide specific instruction in how to complete a driving assessment. Most states require that a physician make a referral to the Department of Motor Vehicles (DMV) if dementia is diagnosed, but do not require the physician to state whether the patient can or can't drive. In fact, it may be preferable for the physician not to be seen by the patient as the decision maker regarding a loss of driving privileges. Loss of driving privileges is, after nursing home placement, the most feared of events for an elderly person. Age alone does not cause impairment behind the wheel; it is the mental and physical changes associated with aging that cause the problem. All drivers who suffer from a cognitive deficit should be screened for a high-risk classification by the DMV. Screening test administrators are looking for four mental requirements in the driver: Proper integration of sensory input, focus of attention, proper association of thought, and appropriate judgment. The presence of mild dementia is not necessarily a cause for a license revocation, but a clinical diagnosis of Alzheimer disease is usually grounds for revocation of driving privileges.

Living Will, Advanced Directive, and Durable Power of Attorney

The device of a living will has emerged as a way for people to control their

medical care in the event they become incapacitated. Typically, they authorize withdrawal of life-saving treatment (or failure to initiate it) in the event the person is terminally ill or in a persistent vegetative state. There are certain issues that are controversial, such as whether they can authorize termination of artificial hydration and nutrition. Another issue is whether living wills can allow termination of treatment in cases other than terminal illness or a persistent vegetative state (e.g., profound dementia). While living wills have been hailed in allowing people to effectuate the kind of care they desire should they become incapacitated, there is considerable evidence that they are not widely enacted or used.

Related to a living will is an advance directive that specifies kinds of treatment one wishes and doesn't wish for in the event of incapacity. For instance, in the mental health context, one might specify which medications one prefers or whether one prefers not to have medication at all. Also related is the durable power of attorney for health care. This is a person appointed by the elder to make decisions for him or her in the event of incapacity. Because it is the elder who designates this person, it is more likely that the person can effectuate the elder's needs and desires.

ADMINISTRATIVE ASPECTS OF FORENSIC GEROPSYCHIATRY

The Elderly Impaired Physician

Life expectancy is generally rising in Western societies, and upper income, highly educated persons with upper middle class lifestyles (like physicians) are likely to live and work even longer than the national average. Impediments to working in old age may include physical infirmities (a parkinsonian tremor may cut short a surgical career) or mental infirmities (mild cognitive impairment). If the affected individual is a physician, this is most likely to come to the attention of a medical board through a complaint made by an unhappy patient, usually after a bad clinical outcome.

The geriatric psychiatrist may be asked to evaluate the elderly physician in order to help the medical board reach a conclusion. The evaluating geropsychiatrist should avoid giving a conclusion ("the doctor should keep or not keep his or her medical license"), but should clarify the specific question that is to be addressed. The report of the doctor who can evaluate the various strengths and weaknesses in the elder's capacity to plan, organize, sequence, and abstract (the executive functions) and identify any impairments (in attention, memory, language, and social skills) that affect those executive functions will be more useful than the report that reaches a final conclusion (which should usually be a function of the board).

Elderly Applicants for Disability Benefits

Some provision, public or private, protects almost all working individuals against the risk of becoming disabled, physically or mentally. In the private

sector, there are many policies, and generally the benefits are related to the premiums. In the public sector, most citizens are covered by the Social Security Administration's policies, which are not designed to generate a profit, but have humane motivations (that no disabled persons be unable to provide for themselves if they lack the capacity to work). The Social Security Administration therefore processes many claims for alleged disability and the geriatric psychiatrist may be asked for a forensic opinion regarding the validity of such a claim.

The geriatric psychiatrist should resist the temptation to give an opinion as to the ultimate issue (i.e., the claimant can or cannot work), which is an administrative, not medical, judgment based on social security law. Rather, the doctor should give an opinion regarding the penultimate medical issues, which are forming an opinion as to the quality and quantity of impairments in four areas: (1) activities of daily living; (2) social functioning; (3) concentration, persistence, and pace; and (4) decompensations. In two of these areas (activities of daily living and concentration, persistence, and pace), there is a normal decline in performance with age, which makes the evaluation difficult. The Social Security Administration (SSA) will ask the psychiatrist to rate any impairments in terms that are poorly defined (mild, moderate, severe), and the difference between a claim that succeeds from one that fails may depend on whether the psychiatrist assesses the impairment as "moderate" or as "severe" in the absence of good definitional guidance around these terms. The SSA guidelines are sensitive to the demands of age; the same level of impairment may result in a failed claim if the applicant is young, but succeed if the applicant is elderly. If impairment is indeed present, the doctor should relate it to a causal factor, which could be a mental disorder (dementia) or a condition that is not a mental disorder (lack of English language skills). Based on this (medical) opinion, the SSA will then determine whether the applicant does or does not qualify for disability benefits.

CORRECTIONAL ASPECTS OF FORENSIC GEROPSYCHIATRY

Opportunities for the geriatric psychiatrist to provide clinical services within the correctional system abound and are likely to increase exponentially over the ensuing years. It is important to recognize that the correctional psychiatrist *treats* the incarcerated elder and hence plays a different role than the forensic psychiatrist, who *evaluates* the incarcerated elder to truthfully answer a medicolegal question. The last 10 years have been significant for a rising awareness of the impending problem of elderly prisoners in the criminal justice system. Virtually every major newspaper in the United States has run a story on how the "graying" of the incarcerated population is likely to present a serious ethical/moral challenge and/or economic crisis for the penal system. There are presently more than

125,000 prisoners over the age of 50 and 35,000 prisoners over the age of 65 in U.S. correctional facilities. Due to sentencing laws and demographic shifts in the population, the U.S. Census Bureau estimates that in 2030, one-third of the jail population will be over 55 years of age.

From a forensic perspective, the geriatric correctional psychiatrist may be asked whether an aging prisoner should go free. There are a number of considerations: 97 percent of elderly inmates are nonviolent offenders and less than 1 percent of those on probation or parole who are returned to jail or prison are older than 60. Furthermore, the poor health conditions of prisoners combined with harsh prison life make the prison environment particularly conducive to fostering disease. There is, however, no legal statute that is likely to provide elders with any specific rights beyond the general right to medical care and the right to be free from cruel and unusual punishment. A possible related question is whether age should be a basis for execution exemption. There are presently over 100 people age 60 or over on death row. The Supreme Court has ruled that it is unconstitutional to execute certain special populations (juveniles and the mentally retarded) due to violation of the Eighth Amendment's prohibition against cruel and unusual punishment. In the case of the elderly prisoner, however, most are presumably fully functioning at the time of the crime. The strongest argument might be if the elder suffers from dementia or some other age-related mental deficiency that impairs capacity to understand why he or she was being executed at the time the sentence was carried out.

NOSOLOGICAL/THEORETICAL ISSUES

In routine clinical practice, most geropsychiatrists use the DSM-V and follow the "spirit" of the text. Good clinical practice (they would argue) has to do with using the diagnostic criteria in a manner that promotes communication and increases patient well-being. Consider the case of an elderly patient recently retired, now bored and unhappy. Since he may respond to antidepressant medication, many psychiatrists would label such a case as one of depression (a mental disorder) rather than "occupational problem" or "phase-of-life problem," both of which are not mental disorders but rather mental conditions (and hence coded with a "V" code). The fact that each one of the specific DSM-5 criteria may not be exactly met is less relevant than the fact that following the spirit of the text, rather than the letter, creates more good than harm.

In clinical practice, the doctor has a financial incentive to diagnose in a manner that promotes reimbursement; usually, the diagnosis and treatment of a mental disorder does result in monetary reimbursement, while the diagnosis and management of a mental condition may not. In forensic cases, the doctor is more likely to be rewarded for telling the truth (or at least whichever "truth" the payer is seeking); in such cases, the

doctor is more likely to consider the mental conditions (as well as the mental disorders) in the differential diagnosis.

In court testimony, the doctor swears to tell the whole truth, and if the diagnoses do not follow the letter of the text, the doctor should truthfully acknowledge that. But the truth may be difficult to determine—forensic geropsychiatrists are often asked to clarify boundaries that may be fuzzy, including the boundaries between (1) cognitive disorder/age-related cognitive decline, (2) antisocial personality disorder/adult antisocial behavior, and (3) depressive disorder/bereavement. The former are all mental disorders, while the latter are not. The boundary between the two is often vague and ill-defined, and there may be temptations to place the boundary in a manner that promotes values that are ethical (compassion) or policy based (access to care), rather than scientific (nosology). While it is admirable for the clinical geropsychiatrist to be compassionate or to advocate for greater access to health care for untreated patients, the forensic geropsychiatrist subscribes to a code of ethics that emphasizes truth telling, rather than the traditional ethical values of promoting health. In an ideal world, there will be no clash between such competing values. But since there is often an adversarial quality to forensic practice, the forensic geropsychiatrist may have to make difficult choices, between acting on values that promote health (the traditional values of clinical ethics) or on those that promote the truth (the values of the forensic expert). If there is a choice between promoting health and promoting patient autonomy, the ethical doctor may be troubled and unsure about the resolution of such a dilemma. With the growth in both the population of the elderly and the number of regulations that govern the care of the elderly, the forensic geropsychiatrist is likely to see more such dilemmas.

Future research in forensic geriatric psychiatry may therefore be of two types: (1) quantitative (data-based) research—especially in the sciences pertaining to nosology (to clarify the proper boundaries of the various mental disorders that may be a basis for forensic opinions) and decision science (to better delineate the pathways to good and bad judgment [cognitive, social, moral, logical] that often form the basis of findings of mental incompetence in the elderly) and (2) qualitative (conceptual) research—integrating findings from the biomedical aspects of geropsychiatry (i.e., whether a brain disease is or is not curable), with the implications of such findings (legal protections for the rights of the elderly mentally ill and ethical concerns regarding allocation of limited health care resources to a population of the elderly that may have unlimited growth).

57.6c Ethical Issues

NATHAN FAIRMAN, M.D., SCOTT A. IRWIN, M.D., PH.D., AND BARTON W. PALMER, PH.D.

Geriatric mental health care is often fraught with complex issues of bioethics. Most of these challenges have parallels in the ethical care of nonelderly mental health patients, as well as in the care of medical patients of all ages. The issues of general psychiatric ethics are considered elsewhere in this volume. The intent of this section is to review the core bioethical principles and consider their application in the context of geriatric mental health care. Although mere identification of core principles does not automatically provide an unambiguous solution for a particular ethical dilemma, such clarification does foster wider recognition of subtle, if common, ethical issues and helps to highlight the areas that need consideration when developing a plan for resolution or management of such dilemmas.

Following a review of the historical roots of bioethics and a presentation of the core principles, several general applications of these principles to patient care and research in geriatric mental health will be reviewed. Finally, a more detailed consideration of one specific component of bioethics—particularly important in geriatric mental health—will be provided, that is, informed consent and decision-making capacity. The rationale for this focus is that many of the commonly encountered ethical challenges in geriatric mental health involve questions of decisional capacity, particularly in cases marked by deficits in cognition or affective states which may be felt to undermine capacity. Moreover, older adults and others with chronic, life-limiting illness will increasingly encounter

decisions that may influence the timing of death—a possibility which, to some, may seem to "raise the stakes" surrounding questions of decisional capacity. Since deficits in cognition and affective conditions such as depression, grief, and demoralization are common among older adults, careful attention to decisional capacity and informed consent can help to ensure sound clinical and ethical decision making at the bedside. In addition, informed consent and decisional capacity constitute an area of bioethics that has received particularly rich empirical attention over the past decade and thereby serve as a model for how empirical data may complement moral, philosophic, legal, and public policy perspectives on bioethical issues in patient care.

HISTORY

Consideration of moral and ethical principles in health care has ancient beginnings, including the Hippocratic Oath from the fifth century BCE. In terms of development of contemporary ethical codes, a key historical marker was reached in 1803, with the publication of Thomas Percival's *Medical Ethics*. Although his was not the first ethics code developed, it is widely credited as providing the foundation for many subsequent formal ethics codes in Western medicine, including that adopted with the founding of the American Medical Association in 1847.

The 1960s and 1970s witnessed the emergence of bioethics as a term and formal discipline of inquiry. During this period, several key bioethics centers were founded, including the Hastings Center in 1970 and the Kennedy Institute of Ethics in 1971. The rising interest in clinical ethics during this period appears to have been partially due to advances in medical care that brought new challenges, such as the introduction of increasingly technical (and costly) medical procedures (and therefore questions about how to fairly allocate finite medical resources), evolving public attitudes about care near the very end of life, and advances in genetics and various aspects of reproductive medicine. In reference to geriatrics, it may also be noted that the 1960s to 1970s was precisely the period when recognition and interest in Alzheimer disease and other neuropsychiatric conditions associated with aging began to gain wider public, professional, governmental, and empirical attention. The increased attention to such conditions, as well as advances in medical care for many chronic but life-limiting conditions, also brought into focus a modern dilemma: balancing quality of life with mere extension of life.

The growing attention to the ethics of clinical care in the later half of the 20th century was also catalyzed by parallel growth in the related field of medical research ethics. In particular, the Nuremberg Code, published in 1948 in response to the Nuremberg trial in the aftermath of World War II, and the Declaration of Helsinki, first published in 1964, represented major multinational collaborative efforts to specify the limits and requirements

for ethical medical research, such as the strong emphasis on the need for voluntary informed consent. Public, professional, and government attention to health care ethics was also fostered by Henry Beecher's now classic 1966 account of unethical research practices, exemplified in 22 contemporaneous studies that had been published in leading peer-reviewed medical journals, and by the public revelations in the early 1970s of the now-infamous Tuskegee and Willowbrook experiments.

Two key bioethics documents were developed in the late 1970s: (1) the *Principles of Biomedical Ethics*, by Tom L. Beauchamp and James F. Childress and (2) *The Belmont Report* from the U.S. National Commission for the Protection of Human Subjects. Beauchamp and Childress described bioethics in terms of four core principles: respect for autonomy, nonmaleficence, beneficence, and justice. Nonmaleficence and beneficence were fused together in *The Belmont Report*, which identified the fundamental principles of ethical medical research as respect for persons, beneficence, and justice.

CORE PRINCIPLES

Whether in geriatric psychiatry, general psychiatry, or general medicine, the core principles of bioethics—described in further detail below—do not, in themselves, explicitly specify the full range of ethical responsibilities clinicians or researchers have to their patients and research participants. Obligations to patients may be rooted in other principles, or may entail other ethically relevant considerations. Nonetheless, most of the cardinal bioethical concerns can be understood as derivatives of these core principles.

Respect for Persons/Autonomy

As defined in *The Belmont Report*, respect for persons includes two potentially conflicting components: (1) respect for the rights of individuals to autonomous decision making, and (2) recognition of the need to protect those with impaired capacity for autonomous decision making. The principle of respect for persons is widely represented in the contemporary ethics codes of various health and mental health professions. For instance, the second decree in the World Medical Association's *International Code of Medical Ethics* reads "A physician shall respect a competent patient's right to accept or refuse treatment." Another example is Principle I, Respect for the Dignity of Persons, from the *Canadian Code of Ethics for Psychologists,* which includes explicit recognition of the need to protect vulnerable individuals as well as respect their wishes and human dignity. Indeed, as shall be seen, many of the prototypic ethical conflicts in geriatric medicine and mental health care can be understood as arising, at least in part, from tensions between these two related (but often competing)

obligations: the duty to respect autonomy and dignity and the duty to protect those with impaired capacity for autonomous decision making.

Beneficence and Nonmaleficence

In *The Belmont Report,* beneficence is conceptualized as encompassing two complementary ethical mandates: "(1) do not harm and (2) maximize possible benefits and minimize possible harms." Some authors, including Beauchamp and Childress, separate these two mandates, identifying the former as the principle of nonmaleficence (construed as an obligation to minimize harm), and reserving the term beneficence to connote an obligation to the promotion of good. There is little disagreement that both components are germane to patient care and clinical research. For instance, in describing the concept of beneficence, Beauchamp and Childress note: "Morality requires not only that we treat persons autonomously and not harm them but also that we contribute to their health and welfare." Notions of beneficence and nonmaleficence are also widely recognized in contemporary codes of bioethics. The World Medical Association's *International Code of Medical Ethics,* for example, dictates that "A PHYSICIAN SHALL act in the patient's best interest when providing medical care." The current ethics code from the American Medical Association includes the statement that "A physician shall, while caring for a patient, regard responsibility to the patient as paramount." Similarly, the Canadian Medical Association's code of ethics lists the first fundamental responsibility of the physician to "Consider first the well-being of the patient." A final example is seen in the current ethics code from the American Psychological Association, which includes beneficence and nonmaleficence together as Principle A, noting: "Psychologists strive to benefit those with whom they work and take care to do no harm."

Justice

From an ethical perspective, the term justice is generally interpreted in reference to "fairness" or "fairness in distribution." Issues of justice are often most readily identified at the systems level, for example, in reference to concerns about resource allocation, access to care, or disparities in health. Nonetheless, justice also pertains to other important domains of medical care: *The Belmont Report,* for example, emphasizes the fairness of benefits and burdens from clinical research. So too, issues of justice often arise in clinical care in geriatric medical and mental health settings. Many of the professional codes of bioethics include at least aspirational goals that clinicians will work toward the betterment of society. For instance, two of the nine principles in the current ethics code from the American Medical Association clearly reflect justice considerations:

VII A physician shall recognize a responsibility to participate in activities contributing to the

improvement of the community and the betterment of public health . . .

IX A physician shall support access to medical care for all people.

Another of many possible examples is Principle D from the ethics code of the American Psychological Association, which reads:

Psychologists recognize that fairness and justice entitle all persons to access to and benefit from the contributions of psychology and to equal quality in the processes, procedures, and services being conducted by psychologists. Psychologists exercise reasonable judgment and take precautions to ensure that their potential biases, the boundaries of their competence, and the limitations of their expertise do not lead to or condone unjust practices.

APPLICATION OF CORE PRINCIPLES OF BIOETHICS TO GERIATRIC MENTAL HEALTH CARE

Several common general applications of the principles of bioethics to geriatric mental health care warrant mention "respect for dignity" and "respect for persons." For example, respect for dignity, an important component of the broader principle respect for persons, is often a paramount consideration in geriatric mental health. As a result of the stigma associated with neuropsychiatric disorders, as well as the loss of function and status sometimes associated with neurodegenerative conditions, patients and family often view health-related decisions in this context through the prism of concerns about dignity. Similarly, the right to confidentiality (closely related to issues of dignity) may also be viewed as an extension of respect for persons. In the context of work with decisionally impaired individuals, confidentiality issues can be particularly complex, as there is often a need to work closely with adult children or other family members, sometimes disclosing information at a level that would be uncommon (and perhaps inappropriate) with a patient whose decisional capacity was intact.

Another key general application of bioethics to geriatric medicine and mental health care involves the issue of professional competency, particularly the skills and knowledge necessary for delivering appropriate treatment to older patients. The need to practice within the scope of one's training and competence is rooted in the principle of beneficence/nonmaleficence, and it is explicitly emphasized in most professional bioethics codes. For instance, in describing the duties of physicians to patients, the World Medical Association's *International Code of Medical Ethics* includes the requirement that "Whenever an examination or treatment is beyond the physician's capacity, he/she should consult with or refer to another physician who has the necessary ability." The ethics code from the Canadian Medical Association enjoins physicians to "Recognize your limitations and, when indicated, recommend or seek additional opinions and services." The issue is stated even more forcefully in the American Psychiatric Association's annotations to the American Medical Association's *Principles of Medical Ethics*: "A psychiatrist who regularly practices outside his or her area of professional competence should be considered unethical."

Two possible responses to the prescription to practice within the limits of one's training and competence include (1) limiting one's practice, or (2) expanding one's training and competence. Given the major growth in the numbers and proportion of older adults with neuropsychiatric conditions, considerations of justice (as well as beneficence and nonmaleficence) should place increasing pressure on general psychiatrists and physicians to pursue the second option, that is, obtain sufficient training in geriatric mental health to at least enable the individual clinician to appropriately discern when consultation or referral to a geriatric mental health expert is warranted. This may be most clearly illustrated in reference to late-life depression. Although rates of clinically significant depressive symptoms are relatively high among older adults, depression in this population tends to be underrecognized (and therefore undertreated). What is more, clinical competence with respect to managing late-life depression includes the knowledge that, even near the very end of life, depression can often be effectively treated. A variety of medications and psychotherapies have been shown to be beneficial in treating depression in palliative care populations, and for this reason, if depression is suspected, the "competent" physician should at least recommend a time-limited therapeutic trial, simply from the standpoint of the principle of beneficence.

Justice considerations also have ethical relevance to the development and testing of psychotropic medications. Although the situation has been improving in the past decade, elderly patients have been traditionally underrepresented in clinical trials of antidepressant and other psychotropic medications. Given potential age-related changes in pharmacokinetics and pharmacodynamics, as well as increased likelihood of drug interactions from polypharmacy, the need for clinicians to extrapolate from data collected from samples of younger patients represents an ethical challenge in terms of justice (as well as nonmaleficence). The latter example also reflects that ethical dilemmas are not always best conceptualized or addressed at the level of individual clinician and patient interactions, but may also occur and require change at the level of public policy—in this case, with respect to setting national (or international) research priorities.

DECISION-MAKING CAPACITY AND INFORMED CONSENT

As the above discussion is intended to illustrate, geriatric mental health care and research activities frequently give rise to a variety of bioethical concerns. In fact, as noted, many of the ethical challenges encountered in the context of geriatric mental health can be understood as arising from conflicts among the core principles of bioethics. Among these, the potential conflict between the two components of the principle of respect for persons (respecting individuals as autonomous agents and protecting those with diminished capacity for autonomous decision making) is one of the most salient and challenging in geriatric mental health care.

Broadly speaking, such conflicts can be particularly difficult to comfortably resolve when the weighing of considerations from competing principles is highly subjective, that is, in those instances wherein "reasonable persons" may disagree and come to divergent conclusions regarding the most appropriate course of action. Consider the controversies around the "right to die" near the end-of-life, often exemplified in discussions about withdrawing or withholding treatment, palliative sedation, or physician aid-in-dying. One can readily identify tensions among the core bioethical principles in such issues, wherein reasonable people might disagree about how to best respect autonomy, balance obligations to beneficence and nonmaleficence, and even address concerns about justice. Some of these tensions are brought to light in the following case:

Sylvia is a 68-year-old woman with advanced chronic obstructive pulmonary disease, a history of breast cancer, and major depression. Though she lives alone, over the past year she has found it increasingly difficult to maintain her independence: she has been in and out of the hospital several times, and after the most recent hospitalization she was discharged to a nursing facility for rehabilitation. She found the brief stay in the nursing facility to be demoralizing—not so much because of the quality of care she received, but rather because the idea of being dependent on others for her most basic needs ran contrary to her own sense of self-worth. She counts her ex-husband, her daughter, and a former colleague among her closest supports, and she has vowed to them that she would "rather die" than to experience "the indignity of wasting away" in a nursing home.

In a subsequent hospitalization—due to yet another bout of pneumonia—she appears more depressed than usual, and there are some new concerns about delirium. She makes an oblique reference to her doctor suggesting that she wishes her life were over: "I'm tired of going through this; when will it end? There must be something you can do to help me . . ."

From the standpoint of bioethics, how should Sylvia's doctor respond? What course of action will strike the right balance among the different—and seemingly opposed—obligations? For instance, how should her doctor negotiate the two components of respect for persons (honoring Sylvia's right to autonomous decisions, while protecting her in the event that her capacity for authentic autonomous decision making is diminished, due to what may be depression or cognitive impairment)? Further, apart from concerns about autonomy, how should the clinician understand "the good" that should be promoted, or "the harm" that should be avoided (so as to respect the dictates of beneficence/nonmaleficence) in a case where a suffering patient, near the end of life, desires that their death come more quickly?

Not surprisingly, in medical ward settings, psychiatrists are frequently asked to provide consultation in cases like Sylvia's—to evaluate the degree to which a patient's refusal of potentially life-extending treatment (or more generally, their desire for hastened death) may reflect compromised capacity for autonomous decision making due to depression, cognitive impairment, or even psychosis. From the perspective of the geriatric mental health clinician, the question of decisional capacity—a component of informed consent, relating fundamentally to the principle of respect for persons—is likely to be instrumental in helping to sort out some of these issues.

Three Components of Informed Consent

Concerns about decision-making capacity relate fundamentally to the doctrine of informed consent, which (in most formulations) involves three interrelated components: first, valid informed consent requires that the

individual's decision be made in the absence of coercion (i.e., the decision must be truly voluntary). Second, informed consent also requires disclosure of all the information relevant to the decision at hand, such as the purpose and nature of the proposed treatment or procedure, viable alternatives, and the foreseeable risks and benefits, as well as potential lack of benefits, from each possible course of action (including doing nothing). Such disclosure is generally documented with a printed consent form that the patient or his or her surrogate signs; however, as cogently noted in a report from the Institute of Medicine:

Conceptually, informed consent should be construed as an evolving decision-making process, rather than as simple "permission." This model of "ongoing conversation and decision making" allows for reinforcement of previously disclosed information, introduction of new information, and respect for autonomous participant decision making. The act of obtaining *written* consent is tangential to the *process* of informed consent and merely provides a mechanism to document and record that ethically relevant communication has taken place.

The third key component of valid informed consent is that the individual has the ability to use the information to make an authentic, informed decision; that is, the individual has "decision-making capacity."

Decision-Making Capacity

Decision-making capacity derives from a set of mental abilities, which together enable a patient to engage in the process of informed consent. Having decisional capacity is a necessary—but not sufficient—element of informed consent, a process which, as noted above, requires the presence of several other important components (absence of coercion, disclosure of relevant information, etc.). Most often, decision-making capacity is distilled into four main elements:

1. Understanding—the ability to comprehend information relevant to the decision at hand;
2. Appreciation—the ability to apply that information to one's own situation and condition;
3. Reasoning—the ability to manipulate and consider pertinent information, so as to rationally assess the different options available; and
4. Communication—the ability to express a stable choice over time.

Note that many experts draw a distinction between "capacity" (a determination made by a physician) and "competency" (a determination made by a judge), but the two terms are often, confusingly interchanged. In general, questions of capacity should relate to specific interventions, at a specific point in time (e.g., a trial of dialysis, or surgical repair of an aneurysm, etc.), rather than a more generalized ability, since the capacity required to engage in a simple, straightforward decision may be

substantially different from the capacity required to engage in a highly complex or risky decision.

In most states, decisional capacity can be determined by any licensed physician (and sometimes also by a small set of nonphysician mental health specialists, such as clinical psychologists). Hence, most consultation requests for "capacity evaluation" can be framed as providing a second opinion, when the primary clinician's assessment is indeterminate or uncertain. In practice, psychiatrists are frequently consulted when serious affective conditions, problems with cognition, or deficits in reality testing are felt to interfere with decision-making capacity.

Capacity determinations are ultimately based on clinical assessment, which is often complemented by an objective measurement of several domains of cognition. Unfortunately, empirical studies suggest poor reliability, even among experienced clinicians, in terms of categorical determinations of an individual patient's capacity to consent to treatment based on standard clinical interviews. However, interrater reliability may improve when the clinicians providing such ratings are given explicit operational guidelines. Several tools have been developed to assist with the assessment of decisional capacity, such as the MacArthur Competence Assessment Tool for Treatment (MacCAT-T), the Capacity to Consent to Treatment Instrument (CCTI), and the Aid to Capacity Evaluation (ACE). The advantages and disadvantages of each instrument (and others) should be considered in reference to the specific purpose of the capacity assessment for an individual patient or research subject. Finally, while published reviews and educational resources often leave the impression that capacity determinations are merely a matter of applying certain criteria in the context of a clinical examination, such assessments in complicated cases are rarely straightforward, and they often involve an uncomfortable degree of subjectivity and judgment.

Impact of Demographics and Disease on Decision-Making Capacity: Is Mental Illness a Proxy for Incapacity?

In 1998, the U.S. National Bioethics Advisory Commission (NBAC) issued a report titled *Research Involving Persons with Mental Disorders That May Affect Decision Making Capacity*. The purpose of the report was to consider whether persons with mental illness require additional protections when enrolled in clinical research, due to the possibility that mental illness may adversely affect their capacity to provide informed consent. Although the intent to protect potentially vulnerable individuals was widely lauded, critics of the report cited concerns that it may have inappropriately singled out persons with mental illness as being uniquely vulnerable to impaired decisional capacity, and thereby, inadvertently risked amplifying the social stigma associated with mental illness. There were further concerns that some of the specific recommendations could

lead to situations in which mental illness was used as a proxy for impaired decisional capacity, thereby making research with certain patient populations pragmatically difficult and hindering the pursuit of research that would be critically important for those very populations.

One clear benefit from the NBAC report was that it catalyzed empirical studies of capacity to consent to treatment or research among persons with schizophrenia, Alzheimer disease, and other neuropsychiatric or medical conditions. The results of that research confirm that some neuropsychiatric conditions are associated with increased risk of impaired decisional capacity, but also consistently reveal substantial heterogeneity within each of the diagnostic groups (as well as within general medical patient groups). This research has also consistently shown, across and within diagnostic groups, that the strongest predictor of impaired decisional capacity is the severity of cognitive deficits, rather than the severity of psychopathology. Indeed, at least among outpatients, positive symptoms in schizophrenia (such as hallucinations or delusions) have little discernable relationship to decision-making capacity. The correlation of age and impaired decisional capacity tends to be modest at best and is virtually zero among persons with schizophrenia. As capacity relates to particular qualities of reasoning in the context of particular interventions, the presence of a psychiatric condition (major depression, Alzheimer dementia, schizophrenia, etc.) cannot be used as a simple substitute in assessing a person's decisional capacity. In short, whether dealing with medical or psychiatric patients and whether dealing with older or younger patients, decisional capacity must be assessed on a case-by-case basis, taking into account both patient factors (cognition, affect, etc.) and factors unique to the decision at hand (complexity, risks, uncertainty, etc.).

Respect for Persons in Persons with Impaired Decision Making

Where does all this leave the geriatric mental health specialist, when faced with a person like Sylvia, who, in the advanced stage of a progressive and terminal illness, experiencing some form of depression as well as possible cognitive deficits, begins to give voice to a desire to die? If Sylvia has decisional capacity, she might, for example, choose to decline antibiotic therapy for her pneumonia and to be discharged home with hospice care, with an expectation that she would soon die. If she lacks capacity, however, should antibiotics be given without her consent? Should she be "forced," against her objections, to return to a nursing facility? From the standpoint of bioethics, uncertainty about these questions reflects tensions arising from the dual obligation to respect the autonomy of persons while protecting people with impaired capacity for autonomous decision making. Hence, in very practical ways, what is done for (and to) Sylvia will hinge on the assessment of decisional capacity.

Often, a careful and systematic process—involving thoughtful

clarification of Sylvia's decision-making capacity, but also comprehensive assessment of other sources of suffering, close coordination with family, realistic assessment of prognosis and the effectiveness of treatment, and therapeutic interventions that are structured in time-limited trials with clear outcomes—can help to achieve an acceptable solution, even in some of the most complicated cases. In Sylvia's case, such a process might include the following:

1. Empathic clarification of the patient's request: what, precisely, is Sylvia referring to when she says "I'm tired of going through this"? As Susan Block and Andrew Billings have observed: "Most patients, in saying that they want to die, are asking for assistance in living—for help in dealing with depression, anxiety about the future, grief, lack of control, dependence, physical suffering, and spiritual despair."
2. Attention to potential sources of coercion (e.g., from financial pressures, or burdens of caregiving).
3. Careful assessment of decisional capacity. When severe depression influences capacity, it often does so through distorted judgments, leading patients to undervalue the likelihood of a meaningful future, to underestimate the possibility that depression could be relieved, or even to be unaware of the presence of depression itself.
4. A thorough exploration of Sylvia's long-held values; how she had made decisions in the past; confirmation from a surrogate that her current choices remain "authentic" in the sense that they are in alignment with her lifelong preferences.
5. Identification and treatment (if consistent with the goals of care) of any potentially reversible causes of delirium.
6. Thorough, expert characterization and appropriate treatment of "depression." Is this another major depressive episode? Grief? Demoralization? An adjustment disorder? etc.
7. Comprehensive review of other forms of distress: physical, emotional, interpersonal, spiritual, practical, etc. Reliance on an interdisciplinary team to respond to the patient's suffering and deliver the plan of care.
8. Interventions structured in time-limited trials with clear outcomes.
9. Ongoing, open communication with the patient, her surrogates, and other relevant stakeholders.

Although treatment "against one's will" is sometimes supported by the obligation to protect vulnerable individuals with impaired decisional capacity, clinicians should also be open to the possibility that in many cases, one can simultaneously respect the person's autonomy and dignity, while also protecting him or her as a person vulnerable to impaired decisional capacity. In particular, efforts to explain and obtain the person's assent, wherever possible, will foster dignity and respect, even when consent must be obtained from the patient's surrogate. As Kim and

colleagues have noted in the context of research consent, some patients may lack the capacity to make the decision on their own, but retain sufficient capacity to identify a trusted proxy decision maker.

57.6d Gender Issues

HELEN H. KYOMEN, M.D., AND MA'AYAN E. LIEBERMAN, M.D.

INTRODUCTION

Gender and age are important factors in the daily practice and science of medicine and are key components in establishing diagnosis, evaluating risks, and determining treatment including the effective and safe dosages of medications. Due to differences in life expectancy, there are more older women than men. In 2013, there were approximately 128 older women for every 100 older men; in those 85 years and older, there were about 196 women for every 100 men. This has significant clinical and scientific consequences. For example, in current psychiatric practice, psychopharmacological interventions are widely used. In general, prescription drugs are used more frequently by elderly women than men. Overall, women reportedly have a 1.5- to 1.7-fold greater risk of adverse drug reactions. Yet women, specifically those of older age, have been underrepresented in medical investigations. Studies designed to establish

the efficacy, safety, and tolerability of medications have been historically biased for incorporating younger men as study subjects. As a result, established therapeutic guidelines may be inadequate or inappropriate for older women.

Great efforts have been made toward filling the knowledge gap that resulted from the historical underrepresentation of women in research studies. In 1985, the U.S. Public Health Service Task Force issued a report on women's health issues that documented that women were disadvantaged in health care and research. Based on this report, the National Institutes of Health (NIH) released a policy encouraging the inclusion of women in clinical research. In 1990, following an investigative study by the Government Accounting Office (GAO) and urging from the Congressional Caucus on Women's Issues, the NIH established the Office of Research on Women's Health to take responsibility for establishing policy and promoting research on women's health. In March 1993, the U.S. Food and Drug Administration (FDA) stated that it would "end its ban on women's participation in most drug safety tests and require companies to carry out analysis by gender in virtually all applications for new drugs." This declaration followed the GAO October 1992 report "FDA Needs to Ensure More Study of Gender Differences in Prescription Drug Testing." Further guidance was issued in 1993, followed by regulations in 1998 and 2000. Federally funded clinical intervention studies would be required to include women, with data analysis by gender. These legal pronouncements, with continued oversight, help to ensure that women are represented in health care research, which informs current evidence-based medical practice and patient-centered care.

Clearly, patients are better served when gender and age are taken into account. This is especially important for older women as after menopause, morbidity and mortality from conditions such as cardiovascular disease, major neurocognitive disorder, or depression reach or exceed rates seen in men. These differences will be highlighted and illustrated in the sections that follow.

IMPACT OF GENDER ON PSYCHIATRIC CONDITIONS

Major Neurocognitive Disorders

Major neurocognitive disorders are an important health concern in aging populations. Major neurocognitive disorder due to Alzheimer disease and major vascular neurocognitive disorder together account for 80 to 90 percent of all major neurocognitive disorders. Of those diagnosed with major neurocognitive disorder due to Alzheimer disease, about two-thirds are women. Being a woman has been associated with an increased risk for developing major neurocognitive disorder due to Alzheimer disease, although the evidence is not as clear for major vascular neurocognitive

disorder. Research using autopsy data suggests that about half of patients with major neurocognitive disorder due to Alzheimer disease have vascular lesions. There is a growing body of scientific literature on how cardiovascular risk factors may play a role in the development of major neurocognitive disorder due to Alzheimer disease. Obesity in mid-life may influence, to a greater degree in women than in men, the development of major neurocognitive disorder. Hypertension and hypercholesterolemia in both women and men predict a higher risk of developing major neurocognitive disorder due to Alzheimer disease with aging. In women older than 75 years of age, rates of hypertension and hyperlipidemia are higher than in men of similar age. Thus, with greater age, hypertension and hyperlipidemia may play a more prominent role in the development of major neurocognitive disorder due to Alzheimer disease in women. The apolipoprotein E ε4 (ApoEε4) genotype seems to be a risk factor for major neurocognitive disorder due to Alzheimer disease primarily in women and seems to have a more deleterious effect on hippocampal gross pathology and memory performance in women than in men. Diabetes, which increases in frequency with age in women to a greater extent than in men, is associated with an increased risk for cognitive impairment and may influence this trend as well. Whether prevention or reversal of these associated factors can cause a decreased risk of major neurocognitive disorder due to Alzheimer disease in women has yet to be clearly established.

Women with major neurocognitive disorder due to Alzheimer disease are at greater risk of having comorbid conditions undetected and inadequately treated, potentially affecting mortality risk. In a cross-sectional study of 340 community-dwelling elderly with major neurocognitive disorder due to Alzheimer disease, women were at greater risk of having a malnourished state that was undetected by clinicians, despite having a low body mass index (BMI) (less than 21). In a retrospective cohort study of 5,831 men and 17,918 women nursing home residents with major neurocognitive disorder due to Alzheimer disease, women were underweight, less likely to be hospitalized and received fewer medications for each disease compared to men. The women in this cohort were also older and more severely cognitively impaired than the men. In an observational study of 28,367 nursing home residents with major neurocognitive disorder due to Alzheimer disease, it was found that although psychotic and depressive symptoms were equally prevalent in both women and men, women were more likely to receive antidepressants and men were more likely to receive antipsychotics. This may be due, in part, to the fact that men were more likely than women to have behavior problems such as wandering, abusiveness, and socially inappropriate behaviors in this cohort. These findings suggest that greater attention by gender to the nutritional, health, and psychiatric status of elderly patients

with major neurocognitive disorder due to Alzheimer disease may be needed so that appropriate, timely interventions may be proactively implemented.

As major neurocognitive disorder due to Alzheimer disease progresses, a decline in cognitive, functional, and overall health status occurs, with the gradual loss of the ability to live independently. Women and men with major neurocognitive disorder due to Alzheimer disease, if admitted to a nursing home, seem to have different reasons for nursing home admission. A 2-year, four-wave follow-up study with 573 patients with major neurocognitive disorder due to Alzheimer disease and their family caregivers showed that men entered an institution primarily for medical and caregiving needs, but women, who showed less physical and cognitive impairment than men on nursing home admission, entered due to family caregiving patterns. This suggests that providing additional education and support to affect family caregiving patterns might delay nursing home placement for women with major neurocognitive disorder due to Alzheimer disease.

Mortality rates in elderly with major neurocognitive disorder due to Alzheimer disease are higher in women than in men. In a 15-year prospective epidemiological study of 1,670 community-dwelling elderly individuals, it was found that having a major neurocognitive disorder due to Alzheimer disease increased mortality risk overall in women but not in men. Cardiovascular risk factors, the lack of detection and adequate treatment of comorbid conditions, and patterns of family care provided to elderly women with major neurocognitive disorder due to Alzheimer disease may possibly influence mortality. If so, interventions to influence these factors might reduce mortality rates in elderly women with major neurocognitive disorder due to Alzheimer disease.

Depression

Depression in the elderly is prevalent and a significant public health problem. It is two to three times more common in elderly women than in elderly men overall. The comorbidity associated with depression in elderly women is significant. Depressive symptoms statistically significantly increased the risk for major neurocognitive disorder in women 85 years and older. The prevalence of generalized anxiety disorder is higher in elderly with depression. In studies with fairly large cohorts, the association of depression with decreased health status, disability, and decreased quality of life in older women is prominent. In a prospective study of 4,657 elderly women, depression, along with underweight status, obesity, and smoking, was associated with the development of frailty. Greater prevalence of depression was found to contribute substantially to greater disability and decreased quality of life in elderly women compared to men in a study of 1,348 elderly patients. In addition, depression and frailty in

older adults, especially in older women, has been associated with an increased risk of death.

In population-based cohort studies, depression was found to be associated with increased rates of hip bone loss and lower bone mineral density (BMD) in older women compared to younger women. Higher rates of hip fracture in elderly women have been attributed to declining bone strength with age; depression may exacerbate this trend by potentially influencing rates of bone loss and BMD. Of note, some antidepressants and antipsychotics that may be used to treat depression may exacerbate bone loss through causing hyperprolactinemia and changes in bone metabolism, leading to bone demineralization.

It has yet to be clearly determined whether preventing or reducing depression might improve the health status, disability, comorbid conditions, and quality of life in older women, or vice versa. In addition, there may be complex fluctuating, interactive relationships among these factors so that affecting one may or may not clearly lead to an association with decreased depression. In such cases, multipronged interventions that influence all implicated factors together may be most effective clinically.

Depression has been associated with psychosocial and lifestyle features. In a cross-sectional study of 580 geriatric hospital patients, depression was associated with fewer social contacts and supports. This association persisted even after adjusting for physical and cognitive impairment and was stronger for women than for men. In a study of 860 community-dwelling elderly from 60 to 96 years of age, decreased depression was associated with both light and strenuous exercise status in both women and men, with light exercise having a somewhat stronger effect on depression in women than in men. These findings, albeit associations without clearly established causality, raise questions as to whether programs that promote social support and light exercise might affect depression even more in women than in men.

Although depression and some associated conditions are more prevalent in elderly women than in elderly men, there are significant adverse comorbid conditions associated with elderly men. Suicidality is associated with depression, and because depression is more prevalent in elderly women than in elderly men, it may be expected that elderly depressed women have higher suicide rates. However, the highest rates of successful suicide in the United States occur in elderly white men, possibly due to men using more-lethal means in attempting suicide. This trend has continued despite the decrease in suicide rates in all age groups over the last 15 to 20 years. In a community-based sample of 4,051 elderly individuals, major depression with psychotic features was found to increase mortality risk in both women and men, but milder “neurotic depression” was found to increase mortality risk in men only. Determining why women seem to be more “protected” with respect to these factors might help lead to

more effective interventions for both men and women who are elderly and depressed.

Psychosis

In women, the onset of schizophrenia peaks at about age 25 to 30 years, with a second, smaller peak after age 45 years. In men, the age of onset is earlier, at about 20 to 25 years of age. Psychosis is often considered to be uncommon in elderly individuals without major neurocognitive disorder. However, a 3-year longitudinal prospective cohort study of 347 elderly individuals living in community or institutional settings found that the prevalence of any psychotic symptom was 10.1 percent, higher than previously reported. Moreover, hallucinations, delusions, and paranoia were each related to an increased incidence of major neurocognitive disorder in elderly aged 85 to 88 years. Hallucinations and paranoia were associated with increased 3-year mortality in women but not in men.

A descriptive, cross-sectional study of 90 outpatients with early-onset schizophrenia and 34 with late-onset schizophrenia found that a greater proportion of women had late-onset schizophrenia compared to men (41 percent vs. 20 percent). Women overall had more severe positive psychotic symptoms than men, and women with late-onset schizophrenia seemed to have less severe negative psychotic symptoms than men or women with earlier-onset schizophrenia.

In general, these data suggest that women may be more prone to developing psychosis later in life compared to men and that positive psychotic symptoms are more severe and associated with greater mortality in women than in men. However, antipsychotics are frequently used to treat psychotic signs and symptoms, and use of these medications may affect mortality rates. Both typical and atypical antipsychotics are associated with greater risk of death, so that cautious use of these medications becomes very important.

Other Psychiatric Conditions

Generalized anxiety disorder is much more prevalent among the elderly population than previously believed. In general, anxiety has been reported to be more frequent in women than in men. Among the elderly population, this trend seems to continue. In one study of 103 elderly individuals with generalized anxiety disorder, women comprised 54 percent (25/46) of patients with generalized anxiety disorder and 70 percent (40/57) of patients with both generalized anxiety disorder and major depression.

Regarding bipolar disorder, one epidemiological study found that elderly patients with bipolar disorder reported having higher lifetime and 12-month rates of alcohol use, dysthymia, generalized anxiety, and panic disorder than those without bipolar disorder. Elderly women with bipolar

disorder reported more panic disorder, whereas older men with bipolar disorder reported more alcohol dependence.

Much more needs to be understood about anxiety and mania in the elderly population, especially with respect to gender issues, before specific recommendations for treatment can be made confidently. However, if the trend toward more anxiety disorders in elderly women persists, it suggests that the judicious use of antianxiety agents might be especially pertinent for women compared to men.

Deterioration of the quality of sleep occurs in both women and men with aging. However, when women enter menopause, they are at higher risk for even greater disruptions in sleep patterns. Gender-appropriate treatment may include time-limited hormone replacement therapy used in the early stages of menopause.

TREATMENT ISSUES

The management of psychiatric conditions includes psychosocial, behavioral, milieu, and other psychotherapeutic interventions, as well as biologically based treatments such as medication or brain stimulations therapies like electroconvulsive therapy and transcranial magnetic stimulation.

Psychotherapeutic Interventions

When treating geriatric patients, there are unique aspects to transference and countertransference that must be addressed. Older patients may view younger therapists as being similar to their children and less experienced or knowledgeable about life issues. The elderly may feel more stigmatized at having to seek psychiatric help. Although the therapist's understanding of the older patient's relationships with both parents continues to be important, it may be even more essential to determine what the patient's relationships with children and other mental health professionals have been to effectively treat the older patient. Therapists must pay special attention to their attitudes and biases regarding aging, sexuality, disabilities, losses, and death so that these vital concerns in aging are not avoided and optimal adaptations can be facilitated with the elderly patient. Ageist and stereotyped views of elderly adults as "shipwrecks at the end of their voyage—hard of hearing, with low vision, physically disabled, asexual, unattractive, slow, unproductive, and close to death"—deny many elderly the professional psychiatric help they need, in a respectful, gender-sensitive, reality-oriented, compassionate, and knowledgeable manner that promotes ongoing growth, development, adaptation, friendship, and enjoyment of life.

Gender-specific developmental theory for later life has not yet been established. However, clinically, eclectic psychotherapeutic techniques

incorporating aspects of psychodynamic, cognitive-behavioral, interpersonal, and problem-solving therapy have been found to be useful for older women and men. Individual, couples, family, and group therapies may all be helpful in appropriate situations, and peer support and education are vital.

A psychotherapeutic issue of focus in elderly patients includes the need to adapt to being more dependent than in their younger adult years. Older women and men who, during their younger adult lives, prided themselves on being self-sufficient and able to nurture others may find dependency on others especially difficult. When assistance with personal care is necessary, older patients may have more difficulty accepting direct care from caregivers of the opposite gender, especially if the caregiver is a son caring for a mother or a daughter caring for a father. Excessive resistance to dependency can result in self-injurious or self-neglectful behaviors. Not wanting to be a burden to others (especially one's children) is a common concern and can often be successfully addressed in psychotherapy by pointing out the vital contributions that the older patient has made to the family over a lifetime. Unrealistic and excessive feelings of entitlement and dependency on others beyond actual need and capacity, often with an excessive focus on losses and somatic concerns, may also require therapeutic attention. The individual etiologies and meaning of such behaviors need to be explored and clarified to patients in a gender-sensitive manner.

Family participation is a vital component of psychotherapy with dependent elderly persons. More women in the advanced years live alone, have more chronic illness, and may need assistance from adult children. The readiness for emotional, physical, and, at times, financial commitment to parental caretaking can vary widely among adult children in a family. The skilled and sensitive psychotherapist can assess and effectively distribute tasks and can help families to function as a quasi-multidisciplinary team while facilitating access to appropriate community resources. By not assuming that the women in the family will take on all housekeeping and caretaking responsibilities, gender barriers to participating in caregiving can, at times, be overcome. Family involvement in medication management and treatment adherence, as well as many other activities of daily living for the elderly patient, remains a professional standard in the therapeutic interventions for the dependent, frail elderly. Even if professional caregiving services are paid for by insurance, family involvement often is essential for the appropriate access and deployment of such services.

Another psychotherapeutic issue of focus for elderly patients relates to the developmental phase of becoming a grandparent. This subject needs attention in theory, research, teaching, clinical practice, and policymaking. The stereotyped image of the grandmother as an unemployed or retired

baby-sitting, meal preparing, cookie baking, and ever-available individual has become less and less of a reality. Usually, no such expectations are made of the grandfather, whose interest and assistance are often appreciated at whatever level he chooses. Grandfathers, especially when retired, may enjoy the new roles of helper and caregiver in which they may not have participated earlier in their lives. A therapist's role in a grandparent's life can include resolution of intergenerational conflicts and facilitation of the development of this new and challenging identity. Grandmothers who live alone and at a distance are less likely to have the financial resources to visit other family members than grandfathers or grandparents who live together. Clinical observations have revealed that depriving older women of the opportunity of regular visits with adult children and grandchildren can contribute to depression and considerable distress. Other clinical observations reveal that older parents who survive alcohol use disorders from their younger years tend to get depressed when rejected by adult children who cannot forgive their abusive behaviors from earlier years. This rejection inadvertently leads to deprivation of the grandparent role.

A third psychotherapeutic issue of focus involves addressing cultural, societal, and economic predicaments that the elderly patient may be facing. The older population includes persons born around the turn of the previous century, as well as those born after World War II. Many members of the aging population came to the United States during various immigration waves. Thus, cultural heterogeneity is vast in both elderly women and elderly men. Intergenerational and gender-based variations in cultural practice and language may lead to conflict, calling for cross-cultural psychotherapeutic intervention.

The elderly have experienced many societal changes in the United States. Gender roles for women have changed from being primarily defined by men in power and authority to being less stereotyped and more self-determined. Yet, it is common knowledge that women who succeed in this male-dominated world, be it in political, corporate, academic, or other venues, remain more often than not in the minority. Most of these women learn the "male rules of the game," and many modify their lifestyles by remaining unattached, delaying childbearing, enduring the trials and tribulations of fertility specialization technologies, adopting children, or having no children. Communication styles, behaviors, and responsibilities within and between genders, families, and generations have changed markedly. Elderly patients may benefit from psychotherapy in dealing with the causes and consequences of these tremendous fluctuations in societal roles and circumstances.

Coping with financial issues, including payment for health care and extended care facility placement, is often a focus of psychotherapeutic intervention for the elderly. Money management is becoming more

complex. Greater numbers of women rise to this task earlier in life, and more women without experience in financial matters have to rise to the task in later life. The economic effects of lower educational levels, traditional work roles, and income discrimination experienced by women in young and middle age become exaggerated as retired women depend on pensions and Social Security derived from preretirement income. Women are about one-half as likely as men to have pensions, and the amount of their pension is one-half as much as that of men. When men die, they are three times as likely to leave an impoverished spouse. Single, widowed, and divorced women often have to purchase the in-home care that married men are provided through their spouses. Women live longer, have more disabilities, and live alone more often than men. Thus, they often require the services of nursing homes more than men do. Seventy-five percent of nursing home residents are women aged 65 years or older. Women are four times more likely than men to use Medicaid for nursing home care because of their relative indigent status. Due to relatively low Medicaid reimbursement to nursing homes, these women have little choice in the selection of a nursing home. They must share a room, their beds can only be held for a limited period of time in case of hospitalization, and medications must be generic. Older men with spouses to look after them at home use more acute care hospital Medicare dollars than women. Medicare does not pay for skilled nursing home care for more than 100 days (with days 21 to 100 requiring a coinsurance payment), only covers rehabilitative nursing home care after a 3-day hospitalization, and provides limited coverage for prescriptions. In the past, Medicare provided only 50 percent coverage for outpatient psychotherapy visits; with the movement for parity in mental health, Medicare covers 80 percent. Many managed care companies with Medicare contracts have discontinued care provision for the elderly population, leaving many without continuation of much-needed medical care from their primary care physicians. Education and problem solving regarding these issues, and psychotherapeutic support that promotes the patient's psychological strengths and resources, may empower patients to cope with these difficult situations with a greater sense of hope and mastery.

Over the last few decades, online (Internet) computer use has grown in the population in general and may be a source of psychoeducational and peer support for the elderly, especially for those who are more isolated. One study of 174 subjects found no significant main effects for gender and online communication and relationship preferences for friends, family, coworkers, or unknown individuals. However, high Internet users had higher scores on online communication and relationship building. Another study found that although access to computers was equal for both women and men, in the year 2000 women were 0.7366 times and in the year 2002 they were 0.5675 times less likely than men to use computers to obtain

web-based health information.

Psychotherapeutic treatment for family caregivers of frail or disabled elderly is important. Family caregivers often continue to work full-time and also may have children for whom they are caring. These caregivers are at times referred to as "the sandwich generation," caught between the tasks of caring for children and elderly. Many sites of employment continue to be unfriendly to family caregiving. Extended-family members, including grandmothers, who traditionally might have been able to provide more care might be employed and less available for helping in child and dependent elder care, or need care themselves. Reconstituted families on their second and third marriages are spread thin between children of spouses. Availability and quality of community resources for caregiving have remained inconsistent because of inadequate funding and staffing. Consequences of many of these changes are manifested in the crisis of informal caregiving of the elderly who are challenged by mental illness, physical conditions, cognitive disorders, and/or functional deficits.

Pharmacological Interventions

The complexities of incorporating gender issues are often not addressed in the scientific literature specifically, especially among the elderly. However, there has been some research evaluating gender differences in the pharmacokinetics and pharmacodynamics of drugs in animals and younger humans.

Pharmacokinetics. Pharmacokinetic investigations in animals and younger patients have revealed gender differences in various factors that affect drug absorption and bioavailability, drug distribution, metabolism, and elimination. Gender differences have been documented for gastrointestinal motility and metabolizing enzyme effects, but studies have not consistently shown a difference in drug bioavailability between women and men. There are few studies examining differences in bioavailability, and these are generally confounded by variability in other pharmacokinetic factors, such as distribution, metabolism, and excretion. The available evidence suggests that gender-based differences in bioavailability are not clinically significant.

Gender-related differences in drug pharmacokinetics may be due primarily to differences in drug distribution, given that many of the factors influencing volume of distribution differ by gender. In general, women, compared to men, have a higher percentage of body fat, lower mean body weight, decreased plasma volume, and less organ blood flow, leading to differences in the rate and extent of drug distribution. In women, compared to men, due to differences in body fat, lipophilic drugs may have greater volumes of distribution and water-soluble compounds may have less. A larger volume of distribution for diazepam has been observed in women

compared to men, thought to be due to differences in proportions of body fat and gender-related protein-binding changes.

Gender-related differences in plasma protein binding may lead to pharmacokinetic differences for certain agents. Although albumin levels usually are not affected by gender, endogenous and exogenous estrogens decrease levels of α-1 acid glycoprotein (AAG) in plasma and induce hepatic AAG-glycosylation. Exogenous estrogens also increase serum-binding globulins such as sex-hormone–binding globulins, corticosteroid-binding globulin, and thyroxine-binding globulin. Variations in levels of such plasma-binding proteins may change the amount of active agent that is available. This may be important to consider when interpreting serum drug levels.

Pharmacokinetic variability is influenced greatly by gender-related differences in drug metabolism. Hepatic drug metabolism is influenced especially by hepatic enzyme activity, as well as by liver blood flow, which is less in women than in men. The cytochrome P450 3A (CYP 3A) subfamily, especially CYP 3A4 in humans, is active in the initial hepatic metabolism of a large number of medications. Other prominent cytochrome P450 enzymes include CYP 1A2, CYP 2B6, CYP 2C9, CYP 2C19, CYP 2D6, and CYP 2E1. Drugs also can be metabolized through intestinal CYP enzymes. The frequency of hepatic metabolizing enzyme variant alleles has been reported to differ among ethnic groups and by gender in younger humans and animals. Gender-based differences in drug levels have been attributed to gender differences in hepatic enzyme activity, which also are influenced by endogenous sex hormone production and hormonal changes associated with exogenous sex hormone use, pregnancy, and menopause. Enzyme CYP 2D6 has been found to be important in metabolizing antipsychotic agents. It has been reported that tardive dyskinesia develops more frequently in Chinese women with schizophrenia than in men due to the increased frequency of defective CYP 2D6 alleles in Chinese women. The activity of enzyme CYP 1A2 has been found to be prominent in the metabolism of antipsychotics and is higher in females than in males.

Drug excretion usually is through the kidney or the liver. Renal clearance of drugs depends on the glomerular filtration rate, which is directly proportional to weight and thus higher in men than women, in general. Gender-related differences in drug renal excretion rates are most likely due to weight differences.

Pharmacodynamics. Pharmacodynamic changes in drug response based on gender have not been as well studied as pharmacokinetic differences. Gender-related pharmacodynamic changes are differentiated from pharmacokinetic effects by showing that a given plasma level of active drug in both women and men does not result in the same pharmacological outcome.

Many psychotropic medications have been reported to have gender-related modifications in pharmacodynamics. Women have greater impairment of psychomotor abilities from diazepam compared to men. This is thought to be due to heightened diazepam pharmacodynamic sensitivity in women. Compared to men, women show more improvement in psychotic signs and symptoms and greater severity of adverse side effects from typical antipsychotic agents. Further studies need to be done to determine whether these differences are caused primarily through pharmacodynamic or pharmacokinetic processes. Some but not all research suggests that women and men appear to show different effects to various antidepressants, although more work is needed to clarify these findings.

FUTURE DIRECTIONS

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) includes sections on Gender–Related Diagnostic Issues for many diagnoses. Yet, it could greatly benefit from more evidence-based gender- and age-specific data, especially regarding the neurocognitive disorders. Incorporating gender into the evaluation and management of psychiatric conditions in an evidence-based fashion is important but extremely complex, given that the differences or similarities in responses and outcomes that are observed between elderly women and men may be due to multiple factors. These factors may be affected by contextual, sociocultural roles and attitudes, genetically based, affected by prenatal hormone organizational effects, related to natural or drug-induced hormone fluctuating activational effects, associated with variable circadian/sleep patterns, or influenced by pharmacokinetic/pharmacodynamic characteristics. In elderly individuals, the sum of these, as well as the effects of aging, may play a role. To evaluate these factors carefully, studies ideally would include standardized psychiatric and functional rating scales that are gender sensitive, incorporate sociocultural contextual measures (such as those evaluating immigration status, ethnocultural and religious values, family and caregiving roles, employment status, and socioeconomic level), assess genetic factors, have greater numbers of observations to account for potential behavioral fluctuations that may be related to changes in hormone levels and circadian/sleep patterns of behavior, evaluate pharmacokinetic and pharmacodynamic factors using gender-appropriate methods, be prospective and longitudinal in nature, and enroll both women and men in adequate numbers to be able to carry out meaningful comparative analyses by gender. Routinely incorporating functional neuroimaging investigations into descriptive and psychotherapeutic/drug interventional studies also may enhance knowledge regarding gender-based differences and similarities in brain function. Data on outcomes with absolute and proportional indices, sociocultural contextual measures,

genetics, pharmacokinetics, pharmacodynamics, adverse effects, dropouts, onset and rates of psychotherapeutic or drug intervention effects, and placebo response should be reported by gender. Such all-inclusive studies are challenging to design, carry out, and complete. Due to constraints in resources, time, subject participation, and other practical considerations that can affect scientific rigor, most studies are planned using partial models, focusing thoroughly on a few aspects of any broadly comprehensive study. Approaches such as study replication/semi replication with convergence of outcomes and statistical techniques using meta-analysis or physiology-based whole-body population models for assessing the influence of individual variability on the pharmacokinetics of drugs are used in an attempt to help shed light on complex issues. Still, information garnered from the appropriate analysis of primary data of well-designed, highly powered studies would be most convincing.

The Society for Women's Health Research (http://swhr.org) highlights many specific alarming gender gaps in knowledge that hinder effective prevention, treatment, and cure for conditions that are prevalent in women. Research, clinical, and educational attention and resources need to be expanded to include the older population in ways that are equitable to their numbers, especially older women.

Gender-based life-cycle studies, of which Erik Erikson, George Vaillant, and others have been the pioneers, should be carried out simultaneously for women and men, rather than sequentially for each gender, to provide the necessary information regarding which lifestyles and conditions promote or hinder healthy aging for women and men. Appropriate and useful engagement of aging men and women regarding the benefits of rapidly changing information technologies needs ongoing attention and development. As psychosocial processes affect illness outcome, so does illness affect psychosocial processes. Thus, affective, cognitive, and functional status need routine assessment in primary care, and all medical records from primary care physicians, including gynecologists, need to be available to the psychiatrist before the patient's first visit. The managed care interfaces with necessary state-of-the-art medical and mental health care need serious attention and overhaul. Interdisciplinary work, rather than mental health carve-outs and fragmentation of medical mental health care, has been shown to benefit patient care and to be cost-effective.

The caregiving crisis needs major policy attention.

Education for all primary care and specialties in age- and gender-sensitive diagnosis and interventions needs to start early in medical school and residencies.

Much progress has been made in promoting gender-sensitive research and the prevention, evaluation, and treatment of illnesses. However, tremendous amounts of work still need to be done to promote greater understanding of the similarities and differences between genders in the

elderly patient relative to the description, etiology, treatment, and intervention of psychiatric illnesses and the enhancement of healthy behavior.

57.6e The Legal and Ethical Analysis of Elder Abuse

PAUL RICHARD GREENWOOD, L.L.B. (HONS.), ANSAR M. HAROUN, M.D., AND DAVID NAIMARK, M.D.

INTRODUCTION

Americans who are 65 years or older are the fastest growing population in the United States and in much of the developing world. As an example, the U.S. Census Bureau has projected that California's elderly residents will nearly double within the next 20 years—from 3.7 million to more than 6.4 million. The mounting statistics suggest that humans are on the verge of essentially being a "graying world." The term "elder abuse" is now as familiar as spousal abuse and child abuse.

In the past, law enforcement has routinely minimized the importance of cases involving elderly victims. Police officers have tended to stereotype older victims, prosecutors have been reluctant to allow seniors to testify, and judges have underestimated the impact of abuse upon the victim. Within the medical profession there has been a reluctance to accept that an obligation is owed not only to the elderly patient, but also to the community, to report suspected incidences of elder abuse.

Most states have specific statutes in their criminal codes addressing "elder abuse" crimes, yet few prosecutorial agencies take advantage of such laws, in part because of outdated perceptions about seniors. Some of the classic stereotyping of older citizens portrays them as being senile, fragile, long-winded, grumpy, hard of hearing, and unable to see well.

It is not unusual for police officers to write incomplete crime reports when the alleged victim is elderly because of an unfounded belief that the victim is incapable of providing sufficient information that could lead to a successful prosecution, that he may not have a reliable memory, that his senses are not adequate, or that he may not be strong enough physically to pursue prosecution. A number of communities have recognized the failings of such misconceptions and the use of multidisciplinary teams (MDTs) has created an effective response to combat this escalating crime. Psychiatrists are as an essential component of MDTs that can provide much needed information on cognitive issues for law enforcement, adult protective workers, and prosecutors.

DEFINITIONS

For the sake of clarity, a few definitions are proposed. Elder abuse can take three basic forms—physical, financial, and emotional/psychological. Within these broad categories are several other subcategories.

Physical elder abuse includes assault and battery, neglect, and sexual assault. Assault and battery is primarily inflicted by either: (1) opportunists who target the elderly in the streets with muggings and robberies, (2) family members (typically sons, daughters, or grandchildren) who systematically wield aggression against the elderly relative, or (3) care providers who, out of a sense of frustration, lash out in anger against the victim.

Neglect may be present when a care provider willfully or deliberately fails to provide basic services of hygiene, medical support, or nutrition to the victim. The term "willful" encompasses circumstances where a caregiver intentionally "turns a blind eye" to an obvious condition that requires a positive act in order to alleviate a situation that is endangering the health of the elderly patient. Examples of neglect would include a failure to turn a bedridden elder (causing Stage 4 pressure sores) or a deliberate withholding of crucial medications (resulting in deterioration in the elder's health).

Sexual assault typically occurs through force, threats, or deception and culminates in unwanted sexual activity. Such conduct can include rape, nonconsensual kissing or fondling, and the taking of sexually explicit photos or videos of the elderly victim.

Financial elder abuse manifests in several forms:

Theft—Most commonly, thefts of personal items including jewelry and antiques (taken by a care provider) that inevitably wind up in the local pawn shop.

Theft of individual checks—Again, most commonly committed by a trusted care provider, checks are usually ripped from the back of the victim's checkbook and when cashed, are typically out of sequence.

Misuse of an ATM card—Is likely to be perpetrated by somebody who has gained the trust of the victim, or by the use of threats and intimidation.

Credit card fraud—Going beyond just the misuse of personal credit, the perpetrator successfully forges the victim's details into a new credit application that has been obtained without the victim's consent or knowledge.

Theft of assets—Involves large-scale pilfering of assets such as savings accounts, stocks, or real property. Trusted individuals may employ a power of attorney (POA) or quitclaim deed, either of which will be obtained through stealth or intimidation. A POA is a legal document that permits another person to make legal decisions on behalf of the elder. Depending on how the document is drafted it may permit the other party to sign checks, open new accounts, or transfer assets belonging to the elder. A quitclaim deed is a legal document that transfers an interest in real property to another person.

Scams—Today's uncertain financial climate is fertile ground for crooks and conmen to target the elderly with a wide variety of schemes. A few are listed here:

Telemarketing fraud such as bogus charity schemes, illegal sweepstakes, and false investments take advantage of susceptible elders.

Door-to-door salespeople who convince the elderly victim to pay up-front for labor services such as a new roof, driveway, or other home improvement. These con artists may make off with the up-front money or stay around to bilk the senior out of his or her savings.

Pretending to be representatives of utilities or roofing companies or some other trustworthy agency, thieves gain access to a senior's home with the intention of either stealing what they can, or casing the residence for a return visit and a more comprehensive theft

opportunity.

Exchanging a senior's assets in return for a false promise of "lifetime care" relies on a fear that often haunts a senior's contemplation of the future, when he or she may be less self-reliant.

Telephone scams involve a caller pretending to be a relative, such as a grandchild, who is in some kind of trouble and needs money.

Emotional/Psychological elder abuse—Normally presents as verbal threats by a family member. Psychological abuse may include threats, intimidation, humiliation, or other such degradation. Threats may encompass hints of personal violence against the victim, a loved one, or a pet if the victim fails to deliver on financial "commitments."

NOSOLOGY

DSM-IV-TR contained a section on "Problems Related to Abuse or Neglect," which included a subsection on "Abuse of Adult," both physical and sexual, but not psychological! The more recent DSM-5 renames this area as "Adult Maltreatment and Neglect Problems" and continues with Adult Physical Abuse and Adult Sexual Abuse, but also adds Adult Psychological Abuse. This change reflects the growing realization that maltreatment may take many forms, including:

- Physical and sexual abuse, recognized in both DSM-IV-TR and DSM-5.
- Psychological abuse, now recognized in DSM-5.
- Neglect, which has a DSM-5 code for both child neglect and for spouse or partner neglect, but not for adult neglect (where neglect of elders may be coded).
- There remains no DSM-5 code for
- Self-neglect, where there is no perpetrator, but the elder fails to provide for self in a proper manner, thus threatening personal health or safety.
- Abandonment, when a caretaker or legal guardian leaves the elder to fend for herself.
- Exploitation, where a vulnerable elder is the victim of some scam, usually material or financial.

FACTORS ASSOCIATED WITH ELDER VULNERABILITY

Old age can create a unique profile, sometimes enabling exploitation. The elderly are likely to have:

- desirable assets (money in various forms)
- legal rights to control those assets through their decision-making
- some impairment in decisional capacities
- psychological desire to exercise autonomy

Because elders often recognize some of their limitations (in their knowledge or in the process required for wise decision-making), they may develop relationships to enhance such decision-making, and thus be guided by advisors whose selection is based on:

- trust (family members who are trust worthy, but not necessarily wise)
- expertise (lawyers and financial planners who may be clever, but not trustworthy)
- legitimate (blessed by some authority, like a legal guardian or a priest)
- knowledgeable (such as their treating doctor)
- able to reward or punish (their caregiver or whomever gives them spending money)
- charismatic (able to charm the elder)

These characteristics have no relationship to the moral character of the advisor, who may be a saintly figure (determined to promote the interests of the elder), or a "scoundrel" (interested only in self-interest). The combination of an advisor who is motivated only by self-interest and an elder who is vulnerable, accordingly raises the risk of exploitation. Such exploitation may violate the law, or ethics, or both. The law is written in language that is precise, so there is usually a crisp boundary between what is legal and illegal, and such (illegal) exploitation is thus easy to recognize. It may be more difficult to recognize some behaviors as exploitative if they do not violate the law, but are ethically questionable.

MULTIDISCIPLINARY TEAMS

In recent years, in response to the escalation in reported elder abuse incidents, many communities have developed an MDT. Some states have provided for the creation of such teams through legislation. Examples are the establishing of a Financial Abuse Specialist Team (FAST) or an Elder Death Review Team (EDRT). Key members of an MDT are representatives from Adult Protective Services (APS), law enforcement, prosecutors, financial institutions, medical examiners, hospital personnel, mental health case workers, the Public Guardian, and psychiatrists.

APS is the agency in the majority of states that provides social services to elders and adults with disabilities. However, unlike their counterpart Child Protective Services, APS relies heavily upon the cooperation of the "client." If the victim refuses services offered by APS, then typically the investigator has no option other than to walk away and close out the case.

There is no uniform definition for an elder who falls under the jurisdiction of APS. Some states use age as definitive. For example, California defines an elder as anyone 65 years of age or older, while Illinois regards an elder as anyone 60 years or older. Other states use a variety of definitions including "endangered adult" or "vulnerable adult."

Psychiatrists should become familiar with their local APS agency and with their State's definition of "elder." A useful starting point is to contact the National Adult Protective Services Association (NAPSA). Additionally, inquiry should be made of the local APS as to whether an elder abuse prevention MDT exists. Psychiatrists can provide valuable insight at such meetings, particularly when there are discussions about undue influence and consent. Most MDTs have a Memorandum of Understanding (MOU) that clarifies issues of confidentiality and potential conflicts of interest.

An important role of the MDT is to provide ongoing education to professionals about current elder abuse issues. Special attention should be aimed at improving interviewing techniques, the importance of photographs and videotaped victim interviews, and in spotting red flags and indicators of abuse.

Mandated reporters need to understand their duty to report suspected elder abuse. There should be ongoing discussions about enhancing or establishing a public awareness campaign that informs the community of the correct channels for reporting suspected cases of abuse. MDT members should orchestrate community efforts to create billboards, posters, and public service announcements on local television and radio. Slogans such as "abuse is getting old" have been found to be an effective means of getting the message out to the public.

The MDT sessions should use every opportunity to educate personnel who deal with elders in need, such as APS case workers, emergency room nurses and doctors, paramedics, and fire officers in awareness, recognition, and response:

APS workers: after an initial referral is made via a "1-800" telephone number, a caseworker is assigned to pay an unannounced call upon the senior. These workers need to be tuned into looking for possible signs of abuse in order that they will know when to bring in law enforcement.

Emergency room and other medical personnel: sometimes an elderly patient will appear at a hospital suffering from injuries sustained from an assault or through neglect. Medical practitioners need to be able to differentiate between accidental and intentionally inflicted injuries. The victim may be unwilling to explain the cause of such injuries truthfully, and it will be up to the triage nurse to obtain as many details as possible regarding the patient's living conditions and the events leading up to the patient's arrival at the hospital.

Paramedics: at times, these professionals are the first responders to a domestic call for assistance when an elderly person is in need. If the paramedic is not trained to observe certain indicators of abuse or neglect, there is a danger that the police will not be called to the scene. Fire officers, like paramedics, are often the first responders to the home of an elderly victim. They also require training to spot potential abuse or neglect.

Financial workers: the venue for many crimes of financial elder abuse is

a bank, credit union, or stockbroker firm. The perpetrator will often take the elderly victim into a financial institution in order to prepare a POA or arrange for a transfer of monies. The staff at these institutions may or may not be trained to spot various techniques used to exploit seniors. MDT members dealing with personnel from financial institutions can help alert them to red flags and suggest possible responses. For example, financial staff should make it a policy to discuss any alterations in financial arrangements or substantial withdrawals with elderly customers in private, away from the elder's companion. Some states have already established protocols—notably Massachusetts and Oregon—and these protocols provide excellent resources for other states. Several states have enacted laws that provide immunity to banks when reporting a suspected case of financial elder abuse to APS or to law enforcement.

Attorneys who provide legal assistance to elderly clients: need to be educated about the signs of dementia and the impact that cognitive impairment can have on the elderly client's decision making. Psychiatrists can give valuable insight to these professionals about the need for sensitivity in gauging an elder's capacity to make sound legal decisions.

THE RED FLAGS AND INDICATORS OF ABUSE OF AN ELDER

At times, signs of elder abuse may be mistaken for the initial symptoms of dementia or merely the result of increasing frailty. Caregivers may offer logical-sounding explanations for everything from unusual bruising to abnormally frequent check writing. While many caregivers are warm and caring people who are trustworthy, professionals who interact with elders need to examine situations with a keener eye than the general population.

A victim of elder abuse may become increasingly withdrawn from the community and much more dependent upon the perpetrator. If an unannounced visit by a caseworker from APDS is made, the perpetrator may insist that: "this is not a good time." Excuses might include that the victim is sleeping or is unwell. Even if access is given, the caregiver may try to prevent a private conversation between victim and the social worker or friend by leaving the door open or by hovering over the victim. Family and friends who attempt to make telephone calls are often prevented from speaking directly to the victim or the perpetrator will monitor the phone call in some fashion.

Notable physical signs include:

1. Unexplained signs of injury such as bruises, welts, or scars. It is especially concerning if they appear to be symmetrical or shaped like a specific object.
2. Broken bones, sprains, or dislocations.
3. Overdose of prescription drugs or indications of medication not being taken regularly (a prescription has more remaining than it should, or

remains unfilled).
4. Broken eyeglasses or frames.
5. Signs of physical restraints (marks around the wrists or ankles).
6. Unaccounted weight loss, signs of malnutrition, and dehydration.
7. Untreated physical problems (bed sores, urinary tract infections, etc.).
8. Unsanitary living conditions (dirt, bugs, soiled bedding, and clothes).
9. Elder being unbathed and unkempt.
10. Unsuitable clothes for the weather.
11. Living without essentials (no heat or running water, faulty electrical wiring, and other fire hazards).
12. Elder left alone in a public place.

In financial transactions at a bank, the suspect caregiver will often attempt to control the conversation with the bank official and will endeavor to speak on behalf of the victim. The bank clerk may be told that the elderly customer is sick or hard of hearing. The suspect will justify the need for a POA, or will insist that any withdrawals are made in cash.

Other financial red flags include: larger than usual withdrawals, sudden changes in the elder's financial condition, items or cash reported missing from the senior's home, suspicious changes in wills, POA, titles, and policies. Sometimes, names are added to the senior's signature card and bills are uncharacteristically left unpaid. There may be evidence of financial activity that the senior could not have initiated because of physical impairments, contracts for unnecessary services, goods, or subscriptions, or evidence of over- or under-medication.

SENIORS AND THE COURT SYSTEM

For many seniors, their own abuse situation will be their first exposure to the criminal justice system. There are often fears, misconceptions, and feelings of reluctance. It may be important for a treating psychiatrist to discuss such feelings with their patient prior to a hearing where the elder will be required to testify. Moreover, with the elder's permission, it could prove helpful for the psychiatrist to reach out to the prosecutor or victim advocate prior to the hearing to discuss any major concerns.

Competency of a witness to testify—the general rule is that every person is competent to be a witness in a court proceeding. The threshold is low; and typically the witness need only show that he or she understands the significance of taking the oath and be able to appreciate the difference between telling the truth and a lie.

ESTABLISHING A "THEFT" IN ELDER FINANCIAL ABUSE

Sometimes it is difficult to ascertain whether sufficient evidence exists to prove that a suspect has taken property from the victim without consent and with the intent to permanently retain said property.

Three different scenarios often surface:

Scenario One—The victim is able to testify competently that the defendant took money or property without consent. The victim may be asked to look at a check and confirm that the signature is a forgery or that a series of ATM transactions were not authorized.

Scenario Two—The victim is incompetent to testify because of advanced dementia. The transaction took place at a time when the victim was already diagnosed with that advanced condition. A treating physician for the victim will need to lay the appropriate medical testimony foundation to establish that the victim would have been unable to provide the necessary consent at the time of the transaction.

Scenario Three—The victim is marginally competent to testify, although there may be some signs of short-term memory loss. The victim appears to have voluntarily transferred assets to the suspect and appears to understand the nature and extent of the transaction. The suspect may describe the transfer as either a gift or a loan. Law enforcement may have refused to investigate such a scenario on the basis that no apparent crime has been committed. The scenario may be further complicated by the fact that the victim, prior to the transaction, was taken to meet with an attorney (unsurprisingly, chosen by the suspect) to discuss the impending transfer. That attorney will likely testify that the client understood the significance of the transaction and wished to proceed. This last scenario is the most difficult one to prove as a theft. The suspect has clearly manipulated the elderly victim to bring about the intended result. Lawyers refer to that conduct as "undue influence."

Historically, the concept of undue influence has been used widely in civil actions such as will contests or contract disputes. But only a few states recognize undue influence as a criminal concept. As a result, creativity is required in order to introduce evidence of manipulation that will demonstrate that the transaction was completed without the victim's consent. Often a psychiatrist can provide valuable testimony—either as an expert witness to explain undue influence, or as a percipient witness to discuss the victim's susceptibility to manipulation.

Consent is the cornerstone of many financial elder abuse cases. In California, the trial judge in a criminal financial elder abuse case can instruct the jury with the following definition of consent:

To consent to a transaction a person must:

- Act freely and voluntarily and not under the influence of threats, force, or duress
- Have knowledge of the true nature of the act or transaction involved

- Possess the mental capacity to make an intelligent choice whether or not to do something proposed by another person

The judge will then conclude: "Consent requires a free will and positive cooperation in act or attitude."

In grappling with the question of whether an elder was susceptible to undue influence, certain factors should be weighed:

1. The length of the relationship between the victim and the suspect. The longer the friendship, the less likely it is that fraud can be established.
2. The nature of the relationship between the victim and the suspect. If the suspect performed certain services for the victim without any other evident remuneration, an assessment must be made to determine whether the amount of the transfer was a reasonable exchange for services rendered.
3. The spending habits of the victim prior to the transfer. If it can be established that the victim had a history of frugal spending, it might be possible to show that this particular transaction was completely out of character.
4. The amount of the transfer compared to the residual left for the victim. Sometimes, the victim is left with insufficient funds to provide for unexpected emergencies after the transaction has been completed.
5. The documentation that accompanied the transaction. If the suspect maintains that the monies were given in the form of a loan, then it might be expected that supporting paperwork evidencing a loan were drafted at the same time.
6. The question of whether the lawyer who prepared the documentation was introduced by the suspect to the victim.
7. The issue of whether the victim demonstrated any changes in behavior prior to the transaction that might point to signs of short-term memory loss, confusion, or a decrease in the ability to make wise decisions.
8. The methods used by the suspect to develop the friendship with the victim. Did the suspect create a false persona to be more interesting to the elder? Did the suspect gradually isolate the victim from other friendships and family, causing the victim to become increasingly dependent upon the suspect? Did the suspect ply the victim with alcohol to wear down the victim's defenses?

EXCUSES AND JUSTIFICATIONS IN ELDER ABUSE

The psychiatrist should be familiar with common reactions to accusations of elder abuse. The alleged perpetrator may first deny that there was abuse. Since elder abuse requires some combination of actual harm, intended harm, and bad motive, the alleged perpetrator may argue that any of these factors is absent. But if confronted with evidence of proven abuse, the perpetrator may employ some excuse or justification.

In an excuse, the perpetrator admits that abuse happened and further admits that such abuse should not have happened, but nevertheless has an excuse like:

- "it was an accident" (with no intent to perform the action), or
- "it was a mistake" (the action was indeed intended, but executed in some faulty manner), or
- "the victim provoked me," or
- "I was impaired" (tired, intoxicated, overwhelmed), or
- "Most nursing homes treat their elders just as I did, so I was following the norm."

In contrast, if a perpetrator invokes a justification, he alleges that while the abuse was regrettable; given the circumstances, it was the right thing to do:

- "I did provide substandard care (abuse), but if I had demanded more resources for better care, I would have been fired. If that were to happen, then the nursing home would not have any doctor, so the residents would be without any medical coverage."
- "Since some medical coverage (even if it is substandard) is better than no medical coverage; given the circumstances, I was justified in doing what I did."

ETHICAL ANALYSIS OF SUSPECTED ELDER ABUSE

1. The difference between threats and offers–

most people think threats are ethically bad, while offers are ethically acceptable, but the distinction may be difficult to see:

Vignette 1

facts:

a child says to parents:

"either – leave all your assets to me in the will,

or ———I will put you in the cheapest nursing home, since you cannot take care of yourself."

analysis:

this is a threat, and it seems the child is exploiting the parents' lack of capacity for self-care, and this may qualify as elder psychological abuse

Vignette 2

facts:

a child says to parents:

"if you leave all your assets to me in the will,

then—I will not put you in a nursing home, but buy a larger home, and you can live with me in your old age."

analysis:

this is an offer, thereby not exploitative, and likely does not qualify as

elder psychological abuse

In both cases, the parents are invited to consider a deal, and both deals are substantively very similar. But in, one case it is manipulative, while in the other it is not.

2. The difference between shoves and nudges–

An advisor or caregiver should presumably respect the autonomy of the elder; violating such autonomy is unethical. "Shoving" an elder into a decision (forcing a decision onto an unwilling elder) is clearly unethical, but the ethics of "nudging" (where the elder retains autonomy) remains controversial.

Competent elders should be masters of their own agency, but examples where such agency can be changed, altered, or influenced includes:

- Reframing Information

An elder's medical interest would be promoted by taking a first-generation antipsychotic, but the elder refuses such treatment. The patient will only consent to meds that help him "relax." The doctor mentions "Mellaril" and when the patient asks if that will cause him to feel "mellow," the doctor reports affirmatively, and the patient consents to Mellaril (to feel mellow). Since the patient did exercise autonomy, there was no shove. The doctor nudged the patient, by the reframing of information, which was not a lie (Mellaril does have a sedating action, which is "mellowing"). This nudge benefits the recipient of the nudge.

- Overcoming Queasiness

An adult child knows his parents' views on postmortem organ donation and therefore encourages them to do the paper work, but they keep avoiding it, out of queasiness. Finally, the child employs a nudge to get this done. Such a nudge benefits neither the nudger, nor the nudgee, but rather, society as a whole.

- Overcoming Procrastination

An adult child wants his parents to write their will so that he will get his inheritance easily, rather than be forced to go through probate. The elderly parents keep postponing this task, out of procrastination. Finally, the child employs a nudge to get this done. All the benefit of such an action (writing the will) goes to the child, not to the elderly parent (who will be dead).

CONCLUSION

Over the last few years, elder abuse has become one of the most common crimes in the United States. It is important to prepare now to meet the challenge by developing an expertise so that the abuse can be identified, and the abusers held accountable. The responsibility to watch out for the senior population is a collective one. Psychiatrists will play an increasingly

important role in the fight against elder abuse over the next few years. Becoming an active member of a local MDT that develops protocols to combat elder abuse is an effective first step.

CASES

Profile of a Physical Abuser of the Elderly

Very often the abuser of an elder is the son of a widowed woman. He is either divorced and has come back to live at home with his mother because of financial pressures borne by the divorce or he is single, and has never left home. He tends to be in his late-30s to mid-40s, while his mother is usually in her mid-to-late 70s. In the majority of cases, the son is lazy and unemployed. He will have used a variety of excuses as to why he is unable to work, and his mother has accepted such excuses. He will be addicted to alcohol (normally beer), narcotics, or gambling. In order to feed his habit, the son extracts money from his mother. There may come a time when the mother refuses to provide any more money, and this tends to be the flash point for violence. Violence may begin with him breaking objects in the home that he knows the mother values. An escalation of violence may materialize as grabbing his mother's arms and shaking her or pushing her into furniture or throwing an object at her. Characteristically, the mother will not immediately call the police, perhaps out of a sense of failure or shame. Often, neighbors hear the altercations between the son and his mother, but they may also be reluctant to involve the police.

Profile of a Financial Abuser of the Elderly

The profile of the financial abuser is more difficult to describe. The exploiter can be a family member who has been distant for many years; then after the death of a spouse, the elusive relative surfaces to befriend the widow or widower in the hope of acquiring some or all of the anticipated inheritance. Alternatively, the abuser can be a trusted individual such as the victim's attorney, realtor, accountant, pastor, or physician. Ultimately many financial abusers of an elder will rely upon portraying the transfer of assets as either a "gift" or a "loan." For that reason many alleged thefts from elders are mistakenly judged to be "civil" violations, rather than criminal.

57.6f Sexuality and Aging

ABESH KUMAR BHATTACHARJEE, M.D., PH.D., AND DANIEL D. SEWELL, M.D.

An estimated 10,000 Americans turn 65 years old everyday and are joining the pool of about 40 million individuals who are presently over 65. As a result, by 2030, the number of individuals in the United States who are 65 years old or older is expected to grow to 72 million. The fastest growing segment of the population is people over 80. Issues affecting older people, therefore, are becoming increasingly more important. Traditionally, aging has been viewed as a period of progressive decline in physical, psychosocial, and cognitive domains, which consequently increased the health care burden. This negative view of old age contrasts starkly with the recently ascendant concept of *healthy aging* or *successful aging*, which is supported by existing research on older adults who continue to function well and to be active, productive, and engaged in life. Self-rated *successful aging* indicates that it is a subjective perception of an individual's quality of life, which comprises physical, social, and spiritual dimensions. Sexual activity and enjoyment are considered components of these quality of life dimensions, particularly the physical and psychosocial dimensions.

Regardless of how long a person lives, experiencing human closeness and intimacy remains important. Individuals and societies react in a variety of ways to sexual intimacy among older people. Despite the rapid growth of the older population and the aggressive marketing of products aimed at sexual health in later life, sexuality in older adults has received relatively limited research attention. A review of cross-cultural data from 106 traditional societies determined that sexual behavior in older men and women was very common though not invariably observed. For example, 84 percent of the studies, which included information about sexual behavior in older females, documented continued sexual activity and interest among older females. The authors of this review concluded that the continued sexual activity among older members of many traditional societies and the cessation of sexual behavior among older members of other traditional societies suggested that cultural, as well as biological factors, might be important determinants of sexual expression in later life in these societies.

Cultural and biological factors also appear to be important determinants of sexual behavior in the industrialized world where many still believe that older people stop having sex or believe that it is dangerous for older people to be sexually intimate. For some, certain cultural taboos from the Victorian era may, even today, inhibit sexual behavior, and provoke both intrapsychic and interpersonal conflict. Older people may internalize the myth of sex in older age being "wrong" or "inappropriate" and some may choose to repress their sexual urges rather than become objects of derision or disapproval (e.g., being considered "a dirty old man"

or, in the case of women, “a cougar”).

Fortunately, over the past 50 years, attitudes about later-life sexuality have been evolving. Contrary to persistent stereotypes, recent studies have indicated that many older men and women remain sexually active, experience sexual desire, and regard sexual activity as an important aspect of their lives. Moreover, multiple aspects of sexual health in older adults are positively associated with self-rated health and indicators of physical function. The Women’s Health Initiative Study found that activity and satisfaction with sexuality were associated with higher self-perceived successful aging and quality of life. The acceptance of hormone replacement therapy for menopausal and postmenopausal women, the increasing popularity of the oral erectogenic agents, and the incorporation of “ED” into the common vernacular, all indicate changing attitudes about sexuality in later life.

It is possible to live a happy and fulfilling life without sex. A clinician who is knowledgeable about sexuality in later life and willing to discuss sexuality with older patients has the challenge of creating an open, safe environment for discussion without implying that any problem necessarily exists. Ironically, a therapist who addresses these issues must be aware that the introduction of the topic may be perceived as very helpful or may unintentionally trigger feelings of inadequacy or incompleteness in patients for whom sex never was or is no longer a central part of life. Sexual disinterest is a matter of concern only if a person finds it troubling or if it causes problems in relating to others. All things considered, it is better to ask with sensitivity about sexual behavior, listen carefully to determine if sexual problems exist, and to remember that whatever reaction ensues will serve as an opportunity for a deeper understanding to develop between the patient and the clinician.

In order to help older individuals who are experiencing a discrepancy between their desire for sexual intimacy and their actual experience of it, knowledge about the following may be useful: (1) the neurobiology of sexual function; (2) the effects of aging on sexual function; (3) the recommended guidelines for how to take a sexual history; (4) the types of sexual dysfunction, their causes, and their recommended treatments; and (5) the impact of institutional living on sexual expression.

NEUROBIOLOGY OF SEXUAL FUNCTION

The neuroendocrine perspective of sexual behavior can be summarized in a five-component model focused on neurological and hormonal mechanisms that lead to behavioral and motivational changes during human development. These components of sexuality are sensorimotor (prenatal and neonatal spinal reflexes, such as penile or clitoral erections), valence or salience (sensory stimuli developed in late juvenile period), attractiveness (a wide range of behaviors intended to increase sexual attractiveness),

receptivity (the willingness to engage in sexual activity), and solicitation or proceptivity (the urge to seek out partners). With reproductive maturity, all become tightly coordinated until later in life when these components may become uncoupled again because of different rates of change associated with aging.

The neuroendocrine model acquires a new level of nuance and complexity when considered through the lens of sociological and psychological conceptualization of sexual motivation. Historically, the scientific literature tends to consider sexual interest and motivation in terms of desire and arousal and places sexual desire in a nested framework of contexts, from dyadic relationships, to communities, to cultures. Such a perspective on sexual motivation shares much with the interactive biophysical model of health, which posits that health is a function of biophysical and psychocognitive dynamics between individuals over time.

Various models of sexual arousal and response have been proposed over the past century. Masters and Johnson described four sequential phases to the "sexual response cycle": excitement, plateau, orgasm, and resolution. Kaplan proposed a triphasic model of sexual response, which highlighted the interdependence of the three components (desire, excitement, and orgasm) and proved to be clinically helpful because the phases correlate well with various common sexual problems. For example, low libido or hypersexuality are problems with phase I or the desire phase, erectile dysfunction (ED) or dyspareunia are problems with phase II or the arousal phase, and anorgasmia or premature ejaculation are problems with phase III or the orgasm phase. The *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-5) uses these phases as a basis for classifying the sexual dysfunctions. One of the more recent refinements of the sexual response cycle has been the addition of the concepts of "spontaneous desire," which is believed to be more typical of men, and "stimulus-driven desire" which is believed to be more significant for women and refers to desire aroused by stimuli such as the behavior or appearance of the partner. Hypoactive sexual desire disorder is significant among women. Additional information about the neurobiology of the sexual response cycle can be found elsewhere in this text.

AGE-RELATED CHANGES IN SEXUAL FUNCTION AND BEHAVIOR

Aging may have both positive and negative impacts on sexual expression. Normal age–associated changes in sexual function are summarized in Table 57.6f–1. For women during and after menopause, lowered estrogen levels cause atrophy of the vaginal epithelium, labia majora, and Bartholin glands, as well as shortening and loss of elasticity of the vaginal canal. Reductions in vaginal blood flow, genital engorgement, and vaginal lubrication lead to delay in achieving sexual arousal. Loss of lubrication may also contribute to dyspareunia. While orgasmic capacity is retained

with age, decreased muscle tone may decrease sensitivity, orgasm may require a longer period of direct stimulation, there may be reductions in the number and intensity of vaginal contractions and some women may experience painful uterine contractions during orgasm.

Testosterone in the central nervous system influences female sexual behavior and women experience declines in androgen levels with age, especially between the third and fifth decades of life. There is not yet consistent evidence demonstrating a direct relationship between reduced testosterone levels and change in sexual functioning in women but, in general, lowered levels are thought to contribute to decreases in libido, arousal, responsiveness, genital sensation, and orgasm. Some recent research suggests that both estrogens and androgens may work together to enhance sexual arousal and response in women. For example, the administration of estrogen plus small amounts of testosterone to menopausal women may provide greater improvement of psychological symptoms such as sense of well-being, depression and fatigue as well as of sexual problems related to the effects of estrogen deprivation on the genitalia, decreased libido and anorgasmia. Perhaps even more than in men, however, variability of sexual response in women is likely to be contextual, partner based and relatively independent of biological control systems. In general, for women the response to sexual stimuli is largely influenced by the quality of emotional intimacy with the partner. Frequently, the emotional and relationship well-being a woman experiences contribute more to sexual enjoyment than the physiological response.

Table 57.6f–1.
Normal Age–Associated Changes in Sexual Function

Function	Male Changes	Female Changes
Sex hormones	Decline in testosterone levels	Cessation of estrogen production Decline in testosterone levels
Genitals	Fewer and less functional sperm Decreased penile blood flow Decreased penile smooth muscle relaxation	Cessation of ovulation Decreased pelvic blood supply Shortening and narrowing of vagina Atrophy of vaginal mucosa, labia majora, Bartholin glands Decreased vaginal elasticity Decreased muscle tone
Fertility	Reduced rates of conception	Ceases after menopause
Libido	For some, may decline due to lower testosterone	For some, may decline due to lower testosterone
Arousal	Requires more tactile stimulation Erections take longer to achieve Erections are less firm Erections more difficult to sustain	Requires more tactile stimulation Decreased vaginal swelling/lubrication Decreased clitoral sensitivity

Orgasm	Takes longer to achieve Ejaculation is less forceful Decreased ejaculate volume	Takes longer to achieve Fewer, less forceful vaginal contractions
Refractory period	Lengthened by hours to days	Lengthened

In men, testosterone is necessary for normal libido and optimal erectile function. In men, as in women, testosterone levels also progressively decline with age, particularly beginning around the fifth decade of life, while levels of sex hormone–binding globulin increase. These changes result in more bound testosterone and less free or physiologically available testosterone and are believed to be responsible for the gradual decline in sexual responsiveness in men as they age. Specifically, psychic and tactile stimuli are less effective and full penile erections occur more slowly. Maintenance of erections also requires more direct genital stimulation. The force and volume of ejaculation may diminish, ejaculation may not even occur with every sexual encounter but difficulties with rapid ejaculation tend to lessen with increasing age. Other age-related changes include possibly less intense orgasms, retrograde ejaculation, more rapid penile detumesence, and longer refractory periods.

Despite the clear role that testosterone plays in male sexual behavior in later life, the relationship between them still remains unclear. For example, the observation that men with a deficiency of testosterone may be capable of an erectile response demonstrates some independence of sexual arousal from testosterone levels and underscores that a lack of sexual interest in men does not result only from a lack of testosterone. Many psychological and relationship factors may contribute to libido in men such as the perceived level of attractiveness of the partner, various feelings toward the partner such as resentment or hostility, issues related to maintaining control or feeling controlled, and difficulties dealing with sexual dysfunction in himself or his partner.

Until relatively recently, surveys of the frequency of sexual function in later life have, in general, been limited by methodological shortcomings such as relatively small, nonrandom subject samples of convenience and questions which narrowly define sex as coitus. In addition, the studies of the effects of aging mainly involve white, middle class, well-educated predominantly heterosexual populations, so there is currently much less information about the role that race, culture, sexual orientation, gender identity, education, and socioeconomic conditions play in determining sexuality. According to several major surveys, 50 to 90 percent of men and women over 60 continue to be sexually active, usually defined as having sexual intercourse at least once a month.

Perhaps the two best recent explorations of this issue have come from the National Social Life, Health, and Aging Project (NSHAP) which provided researchers with data from a nationally representative probability

sample of 3,005 community dwelling older US adults in wave 1 of this study (1,550 women and 1,455 men) who were 57 to 85 years old, defined sex or sexual activity as "any mutually voluntary activity with another person that involves sexual contact, whether or not intercourse or orgasm occurs," and included in-home interviews conducted in English and Spanish by professional interviewers. Analysis of this data revealed that sexual activity over the past 12 months declined with age. Overall, men were more likely than women to be sexually active, report a good quality of life, and be interested in sex. These gender differences increased with age and were greater among the 75- to 85-year-old group. For men, 84.4 percent for those 57 to 64, 67.4 percent for those 65 to 74 and 38.9 percent for those who were 75 to 85 years old were sexually active whereas for women 61.9 percent for those 57 to 64, 39.8 percent for those 65 to 74 and 16.8 percent for those who were 75 to 85 years old were sexually active. The wave 2 of this study focused on measuring sexual interest, behavior, sexual experience, frequency, and appeal of physical contact in 3,377 community dwellers who were 62 to 90 years old, and of whom 73.7 percent (n = 2,487) had a spouse or cohabiting partner. It is important to note that 54.8 percent (n = 1,365) engaged in touching genital organs of their partners. Fifty-nine individuals who were 80 to 90 years old had sexual intercourse in the last 12 months, compared with 383 individuals who were 62 to 69 years old. In general, the measures for the salience/valence and receptivity (terms defined in an earlier paragraph under neurobiology of sexual function: neuroendocrine model) components decrease with age. Other noteworthy findings from this study included: the inclination to make one's self sexually attractive to others is stronger in women, two-fifths of the men and women reported dissatisfaction with their partner's frequency of caring behavior that makes later sexual behavior pleasurable, a fifth of women and quarter of men had vaginal sex in the past year and physical contact is frequent among those living with partners, whereas it is rare among those living alone.

Perhaps as the result of biological factors, social conditioning, or some combination of both, some older people were not especially interested in sex when they were younger and, even with the increased acceptance of later-life sexuality, growing older has not increased their interest. For other older individuals, sexual intimacy has become associated with painful emotional conflict resulting from or causing difficulties with their partners. One member of a couple may have a significantly different level of interest or functional ability than the other. For these individuals, the stereotype of "sexless old age" may provide a comfortable shelter from what are experienced as vexing and/or insurmountable obstacles to the achievement of sexual satisfaction. Still other older individuals may have simply grown tired of sex and have replaced sexual intimacy with other satisfying nonsexual activities. Some older individuals become celibate as the result

of a deliberate decision to share sex only with a particular partner who may have become too ill or disabled to have sex or who may have died. The sexual behavior of some older people may be influenced by a religious belief that sex is solely for procreation and, therefore, ends with the completion of menopause. Although it is important to be aware of older people's sexuality, clinicians must be careful neither to oversexualize the aging process, nor to overmedicalize declining sexual function and interest.

Sexually active older adults need and benefit from sex education. Table 57.6f–2 includes strategies for enhancing sexual function in later life. Older adults also need education about HIV and other sexually transmitted diseases (STDs). HIV infection and acquired immunodeficiency syndrome (AIDS) are no longer problems associated only with those who are members of high-risk groups such as gay men, sex workers, and intravenous drug users. Older individuals have also become part of the epidemic although, fortunately, from 2008 through 2012 the estimated annual numbers and rates of HIV/AIDS diagnoses in 65 years old and older aged groups remained stable in the United States. In 2008, according to the Center for Disease Control (CDC), among persons 65 years old and older in the United States, the estimated number of diagnoses of HIV infection was 896 (rate = 2.4 per 100,000 persons) and persons living with HIV infection ever classified as stage 3 (AIDS) was 748 (rate = 2 per 100,000 persons). In 2012, among persons 65 years old and older in the United States, the estimated number diagnosed with HIV infection was 792 (rate 2.1 per 100,000 persons) and stage 3 (AIDS) was 673 (rate = 1.8 per 100,000 persons). In terms of racial and ethnic minority differences, individuals who self-identify as Black/African American or White continue to rank highest among racial and ethnic minorities in terms of the number diagnosed with HIV infection and with AIDS.

Table 57.6f–2.
Strategies for Enhancing Sexual Function in Later Life

Optimize your physical health
Maintain a heart healthy diet
Get sufficient rest
Have your hearing evaluated and corrected if necessary
Learn and practice good dental hygiene which includes flossing and seeing a dentist on a regular basis
Take good care of your skin
Avoid tobacco products
Minimize alcohol intake
Engage in regular physical exercise
Learn and perform specific exercises that can improve your appearance and function such as crunches and knee raises for a protruding abdomen and Kegel exercises for weakened pelvic muscles
Obtain optimal treatment of any medical illnesses
Inform the clinicians who prescribe medications for you that you wish to avoid medications which are likely to cause problems with sexual function

Pretreat symptoms of pain or dyspnea that interfere with sex
Use lubrication to counteract vaginal dryness and sensitivity

Optimize your psychological health

Foster a positive attitude toward sexuality in later life
Put aside unrealistic expectations of sexual performance

Optimize the health of your relationship with your sexual partner

Maintain open, honest communication
Identify and discuss changes in sexual function
Discuss ways to adapt sexual practices to these changes
Focus extra time and energy on sensual foreplay
Select sexual practices and positions that account for declines in strength and endurance

HOMOSEXUALITY AND OTHER SEXUAL MINORITIES IN LATER LIFE

While it was once thought that gay people represented 10 percent of the adult US population, more reliable recent data estimate the prevalence of homosexuality as between 1 and 5 percent. The 2013 National Health Interview Survey (NHIS) was the first national survey to include a sexual orientation question. In this survey, 2.3 percent of survey participants characterized themselves as LGBT, a relatively new term designed to include bisexual and transgender persons under one umbrella with those who identify as gay or lesbian because all of these individuals are members of sexual minorities and, as a result, remain at risk for misunderstanding, rejection, discrimination, and violence due to their sexuality. The use of this term represented an effort by the surveyors to use the most up-to-date vernacular in order to obtain the most reliable and trustworthy data regarding the number of individuals who belong to a sexual minority.

The NHIS included interviews of a nationally representative sample of 34,557 adults aged 18 and older. The NIHS found that 1.6 percent of adults identified as gay and lesbian and 0.7 percent identified as bisexual. A higher percentage of women than men identified as bisexual (0.9 percent compared with 0.4 percent). Among people 65 years old and older, 0.7 percent identified as gay and lesbian and 0.2 percent identified as bisexual. It is important to be aware of the possible role that methodology has on research findings in this area. For example, the sexual orientation/identity question consistently yield a lower percentage of people saying that they were LGBT, on average about 3.5 percent, then the percentage obtained when people were asked if they engage in same-sex behavior, which was around 8 percent. In addition, the question about same-sex attraction yielded the highest response rate of around 11 percent.

In an ongoing effort to include all sexual minorities under one umbrella due to their shared experiences, the term LGBT continues to evolve and a more recent version of this term is LGBTQ where the “Q” stands for questioning or queer. When the “Q” is used to denote questioning, it refers to individuals who remain uncertain of their sexual orientation. In some instances the “Q” is used as a shorthand for “queer” which historically has

been a pejorative term for gay, but which is now being reclaimed by some gay men, lesbians, bisexuals, and transgendered persons as a self-affirming umbrella term. Keeping the geriatric theme of this chapter in mind, the authors recommend caution when using the term "queer" because this term may still be experienced as extremely offensive when used as an epithet, especially among older members of a sexual minority group.

The current older generations of the LGBTQ community grew up during a time of pervasive homophobia, heterosexism, and associated discrimination and hate crimes. Before the turn of the 20th century, few LGBTQ individuals had any sense of connection to others like themselves or acceptance by society at large. Most married opposite sex partners had either lived double lives or suppressed all homosexual sexual inclinations. Not until the Stonewall riots in 1969 gave birth to the modern gay liberation movement, did the LGBTQ community begin to develop a sense of solidarity and systematically begin to pursue greater social acceptance. As a result, many older LGBTQ individuals have endured major traumas personally, politically, and socially. Many older LGBTQ couples are still living completely or partially in the closet. The complicated challenges of the AIDS crisis have in some ways both helped and hindered efforts to increase acceptance and have diverted both attention and resources away from other important issues which impact the LGBTQ community such as cancer research.

Contrary to the long held societal belief that older members of the LGBTQ community are destined to be single, lonely, and unhappy, many have long-term relationships, are emotionally stable, and may be just as likely (or as unlikely) to be successful and happy in their later years as heterosexual individuals. The majority of the potential challenges faced by older LGBTQ couples are identical to those faced by older heterosexual couples but a few of the challenges may be different. Older LGBTQ individuals may find themselves socially isolated with few or no role models for growing older. An older member of the LGBTQ community may experience a lack of support from friends, relatives, neighbors, coworkers, as well as various forms of discrimination from hospitals, various levels of government and other institutions such as insurance companies. This isolation and unequal treatment can become particularly difficult when a partner is ill or dies. For example, some hospitals do not recognize LGBTQ relationships in terms of visitation rights and consultation with medical professionals. At the time of this writing, 37 states, plus the District of Columbia, now allow same-sex marriage, and 13 states prohibit same-sex marriage or civil unions. Seven out of ten US residents now reside where same-sex marriages are legal. The state-by-state trend toward legal recognition of same sex marriage, as well as changes in certain institutional and federal policies, have helped eliminate forms of discrimination and unequal treatment in a variety of situations such as hospital visitation,

income tax benefits, insurance, retirement benefits, and inheritance but the legal rights of LGBTQ couples in states where same sex marriage is not legal, generally remain unclear and unprotected. In January 2015, the US Supreme Court announced its intention to issue a ruling on this issue.

A number of organizations now exist which may provide support and guidance to more senior members of the LGBTQ community. The existence of these organizations may be especially important for the older individual who begins the process of *coming out* when older. *Coming out of the closet*, or simply *coming out*, is a figure of speech for self-disclosure of belonging to a sexual orientation or gender identity minority group. Framed and debated as a privacy issue, coming out of the closet is a multifaceted experience in which each person may have shared unique experiences. These organizations include: the Senior Action in the Gay Environment (SAGE) which offers a variety of social services to older gays and lesbians and has independent affiliates in various cities in the United States and Canada; the Lesbian and Gay Aging Issues Network (LGAIN), which is sponsored by the American Society on Aging, and the National Association of Lesbian and Gay Gerontologists which has created a resource guide for older gays and lesbians. In addition, LGBTQ community centered around the country often sponsor or support social organizations for older members of the LGBTQ community. For example, in San Diego, California the LGBTQ community center supports a social organization for older members of the LGBTQ community called Fellowship of Older Gays (FOG).

HOW TO OBTAIN A SEXUAL HISTORY

Knowing how to take a sexual history is the first step in helping an older person with their sexual quality of life. Many patients think that all psychiatrists are knowledgeable, skillful, and interested in addressing sexual concerns. Unfortunately, education in human sexuality and on how to take a sexual history is not always emphasized in medical school curriculums and residency training programs. Though the ability to take a sexual history is not especially difficult to master, doing so may provoke certain fears such as: (1) the clinician or patient experiencing arousal while talking about sex; (2) not knowing what questions to ask or how to help with a patient's sexual problems; (3) unexpectedly becoming aware of one's own sexual concerns; or (4) having the patient see one's moral repugnance or personal distaste about certain sexual practices. These apprehensions will be reduced by: (1) identifying them in yourself; (2) thinking about them rationally; (3) learning about the broad range of sexual expression; (4) understanding professional boundaries; and (5) acquiring more knowledge and experience regarding the diagnosis and treatment of sexual dysfunctions.

Recent research has found that psychiatrists are less likely to obtain a sexual history from older patients presenting with depressive symptoms

compared with younger patients and they are also less likely to refer to appropriate services if sexual dysfunction is identified. On the other hand, many older people are reluctant to seek help for asexual problems even if they have a significant effect on quality of life. The evaluation of the sexual functioning of an older individual is similar to the evaluation of a younger adult, although for the younger clinician it may be more difficult due to ageist beliefs or fears of appearing disrespectful. General considerations include: (1) establishing rapport which may require that this topic not be explored until at least the second or third contact; (2) introducing the topic by putting it in context (e.g., sexual behavior is both an indicator of health and a contributor to health); (3) accepting that the first few times you introduce the topic, you may feel uncomfortable and may even blush but not letting this stop you; (4) being aware of your own potential prejudices and subconscious feelings; (5) not waiting for the patient or patient's partner to introduce the topic because they may assume that you are only interested in "medical problems" or may view sexual problems as trifling (partner's caring for a partner with dementia may be especially prone to make this assumption because of fears that asking about may portray them as selfish or as inadequate caregivers); (6) beginning with a neutral, nonjudgmental statement like "have you experienced any changes in your sexual life?" or, when the older individual is being assessed for depression, "sometimes when people feel very low and depressed, they lose all interest in sex. Do you think this is an issue for you?"; (7) using open-ended questions and active-listening techniques; (8) demonstrating sensitivity to the patient's values and beliefs; (9) establishing a private and comfortable environment; (10) allowing sufficient time for discussion which means bringing up the issue no later than the midpoint of the time period set aside for the meeting; (11) not making assumptions like the person is heterosexual (less than 10 percent of older persons are questioned about their sexual orientation) or that the person has a sexual problem; (12) being clear that sexual activity includes both coital and noncoital behaviors; (13) providing information about HIV and other STDs including the fact that condom use not only prevents conception but also prevents transmission of STDs; (14) educating patients regarding age-related changes that may affect sexuality, like "often women around the time of the menopause can suffer not only with the hot flushes you have described, but also with sexual problems such as vaginal dryness. Is that something you have experienced?" or "people at your age may experience ED. Is that something you have experienced?" and, if clinically indicated, discussing noncoital methods of achieving sexual intimacy; (15) possibly using humor. (Note: A phenomenological study with experienced nurses in long-term care found that the use of humor was an effective method of addressing the sexual needs of older adults.)

HOW TO ASSESS SEXUAL DYSFUNCTIONS IN OLDER PATIENTS

Because sexual dysfunction in later life can result from psychological, psychiatric, medical or social causes, or from some combination of these factors, an optimal evaluation should cover of all of these areas. For example, psychological factors that impact sexual function in later life include decreased self-esteem or a decreased sense of sexual attractiveness due to physical changes which may be natural changes associated with aging or changes brought about by illness or the treatment of illness such as a mastectomy for breast cancer. Sexual dysfunction may also develop when a member of a couple experiences an illness such as a depression, dementia, or stroke, which precludes emotional intimacy. Social issues may also trigger sexual dysfunction. The lifespan of men in the United States is shorter than that of women (life expectancy in 2010 for US males was 76.2 years and for US females was 81.0 years) which often leaves older women without sexual partners.

In the large recent survey of community dwelling older adults referred to above, among respondents who were sexually active, about half of both men and women reported at least one troubling sexual problem. The most prevalent sexual problems among women were low desire (43 percent), difficulty with vaginal lubrication (39 percent), and inability to climax (34 percent). Among men, the most prevalent problems were erectile difficulties (37 percent), performance anxiety (27 percent), and climaxing too quickly (26 percent). Rating one's health as poor was associated with decreased likelihood of being sexually active and, among those sexually active, being more likely to report sexual problems. The prevalence of discussing sex with a physician since age 50 for men and women was 38 and 22 percent, respectively.

The following are some guidelines on how to optimally assess sexual dysfunction in an older patient. When a sexual problem involves both the person with the dysfunction and his or her partner, then inclusion of both individuals in the assessment is essential. Often each person will have a somewhat different version of the problem. To initiate the interview, the clinician should ask the identified patient to describe the problem and then ask the partner "What do you think about this report?" Such open-ended questions can be followed up by more specific questions designed to pinpoint which phases of the sexual response cycle (desire, arousal, or orgasm) are involved for the patient and the patient's sexual partner. Illnesses which cause pain, malaise, or actual physiological or anatomical limitations may impact any of the phases of the sexual response cycle.

After the joint interview, each person should be interviewed individually. For widowed patients who are in second relationships, it may be difficult to acknowledge in front of the new partner that guilt regarding the deceased partner is contributing to the sexual problem. In fact, the loss of a partner may be the biggest barrier to sexuality for older individuals,

especially for older women. Certain societal taboos, though waning, may still prevent a surviving partner from seeking a new mate. Even when a new mate is found, an older person may experience sexual difficulties as a result of guilt arising from a perception of being unfaithful to a former partner and anxiety about overcoming old patterns of physical intimacy and establishing new ones. Masters and Johnson called this "the widower's syndrome."

It is essential to learn about the role of sexuality in each person's life and about past sexual experiences. Potentially useful questions include: what would be the optimal frequency? have there been any problems before? what has changed in your relationship? and what is the meaning or value of intimacy? Some individuals may view emotional intimacy as an essential precursor to quality physical or sexual intimacy while for others the primary value of sex is to assuage libido.

Elucidating the time course of the development of the sexual problem may help uncover underlying etiologic factors. For example, if the problem's appearance coincided with the onset of an illness of the initiation of a particular medication, then a causal connection should be considered. Asking a question like "sometimes a person taking these medications notices sexual problems; is this something that has affected you at all?" may be helpful. Many medications, including medications with psychiatric indications like selective-serotonin reuptake inhibitors (SSRIs), have the potential to impact one or more aspects of sexual function. An abrupt onset of a change in sexual function temporally related to the introduction of a medication strongly suggests that this medication may be the cause.

In general, a gradual onset suggests an etiology related to chronic medical illness. For example, does osteoarthritic pain limit movement or physical position? does cardiovascular disease reduce physical stamina? are physical changes associated with aging or illness provoking embarrassment in the person or impacting sexual interest in the partner? is a previously unrecognized or suboptimally treated psychiatric or substance use disorder present? and what is the patient's current sexual ability? It may be helpful to elicit a detailed history of the patient's most recent previous sexual experience. The ability to achieve orgasm during masturbation suggests that the sexual problem may have a psychological origin.

THE TREATMENT OF SEXUAL DYSFUNCTION IN OLDER ADULTS

Just as in a younger adult, sexual dysfunction in an older patient may cause significant distress. The clinician must integrate all of the pertinent information into a compassionate and reasonable treatment plan. If there is a contributing psychological problem, individual and/or couples psychotherapy should be provided. If the sexual problem has a relevant physical or biological component, then education and medications may be helpful.

The treatment of sexual dysfunctions may be viewed through the lens of the sexual response cycle. The first phase of the sexual response cycle is "desire." Desire may be influenced by psychological, psychiatric, or medical problems. For example, illnesses whose optimal treatment requires surgery may result in physical disfigurement (e.g., mastectomy), which, in turn, triggers low self-esteem and feelings of being no longer sexually attractive or desirable. Psychiatric illnesses, which may decrease desire include major depression and alcoholism. Mania is often associated with hypersexuality and the various forms of dementia may lead to increases or decreases in libido.

A variety of medical illnesses have the potential to reduce libido. One common pathway for certain medical illnesses to trigger decreased libido is through reduction in androgen levels. Illnesses associated with lowered androgen levels include chronic renal failure, chronic pulmonary disease, hepatic cirrhosis, hyperthyroidism, and HIV. A number of medications such as anticonvulsants and tamoxifen may also lead to lowered testosterone levels. In 2013, the Endocrine Society convened a task force which updated and published online a clinical practice guideline for treatment with testosterone in adult men. These guidelines recommend making a diagnosis of androgen deficiency only in men with consistent symptoms and signs and unequivocally low serum testosterone levels. The measurement of morning total testosterone level should be repeated and in some patients, measurement of free or bioavailable testosterone level is necessary. Initiation of testosterone therapy is recommended for men with symptomatic androgen deficiency to induce and maintain secondary sex characteristics and to improve their sexual function, sense of well-being, muscle mass and strength, and bone mineral density. (Table 57.6f–3summarizes the symptoms and signs of testosterone deficiency for both men and women). Testosterone therapy should not be initiated in patients with breast or prostate cancer, a palpable prostate nodule or induration or prostate-specific antigen greater than 4 ng/mL or greater than 3 ng/mL in men at high risk for prostate cancer such as African American men or men with first-degree relatives with a history of prostate cancer without further urological evaluation, a hematocrit greater than 50 percent, untreated severe obstructive sleep apnea, severe lower urinary tract symptoms with International Prostate Symptom Score above 19, or uncontrolled or poorly controlled heart failure. Men receiving testosterone therapy should be monitored regularly. The task force members who created this guideline favored a cutoff for men of levels less than 300 ng/mL while others favored 200 ng/mL. Finally, another unresolved controversy is the method by which testosterone levels should be measured. The gold standard is equilibrium dialysis but this test is expensive, labor intensive, and not widely available. Most laboratories measure free testosterone by the analog method, which often yields less reliable results.

Table 57.6f–3.
Signs and Symptoms of Low Testosterone

Men
Erectile dysfunction
Infertility
Women
Impaired arousal
Decreased genital sensitivity
Both
Breast discomfort
Decreased libido
Decreased muscle strength
Depression
Hot flushes, sweats
Inability to concentrate
Lethargy
Mild anemia
Sleep discomfort

Based on currently available data, it is clear that sex steroids influence female sexual function but the measurement of androgen levels in women presenting with low sexual function is not helpful and should not be used for the purpose of diagnosing androgen insufficiency in women. Although a recent report suggests that many women following oophorectomy have no decline in sexual function, a subset of women with lowered androgen may experience lowered libido and there is some evidence that testosterone therapy in this setting may be helpful. Whether testosterone treatment is appropriate for women who have normal testosterone levels and lowered libido but no other signs or symptoms of androgen deficiency has not been established. Currently, there are no approved medications for female hyposexual desire disorder.

The Endocrine Society Clinical Practice Guideline reappraised androgen therapy in women after the Task Force established by the Endocrine Society commissioned two systematic reviews of published data and reviewed several other existing meta-analyses. The Task Force recommended against: (1) making a diagnosis of androgen-deficiency syndrome in healthy women because there is a lack of a well-defined syndrome and data-correlating androgen levels with specific signs or symptoms were unavailable; (2) the general use of testosterone for the following indications: infertility; sexual dysfunction other than hypoactive sexual desire disorder; cognitive, cardiovascular, metabolic, or bone health; or general well-being; (3) the routine use of dehydroepiandrosterone due to limited data concerning its effectiveness and safety in normal women or those with adrenal insufficiency; and (4) the routine prescription of testosterone or dehydroepiandrosterone for the treatment of women with

low androgen levels due to hypopituitarism, adrenal insufficiency, surgical menopause, pharmacological glucocorticoid administration, or other conditions associated with low androgen levels because there are limited data supporting improvement in signs and symptoms with therapy and no long-term studies of risk. Evidence supports the short-term efficacy and safety of high physiological doses of testosterone for postmenopausal women with sexual dysfunction due to hypoactive sexual desire disorder. Importantly, endogenous testosterone levels did not predict response to therapy. At present, physiological testosterone preparations for use in women are not available in many countries including the United States and long-term safety data are lacking. Any woman receiving testosterone therapy should be monitored for signs and symptoms of androgen excess.

Sexual problems of the arousal phase of the sexual response cycle include ED, vaginismus, and dyspareunia. ED is defined as the inability to achieve and/or maintain an erection satisfactory for sexual function. Studies have found that the prevalence of ED is significantly higher among older men as compared to those in younger age groups. The Massachusetts Male Aging Study found a tripling of the prevalence of complete ED among men aged 70 years as compared to those aged 40 years. Compared with men in their 20s, those in the oldest age group (70 to 75 years) had a 14-fold higher relative risk for ED. In this study, age was found to be the strongest predictor of ED. Other age-adjusted risk factors significantly associated with ED included hypertension, diabetes, heart disease, obesity, smoking, hypercholesterolemia, lack of physical exercise, poor health, depressed mood, and prostate disease.

There are now a handful of medications that may be helpful to men with sexual dysfunctions involving the arousal or orgasm phases of the sexual response cycle. Phosphodiesterase V inhibitors act peripherally on the penile vascular system to improve tumescence. These medications increase cyclic GMP in the corpus cavernosum, which relaxes smooth muscle in the penile vasculature and fosters blood flow. Three medications in this category are now available: sildenafil, vardenafil, and tadalafil which essentially only differ in their half-lives. Other agents for ED include transurethral and injectable prostaglandin E1, which are less convenient to administer but may appeal to some men who value the immediate and predictable response and who show poor response or intolerance to phosphodiesterase V inhibitors. Alprostadil, a synthetic form of prostaglandin E1, is currently used and it has a unique role in men with ED secondary to diabetes and secondary to radical pelvic surgery (e.g., radical prostatectomy). Based on a variety of factors including effectiveness and patient preference, vacuum pump devices are an alternative treatment for ED. Both manual and battery-operated devices are available and, if determined to be medically necessary, will be paid for by Medicare. Surgical implantation of a penile prosthesis is a third option for treatment

of ED and is generally considered only after the less invasive interventions have proven unsuccessful.

Premature ejaculation and anorgasmia are sexual dysfunctions of the orgasm phase of the sexual response cycle. Increasing age often diminishes, or sometimes even resolves, problems with premature ejaculation. Finally, there are data that bupropion may have some value for improving sexual function. In one study, both normal subjects and patients who took bupropion reported improvements in desire, arousal, and orgasm and these effects appeared to be independent of antidepressant efficacy.

The definitions of female sexual dysfunction have recently been revised in the DSM-5, with merging of hypoactive sexual desire disorder and female sexual arousal disorder into female sexual interest/arousal disorder. There are no FDA-approved medications for female arousal disorders or orgasmic disorders. The value of phosphodiesterase inhibitors for women with sexual dysfunction remains unclear. An open-label nonrandomized study found that sildenafil 50 mg was well tolerated in postmenopausal women with sexual dysfunction and was associated statistically nonsignificant improvement in vaginal lubrication, clitoral sensitivity, and orgasm frequency and overall sexual desire or satisfaction with sexual intercourse did not improve. A controlled study of sildenafil 25 or 50 mg as needed found that both doses resulted in greater arousal, more frequent orgasms, and greater sexual satisfaction compared with placebo. Bupropion may also be useful for sexual dysfunction in women. One small study (n = 20), found that women had significant improvement relative to placebo in all aspects of sexual function including intensity of orgasm on either bupropion-SR 150 mg or 300 mg daily. It is important to note that several small-scale studies have assessed the effects of the above-mentioned drugs. The results are still conflicting and the drugs are not devoid of adverse effects. Currently ongoing phase I and II clinical trials for drugs to treat for female sexual dysfunction include topical alprostadil, bremelanotide (BMT), intranasal testosterone (TBS-2), intravaginal dehydroepiandrosterone (DHEA), sublingual testosterone with sildenafil, apomorphine, bupropion and trazodone.

The treatment of sexual dysfunction can also be viewed through the lens of specific illnesses. Almost any illness may cause sexual dysfunction. Some of these illnesses may be gender specific, for example, “senile” vaginitis and prostate cancer, and others may impact both genders. Those most often associated with sexual dysfunction are illnesses which negatively impact physical stamina or cause pain, those that require medications that adversely impact sexual function, or those that impact the endocrine system, the reproductive system, or the nervous system. Table 57.6f–4 lists some of the illnesses, which may cause sexual dysfunction in later life. Given that the prevalence of serious medical illness increases with age, it is not surprising that sexual dysfunctions are more common in older patients.

In a patient with chronic renal disease, sexual function may be diminished due to fatigue and malaise. Chronic renal disease may also lead to sexual dysfunction due to associated vascular disease, neuropathies, and endocrine abnormalities. For example, both free and total testosterone levels are lowered in chronic renal disease but may return to normal following transplantation. In patients with chronic renal disease, sexual dysfunction may also be related to abnormalities between the pituitary and the Leydig axis. Both vitamin E and erythropoietin have been reported to improve sexual function in men with renal failure.

Table 57.6f–4.
Some of the Medical and Psychiatric Conditions Associated with Sexual Dysfunction in Later Life

Diseases that negatively impact physical stamina or cause pain
AIDS
Chronic fatigue
Chronic obstructive pulmonary disease
Congestive heart failure
Coronary artery disease
Degenerative joint disease
Fibromyalgia
Irritable bowel syndrome
Peripheral vascular disease
Renal failure
Diseases that require medications that adversely impact sexual function
Cancer
Hypertension
Disease of the endocrine system
Diabetes Mellitus
Hypercortisolism (Cushing syndrome)
Hyperpituitarism (acromegaly)
Hypopituitarism
Hyperthyroidism
Hypothyroidism
Reproductive system diseases
Breast cancer
Cervical cancer
Ovarian cancer
Prostate cancer
Testicular cancer
Uterine cancer
Diseases of the nervous system
Alzheimer dementia
Epilepsy
Generalized anxiety disorder
Major depressive disorder
Multiple sclerosis

Obsessive compulsive disorder
Panic disorder
Parkinson disease
Schizophrenia
Substance use disorders

Studies have found that cardiovascular disease including myocardial infarction (MI) may physically and psychologically interfere with sexual functioning and negatively impacts all three phases of the sexual response cycle in older women as well as older men. Following an MI, many patients have concerns about intercourse that include anxiety about inability to perform or fear that one may die during coitus. Angina may contribute to fears of having an MI during sex and reduce libido. In addition, the anxiety and depressive disorders that commonly occur after an MI may themselves cause sexual dysfunction.

Sexual intercourse places roughly the same demands on the heart as a vigorous walk around a city block. There is great intersubject variability in blood pressure and heart rate increases during sexual intercourse. Generally, an individual who can walk vigorously or pedal 600 kpm/min on a stationary bicycle without symptoms, increased blood pressure, or electrocardiogram changes can safely engage in sexual intimacy including coitus. Sexual abstinence is recommended for 8 to 12 weeks after MI, although there is minimal evidence to justify this in uncomplicated patients. After this period of abstinence, gradual resumption of sexual activity is recommended, often beginning with sexual experiences other than sexual intercourse. Because superior positions may heighten cardiac demand, side-by-side or patient inferior positions may be recommended when coitus is initially resumed. Prior to intercourse, in selected patients the use of beta blockers and sublingual nitrates may reduce angina. Patients who benefit from the use of nitrates must be instructed not to use phosphodiesterase inhibitors.

Chronic pulmonary disease impacts sexual function in at least two ways: chronic arterial hypoxia is believed to cause testosterone reductions and associated diminished desire in both men and women and shortness of breath may limit physical ability to engage in sexual activity.

Both insulin-dependent (type I) and noninsulin-dependent (type II) diabetes mellitus (DM) may contribute to sexual dysfunction in men and in women. ED has been reported in up to 50 percent of men with type I DM and in up to 33 percent of men with type II DM. As men living with DM age, the rate of ED may approach 70 percent and comorbid smoking and alcohol abuse predict an earlier onset of ED. Men living with DM are believed to develop ED secondary to neurologic or microvascular lesions and, as a result, the presence of any of the “opathies” will be associated with ED. Sexual dysfunction in women with DM is often overlooked but may

occur at a rate as high as 50 percent. Dyspareunia secondary to decreased vaginal lubrication and difficulty achieving orgasm are among the problems reported by women living with DM.

A patient living with cancer may experience sexual dysfunction due to psychological factors, physical problems directly related to the cancer including pain, and side effects of the treatments. Women diagnosed with breast cancer may experience grieving and fears of death and disfigurement that decrease libido even before any treatment has been provided. Women whose treatment includes mastectomy and who have a history of marital difficulties and who do not discuss with their spouse the possibility of mastectomy are at increased risk for sexual problems. A recent study compared women who had a lumpectomy to women who had a mastectomy and found that having a lumpectomy was associated with a greater sense of sexual desirability but no difference in frequency of sexual experiences or of orgasms.

The treatment of sexual dysfunction following mastectomy includes minimizing medical problems that are inhibiting sexuality. Medical issues that contribute to sexual dysfunction in women undergoing treatment for breast cancer include dyspareunia and other forms of pain, fatigue, ovarian dysfunction from chemotherapeutic agents such as tamoxifen, and nausea and vomiting associated with chemotherapy. If possible, open communication between the patient and her sexual partner is helpful during all stages of treatment. It is helpful for the partner to observe the mastectomy wound soon after surgery. Rapid resumption of sexual activities is also believed to be helpful and alternative sexual positions and vaginal lubrication may be helpful. Finally, breast reconstruction may help improve self-image and restore self-esteem both of which may contribute to improved sexual functioning.

Although testicular cancer is relatively uncommon in older men (incidence is highest at about 35 years of age, then declines to nearly zero by the age of 80), staging surgery may result in ejaculatory dysfunction and ED. Even in the absence of these problems, surgical removal of one or both testicles may cause problems with self-esteem. Prostate cancer increases in frequency with age. The relative success of nonsurgical interventions and the introduction of surgical techniques which are nerve sparing have helped to decrease ED and other sexual problems in men being treated for prostate cancer. Patients may need to wait 2 to 3 years following surgery for maximum sexual function to return. One study reported that radiation therapy caused ED in over 50 percent of the men who were studied.

As is true for male genital malignancies and for breast cancer in women, female genitourinary cancers are often associated with serious emotional problems which impact sexual function. Sexual difficulties with cervical carcinoma vary with treatment approach. In general, surgery has fewer side effects than radiation therapy. Radical hysterectomy compromises sexual

function because of vaginal shortening but this may improve when there is ongoing sexual activity. The most important variable predicting sexual dysfunction following hysterectomy is whether the ovaries are removed. Radiation therapy promotes vaginal atrophy and stenosis due to impaired ovarian function. The extent of surgical treatment for vulvar carcinoma often determines sexual side effects. From a medical perspective, local excision often does not interfere with sexuality. More extensive surgeries may cause numbness.

Sexual problems in patients diagnosed with colon cancer are usually related to chemotherapy-associated side effects or to surgeries resulting in ostomies. Fear of fecal spillage and odor may inhibit sexual enjoyment. Women with ostomies can develop dyspareunia due to fistula formation. Men who require posterior abdominal perineal resection may become impotent due to ablation of autonomic nerves to the penis.

The desire or need to express one's sexuality does not expire with age and for many older people including those living in aged care facility, sexuality continues to be important. A variety of outcomes have been observed when a spouse or significant other has dementia. Research indicates that 73 to 80 percent of the time, the presence of dementia has a negative impact on a couple's sex life. Conversely, about one-quarter of the couples that have been studied continue a warm and satisfying sexual relationship. A significant number of sexually inactive caregiving partners (39 percent in one study) are dissatisfied with the inactivity. Clearly, there is no one right answer for everyone. Ballard and Poer have written that in the absence of a cure or treatment, the most significant thing that can be done for a patient with dementia is to adapt one's approaches with each change in symptoms to make life as meaningful and satisfying as possible. Though written with the patient in mind, this quote and underlying sentiment seems equally relevant to caregiving spouses or partners. For patients with dementia and/or their caregiving partners, the opportunity to discuss their sexual concerns with a health care professional can be tremendously helpful. According to research, however, health care professionals only rarely inquire about the impact that the dementia is having on a couple's sex life.

Among the factors that may influence whether a couple continues to have satisfying sexual experiences are: (1) the type of dementia; (2) the stage of the dementia; (3) the couple's previously established patterns of sexual intimacy; (4) the impact of dementia on the patient's ability to maintain two-sided intimacy; (5) the impact of the dementia on the patient's knowledge of how to engage in and to follow through with varies sexual activities and on the sexual activities may be preferred or even demanded; (6) the influence of the dementia on the patient's personality, libido, grooming, and personal hygiene; (7) the impact of the dementia on the caregiving partner's view of the patient; (8) the effect of caregiving on

the spouse or sexual partner of the patient; and (9) whether the patient with dementia is able to continue living at home or requires institutionalization.

In regard to the partner with dementia, possible changes include remaining interested but developing problems with follow through or with apraxia for one or more sexual acts, becoming hypersexual, or making new or unusual requests regarding sexual activities. At some point, the erosion in intellectual function may make it difficult or impossible to accurately assess the sexual health of the relationship and to provide emotional intimacy.

For a variety of reasons, a caregiving spouse or partner may lose interest in sex. This loss of interest may be the result of overwhelming grief or the physical exhaustion from the demands of caregiving. Sometimes caregiving partners deny their own needs including their sexual needs to assuage survivor's guilt or as a way of showing their respect for and loyalty to the person with dementia. It is also possible that dementia may cause such drastic changes in the patient's values and personality that the caregiving partner sees the patient as a child or in other ways so different that sexual intimacy begins to feel wrong or uncomfortable. Caregiving partners may sometimes need to be reminded that they do not have to participate in an activity that is frightening, upsetting, or no longer satisfying. A caregiving partner has the right not to be abused. Due to the level of the patient's cognitive impairment, a caregiving spouse may wonder if having sex with the partner is a form of rape. Ballard and Poer suggest that if the dementia patient initiates the experience and if the experience is mutually satisfying to both, then it should not be viewed as rape. It is quite possible that the same patient who might be incapable of giving informed consent for medication or research, because of the complexity and novelty of information given, might be capable of giving informed consent to participate in a sexual relationship, a decision that is based more on old learning.

Patients with Alzheimer dementia will usually experience dramatic changes in short-term memory relatively early in the course of illness but personality and social graces do not erode until relatively late in the illness. The preservation of personality and social skills may allow a couple living with Alzheimer dementia to maintain satisfying sexual experiences through most of the illness as long as ED is not problematic. One of the earliest studies of sexual function in patients with Alzheimer dementia found that loss of erection was reported in 53 percent of male patients around the time that they learned of their Alzheimer dementia diagnosis. In addition to ED, another potential situation that may negatively impact the quality of sexual life of a couple living with dementia is when short-term memory deficits trigger delusions of infidelity because the patient with dementia has trouble remembering where the caregiving spouse has gone or how long the

partner has been absent and then begins to suspect that the partner is having an affair.

Patients with frontotemporal dementia (FTD) very often experience personality changes or profound language problems fairly early in the course of their dementia and either of these can negatively impact sexual quality of life. For example, personality changes may cause the patient with dementia to behave so differently that their partner begins to feel as if they are with a stranger. Sometimes the expressive or receptive aphasia seen in patients with FTD is so severe that it is no longer possible to maintain two-side intimacy that for some partners is an essential ingredient for safe and satisfying sexual experiences.

The later the stage of the dementia illness, the more difficult it becomes to maintain sexual intimacy. One study of 20 Caucasian male Alzheimer patients and their nondemented caregiving wives found that the patients with dementia reported no reduction in quality of sexual function regardless of the stage of illness. The wives of these patients, however, reported that the more advanced the stage of the dementia, the worse their quality of sexual life became. The life expectancy of patients with many forms of dementia may exceed 12 years or more. For some healthy, active spouses, this may become an unacceptably long time to live without satisfying emotional and sexual experiences. Certainly, to give and receive affection, physical intimacy, are needs that do not die with the overwhelming responsibilities of becoming a caregiver. As a result, some caregiving spouses may begin a new intimate relationship while continuing to provide for the needs of the ill partner. When this decision is made, the adult relatives of the patient with dementia may have a variety of reactions. Some family members may be very sympathetic. Others may fail to understand the well partner's need for an intimate relationship. Other family members may feel the need to protect the ill partner's interests or may have fears that the well partner's new alliance will threaten financial assets of the ill partner or of their own anticipated inheritance. Sometimes the most difficult aspect of the well partner's decision to begin a new intimate relationship is that this decision makes it impossible for other family members to deny the reality of the tragic illness that has befallen the patient with dementia.

Dementia may also include the development of inappropriate sexual behaviors and the development of behaviors that appear sexual but are actually not. Caregivers of patients with dementia, whether a partner, some other family member, or a paid professional, may experience distress, discomfort, and uncertainty about how to manage inappropriate sexual behaviors. Professionals should assess these behaviors with the assumption that there is a valid need to be met keeping in mind that not all behaviors that appear sexual may actually be sexual. For example, touching the genital area repeatedly may not represent masturbatory efforts but may be

a signal that help with toileting is needed. Climbing in bed with the patient in the room next door may not be an act of sexual aggression but the expression of a desire for comfort, companionship, or protection or simply the expression of a lifelong habit of having a bed partner.

A variety of classes of medications and specific individual medications may cause sexual dysfunction in adults of all ages including older adults. Table 57.6f–5 provides a list of some of the medications, which have the potential to cause sexual side effects. A number of classes of psychotropic medications can negatively impact sexual function. Men may experience ED from serotonin reuptake inhibitors (SSRIs). Both men and women may experience decreased sensitivity of the genitalia, delayed orgasm, or anorgasmia from SSRIs. Any of the psychotropic medications with significant dopamine receptor blocking ability may also cause a variety of sexual problems which are believed to be mediated, at least in part, through medication-associated hyperprolactinemia and associated decreased androgen levels. Drugs, which increase gamma amino butyric acid (GABA) activity, such as benzodiazepine, have been reported to cause less satisfying orgasms for women.

Antihypertensive medications may also impair sexual function although recent research suggests that the beta-adrenergic blockers may not be as problematic as originally believed. Digoxin may decrease sexual desire. Agents which block the histamine receptor subtype 2 (H2 blockers) frequently interfere with penile erections although not all medications in this class may be do this equivalently. For example, cimetidine is more likely than ranitidine to cause ED. Lastly, alcohol, though not a medication, may seriously impair sexual function.

Table 57.6f–5.
Some of the Medications Associated with Sexual Dysfunction in Later Life

Analgesics
Methadone
Morphine sulfate
Anti-infective medications
Ketoconazole
Antineoplastic medications
Tamoxifen
Cardiovascular medications
Amiodarone (Cordarone)
Angiotensin-converting enzyme inhibitors
Calcium channel blockers
Clonidine (Catapress)
Digoxin (Lanoxin)
Disopyramide (Norpace)
Guanethidine (Ismelin)
Prazosin (Minipress)

Reserpine
Spironolactone
Thiazide diuretics

Endocrine medications

Adrenal corticosteroids
Leuprolide (Eligard, Lupron)

Gastrointestinal medications

Cimetidine (Tagamet)

Neurologic and psychiatric medications

Antipsychotic medications
Benzodiazepines
Carbamazepine (Carbatrol, Equetro, Tegretol)
Carbidopa/levodopa (Sinemet)
Divalproex sodium (Depakote)
Lithium carbonate (Eskalith, Lithobid)
Monoamine oxidase inhibitors
Phenytoin (Dilantin)
Primidone (Mysoline)
Selective-serotonin reuptake inhibitors
Trazodone
Tricyclic antidepressants
Venlafaxine (Effexor)

Other

Diphenhydramine (Benadryl)
Cocaine
Hydroxyzine (Atarax, Vistaril)
Nicotine
Alcohol

SEXUALITY IN LONG-TERM CARE

The challenges and difficulties for older people with respect to the expression of their sexuality in the residential care environment have been identified and described in the literature and include negative and judgmental staff attitudes and inadequate staff member knowledge and training. Older members of sexual minorities are especially at risk for challenges and difficulties with comfortably meeting their sexual needs in a residential care environment. A survey of 250 nursing home residents in Texas determined that only 8 percent of them had been sexually active (masturbation or intercourse) during the previous month but 17 percent of the inactive residents said they would have liked to be active but lacked the opportunity.

Although addressing the continuing sexual needs of older residents of long-term care facilities can be a difficult task to accomplish, these should be addressed with the same priority as nutrition, hydration, personal hygiene, and other well-accepted needs. Sexual behavior in residential care facilities is no longer a private matter and is often open to public scrutiny.

In one way or another, sexual behavior in residential care facilities has an impact on staff members, other residents, and the families of residents and is, therefore, much more often inhibited by other residents, staff, and family. Residents of long-term care facilities may experience numerous barriers to achieving sexual satisfaction. Perhaps the biggest of these barriers is the discomfort nurses, physicians, and other health care providers may have in discussing sexuality with older adults. Eighteen states in the United States address the issue of married couples sharing rooms or having conjugal visits unless there is any medical contradiction (Federal regulation 483.10). Only four states allow room for sexual relationship between persons of same gender, as well as persons of the opposite gender who are not married. Such recognition seems to be important to assure that nursing home residents have the same rights as other citizens in this regard. Although there is an increasing emphasis on the application of person-centered approaches to care delivery, many providers of residential care services for seniors still neglect to recognize and address sexuality as a component of well-being. Many are unaware of the importance of the multiple facets of the care environment that impact on resident's ability to express their sexuality and are unaware of what sort of support may be required.

Another barrier to satisfying sexual experiences for long-term care residents is the lack of knowledge and understanding among the residents themselves about later-life sexuality. Studies have found that this lack of knowledge in older adults correlates with less positive attitudes toward sexuality such as embarrassment and apprehension. Finally, family members may also be a barrier to sexual satisfaction for older adults living in a long-term care environment because they may have difficulty understanding and accepting that their older relative is having a sexual relationship with someone new.

For residents of long-term care facilities, emotional intimacy may supplant sexual intimacy and provide similar levels of satisfaction. In one survey of nursing home residents, coital intimacy was rated as the lowest in importance when compared to social, noncoital physical, intellectual, and emotional intimacy. Unmet intimacy needs of older adults may be fulfilled by a simple human touch on the hand, face, or shoulder. It is very important, however, before offering touch to a patient to ask permission and to confirm that the patient accurately understands the intentions of the clinician. Some older patients, especially those with dementia, may misinterpret the touch as a sexual overture.

If a patient living in the long-term care environment expresses a desire for sex, the long-term care facility staff should help arrange a safe and private time and place for the sexual activity and the resident should be advised to keep his or her call light within reach. If necessary, supportive items such as personal lubricant or adaptive equipment such as hospital

beds, side rails, or trapezes may be needed.

Determining whether two patients, both of whom have dementia, should be allowed to share sexual intimacy may provoke feelings of anxiety or discomfort but this has and will continue to be required of health care professionals. Lichtenberg and Strzepek have published guidelines that are based on the principles of informed consent. They recommend assigning one member of the interprofessional treatment team to assess each patient according to three criteria and then to report their findings to the entire team, which then votes on whether the criteria have been met for the patients to have sex. Lichtenberg and Strzepek recommend assessing each patient's awareness of: (1) the relationship (e.g., is the patient aware of who is initiating the sexual contact or is the person being misidentified as someone else such as a deceased spouse?); (2) the potential risks (can the patient describe how he or she will react if the relationship ends?); and (3) the ability to avoid exploitation (does the patient have the ability to state what level of sexual intimacy is desired and to say no to any uninvited or unwanted sexual act?). Although not a part of these guidelines, it may be wise to inform a family member of each patient about the approach that has or will be used to address the situation.

Inappropriate sexual behavior among long-term care residents include using sexually suggestive language, exposing oneself, masturbating, or openly participating in sexual activity with another resident. Whether in the long-term care environment or at home, the approach to sexually inappropriate behaviors is the same. If the problem sexual behaviors are new, a careful evaluation should take place. In order to avoid precipitating a "catastrophic reaction," it is important not to scold, argue, or shame the person. Praising and encouraging acceptable behaviors and ignoring inappropriate behaviors may be helpful. Remaining calm helps to avoid rewarding unwanted behaviors. Sometimes providing attention and affection proactively may prevent or eliminate problem sexual behaviors.

Depending on the specific behavior, different solutions should be explored. For example, for the patient who repeatedly masturbates in public places, providing privacy as well as other things like a vibrator, personal lubricant or condom may be helpful. If a patient disrobes in public, dressing the patient in clothing that makes disrobing difficult may help. For patients who expose themselves unnecessarily during personal care or become sexually aroused, it is important to set limits verbally, involve more than one caregiver, and depending on the patient's sexual orientation, use caregivers whose gender is not the gender which stimulates the patient, and make the interactions as clinical as possible by wearing medical attire like a white coat and gloves, and performing these activities in an examination room rather than in the resident's room.

If behavioral interventions are unsuccessful, a medication trial may be needed. Table 57.6f–6 lists medications that may be helpful including

various forms of estrogen and SSRIs. Mood stabilizers may be useful if hypersexuality is occurring in the context of a manic-like syndrome. Antipsychotic medication may be helpful if the sexual behavior is driven by a delusion of mistaken identity in which the patient is attracted to a person misidentified as the patient's sexual partner.

Below the authors present a case example of a patient who received medication treatment for inappropriate hypersexual behaviors. This case highlights a number of key issues associated with sexually inappropriate behaviors in patients living with dementia: (1) although these behaviors can arise in patients living with a variety of types of dementia, they are most often seen in patients whose dementia has preferentially injured the frontal lobes resulting in problems with judgment and impulse modulation; (2) these behaviors are more likely to occur in later stages of dementia, resulting in sexually inappropriate behaviors occurring in the midst of other types of behavioral challenges; (3) wide variation in both sex hormone levels and their impact on physical characteristics and behavior often limits their value in establishing the etiology of sexually inappropriate behaviors (this patient's measured serum testosterone level was actually low); (4) medoxyprogesterone acetate (MPA) may help reduce but may not eliminate sexually inappropriate behaviors completely; and (5) the use of MPA requires careful monitoring due to potential side effects that limit its usefulness and safety.

Table 57.6f–6.
Medications for Hypersexuality in Patients with Dementia

Medication	Preparation	Suggested Dosage	Potential Side Effects
Hormonal agents			
Antiandrogens			
Medroxyprogesterone acetate (Depo-Provera)	IM injection 150 mg/mL	150–300 mg once a week	Sedation, weight gain, fatigue, hot and cold, flashes, depression
Estrogens (Premarin)			
	0.3-, 0.45-, 0.625-, 0.9-, 1.25-mg tablets	0.625–2.5 mg/day	Increased risk of cardiac death in men with prostate cancer, fluid retention, nausea, vomiting, gynecomastia
(Enjuvia)	0.3-, 0.45-, 0.625-, 1.25-mg tablets		
(Climara)	0.025-, 0.0375-, 0.05-0.06-, 0.075-, 0.10-mg/day transdermal patch	0.05–0.1 mg/day	

Gonadotrophin-releasing hormone analogs			
Leuprolide acetate	Injectable suspensions:	7.5 mg/month	Hot flashes, erectile dysfunction, irritation at injection site
(Eligard)	7.5, 22.5, 30, 45 mg/month		
(Lupron Depot)	3.75, 7.5 mg/month 11.25 mg every 3 months		
Serotinergic agents			
Serotonin reuptake inhibitors			
Citalopram	10 mg/5 mL oral solution, 10-, 20-, 40-mg tablets	20 mg/day	Headache, nausea, diarrhea, loss of appetite, insomnia
Paroxetine	10 mg/5 mL oral suspension 10-, 20-, 30-, 40-mg tablets 12.5-, 25-, 37.5-mg controlled-release tablets	20 mg daily	
Tricyclic antidepressants			
Clomipramine	25-, 50-, 75-mg tablets	150–200 mg/day	Orthostatic hypotension
Trazodone hydrochloride	50-, 100-, 150-, 300-mg tablets	100–500 mg/day	Sedation, hypotension, priapism
Antipsychyotics			
Atypical antipsychotics			
Quetiapine	25-, 100-, 200-, 300-mg tablets	25 mg/day	Orthostasis, sedation, increased death due to cardiovascular events
Mood stabilizers			
Carbamazepine	100-mg chewable tablet 200-mg tablet 100-, 200-, 400-mg extended-release tablets 100-, 200-, 300-mg capsule 100 mg/5 mL and 200 mg/10 mL suspensions	50–300 mg/day	Ataxia, dizziness, rash, sedation, nausea, vomiting, hyponatremia, agranulocytosis, aplastic anemia, falls

Valproate	250-mg capsules 125-mg sprinkle capsule 250-, 500-mg extended-release tablets 250 mg/5 mL syrup 100-mg/mL injection	500–1,500 mg/day	Nausea, sedation, falls, tremor
Other agents			
Pindolol	5-, 10-mg tablets	40 mg/day	Fatigue, hypotension
Cimetidine	200-, 300-, 400-, 800-mg tablets 300-mg/L oral solution	600–1,600 mg/day	Headaches, nausea, arthralgias, delirium

The primary care physician (PCP) of a 91-year-old widowed male, retired engineer with vascular dementia residing in a dementia-specific residential unit, requested a geriatric psychiatry consultation to evaluate depression and inappropriate sexual behaviors. Because of the severity of the patient's cognitive deficits, most of the history was obtained from collateral sources.

Prior to the emergence of the patient's dementia symptoms, the patient had no psychiatric problems or psychiatric treatment of any kind. His cognitive deficits were first recognized several years prior to the time of the consultation request following a stroke which left the patient with residual ataxia and pseudobulbar affect. About 5 months after his stroke, behavioral symptoms including wandering and elopement attempts required the patient to move from an independent living apartment to a dementia-specific assisted living unit. Several months later, a geriatric psychiatry consultation was obtained after the patient slapped the hand of a male peer because this peer had touched the patient's food. Following this incident, the patient told a nurse "if it happens again, I'll break his hand off." The consulting geriatric psychiatrist (CGP) found no undiagnosed medical factors that might have caused the problem behaviors and observed that the patient was struggling with frustration related to both loss of control and problems with memory. The patient stated "If I see a telephone number on the TV that I want to remember, I don't remember that number at all." The CGP recommended discontinuation of quetiapine, given its questionable efficacy and unfavorable risk–benefit profile in patients living with dementia, and initiation of treatment with dextromethorphane/quinidine to target the patient's emotional lability and impulsive behaviors. In addition, the CGP suggested that, if needed, a trial of divalproex might also be reasonable.

Several months later, when sexually inappropriate behaviors emerged, the patient's PCP independently changed the patient's psychiatric medications to escitalopram 10 mg po daily and divalproex delayed release 250 mg po twice daily (which yielded a trough serum level of 30 mcg/dL) and encouraged the staff to use a variety of behavior-modifying techniques including avoidance of the use of ambiguous terms of endearment such as "honey" or "sweetie" and responding to inappropriate sexual behaviors with simple, firm verbal limit setting in order to avoid unintentionally reinforcing these behaviors with excessive positive (laughter) or negative (anger) affect. The patient, however, continued to have frequent and disruptive inappropriate sexual behaviors involving staff members including verbalizing requests for sex, kissing and groping staff members and masturbating in public.

The patient had no known past psychiatric history of hypomanic or manic episodes. The

patient's medical problems included congestive heart failure, DM type 2, hypothyroidism, benign prostatic hypertrophy, a history of sinus surgery, and a stroke 22 months previously. His medications were acetaminophen 500 mg po TID, bumetanide 0.5 mg po BID, clopidogrel 75 mg po daily, divalproex 250 mg po BID, doxazosin mesylate 8 mg po QPM, escitalopram 10 mg po QD, lansoprazole 30 mg po QD, levothyroxine 100 mcg po QD, metoprolol 12.5 mg po BID, probiotic containing saccharomyces boulardii lyo 250 mg po BID, sitagliptin 100 mg po QD, and vitamin B_{12} 1,000 mcg po QD.

On examination, the patient's vital signs were within normal limits. The CGP examined the patient in the common area and observed that he was a casually dressed and groomed Caucasian man who was seated in a wheelchair and had no observed abnormal movements. He was distant, detached and disinterested. He reported feeling "pretty normal," denied any current symptoms of depression or anxiety but was unable to describe his current medications other than saying that he was taking "a bunch" and that he was not aware of any side effects. His affect revealed frustration and irritability, his speech was normal, his process of thought was linear and the content of his speech was noteworthy for concreteness, sarcastic responses to most questions and the absence of clear answers to questions about suicidal ideation, homicidal ideation, delusions, or hallucinations. He was oriented to self and attentive but refused to cooperative with a standardized bedside cognitive screening test.

None of the patient's medications were felt likely to be triggering the patient's sexually inappropriate behaviors and the results of a wide range of laboratory tests obtained by his PCP 1 week prior did not reveal a medical problem that would explain the patient's inappropriate sexual behaviors. These lab results included a random glucose of 123 mg/dL (high), creatinine 1.64 mg/dL (high), albumin 2.9 g/dL (low), total protein 5.3 g/dL (low), hemoglobin 8.6 g/dL (low), hematocrit 25.7 percent (low), TSH 3.09 μIU/dL, prolactin 14.3 μg/L, FSH 15.5 IU/L (high), LH 7.5 IU/L, progesterone 0.5 ng/mL, testosterone 187 ng/dL (low). After obtaining informed consent from the patient's family, a trial of medroxyprogesterone acetate (MPA) 150 mg IM Q monthly was initiated. No other changes in his medications were made in order to clearly assess the impact of the addition of MPA.

One month later, the CGP learned from staff members that the patient was no longer propositioning or attempting to kiss or grope members of the staff although he was masturbating in his room occasionally. When interviewed, the patient reported feeling "in and out" and of being "pushed around" by "people like you (the psychiatrist)." The CGP concluded that the patient was demonstrating a favorable response to the treatment with MPA and recommended continuation of MPA along with ongoing use of nonpharmacologic measures. Two months after initiation of treatment with MPA, the patient had not had any problematic sexual behaviors but had been spending most of the day sleeping, had become apathetic about meals, would eat if spoon-fed and had lost 17 pounds over the preceding 3 months. When interviewed, the patient was oppositional and antagonistic, denied depression and anxiety but reported feeling angry due to "people like you." When the CGP asked the patient to elaborate, he replied "You had better get your ass out of here and never come back." Due to concerns about potential divalproex-associated nausea and weight loss as well as absence of any clear benefit, divalproex was discontinued and a trial of mirtazapine 7.5 mg po QHS was initiated to help with appetite stimulation. Three weeks after this visit, the patient was transferred from the dementia unit to a skilled nursing unit due to poor safety awareness associated with a number of falls. During his first week in the new location he had two episodes of inappropriate sexual behavior: he grabbed a nursing assistant's buttocks and asked her if she wanted to see his "banana" and he was observed patting his groin in a hallway. The CGP examined the patient in a public area of the skilled nursing unit and observed that he was hostile, intermittently scratched himself and patted his exposed abdomen. When asked about the recently concluded music-based activity the patient replied "I was there because they dragged me in there" and he reported feelings of depression because "I have to put up with people like you." No changes in the patient's treatment were recommended. When the patient was assessed approximately 4 months after the initiation of treatment with MPA, the CGP learned that no episodes of sexually appropriate behavior had occurred during the past month but several episodes of verbal and physically aggressive behaviors had been observed including smearing feces, resisting attempts to change his soiled clothing, and attempting to spit and urinate on staff members. The patient informed the CGP that he was seeing a "spirit." His blood glucose at the time of this interaction was determined to be 587 mg/dL. After

consultation with the patient's PCP, a decision was made to discontinue MPA due to concerns that the patient had developed delirium secondary to MPA-associated metabolic/endocrinologic dysregulation.

57.6g HIV and Aging

RAEANNE C. MOORE, PH.D., AND MARíA J. MARQUINE, PH.D.

INTRODUCTION

Once considered a death sentence, HIV has been transformed into a chronic disease as a result of highly active antiretroviral therapy (ART). The life expectancy of HIV-infected (HIV+) adults receiving ART is now approaching that of the general population, and today more than half of HIV+ people in the United States are over age 50. This remarkable success has brought with it a new set of challenges. As people with HIV are becoming older, HIV has become a chronic disease with multiple interacting causes of morbidity and mortality, generating significant public health interest for understanding the multiple factors that can impact aging with HIV.

Recognizing the issues and needs of the increasing older HIV+ population, a White House Conference on HIV and Aging was held in 2010. In addition, the Office of AIDS Research of the National Institutes of Health commissioned a working group to develop an outline of the current state of knowledge and areas of critical need for research in HIV and Aging. The findings and recommendations of the working group are summarized in a published report. While much research is needed to better understand health outcomes in older HIV+ persons, the American Academy of HIV Medicine in collaboration with the AIDS Community Research Initiative of America developed a series of guidelines for clinicians managing older patients with HIV.

EPIDEMIOLOGY

In 2010, the estimated rate of diagnoses of HIV infection among older adults in the United States was 8.5 per 100,000 population. Similar to younger age groups, members of racial/ethnic minority groups are at increased risk of HIV infection among older adults, with rates of infection in 2010 being 41.6 for blacks/African Americans, 15.4 for older Hispanics/Latinos and 3.9 for older non-Hispanic whites. Older males are also at increased risk, with the rate of infection among older males (13.6) being 3.2 times the rate of older females (4.2). As shown in Figure 57.6g–1, the most common forms of transmission vary by gender.

Older persons in the United States are more likely to be diagnosed with HIV infection later in the course of the disease compared to younger persons, which can result in worse disease burden and prognoses. For example, the rates of progression to AIDS in 12 months, among people diagnosed with HIV in 2010, were notably lower among those aged 25 to 29 (24 percent) than older persons (44 percent of people aged 50 to 59, 49 percent of people aged 60 to 64, and 53 percent of people aged 65 and older). Deaths of persons with diagnosed HIV infection may be due to any cause (i.e., may or may not be related to HIV infection). Of the estimated 19,343 deaths among people living with HIV in the United States in 2010, 10,244 (53 percent) were among people aged 50 and older. In 2010, HIV was the 10th leading cause of death among men and women aged 50 to 54.

†Injection drug use.
‡Other transmission risk factors include hemophilia, blood transfusion, and risk factors not reported or identified.
*Heterosexual contact with a person known to have, or be at high risk for, HIV infection.
Due to rounding, percentages may not add up to 100%.

FIGURE 57.6g–1. Estimated diagnoses of HIV infection among adults aged 50 and older by gender and transmission category 2010. (From Centers for Disease Control and Prevention. Diagnoses of HIV infection among adults aged 50 years and older in the United States and dependent areas, 2007–2010. *HIV Surveillance Supplemental Report* 2013. February 2013.)

PREVENTION

Persons over the age of 50 appear to have several of the same risk factors for HIV infection than younger persons, which can be exacerbated by issues unique to older adults. Many older adults are sexually active and a number of them are widowed or divorced and dating again. Yet, they may lack knowledge about HIV, and thus be less likely to protect themselves. Older women who are not concerned about becoming pregnant may be less likely to practice safe sex. In addition, age-related thinning and dryness of the vaginal tissue may place older women at increased risk of HIV infection. For older men, erectile dysfunction medication may facilitate sex for some who would otherwise not have been able to engage in vaginal or anal intercourse.

While there is much left to understand regarding the reasons driving later HIV diagnoses among older persons, some of the key reasons may be that older persons are less likely than younger persons to discuss their sexual habits or drug use with their doctors, and that they might mistake HIV symptoms for those of normal aging. In turn, health care providers may also be less likely to ask about these issues and to test older persons for HIV infection. It also appears that HIV stigma might be of particular concern for older HIV+ persons and may prevent them from seeking care and disclosing their HIV status.

Given these prevention challenges the Centers for Disease Control and

Prevention, and its partners are implementing a high-impact prevention approach, which includes a number of initiatives and programs aimed at providing support and technical assistance to health departments and community-based organizations for implementing prevention programs, raising awareness about HIV in older age groups, supporting HIV testing, and optimizing linkage to care.

NEUROCOGNITIVE OUTCOMES OF HIV AND AGING

HIV and aging are independently associated with central nervous system (CNS) dysfunction. The cooccurrence of HIV and older age appears to have additive or synergistic negative effects on the CNS, with several studies observing elevated rates of neurocognitive impairment (NCI) in older HIV+ cohorts. However, the issue of whether the combined effects of HIV and aging on NCI are synergistic or additive remains controversial, with some studies finding a significant HIV and aging interaction and thus demonstrating a synergistic effect, and others showing an additive effect. For example, initial reports from the Hawaii Aging Cohort indicated twice the rate of HIV-associated dementia in older compared to younger HIV+ cohorts. In general, these reports have found particular problems in executive functioning, psychomotor speed, and episodic memory. In contrast, other studies have failed to detect an interaction between HIV and older age. For instance, the Hawaii Aging with HIV Cohort later did not detect a significant interaction between HIV and older age on NCI, but trends were observed on measures of learning, memory, attention, and timed gait.

The discrepant findings across studies have been attributed to a number of factors, including differences in demographics and other HIV disease characteristics across groups of younger and older HIV+ and HIV– adults, and differences in outcomes (global NCI vs. NCI in specific domains, and NCI vs. specific HIV-associated neurocognitive disorder or HAND, among others). Another factor to bear in mind for future studies in this area is that the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5) uses different criteria for neurocognitive disorders than the established Frascati criteria for HAND. For example, only problems on one neurocognitive domain are required by DSM-5 rather than two (per the Frascati criteria) to define impairment in "global" neurocognitive function implied by the term "cognitive disorder" (whether major or minor). Moreover, the exclusion criteria required for diagnosis of neurocognitive disorders are limited to other psychiatric disorders per the DSM-5 but explicitly include CNS illnesses specific to the setting of immunodeficiency, as noted by both the original AAN criteria and the current Frascati criteria. These disparities in neurocognitive disorder criteria might lead to difficulty with merging research across studies and obscure the findings of future research.

While much is yet to be known regarding key predictors of NCI among older HIV+ persons, a recent study investigated predictors of longitudinal neurocognitive decline in 436 HIV+ adults (age in years: mean = 43.9, standard deviation = 8.4; M follow-up = 35 months). Results from multivariable models showed that key predictors of earlier time to neurocognitive decline included Hispanic ethnicity, notable non-HIV comorbidity, being off ART, having low albumin and low hematocrit, having a lifetime methamphetamine use diagnosis and increased depressive symptoms. These, along with other findings, suggest that a number of different factors (HIV and non-HIV specific) are probably important predictors of NCI in older HIV+ persons.

In an effort to capture both HIV disease and non-HIV disease factors important for health outcomes in older HIV+ persons, multivariate indices indicative of NCI have been developed. One such index is the Veterans Aging Cohort Study (VACS) Index, which is predictive of mortality. The VACS Index combines age, current plasma HIV RNA, and CD4 cell count with non-HIV disease markers. In one recent study, a higher VACS Index score was associated with increased risk for global cognitive impairment, but the effect size was relatively small. Older age, low hemoglobin level, and low CD4 cell count were the components of the VACS Index more strongly linked to NCI.

MENTAL HEALTH OUTCOMES OF HIV AND AGING

Older persons living with HIV face unique emotional issues, including stigma, marginalization, and discrimination. In addition to emotional factors, these adults also often face unique social factors (e.g., lack of appropriate treatment facilities, poor access to health care, financial problems, disability) and unique family factors (e.g., HIV/AIDS in spouse, poor family support). These issues make HIV+ adults more vulnerable to psychiatric illness, decreased well-being, and poorer health-related quality of life (HRQoL). Prevalence rates of mood or anxiety disorders have been reported to be as high as 50 percent among older HIV+ adults, with a similar proportion reportedly having alcohol or other substance use disorders. In addition to being at heightened risk for clinical depression, those aging with HIV are at increased risk for negative mood compared to those without HIV infection. This cooccurrence of mental illness and HIV result in poorer health outcomes, including decreased CD4 T-lymphocytes and increased viral loads, and higher health care HIV costs. However, studies show that among older adults, 40 to 90 percent of mental health concerns are not detected in primary care settings, resulting in a majority of mental health problems going untreated among older HIV+ adults. Efforts to integrate primary health care at Infectious Disease or General Medicine clinics with mental health treatment and to combat the societal stigma that is associated with mental illness and HIV/AIDS are likely to

improve the health and well-being of persons living and aging with this disease.

The role of mental health professionals in treating older persons living with HIV is threefold: (1) identify behavioral factors most saliently impacting the course of HIV and well-being outcomes to determine how and when to intervene; (2) work with the patient's geriatrician and other primary care team members to determine the most appropriate course of treatment; and (3) implement treatment plan, closely monitor progress, and modify as needed.

Emotional Functioning

Depression management is a priority to achieve optimal health outcomes among those aging with HIV. Older HIV+ adults do not show the same age-related declines in depression that is observed among older adults without HIV, making depression all the more relevant in this population. Additionally, research has indicated moderately high levels of overall distress among older HIV+ adults; distress that is compounded by the addition of other chronic health problems. Both antidepressant medications and psychotherapy have showed effectiveness in treating depression among those living and aging with HIV. Effectively treating depressive symptoms can lead to better everyday outcomes, including better medication adherence, sustained virological suppression, reduced likelihood of HIV transmission, improved HRQoL, and longer survival. However, despite the existence of effective treatments for depression, underdiagnosed and untreated depression is highly prevalent. This is likely due to numerous factors complicating the clinical picture of aging with HIV, including individual patient characteristics, somatic symptom overlap between depression and chronic medical illnesses, and competing demands of primary care visits. Physiological changes associated with medication metabolism that may cause symptoms that look like depression also complicate the clinical picture and care planning. Studies have found patient race/ethnicity to be a contributor of depression treatment, with depressed African-American HIV+ patients less likely to receive treatment than their non–African-American counterparts. Additionally, investigators have found HIV+ patients diagnosed as severely depressed in a primary care setting more likely to receive mental health treatment than patients meeting clinical criteria for mild or moderate depression. These investigators also found that if depression was not treated on the day of a patient's primary care assessment, it was unlikely to be treated within the following 90-day period, regardless of depression severity.

It is also important to consider cohort effects when diagnosing and treating older adults living with HIV. The mental health of older adults who have been newly infected with HIV will look different from the mental health of adults who have successfully survived into older age with HIV.

See Figure 57.6g–2 for the authors' model of the inter-relationships between HIV, aging, and cognitive, emotional, and physical functioning on successful well-being outcomes. In addition to duration of infection, individual patients may be experiencing mental health problems for the first time in their lives, or they may have a long-term history of mental health symptoms. These cohort effects impact how older adults perceive mental health problems and treatment, self-identify, experience, and how they describe their emotions and distress. For example, while not recognized by the DSM-5 at this time as a clinical syndrome, many older HIV+ long-term survivors have what some of these patients refer to as AIDS Survival Syndrome. *AIDS Survival Syndrome* has been defined as a latent trauma response that emerges among those who survived the AIDS epidemic. These individuals represent a unique group of older HIV+ adults who lived through a period of history in which they suffered the loss of a majority of their friends, partners, and community, and were faced with the real threat of death to their own personhood. *AIDS Survival Syndrome* is thought to manifest as a cluster of symptoms including one or more of the following: depression, personality changes, flashes of anger, survivor guilt, anxiety, emotional numbness, insomnia, social withdrawal and isolation, hopelessness, substance abuse, sexual risk-taking, and a lack of future orientation. Symptoms can range from mild-to-severe. While empirical evidence is currently lacking on AIDS Survival Syndrome, the authors believe this nomenclature can help clinicians understand and assess the emotional issues faced by this particular cohort of older HIV+ adults, and provide education and develop appropriate treatment plans for these individuals.

FIGURE 57.6g–2. Trajectory of psychosocial outcomes in aging with HIV. HRQoL, Health-Related Quality of Life.

Substance Use

Prevalence rates of substance use are higher in older HIV+ adults compared to their HIV– peers, and range from approximately 20 to 50 percent. Substance use is a known primary risk factor for HIV mediation nonadherence, particularly in those using hard drugs (i.e., cocaine or amphetamines) or injection drug users, or those with multiple-substance use such as combined cocaine and methamphetamine or combined cocaine and heroin. Excessive alcohol use, with and without other substance use, is also a predictor of poor adherence. A large study of substance use patterns among HIV+ adults aged 50 and older found the poorest adherence and greatest self-perceived impairment from substance use among those using alcohol and cocaine/crack or those using multiple substances. Another large study examining excessive alcohol use among older HIV+ adults with poor antiretroviral adherence found the following clinical characteristics to be related to the most severe unhealthy drinking patterns: African-American race, less than full-time employment, alcohol treatment within the past year, and a positive depression screen. The pronounced role of substance use among older HIV+ adults, together with the known negative impact of substance use on medication adherence and other functional outcomes, underscores the need for ongoing substance use screening and treatment in addition to increased prevention efforts on the part of both primary care clinicians and mental health professionals.

HIV and Severe Mental Illness

The literature on the cooccurrence of severe mental illness (SMI) and HIV/AIDS is limited, yet is known to be associated with greater risk for morbidity or mortality than with either illness alone. The association between SMI and HIV differs at an individual level, and may be due to their simple coexistence or SMI preceding HIV infection. Studies in the United States estimate prevalence rates of HIV infection, among patients with SMI, ranging from 3 to 23 percent. Alternatively, among those with psychosis, HIV infection may have a direct impact on the development of psychosis due to effects of the virus or antiretroviral medications on the CNS.

Patients with schizophrenia, in particular, may have difficulty describing their symptoms and may be more susceptible to HIV-related distress. Clinical evaluation of HIV+ older adults with schizophrenia requires a comprehensive assessment of the onset and course of symptoms. Additionally, caution should be taken when prescribing antipsychotic medications and take into account medications' side effects and interactions with antiretroviral medications.

Some evidence exists for the beneficial effects of antidepressant medication on improving antiretroviral adherence among patients with cooccurring HIV, bipolar disorder, and current mental health symptoms. For example, research examining antiretroviral adherence among patients

with HIV and bipolar disorder found antiretroviral adherence was significantly better than adherence to psychiatric medications. These investigators also found a correlational relationship between antiretroviral adherence and psychiatric medication adherence, indicating increasing adherence in one medication may have an impact on adherence in the other. In other research, a disconnect between memory performance on standard neuropsychological tests, subjective memory complaints, and depressive symptoms in this population has been observed, such that memory complaints were not associated with memory performance but were associated with depressive symptoms. In turn, memory complaints were predictive of problems with everyday functioning (e.g., unemployment, dependence on activities of daily living). Compared to HIV+ adults without bipolar disorder, those with cooccurring bipolar disorder had less awareness of their actual memory abilities. Investigators concluded that both subjective memory complaints and objective memory ability should be considered during treatment planning in this subset of patients with HIV, as both appear to impact everyday functioning behaviors.

Successful Aging with HIV

To date, most studies have focused on factors associated with aging with HIV that are predictive of poor functioning, including physical illness burden, immune dysfunction, cognitive impairment, and psychiatric problems. Nonetheless, there is a growing body of literature that suggests the possibility of successful aging in individuals with HIV, and understanding HIV in this light may help identify individual factors related to better quality of life and well-being. Studies have shown that there is a potential for successful cognitive and emotional aging among older adults with HIV, despite significant medical comorbidities and disease burden. Additionally, the impact of negative mood on overall functioning appears to be buffered by protective psychological factors such as resilience and optimism.

In the healthy aging literature, research has suggested that subjective well-being and positive affect may be stronger predictors of morbidity and mortality in seronegative older adults than negative mood and somatic complaints. There is also a rapidly growing body of healthy aging literature demonstrating the benefits of physical activity on health and well-being outcomes. In HIV+ adults, studies have also demonstrated a positive impact of engagement in active lifestyle factors (namely physical, social, and mental activities) on better cognitive outcomes. Among adults aging with HIV, investigators have found an increased number of active lifestyle factors to be associated with better neurocognitive performance and lower prevalence of HAND. Interventions to enhance positive affect, positive psychological traits, and increase engagement in active lifestyle factors

among older HIV+ adults may have beneficial effects on mental health, cognitive, and daily functioning outcomes, as well as HRQoL.

COMORBIDITY AND MULTIMORBIDITY

As HIV-infected individuals are living longer, they are increasingly experiencing fewer AIDS-defining conditions and a wider range of non-AIDS diseases. Some of the more common comorbidities in older HIV+ persons include hypertension, diabetes mellitus and insulin resistance, cardiovascular disease, pulmonary hypertension, liver disease, kidney failure, non-AIDS cancers, osteoporosis, peripheral neuropathy, and "frailty," which are characterized by weight loss, weakness, and increased risk of disability and death.

Although comorbidities in HIV+ persons on ART are often defined as "non-AIDS," they are associated with HIV infection (HIV-associated non-AIDS or HANA), HIV treatment, and/or behaviors, conditions, and demographics more common among those with HIV infection. Thus, while they are also common in HIV– older persons, these conditions may act differently among older persons with HIV infection. Several mechanisms have been suggested, including microbial translocation, chronic inflammation, oxidative stress, and immune senescence. Yet, much work remains to be done to understand the mechanisms underlying comorbidity in older HIV+ persons.

Guidelines are available for the management of common comorbid conditions in older HIV+ persons. It is important to bear in mind, however, that multimorbidity is common among older HIV+ patients and is more than simple comorbidity. Multimorbidity is conceptualized as the presence of several health problems that have the propensity to synergize to worsen a person's functional capacity and increase mortality more than might otherwise seem apparent. When considering diagnosis and treatment in multimorbidity, the sum is greater than the parts. This multimorbidity can result in overlapping injury to multiple organ systems, transforming HIV into a complex chronic disease. This has prompted the need for better methods to track the impact of comorbidities and multiple organ system dysfunctions on the health of people with HIV.

The VACS Index was developed in this context, as a tool to monitor the impact of dysfunction involving multiple organs commonly affected by HIV, using objective measures that are collected routinely in HIV clinics. It includes age, traditional HIV biomarkers (i.e., HIV-1 plasma RNA and current CD4 count), and non-HIV biomarkers (i.e., indicators of renal and liver function, anemia, and Hepatitis C coinfection). The VACS Index has been consistently validated for estimating risk for mortality among HIV-infected persons, including that in diverse cohorts. It has also been associated with NCI, but the strength of this association is relatively weak.

IMPACT ON EVERYDAY FUNCTIONING

Real-world functioning impairment is a known sequelae of HIV infection, and functional disability expenditures have made HIV among the most expensive chronic illnesses. As such, the NIH Office of AIDS Research, and the U.S. Senate Special Committee on Aging have recently emphasized the significant public health priority for research, improving functioning in those aging with HIV. Real-world functioning in aging and HIV is complex and multidetermined. Age and HIV are associated with increased risk for NCI, which, along with numerous risk factors (i.e., certain demographics, depression, anxiety, memory complaints, social isolation), result in older HIV+ adults having a disproportionate disruption in real-world daily functioning. *Real-world functioning* in defined as what a person actually does in their daily lives. In particular, decreases in job-related activities, self-reported problems with basic activities of daily living (BADLs) and instrumental activities of daily living (IADLs), clinician-reported functional outcomes, ART nonadherence, and driving accidents have been found in older HIV+ adults relative to their younger counterparts. These age-related impairments have been found irrespective of neurocognitive status. In terms of *functional capacity*, defined as a person's abilities that are essential to function independent in the community (i.e., what they are capable of doing, not what they actually do), a synergistic effect of HIV and neurocognitive status has been observed, such that older, cognitive-impaired HIV+ adults perform worse on tasks of medication management and finance management than younger and unimpaired groups.

While older age has been found to exacerbate HIV-associated disability in real-world functioning, not all older HIV+ adults evidence functional impairment, which raises important questions about individual clinical characteristics impacting poor functional outcomes. The most well-studied predictor of disruptions in real-world functioning is NCI. The association between neurocognitive and real-world functional impairment is highly complex, and even subtle neurocognitive deficits, such as shallow encoding and forgetting, have been found to be associated with IADL dependence in this population. Factors believed to influence this relationship include the match between the individual's profile of neurocognitive strengths and weaknesses and the specific demands of the real-world activity (e.g., its complexity and cognitive and functional requirements). Motivation, awareness of cognitive and functional deficits, cognitive reserve (i.e., effects of enrichment of cognitive resources through educational and vocational experiences together with a person's innate intellectual ability), and the use of compensatory strategies also play a role in determining the nature of this relationship. Finally, there are a multitude of additional static and dynamic (i.e., changes in one area may impact other areas of functioning) biological, psychological, and social factors influencing the impact of neurocognitive ability on real-world daily functioning. For example, having sufficient home

and community resources, along with appropriately adjusting daily routines to account for physical and cognitive symptoms, have been associated with successful real-world daily functioning among HIV+ adults.

Cognitive reserve may be especially important to consider within the context of aging with HIV. Research has found lower cognitive reserve to be associated with risk for HIV-associated NCI and greater declines in IADLs. Conversely, higher cognitive reserve has been found to be the sole significant clinical cofactor of successful cognitive aging among the older HIV+ adults, whereas among younger HIV+ adults several cofactors affecting successful cognitive aging have emerged (i.e., higher cognitive reserve, Caucasian race/ethnicity, shorter duration of HIV, and lower prevalence of lifetime alcohol dependence). Thus, the evidence suggests that among older HIV+ adults, lower cognitive reserve may interfere with the adaptive ability to initiate the use of compensatory strategies when engaging in behaviors in their daily lives.

Apathy and depression are also two known reliable predictors of adverse functional outcomes among older HIV+ adults. A link between more severe depressive symptoms and over-reporting neurocognitive and functional impairments has been identified. Furthermore, a link has also been found between less severe depressive symptoms and underreporting impairments. Associations between higher self-reported apathy with greater severity of IADL declines and more numerous cognitive complaints have been observed, suggesting that apathy may make a unique contribution to important everyday functioning outcomes. Fortunately, these risk factors can easily be screened for and are amenable to change. One rigorously designed study found no relationship between antidepressant use better daily functioning among older HIV+ adults with a current or lifetime major depressive disorder diagnosis. While to the authors' knowledge the relationship between antidepressant use and daily functioning among older HIV+ adults has only been explored in one study, it may be important for clinicians to consider treatment incorporating a combination of pharmacotherapy and psychotherapy.

When assessing and treating functional impairments in this population, the patient's medical history, medical comorbidity burden, HIV disease burden, culture, and cohort effects should also be carefully considered. In the current era of effective antiretroviral therapy, older adults recently diagnosed with HIV may not have the same downstream effect of HIV disease-specific biomarkers on real-world daily functioning that can be observed in older survivors; thus, disability risks may vary based on duration of infection. In terms of the cultural impact of age and HIV on real-world functioning, assessing the sociocultural context in which HIV infection occurs is important to determine factors impacting functional outcomes. These sociocultural factors may include (but are not limited to) access to health care and antiretroviral treatment, value of employment

versus disability, HIV-associated stigma, and behavioral expressions distress.

THE SPECIAL CASE OF THE VETERAN POPULATION

The Veterans Health Administration (VHA) is the largest single provider of HIV care in the United States, with 1 out of every 250 veterans in care at VHA living with HIV/AIDS. The VA faces challenges to meeting the needs of the growing population of older HIV+ veterans. Up to 63 percent of HIV-infected veterans have at least one mental health diagnosis, and many veterans in need of mental health treatment are not receiving treatment. Primary barriers to treatment include identified targets for intervention, scheduling and availability of a mental health provider, time and travel to and from a VA facility, and privacy concerns.

Older veterans with HIV are at increased risk for depression as well as loneliness and social isolation. Depression affects over half of HIV+ veterans, making it the most common comorbidity in this population. The VACS found social isolation to be associated with greater risk of hospitalization and death in HIV+ and HIV– older veterans, and reported that this effect may be greater in HIV+ veterans. In a retrospective cohort study using data from the national VHA HIV Clinical Case Registry, researchers examined the impact of mental illness among HIV+ veterans on progression to AIDS-defining illness and death, and found substance use to be predictive of AIDS-defining illness, whereas schizophrenia, bipolar disorder, and substance were predictive of all-cause mortality. In summary, data from these studies indicate the need for increased knowledge of the mental health needs of older HIV+ veterans and increased access to care, specifically care targeting the aforementioned risk factors for poor outcomes.

TREATMENT AND MANAGEMENT

With longer life expectancy and improved health outcomes, it is no longer assumed that adults aging with HIV will need to collect disability payments as income, but instead, many may seek to continue working until retirement age. Given the public health burden of functional impairments associated with HIV, it is imperative to understand the risk and protective factors impacting real-world daily functioning. Additionally, it is equally important to understand these risks and protective factors in the context of sociodemographic characteristics, including sex, age, cohort effect, racial/ethnic minority status, and socioeconomic status. A targeted understanding of the most potent factors impacting real-world daily functioning at an individual level will aid clinicians in determining how and when to intervene in order to improve functioning and HRQoL, as well as to identify functional rehabilitation interventions that can be incorporated into clinical care.

Despite the greater availability of knowledge regarding the neurocognitive consequences of HIV disease compared to the psychiatric effects, there remains a paucity of literature on treating HAND and improving overall health outcomes. Evidence has consistently shown that patients with histories of significant immunocompromise (e.g., low nadir CD4) have increased risk of poor neurocognitive outcomes. Therefore, current practice standards recommend prescribing combined antiretroviral therapy (cART) at the time of HIV diagnosis as a prevention strategy against the neuroinflammatory cascades associated with poor immune functioning. However, a meta-analysis suggests the benefits of cART on HAND effects may be modest among older HIV+ adults. In terms of nonantiretroviral pharmacotherapy for HAND, there is some evidence that certain psychiatric medications used to treat mood problems (e.g., lithium, serotonin reuptake inhibitors) may have neuroprotective benefits in HIV. Thus, treating depression and other mood problems may have the added benefit of strengthening cognitive ability. Clinical trials using neuroenhancing drugs for the treatment of HAND have been largely unsuccessful. Overall, there is currently no first-line clinical pharmacotherapy for HAND among adults aging with HIV. While cognitive and behavioral rehabilitation strategies are increasingly being explored, published studies on cognitive neurorehabilitation approaches for HAND are scarce. Solely using pharmacotherapy for HAND treatment is contraindicated, as there is a strong correlation between neurocognitive deficits and medication nonadherence among persons living with HIV. Psychotherapeutic interventions incorporating cognitive and behavioral components with adherence (i.e., cognitive-behavioral therapy for adherence and depression [CBT-AD]) are potentially efficacious supplements or alternatives to pharmacotherapy. Additionally, there is some promising early evidence of the potential efficacy of restorative cognitive rehabilitation approaches.

Lifestyle modification is another potential functional rehabilitation treatment approach. Evidence-based behavioral treatments exist for a vast array of lifestyle factors, including physical activity, stress reduction, mental activity, social engagement, sleep hygiene, and substance use reduction. For example, randomized controlled trials have demonstrated preliminary evidence for the positive effects of mindfulness-based stress reduction on reducing behavioral avoidance, increasing positive affect, reducing depressive symptoms, and reducing cART side effects (e.g., 30). Although many of the aforementioned lifestyle factors have yet to be tested (via controlled trials), specifically among older adults with HIV, many of these factors protect and promote cognitive reserve, increase brain-derived neurotrophic growth factors, and reduce neuroinflammation and oxidative stress, which would have a direct benefit on cognitive and real-world everyday functioning.

FUTURE DIRECTIONS

As long-term survival among persons living with HIV continues to improve, the need for identifying targets for improving outcomes in this population is clear. Comorbid health problems are the norm among persons living with HIV who are 50 years of age and older. Continued efforts to integrate primary health care, geriatricians, HIV providers, and mental health treatment are needed to address the needs of this population. Primary health care providers and HIV providers are unlikely to assess for HAND or mood symptoms; this has a direct negative impact on treatment. Comprehensive assessment and integrated care planning in this population, regardless of age, is necessary. It is increasingly important for the patients, their care providers, and the health care system to expand the focus of clinical research and practice beyond alleviation of symptoms, to consider issues of real-world functioning and HRQoL.

57.6h Technology for Seniors

RUJVI KAMAT, PH.D., COLIN A. DEPP, PH.D., AND IPSIT V. VAHIA, M.D.

INTRODUCTION

With the population of older adults expected to reach two billion worldwide by 2050, there will be a serious shortage of skilled care providers to manage the needs of this population. To cope with the increasing demands for health and social care, there is a great need to reorganize care processes and leverage different technologic solutions. Simultaneously, with the rapid maturing of the "aging in place" movement, there is an unprecedented incentive to optimize an array of technologies to help adults maintain independence in their own homes, and avoid or forestall transition to institutionalization. Over the past decade, there has been a revolution in how technology has both evolved and impacted the global population at large. Canadian social scientists, Wellman and Quan-Haase used the term "hyperconnectivity" to describe multimodal human-to-human and human-to-machine interaction using a variety of platforms including face to face, email, using mobile phone technology, and via the Internet. The implication of this term is that most persons will communicate via a multitude of channels, facilitated by technology, and that human interaction with multiple forms of technology will grow substantially.

In response to this societal shift, there has been an explosion in technologies over the past decade, facilitated not just by seamless communication, but also advances in computing and sophisticated sensors that can increasingly provide continuous objective data on a number of parameters. Although older adults have traditionally been considered late adopters of emerging technology, there is growing consensus that this demographic group, with its needs for increased care and monitoring, especially among the oldest-old with multiple medical needs and reduction in independent functioning, represents a significant opportunity for technology-based innovation.

COMPARATIVE NOSOLOGY

Defining Technology in Aging

The term *technology* is derived from the Greek term *"tekhne,"* which means art or skill. It is defined by the Collins English Dictionary as the "total knowledge and skills available to any human society for art, skills, etc." This is a very broad term, subject to multiple interpretations, and inclusive of technology in all its forms and considerations, from use of flint to make fire to the latest developments in robotics. More recently, within the context of aging, researchers have favored the use of the term "gerontechnology" which has been described as "an interdisciplinary field of scientific application of technologic applications that are directed toward the aspiration and opportunities of the older person." These are broad terms, and as may be expected, they cover a very broad range of technologies. Table 57.6h–1 presents an overview and broad classification of types of technology, based on application. This chapter will focus primarily on Information and Communication Technology and Assistive Technology. Other technologies including Medical Technology and Smart Home Technology are also discussed.

There has been a growing cross-disciplinary effort to develop and apply information and communication technologies (ICTs) for acquiring, processing, presenting, and managing health-related data in older adults. The goal of these technologies is to improve health, quality of life, and social connectivity for less impaired older adults, and assist in clinical care and monitoring of more impaired older adults. Although older adults do not use ICTs as commonly as younger individuals, they do use devices such as smartphones in comparable ways, that is, to communicate, access information (health-related and otherwise), entertainment, and financial management. Emerging data suggest that certain factors, such as perceived advantage of technology and design issues contribute to the lower rates of technology use in older adults. These issues may serve to guide the modification and development of ICTs tailored to engage and benefit older adults.

Table 57.6h–1.
Classification of Technology for Aging

Type	Example	Target Population	Role
Medical technology	Pacemakers, implanted medication infusion systems, vagal nerve stimulators	Focused: Older adults with specific medical issues	Targeted medical role
Assistive Technology	Telemedicine systems, sensors	Narrow: Older adults with medical conditions that	Maintenance of physical health and well-being

	(e.g., accelerometers), monitors (e.g., glucometers)	require monitoring	
Information and Communication Technology	Wi-Fi, smartphones, tablet devices (e.g., iPads)	Broad: Older adults with need and ability to connect to the internet or use cellular technology for communication	Staying in touch with friends or family, more integrated social functioning, access to information
Smart Home technology	Personal Emergency Response Systems, Environmental Sensors	Broad: Older adults with cognitive or functional impairments, invested in aging in place	Facilitating remote monitoring of older adults living independently, minimizing risk of in-home adverse events

Assistive technologies have a more narrow scope and focused application, since they are usually developed to target specific medical conditions or functional deficits. It is important to note that a specific technology may be classified in more than one category. For example, a smartphone is usually considered a platform for an ICT. However, it may be used as a form of assistive technology, if a specific app has a targeted role in monitoring. In addition, there is a new generation of cellphone accessories that aim to leverage the computing capabilities of smartphones to transform them for use as medical devices. For example, a California-based company called CellScope has recently launched a device called the Oto, which fits onto the camera of smartphones, and allows the phone to function as an otoscope. Such devices have the potential to facilitate remote consultations and rapid diagnoses.

Technology and Aging in Place

An important goal of technology for older adults is to compensate for age-associated losses in physical and cognitive functioning. There is growing evidence to support the use of assistive technologies as a way to allow older adults to "age in place." Aging in place is defined by the Centers for Disease Control and Prevention (CDC) as "the ability to live in one's own home and community safely, independently, and comfortably, regardless of age, income, or ability level." Social networking, remote monitoring, and assistive devices have shown promise in enhancing opportunities for aging in place. Since a significant proportion of increased healthcare costs associated with aging is related to the need for intensive monitoring and institutionalized care, promoting aging in place is an important approach to preserving independence and also reducing costs. Both ICTs and assistive technologies have a key role in promoting aging in place. The American Association for Retired Persons (AARP), which has taken on a prominent role in advocacy for aging in place, describes case scenarios on their website of how technology, including pillbox sensors, refrigerator

sensors, and personal emergency response systems (PERS) can help promote aging in place.

SPECIFIC APPLICATIONS OF TECHNOLOGY

Telehealth

Medical providers are increasingly using telecommunication devices in the diagnosis and care of patients in remote locations. These technologic modalities include video, voice, robotic, and remote-access technology to facilitate interactions between providers and patients. Telehealth approaches to observe patients and provide intervention services have direct relevance to psychiatry and geropsychiatry. The use of telemedicine has the potential to be cost effective and improve the ease with which patients may be observed and assessed.

Literature regarding the use of telehealth systems with patients with schizophrenia supports the reliability and feasibility of using videoconferencing as an assessment modality for patients with psychiatric illness. Furthermore, this approach appears to be a useful method of delivering interventions in this population and is associated with good functional and psychiatric outcomes.

Building on the feasibility of using telemedicine in cohorts with psychiatric illness, there has been a growing effort to develop concepts, systems, and devices in a geropsychiatry context. There is a pressing need to develop telemedical services for older adults. Telehealth approaches may mitigate unique challenges faced by this population. For example, distance from providers may restrict regular healthcare visits for older patients with limited mobility. Services such as video consultation and remote monitoring devices facilitate the transfer of information between the patient and doctor and monitor the appropriateness of clinical interventions, thus improving the quality and access to health care. A majority of interventional telemedical studies in the geriatric population have focused on monitoring older adults. This may take the form of routine personal monitoring accompanied by supportive contact between the healthcare provider and the patient and/or measurements of key biomarkers using technologic modalities. Overall, such interventions appear to have a positive impact on important health outcomes such as adherence and behavioral change.

Older patients tend to have physical and cognitive limitations and thus have distinctive needs that must be addressed by telehealth protocols. It is particularly promising that telehealth approaches appear to be feasible and useful in a wide variety of geriatric subgroups. For example, Loh and colleagues developed and examined a videoconferencing protocol for diagnosing Alzheimer disease and found that there was good diagnostic agreement between the telemedical modality and the face-to-face

assessment. Telepsychiatry has also been investigated in nursing home populations. Not only do telepsychiatry visits have a positive impact on the quality of patient care, they also appear to be associated with significant financial savings (approximately $30,000 saved over the course of 278 telepsychiatry visits). Taken together, these data support the potential benefit of telemedical applications in aging cohorts and highlight the need for greater empirical attention to the development and use of these novel approaches.

The application of telehealth concepts to geropsychiatry requires attention to the clinical benefits of these approaches, as well as their feasibility, acceptability, and cost–benefit ratio. As these systems spread in use, it is worthwhile to consider whether demographic factors (e.g., age, gender, race, level of education, and employment status) impact the ease with which older adults use these telehealth modalities. Furthermore, the influence of factors such as dementia, psychiatric illness, and caregiver availability also need to be better characterized. These variables can guide the efforts to maximize the usability and acceptability of telehealth interventions in older adults, and potentially, subsequent public policy.

Telemedicine-based approaches also continue to find application in providing clinical services in underserved areas. A recently published report describes a study conducted in Imperial County, California, which has the nation's highest rate of unemployment, and where over 80 percent of the population is Latino, and approximately 25 percent of the population meets Federal criteria for poverty. In this study, the authors compared neuropsychological testing in Spanish conducted in-person, with testing conducted via telemedicine, for a sample of adults meeting clinical indications for testing. The authors found that test performance was comparable across the telemedicine and in-person modalities. This study used a within-subjects design and randomized participants to determine which modality they received first; the findings are a strong indicator that telemedicine may serve as an acceptable and valid proxy for providing services such as neuropsychological testing.

Thus, as telehealth modalities continue to improve in design and implementation, they will have the potential to provide rapid, high-quality health care for aging cohorts.

Mobile Health

The term *mobile health* (or mHealth) loosely refers to the use of mobile phone technology for health care. In the past 5 years, there has been an explosion of interest in the uses of mobile devices in collecting health-related data, delivering health care and facilitating interaction among patient, clinician, and family stakeholders in the service of improving health. There are several reasons why mobile phones are specifically attractive as a potential platform for healthcare delivery. For one, recent

estimates indicate that the penetration of mobile phones is approximately 90 percent in the United States. This penetration has increased at rapid pace over the past 10 years and is nearing complete saturation. Of note, 64 percent of people own a smartphone, which means that the majority of people (at least in the United States) carry with them an increasingly potent device capable of real-time interactive communication and capture of continuous data on a variety of physiological and behavioral factors. Older adults are, as with other technologies, less likely to own a mobile device than their younger counterparts, but as of 2014, 74 percent owned a mobile device. The use and ownership of cell phones cuts across other sociodemographic strata, with poor and underserved subpopulations often more likely to rely on mobile devices. This ubiquity of mobile devices provides a remarkable new conduit for innovation in healthcare delivery, and both academic and consumer developers have responded with the creation of a wide variety of mHealth applications.

The "value proposition" of mHealth is that it could enable delivering care outside of the typical clinic setting, either by augmenting interventions by providing additional interaction to support everyday health sustaining behaviors (e.g., medication adherence), or by extending them beyond the time frame typically associated with the intervention. Remote mobile technologies can automate tasks that are typically performed by clinicians, such as appointment reminders, symptom and risk assessments, and scheduling, which could increase access to health care by reducing the need for face-to-face interaction. Additional benefits of mHealth are the ability to help compensate for prospective memory problems and facilitate self-management of chronic illnesses. Mobile phones can provide timely reminders for beneficial health behaviors and deliver "just-in-time" interventions that could diminish the time gap between symptom emergence and intervention. Given that large volumes of data are available both through patient-reports and sensors linked with the devices, it may also be possible to identify actionable patterns of symptoms over time in chronic recurrent illnesses, and then intervene based on accumulating knowledge of individual patients so as to personalize care to individuals. Finally, provider-facing applications may assist in managing patient needs and diagnoses, reducing the need for brick and mortar clinic settings, which may be particularly attractive in the developing world. To temper enthusiasm somewhat, while collectively these advantages offer great potential, the mHealth field is nascent and so few mHealth interventions are yet embedded in routine care.

mHealth interventions typically involve a number of elements, which include the following: (1) a patient facing platform. This is an interface that provides interaction, and typical platforms include the feature phone that is not connected to the Internet yet capable of voice or SMS interaction, a smartphone, or a dedicated device that is developed for the mHealth

intervention, (2) one or more active communication channels to the patient, which may include SMS, live or asynchronous voice, email or in-app interaction. Alternatively communication can involve passive sensing, or the collection of data without the need for patient response. Sensors are highly varied, but could include activity measured by GPS antenna or accelerometer embedded in the device or ancillary sensors that couple with the device, such as blood pressure or glucose, (3) a set of algorithms that govern the interaction between data captured on the device and a clinical response. These may be automated and do not involve direct clinical oversight or might flag or prompt interaction from clinicians tasked with monitoring the incoming data, (4) a server that stores and allocates interactive elements to individual users in the intervention network and, finally (5) a clinician facing dashboard or utility that enables a supervising clinician the capacity to manage, monitor, and interact with patients in the mHealth intervention. Many iterations of the above architecture are possible, with some apps that are completely consumer facing without clinician oversight and others offering complex layered interaction with a variety of clinicians and other technologic assets such as the electronic medical record.

A number of reviews have addressed the question as to whether mHealth interventions are effective. To date, the evidence is mixed. While recent systematic reviews have indicated that mHealth interventions seem effective for certain commonly researched areas, in particular smoking cessation and HIV medication adherence, other areas were limited in terms of evidence. A key limitation of the literature is the lack of high-quality randomized clinical trials. Another limitation pointed out by de la Vega and Miro is that there are over 100K health-related apps that are currently available for download in the iOS and Android markets, yet few of these have been subjected to any empirical study. Conversely, very few of the applications that have actually been subjected to rigorous randomized trials are actually available to consumers. As such, the mHealth field is somewhat bifurcated into unproven apps directly available to consumers, and academic products that are not translated to products available to consumers.

mHealth solutions for mental health and aging are far fewer in number than are ones for chronic medical illness. Nonetheless, there are some examples of apps designed for chronic mental illness, including schizophrenia, bipolar disorder, and substance abuse. Review studies have indicated that mHealth applications could provide important resources to support access, initiation, engagement, and sustainment of psychiatric care. A recent study published by Depp and colleagues indicates that even among older adults with schizophrenia, the rate of past exposure to mobile phones is high (78 percent had ever used one) and the great majority felt comfortable with use of mobile devices. Despite high rates of prior use, few

patients currently owned mobile devices, which do create a barrier to future implementation without subsidization of mobile devices. Moreover, data gathered by mobile devices on symptoms appear to be valid—one study indicated that daily mood ratings obtained in a sample of patients with bipolar disorder appear to be more consistent with clinician ratings than were identical mood ratings recorded on paper-and-pencil forms. As such, evidence, albeit limited, suggests that patients with chronic and severe psychiatric impairments are capable of using mobile devices and can report accurately on symptoms that would be the likely focus of intervention.

There have been few randomized trials of mHealth interventions in psychiatric illnesses. Depp and colleagues conducted a 24-week randomized controlled trial in 81 patients trial of a four-session psychoeducational intervention for bipolar disorder augmented by automated personalized reminders contrasted to a four-session intervention without mobile device augmentation. Effect sizes for this trial indicated that the mobile augmented condition was associated with greater reduction in depression, by a medium effect size; the magnitude of this effect is notable given the challenges met by many interventions in impacting bipolar depression. However, these positive effects seemed to dissipate at follow up suggesting that gains made by mobile augmentation did not sustain once mobile intervention ceased. Separate studies by Granholm and colleagues as well as Ben Zeev and colleagues have each reported positive changes in medication adherence, psychiatric symptoms, and socialization in open trials of SMS and smartphone application interventions in schizophrenia. Gustafson and colleagues evaluated a smartphone application designed to extend the impact of rehabilitation for alcohol use disorder and found significant reductions in alcohol use in a randomized trial of more than 300 patients. As such, these emerging clinical trials offer an encouraging indication of the feasibility, acceptability, and effectiveness of mobile interventions that augment psychiatric care. Given the large number of ongoing clinical trials of mHealth interventions in mental health conditions (see ClinicalTrials.gov), it is likely that data on the effectiveness of mental health targeting mobile applications will proliferate in the near future.

There are a variety of exciting and emerging directions for mHealth mental health applications. For one, there is increasing evidence that passive sensors (described in detail in the next section) can identify patterns consistent with change in symptoms. For example, vocal prosody appears to covary with mood symptoms in bipolar disorder. If passive sensors can supplant patient reports, it may be quite possible to efficiently monitor and allocate preventative care to patients without the need for patient-initiated interaction. Second, and relatedly, there is increasing interest in the use of predictive analytics in leveraging the intensive longitudinal data generated by mHealth applications to develop dynamic

personalize risk profiles for serious adverse events like suicide. Thompson and colleagues reported preliminary data on a statistical technique called functional data analysis that is optimized for the noisy repeated data that are generated in mHealth and found that a simple algorithm modeling negative affect highly accurately predicted subsequent increases in suicidal ideation in a small sample of bipolar patients. Other approaches have used natural language processing to identify patterns predictive of suicide. Other frontiers include the use of more sophisticated algorithms to intervene with patients depending upon social contexts or enlistment of social networks and peers in managing mental illnesses. As with mHealth in general, while exciting, each of these novel approaches would need to be adequately evaluated in well-designed clinical trials to move beyond proof-of-concept stages to translate to impact on psychiatric care.

In summary, the field of mHealth is a rapidly evolving one that, while yet to fully deliver on its promise, holds great potential for impacting the landscape of mental health care in older adults with psychiatric illnesses. Globally, older adults are increasingly adopting mobile technologies, and the development and tailoring of mHealth interventions to meet the needs of older adults will be a subject of research for years to come. Next, sensors and their role in quantifying health will be discussed.

Sensors/Self-Monitoring Devices

With accelerometers available readily, monitoring of movement, behavior, balance, as well as physiologic variables such as heart rate and oxygen saturation is becoming simpler. Researchers are developing sensors that can perform blood tests by connecting through ports to the computing chips in cellphones. Qualcomm—a San Diego-based communications company—has initiated a competition encouraging developers to produce a "tricorder," a noninvasive handheld diagnostic device, which can monitor multiple physiologic functions and perform diagnostics without availability of sophisticated labs.

Table 57.6h–2outlines various types of sensors, and the types of roles they can play in promoting aging care.

The use of sensor technology in health care and especially for older adults is a rapidly evolving field. Wrist-worn and body-worn accelerometers have found multiple uses among athletes, and to measure levels of physical activity. Most of these sensors rely on accelerometry to detect motion. However, the new generation of sensors incorporate additional elements such as using highly sophisticated computing chips (such as those found in smartphones), machine learning (i.e., the automated optimization of systems by use of statistical inference to make predictions), and wireless transmission of data and visualization (using software that also relies on the computing power of handheld devices).

Chemical sensors and body-worn sensors are noninvasive alternatives

that have shown promise in in vitro testing. These sensors can be easily produced on a mass scale using 3D printer technology and can be mounted on a variety of platforms such as mouthguards for measuring electrolytes and metabolites in saliva), textile (for measuring sweat or urine), bandaids (for measuring chemicals in interstitial fluids). These sensors can also be integrated with microneedles that are minimally invasive and painless. Currently, sensors in development can measure a wide range of electrolytes and metabolites including glucose, lactate, sodium, potassium, pH, and urea.

Wearable sensors can already measure vital signs, and commercially available devices such as the recently launched Apple Watch can measure and transmit heart rate in real time. These sensors have led to the creation of novel "personal health data." Several health care systems are working on developing infrastructure that can incorporate such data with electronic health records to have a more complete set of data on patient health and well-being.

Table 57.6h–2.
Classification of Sensor Technology

Type of Sensor	Examples	Role	Stage of Development (at time of writing)
Implantables	Nanosensors	Monitoring of parameters in very constrained environments, e.g., small blood vessels, GI	Conceptual development and prototyping Clinical validity not yet established
Neurosensors	Bitemporal EEG monitors	Portable noninvasive monitoring of neurologic (e.g., seizures), psychiatric (e.g., anxiety), and physiologic (e.g., pain) parameters	Commercially available. Clinical validity under assessment
Wearable physiologic monitoring devices	Microneedle-based sensors, tattoo sensors	Noninvasive monitoring of electrolyte and metabolite levels	Prototypes developed. In-vitro device validity and reliability under assessment
Wearable external monitors	Accelerometers, gyroscopes	Monitoring of psychical activity patterns and sleep	Commercially available and clinically validated
Environmental sensors	Motion sensors, gas sensors	External continuous monitoring of activity and functioning	Motion sensors are currently commercially available. Gas sensors are in prototype stage

Wireless electroencephalography (EEG) devices are also gaining popularity. These devices consist of a semicircular band with electrodes on either end, which can be placed bitemporally to collect bitemporal EEG

readings. These devices are also being utilized to gather EEG data to predict emotional states, pain, and anxiety.

As the use of wearable devices and sensors grows, there is a need to develop algorithms that can generate relevant clinical alerts based on changes in physiologic and environmental data. Further, medical providers, caregivers, and the wearers themselves will need tools to visualize these data and use that information to predict or respond to abnormal events.

Smart Homes and Senior Design

Advances in ICT have led to a growing interest in the development of "smart homes," that is, living environments equipped with multiple sensors that can monitor and detect a person's activity. The goal of these technologies is to improve the quality of life and promote physical independence of older adults. Within this context, multiple devices and technologies may be embedded within the infrastructure of the residence and may thus function without the need to train residents on their use. For example, a heat sensor mounted on a stove can detect if the stove has accidentally been left on for a prolonged period. Motion sensors can keep track of a person's mobility in the house and may provide information on clinical issues such as triggers of insomnia and markers of agitation such as pacing. Existing prototype smart homes (e.g., the Awarehome at the Georgia Institute of Technology) serve as research environments that guide development of technologies that may aid development of senior-friendly living.
