Figure 5 Schematic diagram of endochondral ossification.

2.210.3.2. Intramembranous Ossification

During embryonic development, bone formation also occurs by means of a process known as intramembranous ossification, which regulates the formation of nonlong bones such as the bones of the skull and clavicle. The primary difference between intramembranous and endochondral ossification is that the intramembranous process does not rely on the formation of a cartilage template. Instead, embryonic stem cells (MSCs) within mesenchymal tissue of the embryo, derived from primary tissue (germ layers), begin to proliferate and condense to form an aggregate of MSC cells. This nodule is surrounded by a membrane, and MSCs within the membrane begin to differentiate to first become osteoprogenitor cells and then osteoblasts. These osteoblasts line the nodule and secrete an ECM consisting of type I collagen fibrils within the center of the nodule. Some osteoblasts become embedded within the newly formed matrix, and in this environment, they differentiate and form interconnecting cytoplasmic processes to become osteocytes. The cells on the outer surface form a periosteum, and bone growth continues at the surface of the trabeculae. At this time, the nodule is mineralized to form rudimentary bone tissue that is populated by osteocytes and lined by active osteoblasts.[48] This tissue is known as a bone spicule and many spicules fuse to form trabeculae, known as primary spongiosa, which then fuse to form woven bone. Over time, this woven bone is remodeled to become lamellar bone, with concentric lamellae surrounding Haversian systems in what is known as an osteon.[48,72,73]

2.210.4. Bone Structure and Hierarchical Organization

Bone architecture is hierarchical and complex, consisting of component phases at different levels of structural organization,[74] and these can be classified from the organ level to the macrostructural, microstructural, and nanostructural level. This intricate and complex hierarchical organization of bone is fundamental to its function.

2.210.4.1. Bone Tissue Structure and Organization

The bone that comprises that adult skeleton is organized into two main types; approximately 80% of the mass is a bone tissue known as cortical bone and the remaining 20% is known as trabecular bone, which is also known as cancellous or spongy bone. The microstructure of the bone is organized differently depending on the anatomical location and the type of bone involved; however, the basis of the differences between bone types arises predominantly from the microstructural organization of layers, or lamellae, of bone tissue.

Cortical bone is a dense bone tissue that is characterized by a low porosity of approximately 5–10%. It is most commonly found in the shafts of long bones and also forms a shell around the ends of bones such as the vertebrae, scapula, and pelvis (Figure 6(d)). It serves to bear load, transmit mechanical forces from the musculature, and provide levers to facilitate movement. Cortical bone can be further classified into either woven or lamellar bone, and the tissue is organized into structural units known as lamellae and osteons. Woven bone is the term used for immature bone that has a highly irregular organization wherein there is no distinct organization of the collagen fiber bundles or osteocyte cells, but rather they are oriented at random in a meshwork. Owing to the lack of structural organization, woven bone exhibits low strength. Woven bone is present in newly formed bones and is gradually replaced by lamellar bone as growth continues by remodeling (Section 2.210.6.2), but is maintained at tendon insertions and tooth sockets. In lamellar bone, collagen fibrils and osteocyte lacunae are organized into parallel layers known as lamellae, and within each lamella, the collagen fibrils are oriented in the same direction, but collagen fibrils in adjacent lamellae are oriented by 90° relative to each other. This organization of lamellae differs in certain regions in the bone; lamellae that are organized parallel to periosteal and endosteal surfaces are known as circumferential lamellae, whereas in regions of bone tissue that contain blood vessels, lamellae are organized in concentric rings around a Haversian canal that contains a central vessel, and each structural unit is known as an osteon (Haversian system). These blood vessels are essential for providing a nutrient supply to the bone cells that reside in the impermeable bone matrix. The Haversian canal is approximately 70 μm in diameter and the blood vessel is 15 μm.[75] Primary osteons have few lamellae and small vascular channels and are formed in the embryo during mineralization of the cartilage template. Secondary osteons are formed by

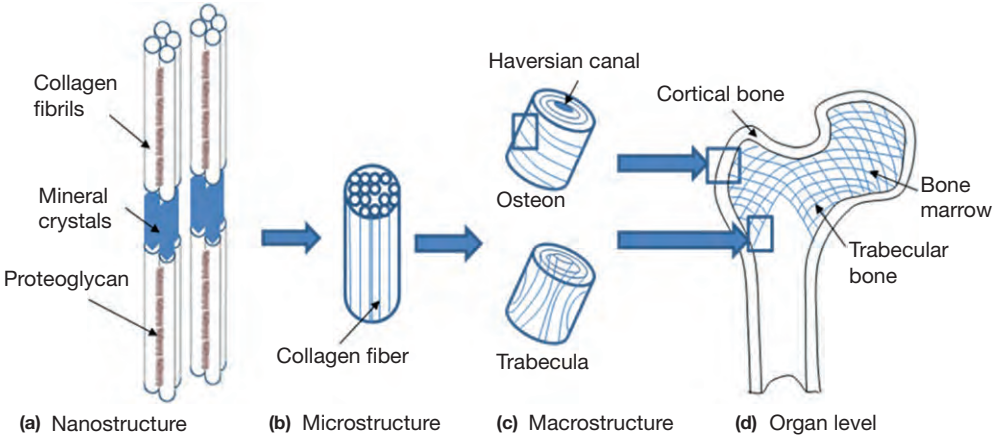

Figure 6 Schematic of bone tissue organization in the cortical and trabecular bone.

replacement of existing bone tissue during remodeling (Section 2.210.4) and are 200 μm in diameter. A significant feature of secondary osteons is the presence of cement lines that mark the interface between adjacent osteons. It is a matter of debate whether this material is less or more mineralized than the osteon,[76–78] and it has been proposed that the cement lines act as mechanical bonds between osteons or transfer energy between osteons to slow crack growth.[76] There are multiple types of microstructural pores within cortical bone tissue, vascular pores, lacunar–canalicular pores, and collagen–apatite pores.[74,79] These pores provide a network to transport nutrients, mineral ions, and waste products to and from the vascular system to bone cells. It is also believed that fluid flow, within these pores, provides essential mechanical stimulation to the cells.

The trabecular bone is a highly porous (typically 75–95%) form of bone tissue that is organized into a network of interconnected rods and plates called trabeculae which surround pores that are filled with bone marrow. This bone tissue is found at the ends of long bones such as the femur, and also in the vertebrae. In the trabecular bone, the lamellae are organized into single trabeculae, which are the structural units of the trabecular bone and are not vascularized. The intervening space between these trabeculae is filled with bone marrow. Human trabeculae are typically 150–300 μm in diameter and can be up to 2000 μm in length, and their shape is determined by their anatomical location and loading situation. It has been hypothesized that these trabeculae are directed along the force trajectories created by weight-bearing forces.[80] This highly specialized hierarchical organization lends bone its unique strength and stiffness to withstand the complex loading experienced during normal activities, but also ensures that bone is sufficiently lightweight to facilitate efficient movement in response to the forces generated by muscles. Extensive research has been carried out to characterize the exact morphology of the trabecular architecture.[81–83] Microarchitecture is a term which refers primarily to the microscopic morphology and organization of the trabecular bone. Bone microarchitecture is typically characterized using techniques such as micro-CT (μCT) scanning, which relies on exposing bone to an X-ray source, and using an X-ray detector to obtain 3D representations of the trabecular architecture at various resolutions. Such techniques have allowed the morphology of the trabecular bone to be analyzed at resolutions ranging from 14 to 250 μm. Quantitative parameters have been defined to characterize the structure of the trabecular bone, such as bone volume, trabecular thickness, trabecular separation, number of trabeculae/mm^2, and trabecular length.

It has been reported that more than 80% of the variance of trabecular bone strength and modulus can be explained by measures of density and trabecular orientation.[84] The degree of porosity of the trabecular bone varies with anatomical location. Besides the porosity associated with the marrow-filled cavities in the trabecular structure, trabecular bone tissue also has a lacunar–canalicular porosity and a collagen–apatite porosity.[79] These different levels of porosity serve to exchange bone fluid with the marrow, to provide mechanical stimuli for bone cells, and to transport nutrients and waste products to and from the marrow to the bone cells.

2.210.4.2. Organ Level

The skeleton consists of 206 bones, which are classified broadly into either the axial skeleton or the appendicular skeleton. The appendicular skeleton is composed of 126 bones, which are essential for locomotion and manipulation of objects in the environment. These bones include the long bones such as the femur, tibia, and fibula of the legs, and the humerus, ulna, and radius bones of the arm. Long bones are tubular in structure and have a shaft comprising dense cortical bone known as the diaphysis, which surrounds a medullary cavity filled with bone marrow. Porous trabecular bone is found in the extremities (epiphysis) and is covered by a thin shell of cortical bone. The epiphyseal plate is a hyaline cartilage plate in the metaphysis of long bones and is the site from where the bone grows in length. Hyaline cartilage covers the ends of bones and serves to prevent friction and absorb shock. Each of these bones is covered by vascular membranes known as the periosteum on the outside surface in regions where there is no hyaline cartilage, which attaches to ligaments and tendons, and an endosteum on the inner surface. Each of these linings is a source for bone cells that are essential for maintenance and remodeling.

The axial skeleton consists of 80 bones in the human skull, the rib cage, the vertebral column, the ossicles of the inner ear, and the hyoid bone of the throat. The vertebrae are primarily composed of the trabecular bone and are covered by a thin layer of cortical bone. In contrast to long bones, vertebrae have no medullar cavity. Short bones are comprised predominately of trabecular bone and have a thin shell of cortical bone surrounding. These bones include the bones of the wrist and ankle, such as the tarsal bones of the feet, the carpal and metacarpal bones of the hands, the phalanges, the pectoral girdles, clavicles, scapula, pelvis, and sesamoid bones.

2.210.5. Bone Mechanical Behavior

Bone is a highly specialized tissue that comprises a composite material which is organized in a complex hierarchical structure, and its biomechanical behavior is accordingly intricate and varies greatly depending on the length scale (i.e., tissue level, organ level) at which it is assessed. Given this complexity, the mechanical behavior has been investigated at different length scales and resolutions to provide a holistic understanding of the biomechanical behavior of the bone. In general, the mechanical behavior can be segregated into the whole bone mechanical behavior, the structural mechanical behavior, and the tissue-level mechanical behavior. The structural mechanical properties are determined by mechanical testing of samples that comprise multiple trabeculae and thereby the measured mechanical behavior encompasses the trabecular architecture and bone mass of the sample (Section 2.210.5.1). In contrast, the properties of the tissue itself are independent of bone mass and architecture and are typically characterized by testing single trabeculae or microscopic samples of bone tissue (Section 2.210.5.2). These studies have provided information regarding the complex hierarchical mechanical behavior of bone at the microscopic and nanoscopic levels. At each scale, bone can be classified as an anisotropic, heterogeneous,

nonlinear material, and the material properties of the trabecular bone vary considerably at different anatomical locations and the type and direction of loading that is applied.

2.210.5.1. Structural Mechanical Behavior of Trabecular Bone

The structural behavior (also known as the apparent behavior) is determined by the mechanical testing of cylinders (typically, 5 mm in diameter) or cubes (5 mm^3) of the trabecular bone. Samples of this size represent the continuum mechanical properties of the bone tissue but are sufficiently large to overcome limitations of the continuum assumption near biologic interfaces (within three to five trabeculae of an interface) and in areas of large stress gradients.[85] Mechanical testing of volumes of trabecular bone from the proximal and distal femur, the vertebral body, or the proximal tibia have provided an important understanding of the heterogeneous mechanical behavior of the trabecular bone.[82,86–88] At this scale, the heterogeneity is largely due to variations in the bone mass (volume fraction) and the 3D architecture of the trabeculae,[89] but variations in tissue composition and organization also contribute to this behavior (Section 2.210.5.2). The trabecular microarchitecture is an important determinant of bone strength and susceptibility to fracture.[90,91] The apparent elastic modulus of the trabecular bone varies considerably within a single vertebral bone, with modulus values ranging from 165 MPa in the superoinferior direction to 43 MPa in the lateral direction.[82] It has also been reported that the mean yield strength of the trabecular bone in tension is 15.6 MPa and that this is 30% lower than the yield strength under compressive loading.[92] The apparent yield strain of the trabecular bone is approximately 0.8%.[88] The fatigue failure criterion of the trabecular bone matrix has also been investigated by testing within normal physiological frequencies that range from 0.5 and 3 Hz, and it has been reported that the number of cycles to failure ranged from 20 cycles at 2.1% strain to 400 000 at 0.8% strain.[93]

The mechanical behavior of the trabecular bone varies across anatomical locations,[84,94,95] and further variations arise between different bones and species. The mechanical behavior of the trabecular bone deteriorates with the process of aging, and it has been reported that the ultimate stress of the trabecular bone from the human femur and spine is reduced by approximately 10% per decade in the adult skeleton.[96–98] Owing to the structure of the trabecular bone, the material properties obtained by testing volumes of the trabecular bone are highly dependent on the architecture of the matrix and do not represent the properties of the mineralized tissue itself.

2.210.5.2. Tissue Mechanical Behavior of Bone

As bone is a hierarchical material, the properties of the tissue must be known to fully understand the mechanical behavior of the bone. In particular, it is often widely assumed that the mechanical properties of the trabecular bone are the same as cortical bone at the tissue level, and that it is their architecture that distinguishes them. Mechanical testing of trabecular and cortical bone specimens has been carried out using a variety of methods such as 3/4-point bending,[99] buckling,[100,101] cantilever beam tests,[102] microtensile testing,[103–107] and ultrasonic measurement.[105] The details of these studies are summarized in Table 1. Reported values for the elastic modulus of trabecular tissue from these studies have conflicted, with values ranging from 0.75 to 20 GPa. One study applied both microtensile testing and an ultrasonic technique to compare the elastic modulus of individual trabeculae and microspecimens of the cortical bone[105] and reported that the elastic modulus of individual trabeculae (10.4 ± 3.5 GPa) is significantly lower ($p < 0.0001$) than that of cortical bone (18.6 ± 3.5 GPa). A system was designed to measure the tensile strength and elastic modulus of individual trabeculae, which overcame previous limitations by eliminating inaccuracies due to sample alignment, geometry, and gripping.[21] The results of this study indicated that the elastic modulus of the trabecular bone is

Table 1 Previous studies to determine the mechanical properties of bone tissue

Study	*Property*	*Mechanical test*	*Specimen origin*	*Elastic modulus (GPa) Mean (SD)*
McNamara *et al.*[103,172] and McNamara *et al.*[104]	Elastic modulus, yield strength, postyield strain	Tensile testing	Rat proximal tibia	2.81 ± 2.09
Townsend and Rose[241]	Elastic modulus	Buckling	Human medial tibia	14.1 (dry); 11.3 (wet)
Runkle and Pugh[100]	Elastic modulus	Buckling	Human subchondral bone	8.7 (3.2)
Mente and Lewis[102]	Elastic modulus	Cantilever beam	Dried human femur	6.2 (1.2)
			Fresh human tibia	11.2 (10.1)
Ryan and Williams[242]	Elastic modulus	Tensile	Bovine distal femurs	–
Ryan and Williams[106]	Elastic modulus	Compression	Bovine femora	0.8 (0.4)
Kuhn *et al.*[243]	Elastic modulus	Three-point bending	Human iliac crest	3.8
Choi and Goldstein[244]	Fatigue strength	Three-point bending	Proximal tibia	–
Choi *et al.*[99]	Elastic modulus	Three-point bending	Proximal tibia	4.6 (1.3)
Rho *et al.*[105]	Elastic modulus	Ultrasonic/microtensile	Proximal human tibia	10.4 (3.5)
Choi and Goldstein[108]	S–N curve	Four-point bending	Proximal tibia	–
Van Rietbergen *et al.*[245]	Elastic modulus	High-resolution FE modeling	Proximal human tibia	5.91
Rho *et al.*[112]	Elastic modulus	Nanoindentation	Human vertebrae	13.5 (2.0)
Turner *et al.*[116]	Elastic modulus	Nanoindentation	Human distal femur	18.14 (1.7)
		Acoustic microscopy		17.5 (1.12)

significantly lower than that of the cortical bone with an approximate elastic modulus of 2.8 GPa.[103,104] Three- and four-point bending tests of individual trabeculae have been applied to investigate the fatigue properties of individual trabeculae from the human proximal tibia and reported that the fatigue strength of trabecular bone tissue is 100–140 MPa and that at these stress levels, the number of cycles to failure is approximately 100 000.[108]

The tissue mechanical properties of the trabecular bone have also been assessed using the nanoindentation technique, which can characterize the submicrostructural (1–5 μm resolution) mechanical properties (elastic modulus, hardness) of bone tissue. Atomic force microscopy or scanning electron microscopy techniques can be used to image the indentation and accurately estimate the indent area. This technique has been extensively applied to compare the nanomechanical properties of bone tissue.[109–112] The stiffness calculated has ranged from 7 to 25 GPa for cortical, trabecular, and interstitial tissue.[109,112–114] The variability between different studies arises as a result of differences in the method of material preparation and degree of moisture of the sample.[112,115,116] Furthermore, nanoindentation systems are particularly sensitive to changes in temperature, humidity, and environmental vibrations.

Acoustic microscopy (30–60 μm resolution) can also be used to evaluate the microstructural elastic properties of the trabecular bone. This method involves producing an acoustic wave in a tiny area just in the vicinity of the surface (near-field area) through different interaction mechanisms. The acoustic properties of materials can be determined at a high resolution from the acoustic wave detected. Turner *et al.*[116] used both nanoindentation and acoustic microscopy to compare the Young's moduli of trabecular and cortical bone tissues from a common human donor.[116] They reported that the Young's modulus of the cortical bone in the longitudinal direction was about 40% greater than ($p < 0.01$) the Young's modulus in the transverse direction. The Young's modulus of trabecular bone tissue was slightly higher than the transverse Young's modulus of cortical bone, but substantially lower than the longitudinal Young's modulus of cortical bone. These findings were consistent for both measurement methods and suggest that elasticity of trabecular tissue is within the range of that of cortical bone tissue.

2.210.5.3. Fracture Behavior

Bone is a composite material, and as a result, its fracture behavior is intricate. Physiological bone fractures occur under creep, fatigue, and impact loading conditions. The fracture and damage occurring in the bone can be segregated into macro-level cracks and diffuse microdamage, which occur in the bone during both normal and extreme loading conditions. Studies have investigated the route of propagation of major cracks,[117–119] and it has been shown that for the most part, fracture occurs at the interfaces between separate bone tissue lamellae.[120] It is believed that this interface provides a toughening mechanism for the bone tissue by absorbing energy and resisting the growth of macro-level cracks. This energy is dissipated elastically to deform the collagen–mineral matrix, to deflect cracks along lamellar interfaces, or by the formation of microcracks prior to catastrophic fracture. In particular, it has been demonstrated that, in the presence of a large propagating cracks, smaller microcracks nucleate, grow, and coalesce to absorb energy from larger cracks in the bone.[121] Other studies have shown that toughening occurs in the bone when microcracks are bridged by collagen fibrils that span the width of the crack, and that this acts to increase fracture resistance in bone tissue.[122–124] The fracture behavior of the bone is anisotropic, and crack growth occurs by brittle mechanisms in the longitudinal direction, becomes deflected in the tangential direction, and is toughened by microcracking in the radial direction.[120] This is due to the organization of the collagen fibril matrix which resists cracks that attempt to drive across the grain, (fiber direction) that is, those that are oriented parallel to the collagen fibril axis.[120]

One of the most important features of the bone is that it has the ability to tolerate microdamage without causing macroscopic failure. Microdamage accumulates in bone tissue from the cyclic loading situations created by everyday activities such as walking and running throughout our lifetime.[125,126] Microcrack accumulation impairs the mechanical properties of the bone by reducing its elastic modulus.[127] The ability of the bone to renew is believed to be vital to remove this microdamage and maintain strength (**Section 2.210.6.2**). The fracture toughness of the bone gives a measure of the ability of the material to resist crack growth. It has been shown that young bone is tough under impact loading, which is less mineralized,[19] but the fracture toughness of the bone deteriorates significantly with age.[128,129] At high strain rates, the postyield region, the capacity for energy absorption, and the microcracking damage reduce significantly.[130,131]

2.210.6. Bone as a Dynamic Adaptive Material

Bone is a particularly fascinating dynamic material that has the capacity to adapt its shape, mass, and microstructural architecture throughout life by means of the physiological processes of bone modeling and remodeling. Bone modeling involves growth and adaptation of bones to produce a mechanically functional architecture,[48] whereas bone remodeling is a process whereby bone is renewed continuously so that it continues to maintain strength throughout life. Both processes are facilitated by the coupled action of osteoclast and osteoblast cells. Bone is also able to renew itself following fracture through a process known as fracture healing, which is regulated by stem cells, cartilage cells, and bone cells. These adaptive processes are fundamental to the normal physiological function of the skeleton as they allow bones to survive and adapt under the variety of loading conditions experienced.

2.210.6.1. Bone Modeling

Modeling is a process that facilitates the growth and change in shape of bones and predominantly occurs during childhood and adolescence. Modeling is defined as the process by which bone resorption by osteoclasts and bone formation by osteoblasts occur simultaneously, but on different surfaces of the bone, to alter the overall bone shape or dimensions.[132] For example, the cells operate to increase the diameter of long bones and develop a marrow cavity when osteoclasts resorb

the endosteum, while osteoblasts form a new bone at the periosteum. This process results in an overall change in the bone morphology and is distinct from bone remodeling.[132] Modeling also occurs in the adult skeleton and serves to regulate overall changes in bone morphology in response to altered mechanical loading. During unloading, bone resorption is not followed by formation and during overloading, bone formation occurs in the absence of bone resorption. Both processes result in changes in both the microarchitecture and whole bone shape.[133]

2.210.6.2. Bone Remodeling

Remodeling is a coordinated physiological process, which is regulated by osteoclast cells that digest aged or damaged bone tissue and osteoblasts that reform new bone tissue in its place. In contrast to modeling, osteoclasts and osteoblasts operate concurrently on the same surfaces and are known collectively as basic multicellular units (BMUs). The action of these cells appears to be coupled, with osteoclasts traveling along trabecular surfaces or tunneling into cortical bone resorbing unwanted or damage bone tissue and osteoblasts subsequently filling in the resorption cavity with new tissue,[134] see **Figure 7**. The process initiates when bone-lining cells degrade unmineralized osteoid and increase expression of growth factors to recruit bone resorbing osteoclasts from the bone marrow that attach to bone surfaces and secrete acids and enzymes to digest bone matrix. Osteoclasts resorb at a longitudinal rate of 40 μm per day, and a typical resorption cavity depth is 40–60 μm.[135,136] At any one spot on the surface, the resorption lasts approximately 2 weeks and the entire resorptive sequence lasts for 40–50 days.[49] After resorption, the osteoclasts undergo apoptosis, and additional growth factors are released which recruit osteoblasts to form layers of osteoid and slowly refill the cavity.[137] In normal remodeling, there is a small bone mass loss (−1 μm) with age, as osteoblasts deposit less bone tissue than the osteoclasts have resorbed.[49] These cells also produce growth factors that inhibit further resorption by osteoclasts. During normal physiology, this continuous cellular activity is coordinated so that bone mass and strength are maintained to allow bones to bear normal physiological loading.

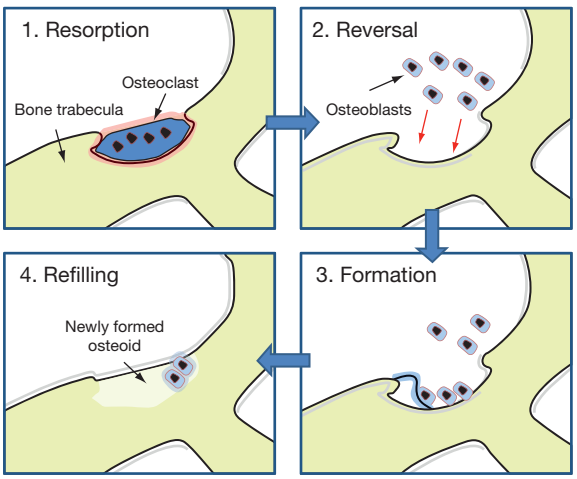

Figure 7 Schematic illustrating cellular activity during the bone remodeling process: (1 and 2) osteoclasts resorb damaged tissue and (3 and 4) osteoblasts refill the cavity with newly formed osteoid, which is subsequently mineralized.

2.210.6.3. Fracture Healing

Even though bone has the ability to repair and remodel itself continuously throughout life, certain traumatic injuries and various pathological diseases, such as osteoporosis, osteogenesis imperfecta, and Paget's disease, can impair these normal functions and lead to bone fractures (**Section 2.210.7**). Fracture healing is a physiological process by which bone fractures are repaired and occurs through the coordinated activity of osteoprogenitor, chondroblast, and osteoblast cells.[138] The process initiates when bleeding results in the formation of a hematoma and inflammatory cells are recruited to the fracture site. Next, cells within the bone and platelets within the hematoma produce cytokines that recruit fibroblasts and MSCs from the periosteum and marrow to the fracture site. These cells produce a granulation tissue, consisting of cells and blood vessels, at the site of fracture. Immune cells, known as macrophages, are also recruited to remove damaged tissues and other debris. The inflammatory period persists for 3–7 days and, after this initial period, the reparative phase begins whereby cells in the fracture site begin to differentiate into either osteoblasts or fibroblasts. Osteoblasts produce woven bone, which quickly forms a periosteal and marrow callus that fills the fracture gap, but has a low mechanical stiffness.[139] In sites of poor blood supply, fibroblasts within the granulation tissue differentiate to become chondrocytes and form hyaline cartilage.[139] The cartilage and woven bone together form the fracture callus. The callus has a larger cross-sectional area than the native fractured bone to compensate for the presence of fibrous tissue and woven bone, which reduce the callus stiffness. Over time, the woven bone is remodeled to become lamellar bone and the cartilage is replaced by means of endochondral ossification. The lamellar bone is vascularized by the invasion of vascular channels. This reparative phase lasts for approximately 1 month and produces new bone that has similar mechanical properties to that prior to fracture. However, the enlarged cross-sectional area at the site of the fracture callus has implications in the efficiency of movement. Therefore, the callus is continuously modeled and remodeled by osteoclasts and osteoblasts until the bone approaches its original geometry, strength, and stiffness. This remodeling process depends to a large extent on the mechanical forces applied to the bone. In some cases, for example, in excessively large fractures or during disease, fracture healing is not activated and as a result, bone fractures do not repair (nonunions).

2.210.6.4. Mechanosensation

It has long been established that the bone can adapt to its mechanical environment, and there is ample evidence of bone loss (atrophy) during disuse and bone formation (hypertrophy) during increased physical exercise.[140] The exact mechanical stimulus for such changes has been much debated, as has the mechanism by which the bone can detect and communicate the need for bone repair. It is most commonly

believed that bone adaptation in response to mechanical loading is regulated by mechanosensitive osteocyte cells that have the ability to direct osteoclasts and osteoblasts to alter bone mass and optimize strength.[55–57,141,142] It has been postulated that osteocytes are capable of sensing several stimuli; matrix strain, pericellular fluid flow, or physical damage.

In particular, it is believed that the bone adapts to changes in the matrix strain to optimize the bone mass and architecture so that the bone is sufficiently strong to bear the loads it experiences but has a minimal mass. Experimental evidence has demonstrated that, at low strains, net bone resorption occurs and that, at elevated strains, net bone formation occurs.[143] It has been shown that cells of the osteoblast lineage (osteoprogenitors, osteoblasts, osteocytes) are capable of transducing strain-based mechanical signals into biochemical stimuli.[141] Based on such experimental evidence, the theory of adaptive elasticity was proposed, which stated that the bone has the capacity to adapt its architecture to attain a remodeling equilibrium strain state.[144] When the loading conditions deviate from normal, the density and mechanical stiffness of the material or the geometry of the bone is adapted to return to the equilibrium strain state. This theory was capable of predicting net surface remodeling of the bone according to adaptive elasticity theory.[145] A number of strain-based mechanoregulation theories have been formulated upon the theory of adaptive elasticity to predict the adaptive behavior of the bone. These have been applied in computational simulations to successfully predict bone adaptation under various conditions.[146–151] This theory has also been used to test the hypothesis that the osteocyte network has a mechanosensory function and is capable of signaling bone cells to adapt trabecular architecture.[152,153]

Although osteocytes are regarded to be the primary mechanosensors in the bone, the precise mechanism by which they can sense mechanical strain is unknown. It has been hypothesized that deformation of the osteocyte lacuna, strain energy density in the bone tissue,[149,153] or strain-derived fluid flow in the osteocyte canalicular channels[154] might stimulate the cell membrane. Experiments have supported such theories by demonstrating that fluid flow[155–157] and matrix strain[158,159] activate an anabolic response by osteoblastic cells *in vitro*. Latest research found that osteocytes may sense matrix strain and fluid flow in bone canaliculi via integrin-based ($\alpha_v\beta_3$) focal attachments between their cell processes and the ECM.[30,160] Theoretical models have predicted that these attachments may participate in osteocyte mechanotransduction by amplifying fluid flow-induced and matrix stresses on osteocyte cell processes.[160] Another study identified cellular structures comprising microtubules known as primary cilia in bone tissue[161]; primary cilia are understood to act as fluid flow sensors in other tissues, in particular, the kidney.[162] Therefore, it has been proposed that primary cilia may facilitate bone cells to sense strain-derived fluid flow.[163,164] *In vitro* studies have supported this premise by identifying primary cilia on osteoblastic cell lines [MC3T3, MLYO4] in cell culture,[165,166] and one study has shown that these cilia play a role in production of proteins associated with osteogenic and bone resorptive responses under *in vitro* fluid flow.[165]

It is known that microdamage accumulates in the trabecular bone, from the cyclic loading situations created by everyday activities such as walking, running throughout our lifetime. *In vivo* microdamage has been identified in the bone by a number of researchers.[125,126] Microcrack accumulation impairs the mechanical properties of the bone by reducing its elastic modulus.[127] Therefore, it has been proposed that bone remodeling may be targeted to maintain bone strength by resorbing damaged bone and replacing it with new bone, thereby preventing accumulation of damage.[167–173] Experimental evidence has shown that resorption cavities occur preferentially in regions of microdamage,[167,174,175] which would suggest that resorption cavities might indeed be initiated in sites where microdamage is present. Studies observed that microcracks, resorption cavities, and osteon formation sites are located near the periosteal surface of the original cortex, but that there were no microcracks in new fibrolamellar bone at periosteal or endosteal surfaces.[176] In a later study, they observed that the average microcrack length is consistent between sites and across species, which supported the idea of a repair mechanism triggered beyond a critical crack length.[125]

Prendergast and Taylor[177] developed a damage-adaptive law for bone remodeling. They hypothesized that, even at remodeling equilibrium, there exists a homeostatic burden of microdamage in the form of microcracks within bone tissue. If the amount of damage changed from this equilibrium amount, then a stimulus for bone remodeling was generated. The repair rate for bone remodeling was determined from the homeostatic stress. Application of the theory was capable of giving physically reasonable predictions of the adaptive response of a bone diaphysis under a change in torsional load.

It has been proposed that physical damage acts as a stimulus to bone cells by rupturing cell processes and interrupting cell signaling,[167,174] by shearing osteocytes' cell processes,[178] or by causing apoptotic death of the osteocyte, which in turn signals for removal of the dead cell.[169,171–173,179]

It is likely that bone cells are responsive to both strain- and damage-based remodeling stimuli, in order to simultaneously maintain bone mass and prevent fracture. Recent models[171,179,180] have predicted that a regulatory system capable of responding to changes in *either* strain or microdamage, but which prioritizes removal of damaged bone, can successfully predict the bone remodeling process (resorption, reversal, refilling) at the cellular level. It was proposed that osteocyte processes can sense changes in strain and fluid flow, but when excessive microdamage occurs, this damage interferes with the signaling mechanism or causes osteocyte apoptosis so that a remodeling response occurs to remove the dead osteocytes.

2.210.7. Bone as a Material During Disease and Drug Treatment

The process of aging and various pathological diseases can impair the capacity of the bone to perform fundamental mechanical functions. The most prominent diseases affecting bone are osteoporosis, osteogenesis imperfecta, Paget's disease (osteitis deformans), osteomalacia, rickets (vitamin D deficiency), and cancer of the bone (osteosarcoma). Each of these conditions severely impairs the ability of the bone and leads to bone fractures, and often these fractures do not repair (nonunions) or cause immobility, severe pain, and deformity.

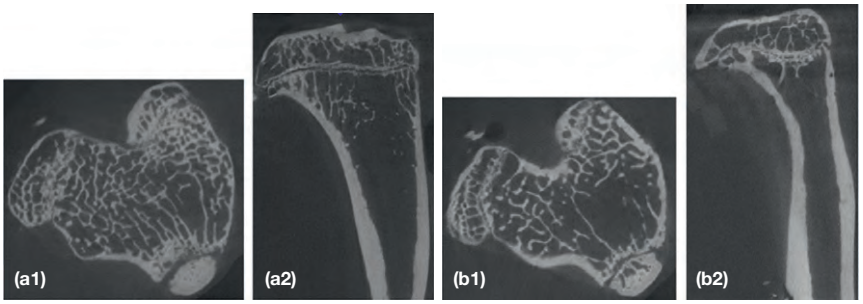

Figure 8 Micro-CT scanning image depicting the deterioration of bone microarchitecture during osteoporosis: (a1, a2) bone trabeculae are interconnected in normal bone tissue and (b1, b2) bone loss and microarchitectural deterioration (loss of connectivity, trabecular thinning) in osteoporotic bone.

2.210.7.1. Osteoporosis

Osteoporosis is a disease, which is most commonly manifested in postmenopausal women, that degrades bone mass and architecture. Physiologically, osteoporosis is manifested as an imbalance in bone cell activity during the remodeling process (Section 2.210.6.2) whereby excessive resorption occurs without adequate new bone formation. The basic bone units (trabeculae) become thin and eventually fracture and resorb altogether.[181] As a consequence, bone mass is reduced, the trabecular architecture is severely degraded (Figure 8), its mechanical strength is reduced, and bones become more susceptible to fracture. Fractures of the hip, wrist, or vertebra are most prevalent and lead to severe pain and spinal deformity.[182] Approximately 40% of women over 50 are at risk of developing the disease,[183] and the disease is the second most significant health threat to women, after breast cancer, with normal mortality rates increasing by 10–20% within a year of experiencing an osteoporotic fracture.[182,183]

2.210.7.1.1. Bone cell biology during osteoporosis

During menopause, the levels of circulating estrogen in the blood are deficient, and this deficiency is believed to play a role in the imbalance in the cellular activity during osteoporosis. Osteoclasts, osteoblasts, and osteocytes – all possess estrogen receptors (ERα, ERβ) that are activated to permit protein synthesis when they bind to estrogen.[184] The effect of estrogen deficiency on bone cell activity has been studied to identify pathways by which postmenopausal osteoporosis is manifested.

It has been found that osteoclastic activity is enhanced by estrogen deficiency, and that the reduced levels of circulating estrogen during osteoporosis are associated with increased rates of bone turnover and bone loss due. These changes occur as a result of an increase in the number and activity of osteoclasts.[185,186] The effect of estrogen deficiency on osteoclast behavior has been extensively characterized: (1) the activation frequency of BMUs and turnover rate is markedly increased,[187,188] (2) more osteoclasts are recruited,[186] (3) osteoclast apoptosis is inhibited,[63] and as a result, (4) the osteoclasts' resorption persists for a longer period, resulting in deeper resorption cavities and trabecular perforation.[189] The perforated trabeculae are removed by further remodeling, and this loss of bone mass, as is illustrated in Figure 8, increases the fragility of bones, resulting in a greater propensity for fracture.[90]

The effects of estrogen deficiency are not restricted to osteoclast activity as osteoblastogenesis also increases.[186,189] It has been suggested that estrogen allows the normal response of osteoblasts and osteocytes to loading.[190] As both cell types possess receptors for estrogen,[184] their function may be affected when estrogen production is deficient during postmenopausal osteoporosis. Previous findings regarding the effects of estrogen (E_2) on osteoblasts are inconsistent; E_2 enhances differentiation and mineralized bone nodule formation *in vitro*,[191] but alkaline phosphatase and osteocalcin expression are stimulated, inhibited, or unaffected.[192] Osteoblastic cells deprived of estrogen display deficient osteogenic responses to mechanical stimuli *in vitro*.[193,194] The osteoblasts may be no longer capable of completely refilling the resorbed space, resulting in irreversible bone loss. Estrogen deficiency induces osteocyte apoptosis,[195,196] which might result in hypermineralization of the surrounding tissue.[51,197,198] In addition, the organization of the osteocyte network is altered[199] and osteocyte density is reduced,[200] which may reduce the mechanoresponsiveness of the tissue.[201]

2.210.7.1.2. Mechanical behavior and structure during osteoporosis

The main concern with the disease of osteoporosis is that bone fractures occur unpredictably and with little force. For this reason, a number of studies have been carried out to characterize the biomechanical behavior of the bone during osteoporosis by assessing the structural degradation of the trabecular architecture and the mechanical consequences of bone loss.

At the onset of osteoporosis, an irreversible reduction in bone mass and volume occurs, leading to thinning and microfracture of trabecular struts and loss of trabecular connectivity.[181,202,203] Fractured trabeculae are eventually resorbed completely, resulting in an overall degradation in the trabecular network (see Figure 8(b)). Furthermore, the trabecular architecture of the osteoporotic bone is significantly more anisotropic than the normal bone, with fewer trabeculae transverse to the primary load axis.[204] Until recently, it was believed that bone loss occurred systemically, that is, bone resorption occurred throughout the trabecular architecture to the same extent, and that this loss was irreversible. However, recent studies have shown that, following an initial increase in bone loss and trabecular thinning in OVX rats, the few remaining trabeculae subsequently slowly increase in thickness.[205,206]

Assessment of the effects of osteoporosis on the mechanical behavior of the bone has been carried out previously using

whole bone testing of vertebrae and femora[207–211] or testing of volumes of cancellous bone[212–215] from rat and dog models. Using ovariectomy to induce osteoporosis in the rat, it has been found, for example, that the compressive strength of rat vertebral bodies and the bending strength of rat femora are significantly compared to the control bone.[208,210,211] In the human bone, it has been reported that the maximum modulus and ultimate stress is reduced in the femur following an osteoporotic fracture.[114,216] Such studies can explain the increase in fracture susceptibility at these sites. However, these observations were accompanied by significant decreases in trabecular bone volume and thus cannot discriminate whether changes were due only to the reduction in bone mass and loss of architecture, or whether a reduction in tissue strength also contributed.

It is essential to develop an understanding of the material behavior at the bone tissue level during osteoporosis to seek to fully address the issues of bone fracture during osteoporosis. It has been reported that trabecular bone tissue from osteoporotic patients had a lower apparent density, stiffness, and strength than age-matched patients with no evidence of disease.[217] In contrast, other studies have demonstrated that, while overall bone mass and bone mineral density are reduced, tissue (single trabeculae) stiffness and strength of ovariectomized rats are increased by 40–90%.[103,104] Despite the macrostructural and micromechanical changes in bone tissue during osteoporosis, to date no studies have confirmed that changes occur on the nanoscale.[218] In an ovine model of osteoporosis, the tissue modulus, as measured by nanoindentation, was significantly less than in the control bone.[219] While variations in experimental methods, animal model, or anatomical location might explain the discrepancies between previous studies, it is still unclear how bone mechanical properties are altered during osteoporosis. Such studies suggest that the primary constituents of bone tissue, namely, collagen, mineral, and NCPs, may be altered during osteoporosis.

A number of studies have been carried out that describe the effects of osteoporosis on the mineral content in the bone tissue with conflicting findings. Some studies report that the mineral content is unchanged or slightly lower in osteoporotic bone tissue,[217,220] and others reveal an increase in mineral content and a lack of collagen.[221–223] Variations in experimental methods, animal model, or anatomical location might explain this variability. The author undertook preliminary studies using a μCT system calibrated for bone mineral content assessment. Interestingly, a significant increase (11%) in mineral content of *remaining* tissue corroborated the unexpected changes in tissue properties.[103,104] Hence, these studies confirmed that, even though overall bone mass and strength are reduced during osteoporosis, the scarce tissue that remains is more mineralized, stiffer, and stronger.

Various changes in the compositional properties of the collagen have been reported at the onset of postmenopausal osteoporosis, in particular that changes in the amount of type I, VI, and III collagen occur.[224] The nature and quantity of the collagen cross-links that is altered,[225,226] in particular, the quantity of ketoimine, pyridinium,[227] aldimine,[224,228] and pyrrole cross-links, are decreased in osteoporotic bone.[229] Interestingly, these changes are more prevalent in the femoral neck, a site which is highly susceptible to fracture,[224] which indicates that such changes increase fracture susceptibility either by altering the strength of the collagen matrix or by secondary changes to the mineralization of this matrix.[224,230]

There is some evidence that the extent of microdamage is increased during estrogen deficiency,[231] which suggests that the tissue may be more brittle and less resistant to crack growth.[232–234] Alternatively, the remaining bone tissue may be more susceptible to damage following significant bone loss. Increased remodeling during osteoporosis has been proposed to be related to an accelerated removal of damaged tissue.[174]

2.210.7.1.3. Approaches for treatment of osteoporosis

The primary aim of drug treatments for osteoporosis is to reduce fracture incidence, and a variety of different treatments have been formulated which are based on the use of hormone replacement therapy, antiresorptive therapy, or anabolic agents. Hormone replacement therapy involves a pharmacological treatment with estrogen, which is often combined with progesterone, as a treatment for postmenopausal osteoporosis. This treatment has been shown to increase the bone mineral density of sufferers and thereby reduces the risk of hip and vertebral fractures in healthy postmenopausal women.[235] However, hormone therapy is no longer a popular choice of treatment, as it increases the risk of stroke, venous thromboembolism, coronary heart disease, and breast cancer. There is a wide range of antiresorptive therapies, such as bisphosphonates, selective tissue estrogenic activity regulators (STEARs), selective estrogen receptor modulators (SERMs), calcitonins, calcium, vitamin D, and metabolites and these represent a popular choice of treatment. While drugs of these types have different modes of operation, the common aim of antiresorptive drugs is to maintain bone mass and architecture by restoring the remodeling imbalance through inhibition of osteoclast activity and reducing bone resorption.[236] The efficacy of antiresorptive drug treatments has been assessed, and it has been found, for example, that treatment with tibolone[208,210,211] and other antiresorptive drugs such as risedronate,[213] etidronate,[209] alendronate,[212] pamidronate,[207] and incadronate[215] increases the structural or bulk trabecular bone strength[212,213,215] and the whole bone strength[207–211] compared to untreated osteoporotic bone by maintaining bone mass and trabecular architecture. PTH was shown to increase BMD and bone mineral content in ovariectomized monkeys.[237] PTH alone or in combination with antiresorptive medications reduces fracture risk of osteoporosis patients by increasing BMD.[238] While these drugs are capable of reducing the propensity to fracture by approximately 50%, even with continuous use of drug treatment fractures still arise.[239] It has been found that treatment with high doses of certain antiresorptive drugs is associated with an increase in the rate of spontaneous fractures of the thoracic spinous process, ribs, and pelvic fractures in animal models of osteoporosis.[209,240] A concern with some drugs for osteoporosis is that inhibiting the remodeling process prevents the necessary osteoclastic bone resorption, which serves as a repair mechanism to remove aged damaged bone tissue.[167,169,171–173,179] This may allow microdamage to accumulate in the bone tissue, so that, although bone mass and architecture are maintained, bone strength at the tissue level may be impaired.

2.210.8. Conclusion

Even with the vast amount of research, the complex biological and mechanical behavior of the bone is still intriguing, as the pathogenesis of bone disease is not fully understood and the occurrence of bone fractures remains a significant clinical issue. This fascinating material will continue to be studied until the normal physiological and mechanical function of the bone has been delineated and the pathogenesis of fracture is characterized.

Abbreviations

BC	Bacterial cellulose
CAD	Computer-assisted design
CATE	Computer-assisted tissue engineering
CHT	Chitosan
CO_2	Carbon dioxide
DA	Degree of acetylation
ECM	Extracellular matrix
FDM	Fused deposition modeling
FN	Fibronectin
GAG	Glycosaminoglycans
GlcNAc	*N*-acetyl-D-glucosamine
GP	Glycerophosphate
HA	Hyaluronic acid
HAp	Hydroxyapatite
HAp/CHT	Hydroxyapatite/chitosan
MMPs	Metalloproteinases
PAAm	Poly(*N*-isopropylacrylamide)
PCL	Polycaprolactone
PEG	Poly(ethylene glycol)
PEO	Poly(ethylene oxide)
PHA	Polyhydroxyalkanoates
PHB	Poly(hydroxybutyrate)
PHBV	Poly(hydroxybutyrate-*co*-valerate)
PPO	Poly(phenylene oxide)
RGD	Arginine–glycine–aspartic acid

SFF	Solid free form
SLS	Selective laser sintering
SPCL	Starch and polycaprolactone
SPLA	Starch and poly(L-lactic acid)
TE	Tissue engineering

2.211.1. Introduction

In the new paradigms of regenerative medicine, the use of biomaterials in contact with biological material (e.g., cells, tissues/organs, physiological fluids, biomolecules) is a current illustration of the need of interdisciplinary scientific approaches that combine the most recent advances in materials science and technology, basic sciences, and life sciences. In tissue engineering (TE), matrices are developed to support cells, promoting their differentiation and proliferation toward the formation of new tissue. Such strategies allow the fabrication of hybrid constructs that can be implantable in patients to induce the regeneration of tissues or replace failing or malfunctioning organs. Different materials have been proposed to be used in the processing of scaffolds, namely biodegradable polymers. Natural-based polymers offer the advantage of being similar to biological macromolecules, which the biological environment is prepared to recognize and to deal with metabolically. Due to their similarity with the extracellular matrix (ECM), natural polymers may also avoid the stimulation of chronic inflammation or immunological reactions and toxicity, often detected with synthetic polymers. In this chapter, the different natural-based materials that have been proposed to be used in TE strategies will be overviewed. An important aspect, also addressed, is the processing of such kind of materials into porous matrices, a task that usually needs other technologies than those usually employed in the processing of conventional synthetic polymers. There is also a clinical need for processing biomaterials into other shapes, including nano-/microparticles (for control release application). Materials containing cells and bioactive agents that can be implanted in a noninvasive way are very attractive approaches in TE and regeneration contexts, which will be also discussed.

2.211.2. Natural-Based Polymeric Systems

The development of successful strategies for the design of biodegradable macromolecular systems for TE applications is directly related with the physicochemical and biological properties of the biomaterials. Thus, the creation and selection/modification of a certain biomaterial is a critical step in the fabrication of scaffolds for TE. Generally, the ideal biomaterial should be nontoxic and biocompatible and should promote favorable cellular interactions and tissue development, while possessing adequate mechanical and physical properties. In addition, it should be biodegradable and bioresorbable to support the reconstruction of a new tissue without inflammation.[1] On the other hand, novel concepts of TE are imposing new and more specific requirements on macromolecular components. Living organisms are able to synthesize a vast variety of polymers, which can be divided into major classes according to their chemical structure: (i) polysaccharides, (ii) proteins, and (iii) polyesters. Nowadays, with the advances in biotechnology, natural polymers can be obtained by fermentation of microorganisms[2] or produced *in vitro* by enzymatic processes.[3] However, the largest amount is still extracted from plants[4–6] and animal[7] sources or from algae.[8]

2.211.2.1. Materials Inspired from the ECM

ECM is the optimized milieu that Nature has been developing to maintain homeostasis and to direct tissue development. Therefore, a great effort has been spent in mimicking the ECM to guide morphogenesis in tissue repair and TE.[9,10] One strategy has been to isolate the main constituents of the ECM and directly use them after purification, with or without further modifications. As ECM plays an instructive role for cell activities, the hypothesis here is that such biomolecules would maintain the biological information and other physicochemical features that would preserve a potential space for new tissue development after cell seeding. This would overcome one of the main drawbacks in the use of synthetic materials, which lack cell-recognition signals. A description of some protein-based biomaterials isolated from ECM follows. These materials are typically extracted from blood plasma and from the skeleton. Other functional proteins, including growth factors, enzymes, and interleukins, used essentially as ingredients to be incorporated in biomaterials, will not be discussed here.

2.211.2.1.1. Collagen

Collagen is the most abundant protein present in mammalian tissues (cornea, blood vessels, skin, cartilage, bone, tendon, and ligament) and is also the main component of the ECM (see **Chapter 2.215, Collagen: Materials Analysis and Implant Uses**). More than 20 distinct forms have been identified, type I being the most abundant and most investigated for biomedical applications.[11] Properties such as high mechanical strength, good biocompatibility, low antigenicity, biodegradability, and the ability of cross-linking emphasize its value as a biomaterial, being currently used in a great number of TE applications.[12] Depending on the purpose, improvement of the physical, chemical, and biological properties of collagen-based materials can be necessary to address some of its drawbacks, for example, its high degradation rate, which leads rapidly to loss of mechanical properties. For example, matrices with adequate mechanical properties have been proposed after chemical glycation procedures or heat treatments.[9] Also, combinations of collagen with other materials have also been prepared. As an example, collagen microsponges may be easily impregnated into previously prepared synthetic polymeric scaffolds that will increase their mechanical performance.[13] On the other hand, growth factors and other active agents can be combined with collagen-based systems, including scaffolds and gels to prolong their release rate and increase their therapeutical effect in TE approaches.[14,15]

2.211.2.1.2. Fibronectin

Fibronectin (FN) is a multifunctional component of the ECM, known to induce cell attachment and spreading through its cell binding site and related synergy sites. It is also a paradigm adhesive protein, nonreactive with adhesion receptor in its soluble state but highly adhesive when insoluble.[16] Nevertheless, the ability of such glycoprotein (a disulfide-bonded dimmer of 220- to 250-kDa subunits) to serve as a substrate for cell adhesion is based on the biological activity of several modules: the arginine–glycine–aspartic acid (RGD) tripeptide in the tenth Fn3 module plays an important role here[17] and has been incorporated onto the surface of numerous biomaterials; several strategies have been summarized by Hubbell.[9] One of

the suggested strategies was to deposit layers of oriented FN in order to enhance the availability of its cell-binding site.[18] On an oriented FN layer, compared with an isotropic layer, human umbilical vein endothelial cells spread significantly faster and in a more spherical way.

2.211.2.1.3. Glycosaminoglycans

Glycosaminoglycans (GAGs) consist of linear chains of the repeating unit of a disaccharide, generically a hexosamine (glucosamine or galactosamine) and a uronic acid component.[19] The extracellular spaces, in particular those of connective tissues such as cartilage, tendon, skin, and blood vessel walls, contain collagen and other proteins embedded in a gel-like matrix that is composed largely of GAGs. Because of their ionic character, GAGs are able to absorb large quantities of water, and this osmotic swelling provides compressive strength.[9]

2.211.2.1.4. Fibrin

Fibrin plays an important role in hemostasis and spontaneous tissue repair (it naturally forms during blood coagulation). Fibrin is a complex network formed by polymerization of fibrinogen in the presence of the enzyme thrombin. Fibrinogen can be isolated from the blood plasma of the patient, limiting the potential for disease transmission and immunogenic reactions. Fibrin is not a regular component of the ECM, but is found as a temporary matrix that will be further replaced by the ECM, and is currently used as fibrin glue in clinical applications. It has excellent biocompatibility, biodegradability, and injectability.[20] Fibrin has been a useful cell delivery matrix for cartilage TE, especially in combination with other biodegradable substances, such as alginate,[21] or hyaluronic acid (HA).[22] It has been also utilized in the regeneration of skin, with considerable success, and even in the loading and posterior release of growth factors.[9]

2.211.2.2. Other Peptide-Based Systems

2.211.2.2.1. Hydrogels enabling enzymatically mediated cell migration

These systems are part of an interesting strategy to mimic the ECM, whose aim is to develop matrices that could promote cell-ingrowth through proteolytic degradation of the matrix, usually requiring the action of metalloproteinases (MMPs) which are secreted by cells. Very elegant works have reported the use of conjugates of poly(ethylene glycol) (PEG) and specific peptides that can be hydrolyzed in the presence of enzymes involved in cell migration.[23,24] Growth factors can be entrapped that can also promote mesenchymal stem cell infiltration and corresponding differentiation.[23,25] Instead of peptide segments, denaturated fibrinogen segments were combined with PEG to form biosynthetic hybrid hydrogels.[26]

2.211.2.2.2. Self-assembling materials

Inspired by Nature, self-assembling molecules have been used as building blocks for the construction of nano- and microscale structures or complex systems.[27] Molecular self-assembly is a process by which noncovalent, weak interactions formed between molecules drive their assembly and organization affording supramolecular structures that define the material.[27,28] Self-assembling materials also aimed at mimicking the ECM have been proposed as hydrogels for TE applications. Peptide amphiphilic-based nanostructured fibrous scaffolds were produced by pH-induced self-assembly that could also induce biomineralization.[29] Three-dimensional (3D) network based on nanofibers formed by self-assembly of peptide–amphiphilic molecules were also used to encapsulate neural progenitor cells, showing the ability to induce very rapid differentiation into neurons, while discouraging the development of astrocytes.[30] In fact, the self-assembling peptide nanofiber scaffolds have been shown a wide spectrum of uses with high potential for regenerative medicine and TE.[31]

2.211.2.2.3. Other protein-derived biomaterials

Animal- or vegetal-derived proteins have shown to have potential to be used as scaffolds for TE applications. Silk proteins, for example, contain a highly repetitive primary sequence that leads to a high content of β-sheets, responsible for the good mechanical properties of silk fibers (see **Chapter 2.212, Silk Biomaterials**). Moreover, silk fibroin can be processed in aqueous solutions into gels, sponges, and membranes, and easily modified due to the presence of amine and acid side chains[32,33] or by conjugation with polysaccharides.[34,35] It has been reported that silk fibroin may have the potential to be used in TE applications, where mechanically robust, long-term degradable materials are needed.[36] For example, porous silk scaffolds were combined with human articular chondrocytes for *in vitro* cartilage TE.[37] Additionally, casein and soybean protein-based materials were found to be promising materials to be used in different biomedical applications, including the production of composites for TE.[38] The major drawback of such materials is the possibility of eliciting some level of foreign body response following implantation *in vivo* that can be minimized, for instance, by purification.

2.211.2.3. Polysaccharides

Polysaccharides consist of monosaccharides linked together by O-glycosidic linkages. Differences in the monosaccharide composition, linkage types and patterns, chain shapes, and molecular weight, dictate their physical properties including solubility, flow behavior, gelling potential, and/or surface and interfacial properties. Polysaccharides are derived from renewable resources, namely from plants, animals, and microorganisms, and are therefore, widely distributed in nature. They perform different physiological functions and may offer a variety of potential applications in the fields of TE and regenerative medicine.

2.211.2.3.1. Plant polysaccharides

Starch is a mixture of glycans that plants synthesize as their principal food reserve. It is deposited in the chloroplasts of plant cells as insoluble granules composed of α-amylose (normally 20–30%) and amylopectin (normally 70–80%).[5] α-Amylose is a linear polymer of several thousands of glucose residues linked by $\alpha(1\rightarrow4)$ bonds. Amylopectin consists mainly of $\alpha(1\rightarrow4)$-linked glucose residues but it is a branched molecule with $\alpha(1\rightarrow6)$ branch points every 24–30 glucose residues in average (**Table 1**). Amylose forms a colloidal dispersion in hot water whereas amylopectin is completely insoluble. Starch has been converted into a thermoplastic[81] or blended with synthetic polymers[39] to enhance the strength of

Table 1 Examples of some polysaccharides available in nature, their relevant properties and examples of their applications in the fields of tissue engineering and regenerative medicine

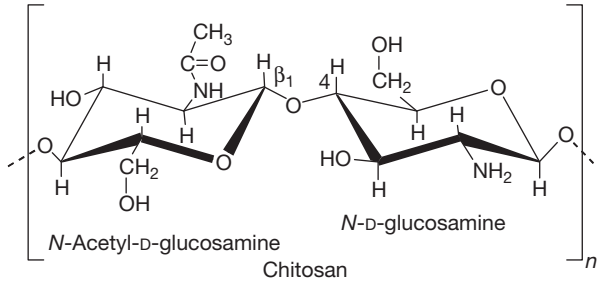
Polysaccharide	*Source*	*Repeating unit*	*Relevant properties*	*Examples of proposed applications*
Starch	Plant (e.g., corn, rice, potato, wheat, tapioca, etc.)[5]		Inexpensive material Easily modified (cross-linked, oxidized, acetylated) Good processability into diverse shaped items (microspheres, 3D porous scaffolds, hydrogels)	3D scaffolds for bone TE[39–42] Microspheres as drug-delivery carriers, TE[43] Fiber mesh scaffolds for cartilage TE[44]
Cellulose	Plant (cotton, wood, straw, etc.)[4] Microbial (bacterial cellulose, *ex. Acetobacter xylinum*)[45]		Resource available worldwide Insolubility in water Easily molded or drawn into fibers	Scaffolds for cardiac TE[46]; cartilage TE[45,47]; bone regeneration[48]

Arabinogalactan (larch gum)	Plant (extracted from the heartwood of the western larch *Larix occidentalis*)[49]		High water solubility (70% in water) Easy conjugation in aqueous medium	Sponges for TE[50]
Alginic acid	Brown algae (*Phaeophyceae*, mainly *Laminaria*) Microbial (bacteria *Pseudomonas mendocina*, *Azetobacter vinelandii*)[8]		Simple gelation with divalent cations (e.g., Ca^{2+}, Mg^{2+}, Ba^{2+}, Sr^{2+})	Cell encapsulation matrix[51]; scaffolds for cancer gene therapy[52]; bone TE[53]; hepatic TE[54]; hydrogels for cartilage TE[55]
Agar	Red algae – *Rhodophycae* (*Gelidium and Gracilaria species*)[8]		Formation of thermal reversible gels (cold setting gels at ~38 °C)	Gels/sponges for cartilage,[55,56] bone regeneration,[57] disk TE,[58] nerve regeneration[59]

(*Continued*)

Table 1 (Continued)

Polysaccharide	*Source*	*Repeating unit*	*Relevant properties*	*Examples of proposed applications*
Carrageenan	Red algae – *Rhodophycae* (*Chondrus crispus*, *Euchema cottonii*, *Euchema spinosum*)[8]		Thixotropic behavior Gel-forming ability	Nanoparticles for drug delivery[60]; polyelectrolyte for cell encapsulation[61]; hydrogels for bone TE[62]; injectable gel system for cartilage TE[63]
Chitin/chitosan	Animal (crustaceans shells, exoskeletons of insects, and other arthropods) Microbial (fungal cell walls)[64]		Enzymatic degradation by lysozyme Susceptibility to chemical modification Film-forming ability Hemostatic, bacteriostatic, and fungistatic activity Wound healing properties	Fiber mesh scaffolds for bone TE[65]; sponges (bone formation); tubes for nerve regeneration[66]; scaffolds for cartilage and osteochondral TE[67,68]



Chitosan

Hyaluronic acid	Animal (synovial fluid, vitreous humor of the eye, umbilical tissue)[69] Microbial (fermentation *Bacillus subtilis*[2,70])		Solubility in water Viscoelasticity Hydrogel ability by covalent and photo-cross-linking Enzymatic degradation by hyaluronidase	Scaffolds for ligament TE[71]; sponges for the treatment of osteochondral defects[72]; photo-cross-linked hyaluronic acid hydrogels as TE scaffolds[70]
Dextran	Microbial (bacterium *Leuconostoc mesenteroides*[73])		Solubility in both water and organic solvents (e.g., dimethyl sulfoxide) Stability under mild acidic and basic conditions Contains large number of hydroxyl groups available for modification/ conjugation with other molecules	Porous hydrogels as scaffolds for TE applications[74]; hydrogels for cartilage TE[75]

D-Glucuronic acid

N-Acetyl-D-glucosamine

(*Continued*)

Table 1 (Continued)

Polysaccharide	*Source*	*Repeating unit*	*Relevant properties*	*Examples of proposed applications*
Gellan gum	Microbial (bacterium *Sphingomonas elodea*[76])	 Native or high acyl gellan gum  Low acyl gellan gum	High acyl gels set and melt at ~70–80 °C with no thermal hysteresis Low acyl gellan gum can form hard, nonelastic and brittle gels in the presence of cations, including Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, and H^{+}	Microparticles for nasal delivery system[77]; hydrogels for cartilage TE[78,79]
Pullulan	Microbial (fungus *Aureobasidium pullulans*[7])		Dissolubility in water Ability to form a stable, viscous solution that does not gel Adhesive properties Easily derivatization	Carboxylated pullulan derivatives as extracellular matrix for TE applications (e.g., endothelial cells)[80]

starch and thus obtain better mechanical properties.[76] Starch-based materials are highly thermosensitive materials which easily degrade at high shear rates and with long residence times during processing. They can be processed by diverse techniques into different shaped items such as 3D porous scaffolds, microparticles, and hydrogels.[39,43,82]

Cellulose, the primary structural component of plant cell walls, is a linear polysaccharide of D-glucose units linked by β(1 → 4) glycosidic bonds (Table 1). The fully equatorial conformation of β-linked glucose residues stabilizes the chair structure, minimizing its flexibility. This highly cohesive, hydrogen-bonded structure gives cellulose fibers exceptional strength and makes them water insoluble despite their hydrophilicity. Cellulosic materials exhibit, however, poor degradation *in vivo*.[46] Moreover, cellulose can be converted into different derivatives (carboxymethylcellulose, cellulose nitrate, cellulose acetate, cellulose xanthate)[4] that can be easily molded or drawn into fibers.[46]

2.211.2.3.2. Exudate gums

Exudate gum polysaccharides are produced at the surface of a plant, usually as a result of trauma or stress (physical injury and/or fungal attack). These exudates are complex, uronic acid-containing polysaccharides, some even associated with proteins.[6] Most gums are soluble in water and have high viscosity. Major uses of gums are in the food and pharmaceutical industries, where their emulsifying, stabilizing, thickening, and gel-forming properties are the main physical requirements.[6]

Arabinogalactan is a major D-galactan obtained from soft woods such as larch (larch gum). It is composed of β(1 → 3)-linked D-galactose units, each containing a side chain at position C6. It is extracted from the *Larix* tree and it is available in 99.9% pure form with reproducible molecular weight and physicochemical properties. The high solubility in water, biocompatibility, biodegradability, and the ease of chemical modification in aqueous media makes it an attractive polymer for the production of scaffolds with application in TE.[50]

Gum arabic is an exudate gum obtained from *Acacia* trees and consists of a variable mixture of arabinogalactan oligosaccharides, polysaccharides, and glycoproteins. It is an acidic arabinogalactan with a complex structure. The main chain of this polysaccharide consists of β(1 → 3) and β(1 → 6)-linked D-galactose units along with β(1 → 6)-linked D-glucopyranosyl uronic acid units. Gum arabic has a high water solubility (up to 50% w/v) and relatively low viscosity[7] but it exhibits emulsification, encapsulation, and film-forming abilities.

2.211.2.3.3. Algal polysaccharides

Alginate, the monovalent form of alginic acid, is a linear polymer of β(1 → 4)-linked D-mannuronic acid and α(1 → 4)-linked L-guluronic acid, which occurs combined with calcium and other bases in the cell walls and intracellular matrix of brown seaweeds, constituting the main structural component.[8] The residues are present in blocks of each monomer, separated by regions in which they are randomly arranged or alternating. The proportions of mannuronic (M) and guluronic (G) residues (Table 1), and the lengths of the blocks, can vary considerably, depending on the source of the alginate. Furthermore, the properties of alginate depend on molecular weight, composition, and extent of the sequences. The polymer undergoes ionotrophic gelation in the presence of divalent cations and gelling depends on the ion binding ($Mg^{2+} << Ca^{2+} < Sr^{2+} < Ba^{2+}$).[7] One of the drawbacks of alginate hydrogels is that the degradation occurs via a slow and unpredictable dissolution process *in vivo*.[83,84]

Galactans, the major polysaccharides of the red algae *Rhodophyceae*, comprise agars, carrageenans, and related hybrid polysaccharides. *Agar* is made of two components, agarose – a nonsulphated fraction, and agaropectin – a mixture of various sulphated molecules. The separation of agarose from the polysaccharide mixture is based on the differences in solubility and chemical reactivity, which is associated with the anionic character of agaropectins.[8] *Agarose* is a linear polysaccharide based on the (1 → 3)-β-D-galactopyranose-(1 → 4)-3,6-anhydro-α-L-galactopyranose unit (Table 1). This arrangement allows the chains to join together and adopt a double helix. The two chains are wrapped together so tightly that any gaps are closed, trapping any water inside the helix.

Carrageenan polysaccharides are linear polymers consisting of chains of (1 → 3)-linked β-D-galactose and (1 → 4)-linked α-D-galactose units, which are variously substituted and modified to the 3,6-anhydro derivative, depending on the source and extraction conditions (Table 1).[85] Three major types of carrageenan are recognized on the basis of their patterns of sulphate esterification: κ (kappa), ι (iota), and λ (lambda). All carrageenans are highly flexible molecules, which, at higher concentrations, wind around each other to form double-helical structures. This gives them the ability to form a variety of different gels at room temperature. In fact, κ- and ι-carrageenans form thermoreversible gels on cooling in the presence of appropriate counterions. A particular advantage is that they are thixotropic,[61] that is, they thin under shear stress and recover their viscosity once the stress is removed.

2.211.2.3.4. Animal polysaccharides

Chitin is the principal structural component of the exoskeletons of invertebrates such as crustaceans, insects and is also present in the cell walls of most fungi and many algae. Basically, the chitin isolation from those sources consists of three important steps: demineralization (acid removal of calcium carbonate), deproteinization (removal of proteins), and depigmentation (removal of pigments), which involve the use of hydrochloric acid baths, alkaline treatment, and a mild oxidizing treatment, respectively.[64,86] Structurally, it is a homopolymer of β(1 → 4)-linked *N*-acetyl-D-glucosamine (GlcNAc) residues.[64] Chitin can be converted into soluble derivatives like chitosan (CHT), carboxymethylchitin, glycochitin, among others.[87] Chitin derivatives possess many unique properties such as biocompatibility, biodegradability, hydrophilicity, adsorption capability, and high reactivity. Moreover, chitin-based polymers are materials with great versatility to be processed in different forms (fibers, sponges, membranes, beads, hydrogels).[87–89] Water-soluble derivatives (e.g., carboxymethylchitin) can also be obtained, extending the domain of applications of chitin, especially in the biomedical field.

CHT is the *N*-deacetylation derivative of chitin; however, this *N*-deacetylation is almost never complete. The number fraction (%) of GlcNAc residues in the polymer chain is designated by degree of acetylation (DA) and influences the CHT physicochemical properties such as solubility, reactivity, biodegradability, and cell response.[64,88,90] This polymer has many

properties such as its polyelectrolyte and cationic nature, mucoadhesion, hemostatic action, film-forming ability, biodegradability, bacteriostatic and fungistatic activity, and the presence of reactive functional groups.[64,86,91] Because of the stable crystalline structure, CHT is normally insoluble in water, but soluble in dilute aqueous acidic solutions. Their solutions have been used in the production of gels, membranes, microparticles, fibers, porous structures, and tubes,[92,93] which combined with its pH sensitivity and high charge density (positive electrical charge) allows the development of drug-delivery devices, composites, and implants for TE.[94] On the other hand, the presence of functional groups (hydroxyl, amine) has been beneficial for chemical modifications to construct a wide range of useful derivatives with satisfactory mechanical, solubility, photoluminescent characteristics, and biological properties for specific use in diversified fields.[94–97]

HA, also known as hyaluronan or hyaluronate, is an important GAG component of connective tissue, synovial fluid, and the vitreous humor of the eye.[69] (see **Chapter 2.214, Hyaluronic Acid**) HA is a linear polysaccharide composed of 250–25 000 $\beta(1\rightarrow4)$-linked disaccharide units that consists of D-glucoronic acid and GlcNAc linked by $\beta(1\rightarrow3)$ bond (**Table 1**). The disaccharide units of HA are extended, forming a rigid molecule whose numerous repelling anionic groups bind cations and water molecules. In solution, hyaluronate occupies a volume ~1000 times that in its dry state. Hyaluronate solutions exhibit clear viscoelastic properties that make them excellent biological absorbers and lubrificants.[98] In addition, HA can be easily and controllably produced in large scales through microbial fermentation, enabling the scale-up of derived products and avoiding the risk of animal-derived pathogens. Owing to its good biocompatibility, widespread availability, and nonimmunogenic and viscoelasticity properties, hyaluronan has been extensively studied and employed as a delivery system, and for cell encapsulation.[98,99,100]

2.211.2.3.5. Microbial polysaccharides

Dextran is a branched bacterial polysaccharide, produced from sucrose via the action of dextransucrase enzyme,[73] consisting of $\alpha(1\rightarrow6)$-linked D-glucose residues with some degree of branching via $\alpha(1\rightarrow3)$ linkages (**Table 1**). The molecular weight and degree of branching is dependent on the source of dextrans and may vary from 0.5% to 60%. Both the degree of branching and molecular weight distribution affect its physicochemical properties. Characteristics as relatively low cost, availability, and hydroxyl functionality for chemical modification have increased the utilization of dextran for TE applications.[75,101,102]

Gellan gum is a high-molecular-weight bacterial exopolysaccharide. It is a linear anionic heteropolysaccharide composed of the tetrasaccharide $(1\rightarrow4)$-L-rhamnose-$\alpha(1\rightarrow3)$-D-glucose-$\beta(1\rightarrow4)$-D-glucuronic acid-$\beta(1\rightarrow4)$-D-glucose as repeating unit (**Table 1**). In its native or high acyl form, two acyl substituents D-acetate and D-glycerate are present. Both substituents are located in the same glucose residue. The high acyl form produces transparent, soft, elastic, and flexible gels which are resistant to heat and acid, whereas the low acyl form produces firm, nonelastic brittle gels. Gel formation is due to a conformational heat-reversible transition from a state of single random macromolecules to a more ordered state where macromolecules pair with each other to form double helixes.[103] In the context of biomedical applications, gellan gum has many advantages such as its lack of toxicity, processing under mild conditions, the ability to use it as an injectable system in a minimally invasive manner, and also the structural similarity it presents with native cartilage GAGs by the presence of glucuronic acid residues in their repeating unit.[78]

Pullulan is an extracellular microbial homopolysaccharide of glucose, produced from starch by fermentation, and consists of repeating units of maltotriose ($\alpha(1\rightarrow4)$-linked) joined by $\alpha(1\rightarrow6)$ linkages (**Table 1**). Some advantages of pullulan are its nontoxicity and lack of immunogenecity.[104]

Xanthan gum is an anionic polysaccharide produced from glucose via fermentation by the bacterium *Xanthomonas campestris*.[105] The structure of xanthan is based on a cellulosic backbone of $\beta(1\rightarrow4)$-linked glucose units which have a trisaccharide side chains of D-mannose-$\beta(1\rightarrow4)$-D-glucuronic acid-$\beta(1\rightarrow2)$-D-mannose linked to C3 every second glucose unit in the main chain. Some terminal mannose units can contain a pyruvate group and mannose residues attached to backbone units are variably acetylated. It has unique rheological properties (high viscosity even at low concentrations) and forms hydrogels by annealing the solution in sol state and subsequent cooling.[106]

Cellulose can be produced by the bacterium *Gluconacetobacter xylinus* (**Table 1**). Bacterial cellulose (BC) has unique properties, including biocompatibility, high water-holding capacity, high crystallinity, a fine fiber network, and high tensile strength in the wet state. In addition to its cost-efficient and relatively simple production, it has the advantage of *in situ* moldability.[45]

Table 1 summarizes the polysaccharides currently used in the field of TE and regenerative medicine. However, there is a wide variety of other potentially useful polysaccharides exhibiting diversity of structures and functions (e.g., pseudoplastic behavior, gelation, water binding, etc.), such as laminarin, gluco and galactomannans, exudate and mucilage gums, levan, curdlan, among others, which remain unexploited within the biomedical field. This situation may be associated with their current availability, difficulty on their isolation/purification and processing, and/or lack of information related with their biocompatibility and toxicity.

An important aspect to consider when using natural materials is that they can induce an undesirable immune response due to the presence of impurities and endotoxins, depending on the source of the material. Additionally, their properties may differ from batch to batch during large-scale isolation procedures due to inability to control the processing techniques. Nevertheless, as knowledge about these natural materials is being built, new approaches, including methods for production, purification, control of material properties (mechanical, degradation rate), and for enhancing material biocompatibility, are being developed for designing better scaffolding materials to support the development of more natural and functional tissues.

2.211.2.4. Natural-Derived Polyesters

Polyhydroxyalkanoates (PHAs) are degradable, biocompatible, thermoplastic polyesters derived from microorganisms, used

as a reserve of carbon and energy. A great variety of materials of this family can be produced, but the use of PHAs in TE has been mainly restricted to two polymers, namely poly(hydroxybutyrate) (PHB) and poly(hydroxybutyrate-*co*-valerate) (PHBV)[107,108]; the copolymerization produces less crystalline, more flexible, and more readily processable materials than pure PHB. Previous works have shown that such materials can be used as cell support for TE applications.[109–111]

2.211.3. Processing of TE Scaffolds

The several requirements that directly dictate the success of TE strategies are well reviewed in the literature. In all, the authors seem to agree that the selection of the appropriate biomaterial and the development of adequate scaffold architectures[112,113] play an important role in supporting the cells adhesion and tissue/organ repair/regeneration. As aforementioned, the scaffold is aimed at providing a temporary 3D structure and template upon which the tissue-specific cells can attach, proliferate, and produce ECM. In addition, the necessary diffusion of nutrients and metabolic wastes in a 3D environment demands highly porous scaffolds.[114] Consequently, we must choose a processing technique that allows for the preparation of scaffolds with controlled porosity, pore size, and interconnectivity, as well as tissue-matching mechanical properties. Of great importance as well, is the need to choose a biomaterial that degrades at a rate that matches with the deposition of ECM. Thus, the criteria for the selection of the best biomaterials and processing methods are of major importance. In this section, our attention is focused on the processing techniques available for the development of natural-origin scaffolds as the types of biomaterials have been reviewed in the previous sections.

Among the myriad processing methodologies, a wide range has been exploited by our group. *Conventional melt-based processing routes*, such as extrusion using blowing agents (which are responsible for inducing porosity), and other based on multistep processes such as compression molding followed by particulate leaching have attracted our research interest.[115,116] The nonthermoplastic behavior of natural polymers has limited their application, especially on the use of melt-based processing methods for the fabrication of TE scaffolds to these materials. For example, starch is a renewable and inherently biodegradable polymer[117] which has been successfully incorporated in many polymeric systems to develop partially or totally biodegradable plastics.[118] Thus, the use of starch materials has attracted great attention in TE applications, as it can allow the designing of scaffolds with an adequate degradation rate, that is, the degradation of the scaffold matching new tissue formation. Our group has been proposing the use of starch-based materials obtained from a blend of starch and polycaprolactone (SPCL) for bone TE applications. The advantages of starch-based materials are that they are biodegradable, present good mechanical properties, and can be processed by different methodologies.[119–123] TE scaffolds based on thermoplastic blends of starch with ethylene vinyl alcohol copolymer and cellulose acetate have also been produced by melt extrusion employing endothermic chemical blowing agents, based on mixtures of citric acid and sodium bicarbonate. Salgado *et al.*[124,125] demonstrated that these scaffolds are noncytotoxic, and exhibited adequate architecture for supporting *de novo* bone formation, *in vivo*. In other works,[39,126] the same approach was carried out to fabricate TE scaffolds based on injection molding. This technique differs from extrusion since it combines heat and shear effects to plasticize thermoplastic formulations. It is also worth to highlight that more recently, physical blowing agents such as supercritical CO_2 and water have been shown to be effective to injection mold polyether–urethane scaffolds[127,128] for TE applications.

Freeze-drying technique has also been widely used for the production of porous structures with different densities, shapes, porosities, and pore size distributions. By simply varying parameters such as polymer concentration,[129–132] type of solvent,[133] freezing temperature,[113,133–137] type of molds,[138,139] and incorporating porogens,[130,132,134,137] we may produce a wide variety of scaffolds. For example, Oliveira *et al.*[68] developed an innovative technique for obtaining bilayered structures with improved architecture, stability, and biological properties for osteochondral TE applications. Hydroxyapatite/chitosan (HAp/CHT) bilayered scaffolds were produced by adopting a two-step procedure. Firstly, HAp porous layer (bone-like layer) was obtained by the sponge burn-out method. Secondly, a 3 wt% CHT solution was prepared by dissolving CHT in 0.2 M acetic acid solution. The bilayered HAp/CHT scaffolds were fabricated by placing the HAp scaffolds into cylindrical silicon molds and transferring the 3 wt% CHT solution. Molds were frozen at $-80\,^{\circ}C$ and lyophilized to completely remove the frozen solvent, and allowed to obtain the 'cartilage-like layer' on the top of the 'bone-like layer.' This work illustrates that polymer solutions should be previously transferred into a mold and frozen before freeze-drying at temperatures typically ranging between -20 and $-80\,^{\circ}C$ to shape these scaffolds. Then, porosity and pore size can be obtained during freeze-drying as the space occupied by the frozen solvent will become empty after sublimation.[140] Interestingly, pore structure can also be tailored by simply varying the freezing rate.[141] However, when using this technique to produce scaffolds, a critical parameter to be controlled is related with the need of guarantee that the final freezing temperature is adequate to maintain all the molecules of solvent in the solid state.[142] Otherwise, the final structure will shrink during the drying process resulting in the formation of a dense external skin-like layer, which can be seen as a disadvantage from the scaffold biological performance point-of-view.

Supercritical fluid technology (SCF) is seen as a clean, inexpensive, and environmentally friendly technology that has also been proposed for developing[143] a wide range of particles and TE scaffolds. The main advantages of this technique are: (i) absence of organic solvents, (ii) ability to incorporate bioactive compounds and growth factors, and (iii) ability to control the architecture of the scaffold. The principle of this technique is based on the fact that supercritical fluids are gases and liquids at temperatures and pressures above their critical points (T_c, critical temperature, and P_c, critical pressure).[144] Of particular interest for supercritical fluids application are the ranges $1 < T/T_c < 1.1$ and $1 < P/P_c < 2$ as the supercritical fluids appear in single phase with several advantageous properties

of both liquids and gases. We will not pay special attention to this topic as several good reviews[145–148] have summarized not only the aspects dealing with the principle, but also those related to processing and applicability possibilities. An interesting review[143] focuses on the SCF-processing methods as a processing tool for incorporation of bioactive compounds into TE scaffolds.

Carbon dioxide is the most commonly used supercritical fluid since it requires less energy consumption, and it is nontoxic, nonflammable, and noncorrosive. Its elimination and the recovery of final products are simple, that is, no residue is left and a dry solid product can be obtained by controlling the pressure. Thus, supercritical carbon dioxide has been regarded as the main candidate to develop alternative clean processes for the preparation of drug-loaded polymeric matrices and foaming of hydrogels.[149] In this respect, our group has shown not only that it is possible to use SCF to impregnate CHT scaffolds[150] obtained by freeze-drying with a pharmacological drug, but we have also shown that using a supercritical phase inversion technique we were able to prepare composite scaffolds of dexamethasone and a polymeric blend of starch and poly(L-lactic acid) (SPLA) in a single step.[151] In another work,[152] we also investigated the possibility of the use of the supercritical immersion precipitation technique to to prepare highly porous and interconnected scaffolds of a polymeric blend of SPLA. Two organic solvents, dichloromethane and chloroform, were tested, and results have shown that chloroform was preferable for the process. This processing technique shows such versatility that also enabled us to prepare composite scaffolds of Bioglass® and SPLA blends in a one-step process.[153] Besides, as supercritical fluids are highly compressible (especially near the critical point), and their density can be carefully controlled by small changes in temperature and/or pressure, it has been shown to be possible the design of particles[144,154] namely, the particle size control or polymorphic purity.

Complexation of polymer of opposite charge, such as CHT and alginate or carrageenan, has been also attracting much attention.[155] When two polyelectrolytes of opposite charge are combined, the formation of a physical hydrogel might take place, the so-called ionotropic hydrogel. The main advantage of such a processing technique lies in the possibility of being able to process in aqueous solutions (possibly incorporate bioactive molecules in a one-step process) and under very mild conditions, thus avoiding the use of organic solvents or other aggressive methods. Thus, the physicochemical properties of these hydrogels depend on the type of forces that can be associated namely, molecular entanglements, ionic forces, hydrogen bonding, and hydrophobic forces. All these interactions are reversible and can be disrupted by changes in physical conditions such as ionic strength, pH, and temperature. By varying the concentration of the polyelectrolytes, different gel structures can be produced, such as beads, microparticles, and nanoparticles. For example, our group recently reported[60] the preparation and characterization of protein-loaded nanoparticles obtained by ionic complexation of CHT and carrageenan. These nanoparticles have been shown to be an interesting drug-delivery system which made possible the loading of albumin (from 4% to 17%) and demonstrated excellent capacity to provide a controlled release for up to 3 weeks. *In vitro* studies using L929 fibroblats revealed that the nanoparticles are noncytotoxic, which in turn are critical for allowing their use in TE and regenerative medicine strategies. Other interesting systems and formulations have been also reported. In a work reported by Wang *et al.*,[254] the spray-spinning technique was carried out to spray a CHT solution into a flowing sodium alginate solution and sheared into streamlines – the elongated streamlines subsequently transformed into alginate/CHT polyelectrolyte complexes fibers. The ability of certain polymers such as gellan gum or alginate to cross-link with cations, that is, to be ionically cross-linked, may also be used to produce scaffolds.[156–159] These polymers have been used in cartilage TE as hydrogels and besides showing appropriate mechanical properties they allow to encapsulate cells during processing and can be used in minimally invasive strategies.

Other interesting techniques used in TE scaffolding include *solvent casting and particle leaching*.[134,137] Particle leaching is widely used since it is a cheap, fast technique that easily allows us to tune the porosity and pore size/geometry of the scaffolds,[119,160] by simply varying the amount and size/shape of the porogen. Thus, the process is based on the dispersion of the porogen particles such as salt or others with a biomaterial, which in turn can be in a liquid or solid state.[134,137,161] After the shaping process using a mold, the porous structure is obtained by eliminating the porogen particles by soaking it in a specific solvent.[162] Despite these advantages, this technique presents a major drawback as it is difficult to control the pores interconnectivity.[163] However, Ghosh *et al.*[164] demonstrated that an increase of interconnectivity in SPLA-based scaffolds can be achieved using salt particles and poly(ethylene oxide) (PEO) as an additional polymeric porogen.

By means of using the previously described methodologies, it is possible to tailor the properties of the different scaffolds, namely their degradation, architecture, and mechanical properties, for several applications in TE scaffolding. In this section, we thought that the processing possibilities to obtain particles and fibers are worthy of special attention, and are therefore reviewed more extensively in the following sections.

2.211.3.1. Microspheres and Microparticles and Their Aggregation

Methods of relevance to TE and controlled release strategies that focus on the incorporation of bioactive molecules such as growth factors or cells within the scaffolds have attracted great deal of attention. For example, Kim *et al.*[165] reported the development of microspheres made of collagen–apatite nanocomposites mimicking the extracellular bone matrix. In this study, they developed microspheres constituted of collagen and apatite for the treatment of skeletal defects. A water-in-oil emulsion method was carried out for obtaining the microspheres starting from an apatite-precipitated collagen solution (30% apatite). Microspheres and microparticles have been used as supports for cell growth, proliferation, and differentiation. Thus, one can easily identify two different approaches: (i) the microspheres can be injected immediately mixed with cells or bioactive molecules[166–169] and (ii) the microspheres can act as a carrier for *in vitro* cell attachment

and injected at a later stage.[170] The example given for the second strategy makes use of poly(D,L-lactic-*co*-glycolic acid) which is a synthetic polymer. Despite many other examples, the use of natural-origin polymers is well reviewed elsewhere.[171] Alternatively, the aggregation of the microspheres/microparticles themselves can be used as a processing technique to produce TE scaffolds. The agglomeration step can be achieved using chemical, thermal, or physical processes. An interesting work has been reported by van Tomme *et al.*,[172] which produced a self-gelling hydrogel by simply mixing dispersions of oppositely charged cross-linked dextran microspheres. In addition, it is also possible the aggregation of dextran microspheres by seeding with cells in order to form a living tissue-engineered construct. Such type of strategies has been reported by our group.[173,174] In these studies, we have demonstrated the possibility of the development of several scaffolds based on CHT particles' aggregation, which were promising in the search for applications in cartilage, bone, and osteochondral TE. Another approach has been also proposed, consisting of a mixture of microspheres (loaded with bioactive molecules or cells) and hydrogels, which are then implanted into the defect area.[175,176] Finally, microspheres and particles can be combined with TE scaffolds either by direct combination, that is, by injecting them together with the TE scaffolds or by the infrequent method in which they are used as a coating for these scaffolds. Interestingly, Noritaka *et al.*[177] reported that the impregnation of the loaded microspheres into the scaffolds is much more effective when compared with the simultaneous injection of the loaded microspheres. Other examples[178] may be found in the literature. Thus, to conclude, we may state that the aforementioned strategies based on microsphere and microparticles showed to be promising adjuvant systems for delivering cells or bioactive agents for application in TE scaffolding strategies.

2.211.3.2. Fiber Meshes and Fiber Bonding

Fiber meshes are alternative structures that have been investigated as TE scaffolds. These can be produced from polymeric solution or melt-spun fibers. CHT alone or combined with other polymers has been wet-spun into fibers using acid solutions.[65,179] Our group has evaluated scaffolds based on starch[180,181] using a methodology based on melt spinning that avoids the use of hazardous solvents, in which fiber mesh scaffolds are produced through the application of a heat treatment to bond fiber bundles.[182,183] In this method, melt-spun fibers are cut to standard length and used in the production of fiber mesh scaffolds using a custom-designed mold. In order to control the final morphology, discrete amount of fibers are randomly placed into the mold cavities and subjected to thermal treatment before the application of predefined compression levels along the *z*-axis, in order to assure the bonding between fibers. Fiber mesh scaffolds such as those obtained by this method exhibited controlled porosity, pore interconnectivity, average pore size, and surface area. **Figure 1** presents the scanning electron micrographs for a scaffold based on a blend of starch with poly-ε-caprolactone (starch/PCL) produced by this method. These scaffolds present a large total surface area that promotes cell anchorage and high pore interconnectivity. Following the experiments-based study,[182] a significant correlation was found between porosity and pore interconnectivity, average pore size, and surface area. **Figure 2** presents the dependence of compression stiffness of scaffolds on the porosity. Porosity was found to be an important factor negatively affecting the compression stiffness of the scaffolds. The scaffolds produced by this method were found to exhibit adequate properties to be used in different TE contexts.[184–187] The control of scaffold morphology is a critical factor when optimizing the biological performance of these scaffolds. In this regard, it was found that intermediate values of porosity appear to be more adequate for enhancing cell seeding as opposed to very high porosities.[182] Inadequate scaffold morphologies can lead to uneven zonal distribution of cells. Upon longer times of culture, local variations in cell distribution are reduced, but partially reflect the initial zonal distribution of cells. There are several advantages for using this processing methodology such as: no use of solvent, attainment of high porosity and pore interconnectivity values and good overall control of scaffold morphology. Nevertheless, thermal-based methods like this one can only be effectively applied to polymers exhibiting thermoplastic-like behavior, which can hamper significantly its use with other natural-based polymers.

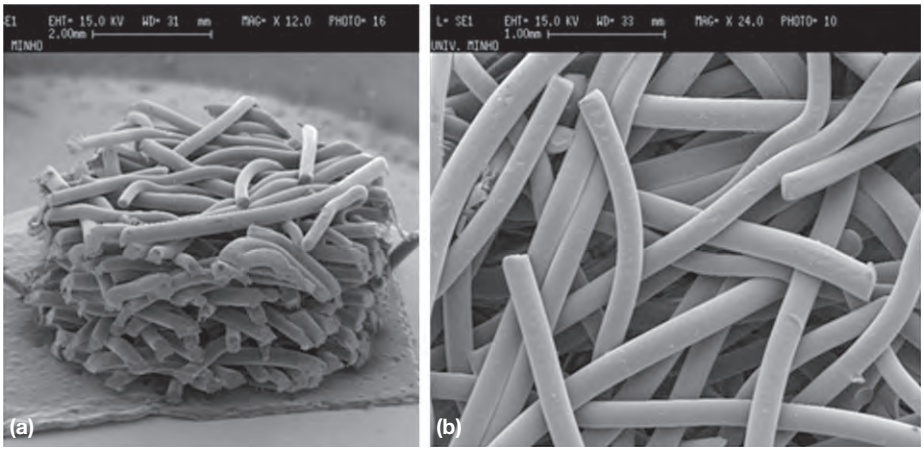


Figure 1 Scanning electron micrographs of a scaffold based on a blend of starch with poly-ε-caprolactone produced by fiber bonding: (a) 12x, and (b) 24x.

2.211.3.3. Rapid Prototyping

During the last few years, investigation has been carried out on the development of alternative processing methodologies based on rapid prototyping (RP). The use of RP allows the design and fabrication of anatomically adapted scaffolds, featuring customized internal architectures, through the integration of computer-assisted design (CAD) tool and medical imaging acquisition and processing techniques. The integration of these technologies into the production of TE scaffolds has been designated as computer-assisted TE (CATE).[188–192] Within the several RP technologies available, few have been applied to the fabrication of TE scaffolds using natural-based polymers. The nonfusible behavior of many natural-based polymers limits the application of many SFF techniques. Among the several available RP techniques, 3D printing is based on the selective bonding of powder particles via the deposition of a binder resin.[193] 3D printing has been originally adopted by Kim *et al.* for the fabrication of TE scaffolds.[194] In this context, starch[41,195] and alginate[196,197] have been used to process 3D scaffolds. Selective laser sintering (SLS) is an additive manufacturing technique that uses a high-power laser to fuse and bond particles into a 3D object. Blends of PCL with a starch, dextran, and gellan gum were processed into 3D scaffolds using SLS.[76] Among the several techniques, fused deposition modeling (FDM) applies heat to a filament of material, which is deposited layer by layer by an extrusion head, according to a programmable path. The temperature and flow of the material is controlled, while the scaffold construction in the *z*-axis is assured by the relative movement of the platform relatively to the extrusion head. Although the development of TE scaffolds by FDM has been reported,[198–203] its application to natural-derived polymers and blends is rather challenging. A possible alternative is the 3D deposition process, referred also as 3D bioplotting, in which the material in the powder or granular form is heated inside a barrel, being the respective molten materials displaced by a plunger or piston. Using this method, it is possible to process blends based on a starch base as they exhibit a thermoplastic behavior. Figure 3 presents, as an example, a scaffold geometry based on starch/PCL blend obtained by 3D bioplotting. Figure 3 presents examples of scaffold architectures obtained for a starch/PCL blend using bioplotting. Both architectures feature an orthogonal orientation pattern between consecutive layers and feature the same porosity. However, they differ relatively in terms of the *xy* positioning of equivalent layers. The main advantage of this RP method is related with the very high control of scaffold morphology, the achievement of fully interconnected pore structure and the use of mild processing conditions.

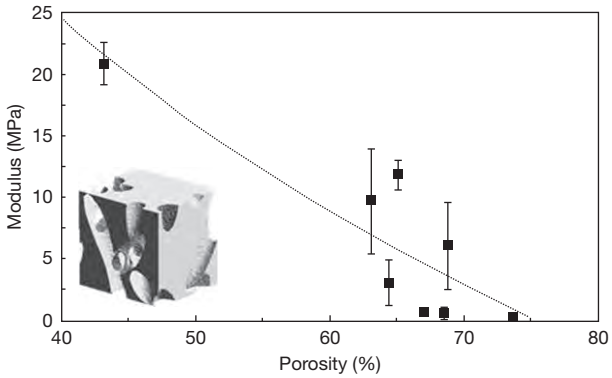

Figure 2 Dependence of compression stiffness from porosity: for scaffolds based on a blend of starch with poly-ε-caprolactone produced by hot fiber bonding. Inner figure: representative free volume for a cubic shape with 1 mm^3 obtained by microcomputed tomography.

2.211.4. Cell Encapsulation in Injectable Biodegradable Hydrogels for TE Applications

2.211.4.1. General Principles

Numerous investigations led to the development of varied and advanced tissue-engineered constructs with different architecture, and tailored material properties that guide and enhance the regeneration of target tissues. Most of the approaches involve the seeding of cells in 3D solid scaffolds exhibiting interconnected porosity.[204,205] Such solid-like structures comprise some advantages in sustaining the mechanical strength and structural shaping of the regenerated tissues; however, the downside within such structures is that cells attach to the walls of the materials' pores, but are not placed in 3D condition and may not exhibit the expected native phenotype.[206,207]

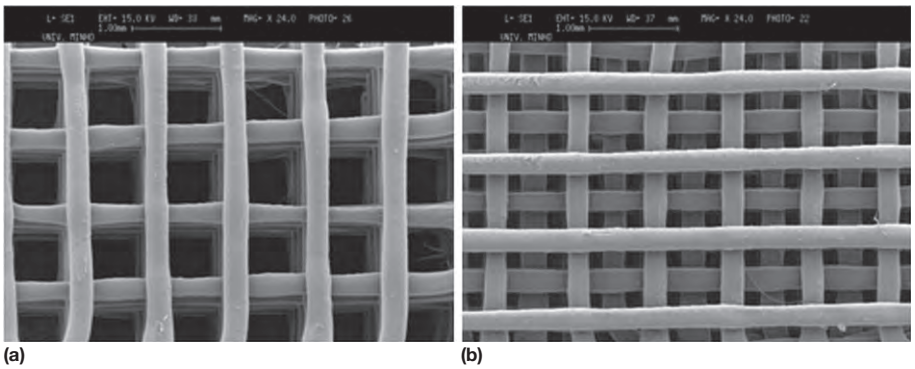

Figure 3 Scanning electron micrographs showing the top view of scaffolds based on blend of starch with poly-ε-caprolactone produced by 3D bioplotting featuring an orthogonal orientation pattern between consecutive layers (a) equivalent *xy* positioning between consecutive layers, and (b) offset positioning between consecutive layers.

Inspired by Nature, many researchers have thought to develop biomaterials that can mimic some essential biochemical and structural properties of the natural ECM of living tissues.[69,204] The morphological and biophysically similar structure of the hydrogels with soft biological tissues makes them attractive candidates as scaffolds for the delivery of cells in medical applications. Hydrogels are water swellable polymers with pore sizes that can be modulated, allowing the diffusion of nutrients and gas, while supporting the growth, differentiation, and enabling the embedded cell population to exhibit phenotypes more akin to those *in vivo*.[208,209]

Furthermore, recent advances in modern medicine and regenerative medicine are continuously driving toward minimally invasive trends, along with the development of improved and sophisticated injectable systems. Hydrogels, liquid precursor solutions where cells are suspended and then delivered to form a gel *in situ*, are used as 3D injectable TE devices that can be implanted without the need of invasive surgery. Many different hydrogel-based materials are available with contrasting properties which hold great promise in the TE field, both as drug delivery and cell encapsulated-based systems.[69,208–210]

Cell encapsulation is a technology, based on the immobilization of cells within a semipermeable biopolymeric membrane, which provides potential therapeutic treatments for a wide array of diseases.[207,211,212] The bioencapsulation within those membranes protects the transplanted cells from immune rejection, overcoming some of the current difficulties relating to whole graft rejection and potentially allowing allo- or xetransplantation without the need of administration of immunossupressants or immunomodulatory drugs.[211]

Many different natural origin-based materials are employed to encapsulate cells. Herein we present a basic overview of the recent advances in the selection of natural origin-based hydrogels used as cell delivery injectable systems for different TE applications.

2.211.4.2. Selected Examples

Collagen is the most widely used derived natural polymer. The ability of its fibers to self-aggregate and to form gels *in situ* is being used in many applications. Collagen gels can be easily manipulated and their mechanical and physical properties enhanced by chemical cross-linkers.

Gelatin is a derivative formed from the hydrolyzation of collagen that easily forms hydrogels by changing temperatures of solutions. Collagen and gelatin have been used to make hydrogels for cartilage regeneration as cell carrier for chondrocytes transplantation.[213] Cartilage constructs using composite HA/collagen I formulation also showed to increase the synthesis and deposition of ECM by chondrocytes.[214] Collagen hydrogels have also been employed in bone,[215] skin,[216] and liver regeneration,[217] as well as in injured spinal cord.[218]

HA is a glycosoaminoglycan present is ECM in a number of tissues that can form hydrogel by covalent cross-liking, and its can be properties tailored for desired applications. HA shows great potential for TE applications such as artificial skin,[216 219] tissue augmentation,[220] facial implants,[221] and wound healing.[222] Studies have also been conducted for cartilage-engineered products.[223]

Fibrin gels can be obtained as a result of the enzymatic polymerization of fibrinogen in the presence of thrombin forms and play an important role in natural wound healing. Fibrin has been used to encapsulate fibroblast[224] and keratinocytes[225] in order to develop skin substitutes, and also shown promising results in cartilage regeneration.[226,227] Fibrin has also been conjugated with other hydrogels such as HA to be used as cell delivery vehicle for chondrocytes.[228] Human mesenchymal stem cells were encapsulated within fibrin hydrogel toward osteogenic differentiation.[229,230] Considering the potential inherent features of fibrin gels, they have been employed in many other TE applications.[231]

Alginate is also versatile and widely used for cell encapsulation. Alginate gel was used as a filling scaffold for periosteum-derived chondrogenesis via minimally invasive procedure,[232] and also in the development of complex-shaped structures in animal models.[233] Alginate has found uses as wound dressing,[234] in the development of skin analogues,[235] and also in the transplantation of hepatocytes[236] and Langerhans islets for diabetes treatment.[237]

Ectopic reconstruction of bone and cartilage using bone marrow stromal cells encapsulated in alginate system was also demonstrated.[238] Alginate injectable systems are also under investigation for intervertebral disk regeneration.[239,240]

CHT and CHT-based hydrogel materials have been evaluated as injectable systems. One of the most interesting systems developed in the past decade is based on the neutralization of CHT with solutions of polyols salts, such as β-glycerophosphate (GP), leading to a temperature-responsive, pH-dependent gelation.[241] These systems are liquid at physiological pH and room temperature, solidifying when heated at body temperature. The CHT/GP formulation has been proposed for different biomedical application, and intensively for cartilage repair[242,243] and disc regeneration.[244] The incorporation of bioactive elements, such as bioactive glass–ceramic nanoparticles or osteoconductive elastin-like polymers may also open the potential of using such systems in bone regeneration.[245,246]

An alternative way to prepare CHT-based hydrogels is by grafting with synthetic polymers, which leads to the formation of thermosensitive formulations. Recently, CHT was grafted with Pluronic®, a family of PEO–PPO–PEO triblock copolymers, and proposed as an injectable cell delivery carrier for cartilage regeneration.[247] PEG was also incorporated into CHT and used as a therapeutic drug-delivery system.[248] A copolymer of poly(*N*-isopropylacrylamide) (PNIPAAm) and water-soluble CHT were evaluated for chondrogenic differentiation of human mesenchymal stem cells,[249] and also for chondrocytes and meniscus cells' encapsulation.[250]

Literature offers countless examples of natural-based materials used for cell encapsulation. Examples of those injectable systems are based on starch,[251] agarose,[252] and gellan gum,[78] among others.[69,205,206,208–210,253]

2.211.5. Final Remarks

In the field of TE, a great deal of effort has been taken to prepare different formulations based on natural polymers. However, and despite all the extensive literature containing

references to so-called 'natural-based' systems, it is the authors' opinion that much work is still needed in order to obtain clinically successful materials. Many improvements can be made in this context, as such systems offer a great versatility; they may be, for example, chemically modified, and combined with ceramics or other polymers (blends, copolymers, interpenetrated networks). Their interaction with cells and tissues may be improved or tuned, by adequate chemical modifications such as grafting with peptides (e.g., RGD) or by surface treatments (e.g., surface plasma modification, or modification of surface chemistry trough grafting with other polymers or functional groups or molecules). Many attempts have been made in order to produce smart natural-derived systems, that could be used in TE applications, including: (i) development of new injectable thermogelling materials, which could be used to deliver cells or growth factors through noninvasive routes; (ii) novel matrices that can be degraded by adequate cell signals; (iii) scaffolds or hydrogels that can deliver relevant bioactive agents in specific conditions (temperature, pH, ionic strength, or presence of specific enzymes); and (iv) self-assembling systems that can be tuned by external signals. Different processing routes have been proposed to produce scaffolds with a great variety of porous architectures. This is an especially delicate task as natural-derived macromolecules are typically nonmeltable (without degradation) and may be insoluble in many solvents. This compromises the use of many of the most traditional techniques to produce TE scaffolds. Efforts should, in fact, be made to develop or improve new or combined processing strategies in order to obtain repeatable porous constructs with controlled porous morphology, preferably at different scale levels (e.g., combination of nano- and microelements or pores), comprising different materials spatially organized and owing the capability to deliver relevant molecules, such as growth factors in a controlled way. Such new scaffolds should be designed for the different applications, addressing particular aspects, such as: to stimulate vascularization, facilitate the deposition of calcium phosphates in predefined regions, guide the regeneration of tissue in certain directions (trough gradient delivery of factors or anisotropic porous architecture), permit the development of different tissues (e.g., regeneration of osteochondral defects), or inhibit calcification and cell adhesion (e.g., in cardiovascular application), just to cite some examples. The field is widely open for new creative researchers to make some dreams come true and materialize in real clinical applications.

Glossary

Biological microelectromechanical systems (BioMEMS) A special class of microelectromechanical systems (MEMS) where biological matter is manipulated to analyze and measure its activity.

Electrospinning Electrospinning is a process that uses an electrical charge to draw very fine (typically on the micro or nano scale) fibers from a liquid.

Layer-by-Layer (LbL) A thin film fabrication technique: the films are formed by depositing alternating layers of oppositely charged materials with wash steps in between.

Spray drying A method of producing a dry powder from a liquid or slurry by rapidly drying with a hot gas.

Waveguide A waveguide is a process in which a light-transmitting material such as a glass or plastic fiber is used for transmitting information from point to point at wavelengths in the ultraviolet, visible-light or infrared portions of the spectrum. Also known as fiber waveguide/optical-fiber cable.

2.212.1. Overview

Silks are generally defined as protein polymers that are synthesized and spun into fibers by many organisms, including silkworms, spiders, scorpions, mites, and flies.[1–18] The more commonly utilized silk, such as from the silkworm, *Bombyx mori*, has been used in the textile industry for thousands of years due to its visual appeal and mechanical properties.[9,12]

Natural silks provide structural roles in cocoon structures, web formation, traps, nest building, safety lines, and egg protection.[9,12] Silks from silkworms can be obtained in significant quantities from naturally spun silk cocoons, and therefore, can be used as natural biomaterials.[9–12] Silks are intriguing materials due to their combination of high toughness and strength.[6,15,17] The toughness of some silks is higher than that of high-performance Kevlar fibers.[15] In addition to their impressive mechanical properties, silks offer a range of useful features, including environmental stability, biocompatibility, controllable biodegradability, and morphologic flexibility.[1,12,16] Thus, silks represent a unique family of structural proteins that are useful in the traditional textile industry, while also providing a wide range of properties for biomedical materials.

The highly repetitive primary sequence of silk proteins leads to significant homogeneity in their secondary structures related to structural material needs, in contrast to the less ordered globular proteins that provide catalytic and molecular recognition functions.[9–12] The secondary structure in silks permits tight packing of stacked beta sheets (crystalline domains) connected by hydrogen bonds between protein chains, generating hydrophobic regions with strength and resiliency.[1,19–23] Therefore, silk materials have significant crystallinity and are insoluble in most solvents, including water, dilute acids, and alkali.[11] The domesticated silkworm (*B. mori*) silk fibroin protein chain consists of two proteins: a heavy chain (~370 kDa) and a light chain (~26 kDa) which are present in a 1:1 ratio and linked by disulfide bond.[5] Compared with other proteins, silks fibroins have repetitive primary structures such as $(Gly\text{-}Ala\text{-}Gly\text{-}Ala\text{-}Gly\text{-}Ser)_n$, $(Gly\text{-}Ala\text{-}Gly\text{-}Ala\text{-}Gly\text{-}Tyr)_n$, or AGVGYGAG motifs.[5] The crystalline regions have been identified as rigid, tightly packed antiparallel beta-pleated sheets which exclude water, in part accounting for the remarkable stability of silk biomaterials.[8,9] Exposure of noncrystallized silk materials to organic solvents,[8,11] application of mechanical stress[15,17] or thermal treatments,[8,24–26] and the addition of metal ions[9,10,12] among other options, all induce the irreversible crystallization of silk proteins, which has become the foundation for processing silk into biomaterials.

In this chapter, we focus on recent progress in designing and producing new silk-based biomaterials, including silk film, sponges, nanofibers, hydrogels, microspheres and nanoparticles, optical biomaterials, and other systems (e.g., silk microfluidic devices, micropatterned materials, direct-write scaffolds, and chemically modified materials). The goal for this chapter is to convey the versatility and medical utility of silk-based systems to provide insight into recent silk material studies for tissue regeneration, controlled release, and biomedical optics applications and opportunities (**Figure 1**).

2.212.2. Silk Film Biomaterials

Silk film formation is an efficient way to mimic the natural process of silk self-assembly and to understand the role of water during structural transitions.[9,10,12,15,17] As a biomaterial, these films offer limited utility other than when used as coatings or perhaps as antiadhesion barriers. Exposure of silk films to organic acids or alcohols, applying physical stretching, or heat above the glass transition temperature induce beta-sheet (silk II structure) crystal formation (>35%) in silk films.[8,11] However, low beta-sheet content and aqueous insoluble silk films, such as alpha-helix-enriched (silk I structure) films, are difficult to produce. Therefore, many methods in the last few years have been developed to generate silk film biomaterials with low beta-sheet crystallinity for improved flexibility of films and for more rapid enzymatic degradation (**Figure 2**).

2.212.2.1. Water Annealed and Slow Drying Silk Films

A 'water annealing' technique was developed to produce the low beta-sheet content silk films.[27] The keys in this process are the preparation of silk films with a subsequent water-vapor annealing procedure. These films degraded more rapidly, as determined *in vitro* via enzymatic hydrolysis, yet supported human adult stem cell expansion *in vitro* in a similar or improved fashion to the high crystallinity films induced by organic solvents (e.g., methanol).[27] Furthermore, slow drying at room temperature also induced the formation of insoluble silk I films.[28–30] By controlling the drying rate, water-insoluble silk films can be prepared with a similar beta-sheet content as soluble silk films (~20%), versus the relatively high beta-sheet content in methanol- or water-annealed silk films (about 40 and 30%, respectively).[29] The high content of silk I structure in these films resulted in more rapid degradation compared with those generated by water annealing or methanol annealing, which leads to an extended range of biomedical material applications, such as where rapid degradation *in vivo* is desired.[29]

2.212.2.2. Electric Field Aligned Silk Films

Another example of new silk film biomaterials is based on the application of electric fields.[31,32] By casting silk solution under an alternating electric field (AC), dramatic changes in the alignment of molecular dipoles and the formation of oriented supramolecular assemblies were achieved.[32] Mechanical, thermal, and surface properties of the films were therefore changed compared to controls without this alignment process.[32] Cell responses were also affected; fibroblasts cultured on these anisotropic fibroin films preferentially spread parallel to the field direction 6 h after seeding.[32]

2.212.2.3. Ultrathin Silk Films

Compared with traditional bulk silk protein films, many advanced film techniques have been developed in recent years.[33–43] One of the examples is the layer-by-layer (LbL) nanoscale thin coating technique for silk fibroin studies.[33,37–43] Through an all aqueous step-wise deposition process, silk fibroin layers can be deposited on a substrate and monitored spectroscopically or with a quartz crystal microbalance.[33,37–43] The silk adsorption process generated stable and reproducible layers, with control of a single layer thickness ranging from a few to tens of nanometers, determined by the concentration of silk solution, salt concentration in the dipping solution, and the method of rinsing.[39–41] Compared with traditional polyelectrolyte LbL techniques, an intervening drying step is added to control the structure and stability of the self-assembled silk fibroin layers.[37,42] The drying process can be used to induce beta-sheet crystal formation in the films, similar to methanol

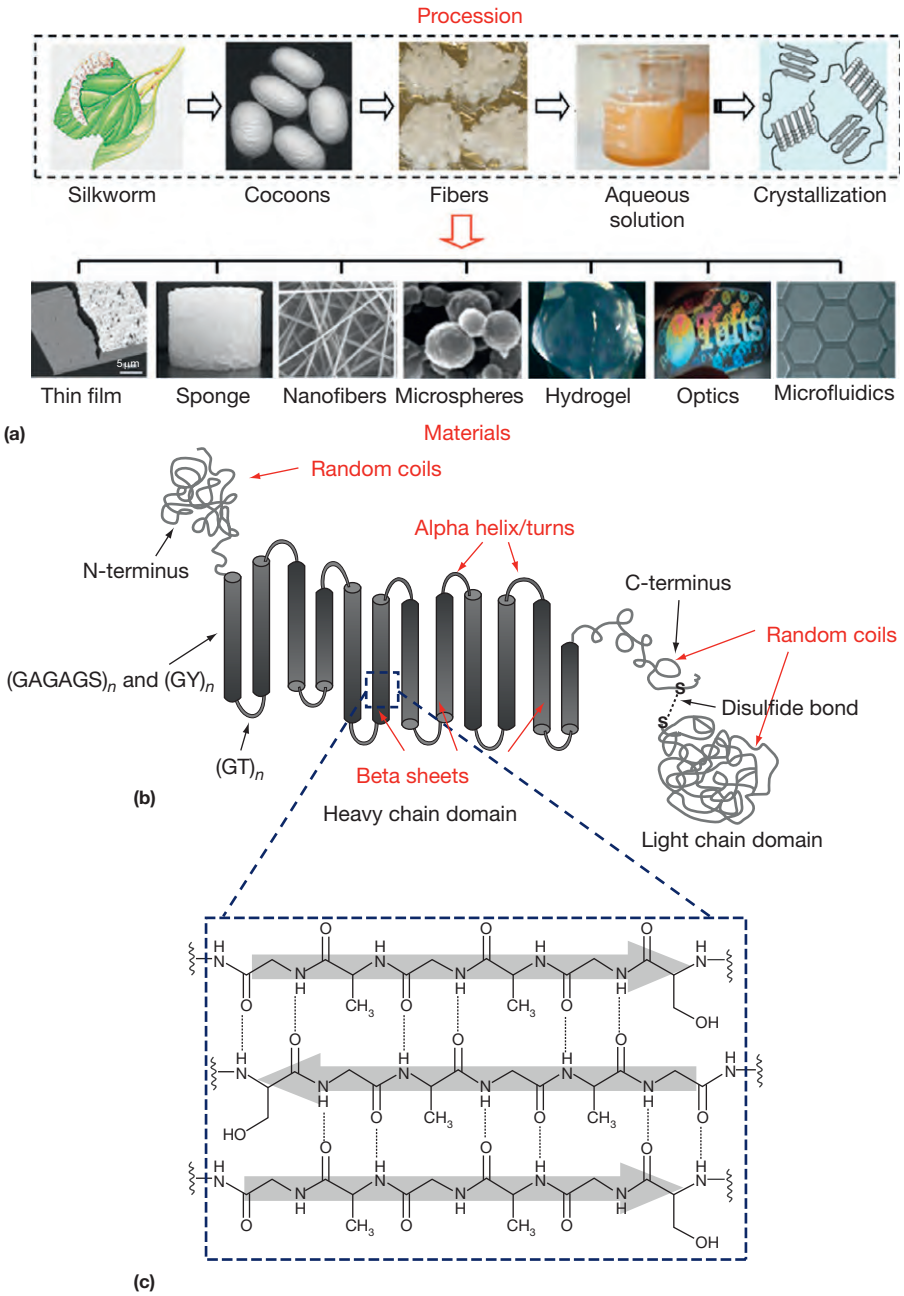

Figure 1 (a) Silk-based materials (*B. mori* silk fibroin protein); (b) secondary structure of one *B. mori* silk fibroin chain; (c) $(Gly\text{-}Ala\text{-}Gly\text{-}Ala\text{-}Gly\text{-}Ser)_n$ amino acid repeat units that self-assemble into antiparallel beta sheets. (b) Modified from Ha, S. W.; Gracz, H. S.; Tonelli, A. E.; Hudson, S. M. *Biomacromolecules* **2005**, *6*, 2563–2569. (c) Modified from Murphy, A. R.; John, P. S.; Kaplan, D. L. *Biomaterials* **2008**, *29*, 2829–2838.

treatment and thereby stabilizing the films to avoid dissolution in water.[37,42] The assembled films were stable under physiological conditions and supported stem cell adhesion, growth, and differentiation, providing new options for engineering biomaterial coatings in medical devices as well as controlling of interfacial properties conducive to specific cellular or tissue responses.[33,38,43]

These LbL nanocoatings were utilized as carriers to incorporate drugs.[38–41,43] Model small-molecule drugs, as well as large proteins such as azoalbumin, were incorporated into the LbL nanocoating process with ultrathin silk films. Control of beta-sheet crystal content and the multilayer structure of the silk coatings provide control of the release properties of these incorporated compounds during *in vitro* studies.[39–41] Higher crystallinity with thicker silk capping layers suppressed the initial burst release and prolonged the duration of release of the model drugs from the silk materials.[39–41] This approach provides an important option to regulate drug release kinetics from silk by controlling its structure and morphology, which is useful in surface engineering of biomaterials and medical devices for regulating the release of drugs.[39–41] The control of release kinetics of therapeutic drugs has also been validated

in vivo in epilepsy animal models with silk-based brain implants.[38,43]

2.212.3. Silk Sponge Scaffold Biomaterials

Silk sponge scaffold biomaterials are frequently used systems for tissue engineering.[1,12,16,44] Silk sponge scaffolds for bone and organ regeneration provide useful features such as biocompatibility, impressive mechanical properties, versatility of chemistry, aqueous processing to entrain bioactive molecules, and cell-controlled degradability.[12,45] Generally, pore size and the porosity of the scaffolds are key factors to consider. Pore sizes larger than 100 μm in diameter are typically considered minimum for tissue scaffolds,[45] based on cell size and migration. Porosity determines how well the scaffold pores are interconnected, which directly controls the ability of the seeded cells to interact and signal one another.[45] Depending on the applications of the scaffolds, mechanical properties as well as degradation rate are also important for supporting tissue function, integration, and growth.[45] The core question during engineering silk scaffold systems is how to produce interconnected pores in a three-dimensional (3D) silk system. In addition, mechanisms to induce aqueous insolubility via beta-sheet crystallization are also required (Figure 3).

At least three methods have been reported to generate porous 3D sponge matrices from silk proteins[44–46]: salt leaching, gas forming, and lyophilization or freeze-drying. Salt leaching utilizes porogen leaching approaches, with granular salt particles (e.g., NaCl) in silk solutions.[44,45] The bulk of the silk particles are retained as solids because of saturation of the solution. Therefore, the sizes of salt particles can be used to control the pore sizes in scaffolds. Some salts (e.g., NaCl, KCl)

also induce beta-sheet crystals in silk protein during the process.[45] After 24 h at room temperature, the insoluble silk scaffolds are formed, and the salts can then be extracted by immersion of the scaffolds in water.[45] Gas forming uses bicarbonate salt (e.g., ammonium bicarbonate or sodium bicarbonate) as the porogen added to silk solution, with a porogen-to-silk weight ratio of 10:1∼20:1.[44] After drying and beta-sheet crystallization in alcohol, the scaffolds are immersed in 95 °C water to induce gas foaming and remove/dissolve the bicarbonate particles.[44] There are a variety of approaches to generate air bubbles in silk solution, after rapid crystallization by alcohol or freezing before crystallization, with the air bubbles used to generate the pores in the scaffolds.[44] The freeze-drying method utilizes ice particles as the source of pores.[44,46] By controlling freezing rate and freezing temperature, the size of the ice particles can be controlled. Therefore, gelation and crystallizing silk solution before freeze-drying, or crystallizing silk solid scaffolds after freeze-drying, can be used to obtain insoluble silk scaffolds for tissue engineering and other biomedical applications.[46] This method avoids organic solvents. Aside from the aforementioned pure silk approaches, additives such as gelatin to the silk fibroin solution can be used to control the conformation of silk with the formation of insoluble porous structures.[46] The pore sizes of scaffolds were controlled by adjusting the silk fibroin concentration.[46] The addition of the gelatin resulted in improved hydrophilicity and *in vitro* cell culture interactions compared to salt-leached silk fibroin scaffolds alone.[46]

2.212.4. Silk Nanofiber Biomaterials

Nanofiber scaffolds can mimic the nanoscale properties of fibrous components in the tissue native extracellular matrix (ECM), and have been broadly explored in tissue engineering, in wound healing, and related medical applications.[22,47–50] Compared with conventional fiber-processing techniques which produce fibers with tens of microns in diameter, nanofibers are at least two orders of magnitude smaller than the conventional fibers, but with similar geometry.[50] Self-assembly, phase separation, and electrospinning methods can be used to produce these types of nanofibers for different biomedical applications. Self-assembly and phase-separation techniques can generate fibers with diameters from 1 to 500 nm, but are effective with only a selected number of polymers.[50] Electrospinning is a versatile technique that enables the development of nanofiber-based silk biomaterial scaffolds.[50] A typical electrospinning setup usually contains three components: a high-voltage supplier, a capillary needle, and a grounded collector.[50] By applying an electric potential to the droplet of protein solution suspended on the needle, repulsive forces produced by charges in the solution and the attractive forces from the collector exert tensile forces on the protein solution. A nanofiber jet can then eject from the apex of the cone and accelerates toward the grounded collector.[50] Many factors can significantly affect the process of the formation of the electrospun nanofibers, including the solution conditions, such as viscosity, conductivity, concentration, surface tension, and molecular weight of the protein[50]; instrument impacts, such as applied electrical potential and morphology of the capillary tube[50]; or environmental parameters, such as temperature, humidity, and air velocity.[50] If the protein solution is too dilute, the fiber may break into microsize droplets before reaching the collector, which results in the phenomenon of 'electrospray.' If the protein solution is too concentrated, electrospinning solution may not produce fiber due to high viscosity (Figure 4).

2.212.4.1. Silk Nanofibers from Organic Solvent

Silk proteins have been widely utilized as electrospinning biomaterials. By choosing organic solvents, such as

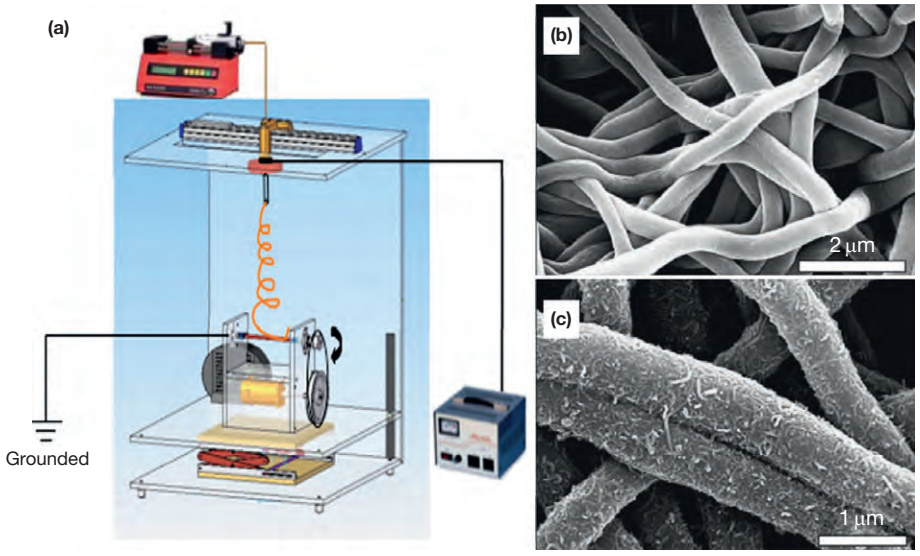

Figure 4 (a) Schematic of electrospinning setup; scanning electron microscope (SEM) images of crystallized and polyethylene-oxide (PEO)-extracted electrospun silk nanofibers, (b) unmodified, and (c) after adsorption of multi-wall carbon nanotubes (MWCNTs). (a) Reproduced from Zhang, X. H.; Reagan, M. R.; Kaplan, D. L. *Adv. Drug Deliv. Rev.* **2009**, *61*, 988–1006. (b and c) Reproduced from Kang, M.; Jin, H. J. *Colloid Polym. Sci.* **2007**, *285*, 1163–1167; Kang, M.; Jung, S.; Kim, H. S.; Youk, J. H.; Jin, H. J. *J. Nanosci. Nanotechnol.* **2007**, *7*, 3888–3891.

hexafluoroacetone (HFA), hexafluoroisopropanol (HFIP), or formic acid, continuous fibers were obtained with variable mean diameters and distributions.[50–52] It is believed that a faster evaporation rate of the solvent leads to the formation of thicker fibers with less elongation and lower beta-sheet crystal content. For example, the mean diameter of electrospun silk nanofibers dissolved in formic acid was smaller (80 nm) than those from rapidly evaporated HFIP solution (380 nm).[51]

2.212.4.2. Silk Nanofibers from Aqueous Solvent

Wang *et al.*[37,42,53,54] first electrospun *B. mori* silk fibroin using an aqueous solution, solving concerns of chemical residuals from organic solvents. Fibers formed when the aqueous silk solution reached 28% (w/v), with diameters from 400 to 800 nm.[37,42,53,54] However, when electrospinning 39% (w/v) silk solution, uneven and ribbon-shaped silk fibers were observed, due to the slow water evaporation from fiber surface.[37,42,53,54] Silk aqueous solutions with a viscosity lower than 40 mPa did not provide sufficient molecular chain entanglements for silk electrospinning.[37,42,53,54] The pH effects on electrospun fiber morphology and properties were investigated.[50] With the combined reduction in pH and concentration, the morphology of the electrospun silk fibers changed from ribbon-like to a uniform cylinder, from 265 nm in 25% (w/v) silk solution at a pH of 4.8 to 850 nm in 33% (w/v) silk solution at pH 6.9.[50] Fiber diameter dependence on electric potential was also observed by Meechaisue *et al.*[55] using 40% (w/v) silk fibroin solutions. The results indicated that when the electric field was doubled, the average diameter of electrospun silk fibers will also double.[55] The major conformations in electrospun silk fibroin nanofibers when spun from aqueous solution were random coil and alpha-helix (silk I), with a little beta sheet (silk II).[50]

However, it is challenging to obtain highly concentrated and stable silk aqueous solutions, as self-assembly leading to gelation can occur.[50,56] To solve this problem, Jin *et al.*[56] blended poly(ethylene oxide) (PEO) with a lower concentration of aqueous silk fibroin solution. From this blend, nanofibers (~750 nm) with comparable diameters to those from pure aqueous system were generated.[56] The water-soluble PEO was extracted out in distilled water after post-treatments of nanofibers to lock in the beta-sheet structure.[56] There are a number of treatments commonly performed to induce insolubility of electrospun fiber matrices. Kim *et al.*[52] used 50% (v/v) aqueous methanol for 10–60 min at room temperature. Conformational transitions of the unmodified silk fibroin nanofibers to crystalline structure were completed within 10 min.[51] Owing to brittle features of these methanol-treated silk fibroin matrices, alternate methods, such as water-vapor annealing, were also developed. Jeong *et al.*[51] reported differences in electrospun silk fibroin matrices after treatment with either aqueous methanol solution (50%) or water vapor. A longer time was required for water-vapor treatment at low temperatures, and different mechanical properties were found compared with MeOH-treated fiber mats, including better elasticity because of the lower beta-sheet content.[51] The efficiency of other solvents, such as ethanol, methanol, and propanol, temperature (25–55 °C) or treatment time was studied in detail.[51]

2.212.4.3. Silk Nanofiber Composites

In addition to pure silk nanofibers, many composite electrospun nanofibrous matrices based on silk, such as silk fibroin/chitin[57] or silk fibroin/collagen[58] mixtures, have been studied, using techniques such as a single-needle or side-by-side spinning approaches.[50] Wang *et al.* successfully encapsulated a silk fibroin core fiber within a PEO shell fiber.[53,54] After water-vapor treatment, PEO was extracted and the crystallized silk fibers with diameters, down to 170 nm, were obtained.[53,54]

Functionalized silk nanofibrous matrices have also been developed for release of molecules including antibiotics, proteins, small molecules, and DNA.[50,59–62] Drugs, enzymes, growth factors, various compounds, and conductive materials can be loaded via prespinning and mixing with silk solutions, and entrained in the fibers during coaxial electrospinning or postelectrospinning by covalently coating on nanofibers.[50] Lee *et al.* immobilized alpha-chymotrypsin (CT) on silk fibroin electrospun nanofibers with amino group preactivation with glutaraldehyde.[61] A significant increase in enzyme loading was observed and the activity of the immobilized CT was almost eight times greater than that on silk microfibers.[61] Li *et al.* incorporated bone morphogenetic protein-2 (BMP-2) into silk fibroin nanofibers in the spinning solution.[62] BMP-2 encapsulated silk fibroin matrices increased calcium deposition from human bone marrow-derived mesenchymal stem cells (hMSCs) when grown on the matrices, with enhanced transcript levels of bone-specific markers.[62] These BMP-2-loaded electrospun silk nanofibrous matrices were efficient delivery systems to improve bone formation.[62]

In addition to biological functionalization, electric property modifications have also been examined in silk electrospun matrices using multiwall carbon nanotubes (MWCNTs).[60,63] A significant amount of MWCNTs were retained on the surface of the nanofibers even after sonication, and the electrical conductivity of the MWCNT-absorbed silk matrices increased significantly at room temperature, compared with pure silk nanofibers.[63] Future research for electrospun silk fiber may focus on combining biological assays with silk nanofiber materials to assess cellular responses.

2.212.5. Silk Hydrogel Biomaterials

Hydrogels are insoluble 3D polymer chain networks that swell in aqueous solution and hold or entrap liquid components such as cells and drugs.[21,64–67] Hydrogels exhibit solid-like mechanical behavior, with high compliance and elastic strain, while consisting mostly of liquid.[21,65,66] The formation of hydrogels from solution is due to the connectivity of the protein chains as a result of 'cross-linking'.[64] Generally, there are two main types of cross-links in hydrogel systems: chemical and physical.[21,66] In chemically cross-linked hydrogels, networks are formed by chemical reactions or polymerization to stitch together the starting materials (such as monomers) via cross-linkers.[21,66] Physically cross-linked hydrogels can be obtained by crystallization, liquid–liquid phase separation, ionic interactions, or hydrogen bonding.[21,66] Silk fibroin aqueous solutions form hydrogels by physical cross-linking, with the rate of this sol–gel transition dependent on silk

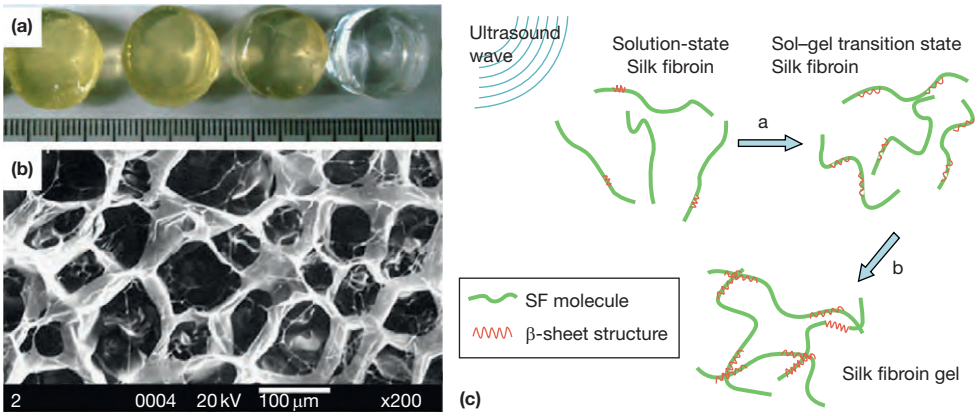

Figure 5 (a) Typical appearance of different silk/polyacrylamide semi-interpenetrating (semi-IPNs) hydrogels, (b) scanning electron microscope (SEM) image of silk/polyacrylamide semi-IPNs with composition ratios of 70/30, and (c) Schematic illustration of mechanism of silk gelation during ultrasonication. The gelation process contains two kinetic steps: (a) structural change from random coil to beta sheet with some interchain physical cross-links occurring in a short timeframe, and (b) beta-sheet structure-extended, large quantity of interchain beta-sheet cross-links, and molecules organized to gel network over a relatively long time frame. (a–b) Reproduced from Mandal, B. B.; Kapoor, S.; Kundu, S. C. *Biomaterials* **2009**, *30*, 2826–2836. (c) Reproduced from Wang, X. Q.; Kluge, J. A.; Leisk, G. G.; Kaplan, D. L. *Biomaterials* **2008**, *29*, 1054–1064; Wang, X. Y.; Zhang, X.; Castellot, J.; Herman, I.; Iafrati, M.; Kaplan, D. L. *Biomaterials* **2008**, *29*, 894–903.

concentration, temperature, metal ions, and pH.[38,43,68–70] The mechanism of gelation is self-assembly of the beta-sheet crystals.[69,70] Silk hydrogels have been used for biomedical applications because of their biocompatibility and adjustable mechanical properties (Figure 5).

2.212.5.1. Natural Silk Hydrogel

Early studies on the formation of silk hydrogels focused on the natural gelation process from silk fibroin aqueous solutions.[69,70] The gelation time of silk hydrogels decreased with increase in protein concentration and temperature, decrease in pH, and addition of PEO or Ca^{2+}.[69,70] However, other ions, such as K^{+}, did not have a significant impact on silk gelation time.[69] Freeze-dried silk hydrogel materials formed with Ca^{2+} exhibited larger pores than pure silk gels.[69] Mechanical compressive strength and modulus of silk hydrogels can be controlled by increasing the protein concentration and gelation temperature.[69] A conformational transition from random coil to beta-sheet structure promoted the formation, insolubility, and stability of silk hydrogels.[68–70] The impressive mechanical properties, biocompatibility, and biodegradability of silk hydrogels prompted additional studies to improve the gelation for different biomedical applications.

2.212.5.2. Ultrasound-Induced Silk Hydrogel

A novel method to accelerate the process and control silk fibroin gelation was reported through ultrasonication, as an energy input to the solution of silk to drive assembly and gel formation.[38,43] Power output and the time of sonication, along with silk fibroin concentration control gelation of silk from minutes to hours, allowing the addition of cells postsonication but prior to final gel formation.[38,43] hMSCs were successfully incorporated into these silk fibroin hydrogels after sonication and proliferated in the 4% silk hydrogels over 21 days.[38,43]

2.212.5.3. Semi-interpenetrating Silk Hydrogels

Other silk-based hydrogel studies focused on producing stimuli-responsive or semi-interpenetrating (semi-IPNs) hydrogel networks by blending silk with other polymers such as gelatin[71] and polyacrylamide.[72] For example, silk/gelatin hydrogel systems were formed with beta sheets formed via subsequent exposure to methanol, which entangled the gelatin molecular chains and stabilized the thermally responsive hydrogel network during the structural transition of gelatin.[71] Swelling and protein release kinetics of silk/gelatin hydrogels were controlled by varying composition. Through chemical cross-linking, silk/polyacrylamide hydrogels were synthesized using different ratios of silk fibroin/acrylamide mixtures.[72] The properties of these semi-IPNs depended on the ratio of two components.[72]

2.212.5.4. Injectable Silk Hydrogels

Injectable silk hydrogel systems have also been developed. By vortexing aqueous solutions of silk, a sol–gel transition was observed, with transition from random coil to beta-sheet structures, and orders of magnitude increase in shear modulus.[73] These vortex-induced silk hydrogels had permanent, physical, intermolecular cross-links, and the hydrogelation kinetics could be controlled by changing vortex time, assembly temperature, and/or protein concentration.[73] Such silk gel systems provide a useful time frame for cell encapsulation. The stiffness of preformed hydrogels recovered quickly, immediately after injection through a needle, enabling the use of these systems for injectable cell delivery systems.[73]

A gel-spinning method for silk tubes formation was developed for device formation.[74] By spinning an aqueous silk solution on a tube around a reciprocating rotating mandrel, the formed silk tube biomaterial exhibited specific winding patterns, porosity, and composite features.[74] Silk tube properties were further controlled via different postspinning

processing mechanisms, such as methanol treatment, air-drying, and lyophilization, which offered numerous tissue engineering applications such as biomaterial matrices useful for blood vessel grafts and nerve guides.[74]

Electrogelation, the application of a low-voltage electric field to an aqueous solution of silk fibroin, generated injectable silk hydrogels with adhesive properties.[75,76] This system demonstrated reversible adhesive properties and functioned on both hydrated and dry surfaces.[75] The structural transition of this silk gel was found to be reversible with random coil to alpha-helix transitions present.[75,76] This system utilizes all biocompatible components and functions in an all-aqueous process at ambient conditions, which provides potential applications in environmentally compatible material and medical device systems, including tissue adhesive functions.[76]

2.212.6. Silk Microsphere and Nanoparticle Biomaterials

Microspheres (1–1000 μm) and nanoparticles (1–1000 nm) are polymer particles used for biomedical applications such as controlled drug delivery and tissue engineering.[39,77–85] These structures can be used to incorporate drugs with controlled release kinetics, while retaining sufficient *in vivo* stability for function, biocompatibility, and degradability and the potential to target specific organs and tissues.[78,79,84] Microspheres are commonly used as depot drug carriers for long-acting delivery and usually administered intramuscularly or subcutaneously.[84] A depot delivery system requires particle sizes above 5 μm in order to remain at the injection site and slowly release drug contents.[84] Nanoparticles are usually designed as short-acting delivery vehicles (as a solid powder or with a liquid carrier) and administrated through intramuscular, intravenous, subcutaneous, oral, or transdermal routes.[84] With a smaller size, they can penetrate through small capillaries, across physiological barriers, and become incorporated into cells for treating various diseases such as cancers.[84]

Silk proteins have been used to produce micro- and nanospheres.[84] Compared with synthetic polymers and other natural degradable materials, silk proteins exhibit useful mechanical properties, tunable *in vivo* degradation rates, biocompatibility, and all aqueous material processing.[39,80,82–85] For drug delivery, small-molecule drugs or protein drugs can be incorporated with high efficiency, and drug release kinetics can be modulated through the control of crystalline beta-sheet content during processing.[84,86] Typical techniques available for the preparation of drug-loaded silk microsphere or nanoparticles are based on spray drying, emulsion-solvent evaporation/extraction, solvent displacement, phase separation, self-assembly, or rapid expansion of supercritical fluid solution. Silk fibroin has been fabricated into microspheres by many of these methods (Figure 6).

2.212.6.1. Spray-Drying Silk Microspheres

Silk microspheres were prepared by spray-drying an aqueous solution of silk, containing theophylline as a model drug with a small amount of ethanol.[87,88] The amorphous silk microspheres were then exposed to a humid atmosphere (89% relative humidity) to induce beta-sheet crystallization.[87] The mean diameter of the microspheres was around 5 μm.[87]

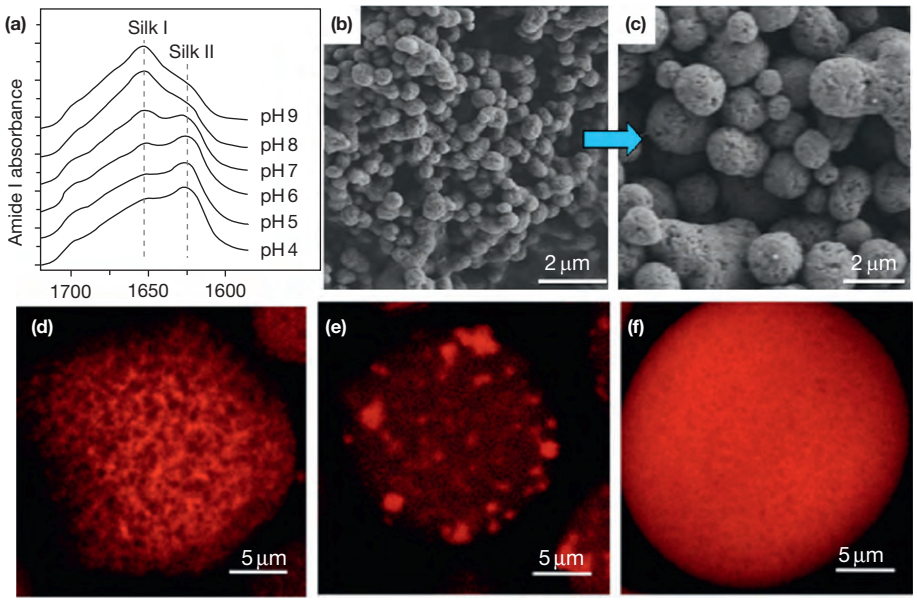

Figure 6 (A) FTIR spectra of silk fibroin particles produced by salting out with potassium phosphate at different pH values; (b and c) scanning electron microscope (SEM) of silk particles produced by salting out with potassium phosphate (pH 8) from a silk fibroin solution of (b) 0.25 mg ml^{-1} and (c) 20 mg ml^{-1}; (d–f) confocal images of loading and distribution of model drugs in silk fibroin spheres prepared from silk/PVA blend solution. 2.212.6.2. Silk Particles from Lipid–Aqueous Separation

Lipid vesicles were used to encapsulate protein drugs in silk protein to form microspheres under mild processing conditions.[40] Freeze-thaw treatments were applied to generate small vesicles with homogeneous size distributions.[40] After lyophilization, the lipid templates were removed by methanol or sodium chloride (NaCl), and the encapsulated silk microspheres were concurrently induced to form beta-sheet crystalline structures to promote the entrapment of the protein drugs.[40] The MeOH-based microspheres had an average size of 1.7 μm, while the average size of NaCl-based microspheres decreased with time of NaCl treatment, from 2.7 μm (1 h) to 1.6 μm (15 h).[40]

2.212.6.3. Silk Particles from Rapid Laminar Jet

Large microspheres for protein drug release were fabricated using a laminar jet with aqueous silk solution,[89] using a nozzle vibrating at controlled frequency and amplitude. The silk particles produced in the process had diameters in the range of 101–440 μm,[89] depending on the diameter of the nozzle and the treatment to induce water insolubility of silk fibroin.

2.212.6.4. Silk Particles from Polymer Phase Separation

Recently, silk microspheres and nanoparticles were produced by phase separation.[82,84] For example, polyvinyl alcohol (PVA) and silk solutions were mixed and subsequently cast into films. Varying the molecular weight of PVA and the ratio between PVA and silk changed the macro- and microphase separation.[84] After film dissolution in water and removal of residual PVA by subsequent centrifugation, silk spheres were recovered with a broad size distribution ranging from 300 nm up to 20 μm, with approximately 30% beta-sheet crystallinity.[84]

2.212.6.5. Silk Particles from Organic–Aqueous Phase Separation

Using 70% (v/v) water-miscible protonic and polar aprotonic organic solvents, silk protein can form nanospheres in a size range of 35–125 nm.[85,90] Silk microspheres can also be prepared via mild self-assembly of silk fibroin molecular chains by adding ethanol and quenching below the freezing point,[90] as ethanol is a poor solvent for silk fibroin, but miscible with water. When a small amount of ethanol was added into the silk aqueous solution, silk fibroin molecules first formed small beta-sheet microcrystals,[90] acting as a seed for the growth of silk fibroin aggregates with continuous stirring. During the freezing procedure, the amorphous phase attached or entrapped the crystalline phase to form spheres. The particles had sizes ranging from 0.2 to 1.5 μm,[90] and the distribution of these silk particles was affected by the amount of ethanol, the freezing temperature, and the concentration of silk fibroin.[90]

2.212.6.6. Silk Particles from pH Variation

For engineered spider silk proteins, microspheres were produced by salting out a high concentration of potassium phosphate at different pH.[91] Sphere size and growth were controlled by protein concentration and mixing rate. The resulting microspheres reached an average size less than 300 nm.[91] Incorporation of active ingredients into spider silk microspheres was obtained by adding a solution with the desired molecules before microsphere formation.[91] A similar method was also applied to silk fibroin to form controllably sized silk microspheres.[86] The engineered spider silk protein could be also assembled at an oil–water interface to form microcapsules.[92] Microcapsules with sizes between 1 and 30 μm were produced by emulsifying the spider silk aqueous solution into toluene.[92]

2.212.6.7. Silk-Coated Polymer Particles

Other than producing pure silk microspheres and nanospheres, silk proteins were also used to coat polymer particles[39,40,80] such as lipid, poly(lactic-*co*-glycolic acid) (PLGA), and alginate microspheres, using an LbL assembly technique.[39] Silk fibroin coatings stabilized microspheres from degradation, but also significantly sustained protein drug release by providing a diffusion barrier with improved mechanical strength.[39] Drug release can be retarded further by controlling coating thickness and crystalline content.[39]

2.212.7. Silk Optical Biomaterials

Silk is the strongest and toughest natural material known and has excellent surface flatness and optical transparency.[93] Free-standing silk films, as large as 40 cm^2, with a thickness between 40 and 100 μm, have excellent transparency across the visible spectrum.[93] These properties are useful to generate functionalized biophotonic components in contrast to inorganic glasses and semiconductors or synthetic organic polymers, which require either chemical postprocessing or high temperatures that negatively affect biological dopants.[93] Silk-based biophotonic materials have been produced recently in a variety of studies for biomedical optics. Silk-based optical elements, which offer biodegradability and biocompatibility, have led to a new class of new devices that could be used in the human body (**Figure 7**).[93]

2.212.7.1. Silk Nano- and Micropatterned Optical Materials

Methods have been developed for the construction of silk fibroin-based nano- and micropatterned optical materials.[93–95] This process included methods to produce optical-grade ultrapure silk fibroin solution, the casting process for patterning silk fibroin films, and the characterization of the smallest nanopatterns in silk fibroin films realized to date.[93] Diffraction gratings on silk films can be formed by replicating holographic gratings with features ranging from 600 to 3600 grooves per millimeter, resulting in optical elements such as lenses, microlens arrays, or 2D diffractive optics.[94] Mechanically robust, optically transparent silk films capable of sub-40 nm transverse pattern resolution were also obtained.[95] By employing this technique, high-quality optical films containing intricate 2D and 3D nano- and micropatterns were fabricated,[95] useful as optical elements in a range of biomedical applications. For example, silk optical elements were used as optical transducers to monitor the spectral response of the embedded biochemical compound.[93]

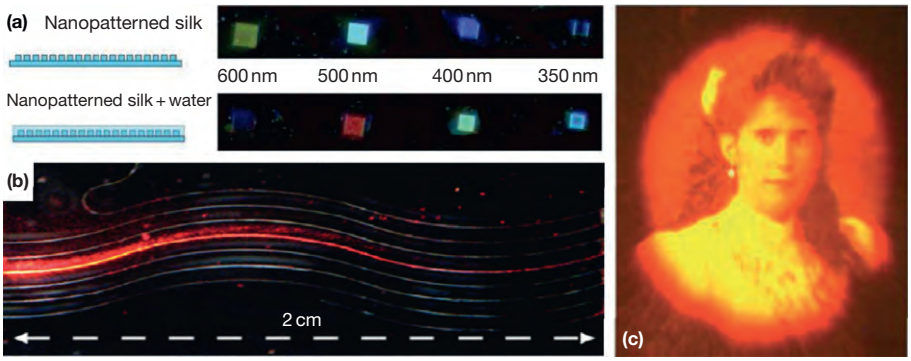

Figure 7 (a) Periodic imprinted nanoholes on silk films (200 nm in diameter and 30 nm deep), illuminated with a supercontinuum light source. The lattice constants vary as 600, 500, 400, and 350 nm. 2.212.7.2. Silk Optical Waveguides

Silk protein was used to generate optical waveguides through direct ink writing of pure or doped silk fibroin solution.[96] The printed silk protein waveguides retain a rod-like morphology by crystallization in a methanol-rich reservoir.[96] Both straight and wavy architectures of silk fibers were produced and found to guide laser light. These printed silk waveguides have potential applications for many optical devices, including implantable medical biomaterials that would resorb over time.[96]

2.212.7.3. Color-Controllable Silk Materials

Color-controllable nanopatterns in pure silk fibroin protein films were also achieved.[20,97] Periodic 2D lattices in silk films with feature sizes of hundreds of nanometers exhibited different colors as a function of varying lattice spacing.[20] Further, when varying the index of refraction contrast between the nanopatterned lattice and the surrounding environment by applying liquids on top of the lattices, colorimetric shifts are observed. This feature enabled silk materials to form a new class of 'biologically active optics,' which can serve as a low-index biosensor platform for integration with microfluidics and other systems as biomaterials.[20,97]

2.212.7.4. Silk-Based Cornea Tissue Engineering

Based on the development of 'silk optics,' cornea tissue engineering with silk biomaterials was also studied.[98,99] Silk protein films were used to replicate corneal stromal tissue architecture. The films emulated corneal collagen lamellae dimensions and were surface-patterned to guide cell alignment.[98] Micropatterns with pores in 0.5–5.0 μm diameter range were introduced in the silk films to enhance translamellar diffusion of nutrients and to promote cell–cell interactions.[99] Human and rabbit corneal fibroblast proliferation, alignment, and corneal ECM expression on these films in both 2D and 3D cultures were successfully demonstrated.[98,99] The mechanical properties, optical clarity, and surface pattern features of these films, combined with their ability to support corneal cell functions, suggested that silk biomaterial systems offer important potential benefits for corneal tissue regeneration.

2.212.8. Other Silk Materials

With the studies and applications of silk-based biomaterials as outlined in the prior sections, many advanced techniques and methods have been introduced in recent years. In this section, we briefly focus on several trends in producing new silk-based biomaterials, which may help to continue to foster growth with these proteins and other polymer systems (**Figure 8**).

2.212.8.1. Silk Microfluidic Devices

Silk can be used as a biomaterial for biomicroelectrical mechanical systems (BioMEMS), due to its biocompatibility, toughness, and slow predictable biodegradation rate. Recently, techniques and materials processing strategies utilized in the fabrication of cell-seeded silk fibroin microfluidic devices were developed.[23,100] Silk-based microfluidic devices promoted adhesion and function of seeded cells, and facilitated protein or growth factor incorporation under mild conditions.[23] Through soft-lithographic techniques, silk microfluidic devices were fabricated. Biocompatibility and functionality of patent devices with cells was studied by seeding and perfusion with human hepatocarcinoma cells.[23]

2.212.8.2. Secondary Structure Micropatterned Silk Materials

A technique for patterning silk secondary structure at the microscale was recently developed utilizing capillary transfer lithography (CTL).[101] A sacrificial polystyrene (PS) mask was first deposited onto a flat silk film. The masked silk film was then briefly exposed to methanol vapor, which induced a localized transition to beta-sheet crystal in the exposed regions.[101] After dissolving away the PS mask, a flat silk film with silk I and silk II regions alternating at the micrometer scale can be fabricated, such as a line pattern with a spacing of 10 μm or a checkerboard pattern with a spacing of 3 μm.[101] The microscale silk I and silk II regions retained their intrinsic chemical and mechanical characteristics and showed well-developed modulation of localized properties, which have potential for tissue engineering, such as patterned silk scaffolds

with uniform surface chemistry and variable mechanical properties or biodegradation.[101] Moreover, exposing the patterned silk I/silk II film to water resulted in selective dissolution of silk I regions, which can be extended to produce micropatterned silk materials in different geometries.[101] With the help of other microprinting techniques, such as inkjet printing, dip-pen lithography, nanosphere lithography, or photolithography, this method could be expanded to other surfaces with higher resolution and over larger areas.[101]

2.212.8.3. Direct-Write Silk Scaffolds

Direct ink-writing techniques were used to fabricate 3D, microperiodic scaffolds of regenerated silk fibroin.[102] Silk fibroin solution was treated as an 'ink' and deposited to become LbL 3D arrays of silk fibers, such as square lattice or circular webs, with diameters of individual fibers of 5 μm.[102] These scaffolds contained feature sizes that were significantly smaller than those produced by other rapid prototyping techniques.[102] Direct-write scaffolds used with hMSCs demonstrated support for cell adhesion and growth as well as enhanced chondrogenic differentiation.[102]

2.212.8.4. Chemically Modified Silk Materials

Although many attempts have been made for chemically modifying silk proteins, such as cyanuric chloride-activated coupling, enzyme-catalyzed reactions with tyrosinase, or sulfation of tyrosine residues with chlorosulfonic acid,[103,104] low reaction yield and a limited variety of functional groups for modification are challenging propositions. Recently, the chemical modification of silk chains using diazonium coupling chemistry was developed to tailor the structure and overall hydrophilicity of silk fibroin protein.[103,104] This reaction allows for the incorporation of a variety of functional groups using commercially available reagents. Five types of aniline derivatives, including carboxylic acid, amine, ketone, sulfonic acid, and alkyl functional groups, were used to modify the tyrosine side chains.[103] The introduction of hydrophobic functional groups promoted structural conversion of the protein from random coil to beta sheet, while the addition of hydrophilic groups inhibited this process.[103] When hydrophobic and hydrophilic silk derivatives were used as cell culture scaffolds, cells such as hMSCs displayed different growth rates and morphologies.[103] The cells were able to attach, proliferate-differentiate, and express osteogenic markers when subjected to osteogenic stimuli, regardless of the silk chemical modification.[103] These studies suggested that versatile chemistry could be widely useful for modifying silk structure and assembly, and providing new options of silk-based biomaterials.

2.212.9. Conclusions

Silk proteins have been exploited recently in a wide range of biomaterials. By processing into a diverse set of morphologies, such as films, nanofibers, microspheres, nanoparticles, hydrogels, or different micro-/nanopatterned devices, the potential

of silk-based biomaterials has expanded for potential biomedical applications. The versatility of silk proteins in terms of processing, including aqueous solutions, the biocompatibility, controllable *in vivo* biodegradation rate, along with the remarkably robust mechanical properties, prompt interest in the biomaterials generated from silk proteins. Further, the myriad of processing tools to control the structural state of silk proteins provide direct control over the mechanical properties and degradation lifetime of silk-based biomaterials. While we have emphasized more routine processing approaches, such as methanol and temperature treatments to crystallize silks, many other physical methods, such as electrical/dielectric field and electromagnetic fields, can induce beta-sheet crystallization in silk proteins, leading to new processing for silk--based biomaterials. We have also focused mainly on some of the more compelling biomaterial-related studies and applications with silk proteins, necessitating the omission of many studies and many areas of potential interest in the biomaterials field. For example, most studies on silk blending with other synthetic polymers and biomacromolecules have been omitted from this chapter.[105–107]

Glossary

Coacervation The process that results in the aggregation of molecules or colloidal particles under the action of electrostatic attractive forces.

Degree of acetylation (DA) Molar fraction of *N*-acetylated units in chitin/chitosan.

Electrospinning Technique used to produce nanofibers, based on the application of a sufficiently high voltage between a needle and a metallic collector, resulting in a very thin jet of fluid which is projected against a collector.

Endotoxin A toxin of internal origin. Endotoxins should be absent from chitosan used for biomedical applications.

Freeze-drying (of chitosan) Polymer solutions are frozen to temperatures that cause the formation of ice crystals, which are removed by sublimation under vacuum, producing a porous structure.

Freeze-gelling (of chitosan) A method alternative to freeze-drying to produce 3D-scaffolds. The method is based on freezing and subsequent extraction of the solution-rich phase by a nonsolvent for the polymer, while the polymer-rich phase is gelled under the action of a neutralizing agent.

Glycosaminoglycans A gel-forming repeating disaccharide units of the extracellular matrix.

Neuroma A growth or tumor of nerve tissue.

Polycation A macromolecule with many positively charged groups.

Polyelectrolyte complexes Self-assembled structures formed by reacting two oppositely charged polyelectrolytes in an aqueous solution.

Proteoglycans A constituent of the extracellular matrix resulting from the association of a protein and glycosaminoglycans.

Abbreviations

A	Absorbance
DA	Degree of acetylation
EC	Endothelial cells
ECM	Extracellular matrix
FN	Fibronectin
FT-IR	Fourier transform infrared spectroscopy
GAG	Glycosaminoglycan
H&E	Hematoxylin and Eosin
HA	Hyaluronic acid
HLC	Human-like collagen
IVD	Intervertebral disc
LbL	Layer-by-layer
M_n	Number average molecular weight
MSC	Mesenchymal stem cells
M_w	Weight average molecular weight
NMR	Nuclear magnetic resonance
PDGF	Platelet-derived growth factor
PECs	Polyelectrolyte complexes
PEO	Poly(ethylene oxide)
PLGA	Poly(lactic-*co*-glycolic acid)
PLLA	Poly(L-lactic acid)
SEC	Size exclusion chromatography
SEM	Scanning electron microscopy
TCP	Tricalcium phosphate
TGF-β1	Transforming growth factor beta 1
γ-PGA	Gamma-poly(glutamic acid)

2.213.1. Sources, Analysis, and Properties

2.213.1.1. Chemical Structure

Chitosan is a linear copolymer of D-glucosamine and *N*-acetyl-D-glucosamine in a β-(1–4) linkage, in which glucosamine is the predominant repeating unit (Figure 1). Chitosan itself may be found in the mycelia of certain fungi in association with other polysaccharides, but is mostly obtained by deacetylation of chitin. Chitin is the second most abundant polysaccharide in nature after cellulose, occurring in the cell walls of certain fungi[1] and yeasts, in plants as the equivalent to cellulose, and in many invertebrate groups such as mollusks and arthropods as the fibrous support of the inorganic mineral phase of their exoskeleton, as an alternative to collagen.[1] Chitin is a high molecular weight crystalline polysaccharide, which is theoretically comprised entirely of *N*-acetylated D-glucosamine units. Naturally occurring chitin, however, is mostly present as a copolymer, containing different proportions of *N*-glucosamine units, dependent on the source.[2] In chitin, the chains are arranged in sheets or stacks, the chains of each sheet having the same direction and being bonded through intrasheet hydrogen bonds between two adjacent chains. Naturally occurring chitins are found in three polymorphic forms, α-, β-, and γ-chitin, which differ in the arrangement of chains within the crystalline regions. In α-chitin, which is the one found in crab, lobster, and shrimp shells, adjacent sheets have opposite directions, and thus it has an antiparallel chain arrangement. In β-chitin, which is the form occurring in the pen of the squid genus *Loligo*, adjacent sheets have the same direction, and thus it has a parallel chain arrangement. In γ-chitin, every third sheet has the opposite direction to the previous two sheets. In addition to intrasheet interchain hydrogen bonds, α-chitin also presents hydrogen bonds between adjacent chains. These intersheet bondings are responsible for the lack of swelling in water of α-chitin, whereas β-chitin swells readily in water and forms hydrates.[2] Chitosan is also crystalline, but as compared to chitin, presents a longer distance between adjacent chains belonging to the same sheet, due to the removal of the *N*-acetyl groups during the conversion from chitin to chitosan, which hold together adjacent chains through C(2)N–H···O=C(7) hydrogen bonds.[2] Instant differentiation between chitin and chitosan can be made based on their solubility. While chitin is soluble in *N*,*N*-dimethylacetamide (DMAc) in the presence of 5–10% (w/v) lithium chloride and insoluble in dilute acid solutions, the reverse is true for chitosan.[2,3] In chitin/chitosan terminology, the molar fraction of *N*-acetylated units is termed the degree of acetylation (DA), expressed in percentage, or fraction of *N*-acetylated units (F_A).[4,5] Since a DA around or lower than 50% is usually required for chitosan solubility in dilute acidic solutions, the term chitosan is applied both to fully-deacetylated chitin and partially deacetylated chitin with DAs $\leq$ 50%.

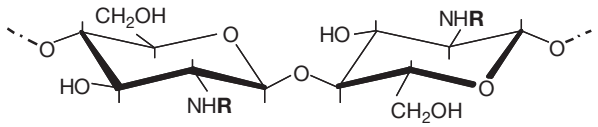

Figure 1 Chemical structure of chitosan, a linear copolymer of D-glucosamine (R=H) and *N*-acetyl D-glucosamine (R = $COCH_3$) in a β-(1–4) linkage. Glucosamine is the predominant repeating unit.

2.213.1.2. Solution Properties

Chitosan is neither soluble in water nor in organic solvents. However, after protonation of amine functionalities from glucosamine units by acid, the electrostatic repulsions between NH_3^+ groups lead to the destruction of interchain attractive interactions, such as hydrogen bonds and hydrophobic interactions, and consequently to chitosan solubility. At pH lower than its pK_a, which may range from ~6.5 to ~7, chitosan is a polycation and at pH 4.0 and below, it is completely protonated.[6] Chitosan solubility depends on chitosan charge density, which is tightly connected with structural parameters such as DA, chain length, and distribution of *N*-acetylated glucosamine units, as well as on environmental parameters, such as pH, ionic strength, and dielectric constant of the media.[7] The solubility range increases on increasing the DA, due to the increase of the steric hindrance related to the increase of the number of the acetyl groups, together with the increase of the intrinsic pK_a. According to Sorlier *et al.*,[6] the intrinsic pK_a of chitosan increases from 6.46 to 6.8 as the DA increases from 5% to 35%, respectively, revealing an increase of

cationicity of amine functionalities on increasing the DA. As a result, chitosans with DAs in the range of 45–55% are water-soluble, providing that the *N*-acetylated units are randomly distributed. In the presence of high ionic strengths, solubility is reduced. The high concentration of protons leads to the screening of the electrostatic interactions occurring between polymeric chains, with subsequent establishment of chain interactions and polymer precipitation. As a result, chitosan is not soluble in strong acids such as hydrochloric acid solutions with molarities higher than 0.1 M.[7]

2.213.1.3. Chitosan Preparation: Chitin Isolation and *N*-deacetylation

Commercially available chitin is most commonly prepared from the exoskeletons of crab, shrimp, and prawn, obtained as waste from the seafood processing industry. In these, chitin is tightly associated with proteins, inorganic material (mainly $CaCO_3$), pigments, and lipids. Deproteinization and demineralization are generally carried out by treatment with 1–2 M NaOH at 70 °C or higher temperature, and 1.25 M HCl at room temperature, respectively, deproteinization being usually done prior to demineralization. Both treatments may lead to the cleavage of chitin polymeric chains. In this sense, a number of alternative methods have been proposed in order to minimize the hydrolysis of glycosidic linkages during chitin extraction, including the use of proteolytic enzymes to remove protein and EDTA to remove mineral. Finally, the pigments present in the exoskeletons of crustaceans can be extracted with ethanol, acetone, or oxidizing agents such as $KMnO_4$.[2] The preparation of squid chitin, although similar, occurs under milder conditions, as β-chitin is composed exclusively of chitin and proteins, with only traces of metal salts.[8]

Deacetylation may be carried out under acid or basic conditions, but basic conditions are preferred, due to the susceptibility of chitin glycosidic linkages to acid hydrolysis. The deacetylation of α-chitin is usually carried out using strong aqueous bases at 90–150 °C for a few hours, to produce chitosan with a DA between 5% and 30%.[2,4,5,9] High reaction temperatures reduce the time required for deacetylation, but result in increased hydrolysis of polymeric chains. Deacetylation of chitin proceeds rapidly in 50% (w/v) aqueous NaOH at 100 °C during the first hour of alkali treatment, but extension of the reaction time results rather in chain hydrolysis than in significant deacetylation.[2] To obtain chitosans with low DAs (<15%), multistep alkali treatments with interspersed washing are required.[10] The washing with water in-between treatments induces the swelling of chitin chains, and increases the accessibility of chitin for subsequent deacetylation. In order to reduce chain cleavage during alkaline deacetylation, reactions are carried out at as low temperature as possible, under inert atmosphere, such as nitrogen or argon, or in the presence of oxygen scavengers or reducing agents, such as $NaBH_4$. As chitin is not soluble in such systems, deacetylation occurs under heterogeneous conditions. During deacetylation of α-chitin, NaOH acts initially on the amorphous regions of the polymer, and only afterwards on the crystalline regions. Heterogeneous deacetylation leads therefore to a block distribution of acetylated units, rather than a random distribution of the same. As a result, the characteristic infrared (IR) bands attributed to crystallinization of blocks of poly [β-(1→4) D-glucosamine] are only perceptible for DAs ≤ 9%, due to the later deacetylation of segments originally present in the crystalline region of chitin.[2,10] As compared to α-chitin, β-chitin present in squid pens is much easier to deacetylate, due to the absence of intersheet hydrogen bonding, which makes crystalline regions more accessible to reactives.[9] During deacetylation of β-chitin, the crystallinity decreases rapidly compared to that of α-chitin, and a completely amorphous product is obtained.[11]

Chitosan isolated from the cell walls of fungi have recently become commercially available.[12] As compared to chitosan obtained from marine animal resources, chitosan isolated from fungi cultured under controlled growing conditions presents higher reproducibility among batches and traceability, which makes its use in medical and pharmaceutical applications interesting.

'As received' chitosans are often subjected to purification steps, mainly to reduce the content of insoluble matter. The most frequently used method involves the filtration of chitosan acidic solutions to remove undissolved or gelatinous particles and the subsequent precipitation in an alkaline solution. The regenerated chitosan is then thoroughly washed in distilled water and finally freeze-dried. Precipitation by addition of NaOH under rapid stirring leads to a product with a high crystallinity index after drying, the so-called microcrystalline chitosan.[13]

Chitosans with specific DAs can be prepared by *N*-acetylation of almost fully-deacetylated chitosans.[9] Chitosan *N*-acetylation is usually carried out at room temperature and under homogeneous conditions, leading to the random introduction of acetyl groups with minimal hydrolysis of polymeric chains. This involves the dissolution of chitosan in a diluted acidic solution, prior to adding a cosolvent and a variable amount of the acetylating reactive, acetic anhydride.[14] The acetylation of chitosan under homogeneous conditions is also very useful to prepare water-soluble chitosans.

2.213.1.4. Chitosan Characterization

Regardless of the application envisaged, the degree of *N*-acetylation (DA) and the average molecular weight are the parameters most frequently assessed due to their impact on chitosan properties. Crystallinity, viscosity in aqueous solutions, dry matter content, amount of insoluble impurities, and ash content, are other parameters commonly analyzed. For the application of chitosan as a biomaterial, its characterization in terms of microbial contamination (bioburden), toxic heavy metals, protein content, and bacterial endotoxin levels is of crucial importance. For this purpose, the American Society for Testing and Materials (ASTM) has established standard guidelines for the characterization and testing of chitosan for use in biomedical and tissue-engineered medical product applications.[15] The two most important parameters affecting chitosan properties are discussed below.

2.213.1.4.1. Degree of acetylation

The DA is a structural parameter influencing charge density, crystallinity, solubility, as well as chitosan susceptibility to enzymatic degradability. Therefore, its accurate determination is of major importance. A number of methods have been developed for the determination of the DA of chitosan,

including elemental analysis, colloid titration with a polyanion, dye adsorption, and spectroscopies such as ultraviolet (UV), IR, and liquid/solid state nuclear magnetic resonance (NMR). The advantages and drawbacks of each technique have been discussed.[2,4,5] Among these, high-resolution proton NMR (^{1}H NMR) is considered the most accurate technique for the determination of the DA of chitosan. ^{1}H NMR is usually performed in D_2O containing DCl, the DA value being determined from the relative integrals of acetyl (*N*-acetyl and AcOH) and combined H2–H6 protons.[16,17] For chitosans with high acetyl contents, the use of solid state ^{13}C CP/MAS NMR is preferred to ^{1}H NMR, since complete dissolution of the sample prior to analysis is required for ^{1}H NMR. Because of its simplicity associated with accuracy, IR spectroscopy is the most frequently used technique. The use of FT-IR spectroscopy for the determination of the DA is based on the variation of an absorbance band characteristic of *N*-acetyl groups, as a function of an internal reference band. The DA value can be extrapolated from a calibration curve established using an absolute technique, such as NMR. A number of different methods have been proposed, differing in terms of the analytical and reference IR bands used, as well as in terms of the baselines used for the determination of the correspondent absorbance values.[18] One of the most frequently employed method is the one described by Baxter *et al.*[19] It uses the amide I band at 1655 cm^{-1} as the analytical band (the baseline is the one originally proposed for the A_{1655}/A_{2867} ratio) and the hydroxyl band at 3450 cm^{-1} as the internal reference band. The sample has, therefore, to be perfectly dry and the IR spectra immediately recorded. The DA is determined as follows:

$$DA(\%) = (A_{1655}/A_{3450}) \times 115$$

This relation was validated by dye adsorption, for DAs comprised between 0 and 55%. Later on, Brugnerotto *et al.*[20] proposed the use of the amide III band (C–N stretching coupled with N–H in plane deformation) at 1320 cm^{-1} as the analytical band and the band at 1420 cm^{-1} as the internal reference band. The authors analyzed chitin/chitosan samples covering the entire range of DAs, and used samples from different sources. A very good linear correlation between the ratio of absorbance bands (A_{1320}/A_{1420}) and the experimental values obtained from NMR was found in all the range of DA values, which could be expressed by the following relation:

$$A_{1320}/A_{1420} = 0.3822 + 0.03133 \times DA(\%)$$

Brugnerotto *et al.* found superior agreement between the experimental and estimated DA values using this ratio of absorbance bands than those involving the band at 3450 cm^{-1} (Figure 2).

2.213.1.4.2. Molecular weight

Depending on its source and preparation procedure, chitosan molecular weight may range from 300 to over than 1000 kD, squid pen chitosans presenting usually higher molecular weight, as compared to chitosans obtained from the exoskeletons of crustaceans.[21] Several techniques can be used to estimate the average molecular weight of chitosan. Among them are capillary viscometry, ultracentrifugation, and size exclusion chromatography (SEC) coupled with light scattering. Whatever the technique used, the tendency of the polymer chains to aggregate in solution constitutes a problem.[2,22] SEC is the most direct one, providing, in a single measurement, the weight-average molecular weight and the number-average molecular weight. From these two values, the polydispersity

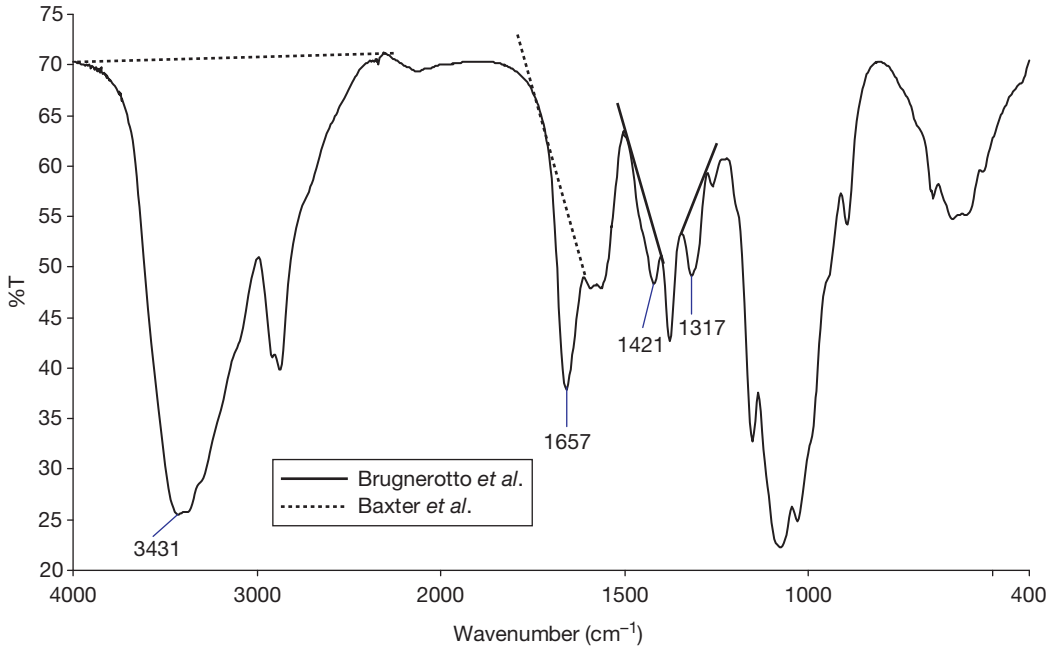

Figure 2 Squid pen chitosan infrared spectra, showing the baselines proposed by Brugnerotto *et al.*[20] and Baxter *et al.*[19] for the determination of the A_{1320}/A_{1420} and A_{1655}/A_{3450} ratio, respectively.

index Mw/Mn can be easily determined. Still, this technique requires previous calibration of the SEC system with narrow polydispersity standards of known molecular weight. The association of a light-scattering detector with SEC provides information on the absolute molecular weight as well as on molecular size parameters, such as the radius of gyration Rg. The analysis is usually performed using CH_3COOH/CH_3COONa buffers at pH near 4.5 as mobile phase, salt being added to screen electrostatic repulsion between protonated amine groups in chitosan.[23] For the analysis, the refractive index increment value (dn/dC) of chitosan in the CH_3COONa/CH_3COOH system used is required. The dn/dC values for chitosan may be found in literature, including some that are dependent on the DA.[24] In this case, previous characterization of the DA may be required. Alternatively and if possible, the dn/dC value can be measured using a differential refractometer. SEC coupled with light scattering is also the technique described in ASTM guidelines for the determination of chitosan molecular weight.

2.213.1.5. General Aspects of Biological Behavior

2.213.1.5.1. Biocompatibility

One of the major issues that have to be addressed while envisaging biomedical applications of a biomaterial is biocompatibility. The nontoxicity of chitosan films was initially showed by Rao and Sharma[25] using standard *in vivo* toxicological tests to evaluate chitosan safety and haemostatic potential. The biocompatibility of films with different DAs was examined by Tomihata and Ikada,[26] using a rat subcutaneous implant model. While chitosan films with DA 31% induced a relatively severe inflammatory reaction, with almost complete resorption after 4 weeks of implantation, films with lower DAs led to a lower inflammatory reaction and degraded at a slower rate. Films with DAs $\leq$ 16% showed a very mild tissue reaction. The biocompatibility of chitosan porous scaffolds (DA 8%) was addressed by VandeVord *et al.*,[27] using a mouse intraperitoneal and subcutaneous implant model. Histological assessment revealed an early migration of neutrophils into the implantation area, which resolved over implantation time. Besides this early accumulation of neutrophils, which are cells usually associated with acute inflammation, no evidence of other signs associated with an inflammatory response, such as erytema and edema, were found. A very low incidence of chitosan-specific immune reactions was observed and, with time, collagen deposition within and surrounding the implant, with capsule formation, was found. However, the capsule was always highly cellular and its thickness decreased over time. Angiogenic activity associated with the external implant surface was observed. Overall, chitosan with DA 8% was found to have a high degree of biocompatibility. Recently, we assessed the inflammatory response to chitosan porous scaffolds with two different DAs (DA 4% and DA 15%) using a subcutaneous air-pouch model of inflammation.[28] Implantation of chitosan scaffolds with DA 15% induced a higher recruitment of neutrophils and increased adhesion of inflammatory cells during the early phase of implantation, while DA 4% merely caused a slight increase in the number of leukocytes present in the inflammatory exudates. With time, chitosan scaffolds with DA 15% induced the formation of a thicker collagenous capsule and a high infiltration of inflammatory cells within the scaffold. Since inflammation and healing are interrelated, these results showed the importance of the careful selection of the DA while developing chitosan porous implants for tissue repair and regeneration.

2.213.1.5.2. Cytocompatibility

A wide number of cells have been successfully cultured on 2D and 3D chitosan matrices envisaging cell-based regenerative therapies, among them keratinocytes,[29] chondrocytes,[30,31] osteoblasts,[32–34] hepatocytes,[35] and Schwann cells.[36] The DA was found to be an important parameter affecting cell adhesion, lower DAs favoring cell adhesion. This effect was reported for a number of anchorage-dependent cells, such as keratinocytes,[29] fibroblasts,[29,37] dorsal root ganglion neurons,[38,39] and Schwann cells.[40] In our lab, we investigated the DA effect on the behavior of osteogenic cells on chitosan films and porous matrices, using DAs in the range of 4–49%.[32,33,41,42] These studies revealed a similar tendency to increased cell adhesion on decreasing the DA, and showed that differences in the DA as small as 9% can be critical in terms of osteoblastic response to chitosan.[41,42] For instance, in the case of rat bone marrow stromal cells, cell adhesion, cytoskeleton organization, proliferation, and osteogenic differentiation were only observed on chitosan with DA 4%, while the same were hampered on chitosans with higher DAs ($\geq$13%). We hypothesize that the DA could influence cell adhesion and osteoblast differentiation by influencing the adsorbed layer of adhesion proteins. For that, we performed protein adsorption studies using ^{125}I-fibronectin. In line with the higher cell adhesion levels found, chitosan with DA 4% showed the highest fibronectin (FN) adsorption both from a single FN protein solution and from diluted serum.[32,33] From these results we may speculate that protonated amine groups from glucosamine units in chitosan may modulate cell adhesion to chitosan by promoting the adsorption of cell adhesive proteins such as FN.

To improve cell behavior on chitosan matrices, several attempts have been made, including physiadsorption of adhesive proteins[43] and covalent binding of cell adhesion peptides.[44,45] For instance, endothelial cell (EC) adhesion to porous chitosan matrices is significantly enhanced upon previous incubation of chitosan matrices in an FN solution.[46] Interestingly, we found that EC adhesion to FN-coated chitosan matrices is also dependent on the DA. While cell adhesion was impaired on DA 15%, ECs were able to adhere, spread, and colonize chitosan matrices with DA 4%. Later on, protein adsorption studies on scaffolds with DA 4% revealed a higher number of exposed FN cell-binding domains, as well as greater ability to adsorb FN and to retain and exchange adsorbed FN in the presence of competitive proteins, in agreement with the higher cell numbers found.

2.213.1.5.3. Bacteriostatic and fungostatic properties

Chitosan exhibits an intrinsic antibacterial activity, inhibiting bacteria and fungi growth. As an example, in *Staphylococcus aureus* cultures, chitosan treatment promotes structural changes in the so-called membrane–wall complex leading to the impairment of surface cell structures and to bacterial

death.[47] The biological mechanisms underlying this property remain poorly understood. Bacterial growth inhibition is believed to be related to chitosan ability to establish electrostatic interactions between chitosan cationic amino groups and anions, such as *N*-acetylmuramic acid, sialic acid, and neuraminic acid, present on the bacterial cell wall. In addition to electrostatic interactions, hydrophobic interactions resultant from the presence of *N*-acetylated residues in chitosan are also thought to contribute to chitosan bacteriostatic properties, highly acetylated chitosans being reported to be excellent flocculants of *Escherichia coli* suspensions.[48]

2.213.1.5.4. Enzymatic degradation

In nature, chitosan can be hydrolysed by chitinases, chitosanases, and lysozymes, as well as by nonspecific hydrolases, such as α-amilases and lipases. In addition, like all polysaccharides, chitosan is vulnerable to acid hydrolysis and to oxidative–reductive depolymerization reactions.[49,50] In *vivo*, the human enzymes involved in chitosan hydrolysis are only partially known.

In human serum partially, *N*-acetylated chitosans are mainly depolymerized by lysozyme.[50] Lysozyme is normally present in the human serum, saliva, and other fluids, hydrolyzing preferentially the β-(1–4) glicosidic linkages between *N*-acetylglucosamine (NAGA) and *N*-acetylmuramic acid residues that occur in the cell walls of bacteria. Therefore, in addition to its natural substrate, lysozyme can hydrolyse partially *N*-acetylated chitosans. The active site of lysozyme binds six sugar rings, and three consecutive *N*-acetyl-D-glucosamine residues are required for lysozyme catalytic activity.[51] As a consequence, the susceptibility of chitosan to lysozyme depolymerization *in vitro* depends not only on the DA but also on the distribution of *N*-acetylated units along chitosan chains. The initial degradation rate increases with the DA, and this increase is more pronounced for *N*-acetylated chitosans prepared under homogeneous conditions than for chitosans obtained by heterogeneous deacetylation.[50,52] The same trend was observed *in vivo* upon subcutaneous implantation of chitosan films in a rat animal model.[26] Chitosans with low DAs may last several months *in vivo*.[27] Crystallinity is another parameter significantly influencing chitosan susceptibility to lysozyme hydrolysis, by reducing lysozyme accessibility to the substrate. For instance, the low degradation rates reported for chitosans with very low DAs have been frequently associated with the high levels of crystallinity and inter-molecular bindings present in these chitosans.[26,27] Finally, chitosan solubility may eventually shade the effect of lysozyme on chitosan degradation. This is the case of the accelerated mass loss observed for chitosans with DAs close to 50%, attributed to the enhanced solubility of chitosan molecules at physiologic pH.[38,39]

The enzymatic hydrolysis of chitosan in wound-healing process was addressed by Muzarelli.[49] Upon hydrolysis of chitosan by lysozyme, the oligomers released activate macrophages, inducing the production of diffusible molecules, such as interferon, tumor necrosis factor-α, and interleukin-1. Activated macrophages secrete more lysozyme as well as *N*-acetyl-β-D-glucosaminidase and chitinase, which further catalyze the depolymerization of chitosan into monomers. These become available for further incorporation into hyaluronate, keratan sulfate, and chondroitin sulfate.

2.213.1.5.5. Immunoadjuvancy

Chitosan is chemotactic for neutrophils, which has been attributed to specific interactions of chitosan or its oligosaccharides with neutrophils receptors, such as selectins.[27] In addition to being chemotactic to neutrophils, chitosan shows a biological aptitude for activating macrophages for tumoricidal activity and for production of interleukin-1,[53] as well as nitric oxide.[54] The immunoadjuvant properties of chitosan have been attributed to the NAGA units, rather than to the glucosamine units. Macrophage activation appears to be dependent on binding of NAGA to specific cell membrane receptors, namely involved in the binding of mannose- and NAGA-glycoproteins.[54]

2.213.1.5.6. Hemostatic and blood clotting properties

Chitosan is a powerful hemostatic agent[25] that induces blood clotting, even in the presence of extensive anticoagulation therapy.[55] Blood clotting was suggested to be related to the possible formation of polyelectrolyte complexes (PECs), involving chitosan amino functionalities and negatively charged acidic groups present at the surface of erytrocytes. Benesch and Tengvall[56] suggested that the procoagulant activity of chitosan could be related to the ability of chitosan to bind fibrinogen. In contrast, chitin displays anticoagulant properties, increasing upon *O*-sulfation,[57] which is attributed to its similarity to heparin, a naturally occurring sulfated glycosaminoglycan (GAG) used as anticoagulant agent in clinic.

2.213.1.5.7. Cell-binding properties

Chitosan is able to agglutinate a variety of mammalian cells in suspension. Cell adhesion to chitosan is attributed to nonspecific electrostatic interactions occurring directly between protonated amine groups from glucosamine units and negatively charged carboxylate and sulfate groups found in cell surface proteoglycans.[29,58] Close to the physiologic pH, the majority of chitosan ammonium groups are dissociated and subsequently uncharged. Still, the presence of a small amount of nondissociated ammonium groups in chitosan chains is sufficient to provide enough cationic sites and allow the establishment of electrostatic interactions.[30]

2.213.1.5.8. Wound-healing properties

Chitosan has been found to accelerate dermal wound healing and inhibit fibroplasia, showing a biological aptitude to stimulate cell proliferation and the deposition of an orderly organized connective tissue.[59] This behavior has been related to chitosan ability to activate macrophages for cytokine production (transforming growth factor beta 1 (TGF-β1) and platelet-derived growth factor (PDGF)), upon hydrolysis by lysozyme.[60,61] Moreover, Howling *et al.*[62] suggested that chitosan may interact with growth factors present in serum, potentiating their effect, as chitosan has a stimulatory effect on dermal fibroblast proliferation when added to serum-containing culture medium, highly deacetylated chitosans producing a stronger mitogenic response, as compared to samples with lower levels of deacetylation.

2.213.1.5.9. Bone-healing properties

The osteogenic potential of chitosan was first reported by Borah *et al.*[63] in 1992. In this study, chitosan was used to

treat bone defects, made in the endochondral long bones of the rabbit. Chitosan reportedly stimulated osteogenesis with closure of the critical size bone defects, as compared to controls, in 8–12 weeks. As time progressed, the possible osteogenic, osteoconducting, and osteoinducting properties became the subject of investigation. The most significant works demonstrating the osteoconductive properties of chitosan are possibly those carried out by Muzarelli *et al.*[64,65] In the first work, Muzzarelli *et al.*[65] treated bone defects made in the tibiae of rabbits with freeze-dried methyl pyrrolidinone chitosan. The experimental sites showed signs of neoformed bone tissue, as opposed to controls, originating from the preexisting bone, as well as from the periosteum. Subsequently, Muzzarelli *et al.* prepared a modified chitosan (DA 8%) carrying imidazole groups, to treat bone defects made in the femoral condyle of sheep. Within 40 days after surgery, the neoformed tissue occluded the surgical hole and assumed a trabecular structure in the peripheral area of the lesion. In the control group, no sign of ostegenesis or reparative process was observed and bone marrow was rich in adipocytes. The modified chitosan was reported to have a stimulatory effect on bone formation. Although several works have demonstrated the osteoconductive properties of chitosan, it was often combined with therapeutic molecules, growth factors, or calcium phosphates. The bone regenerative properties of unmodified chitosan are reported in a study of Park *et al.*[66] In this study, unmodified and PDGF-releasing chitosan sponges were applied to rat calvarial defects. Both matrices led to a significant increase in new bone formation, as compared to untreated defects, which became completely filled with fibrous connective tissue. In addition, a marked increase of bone formation and mineralization was observed in the presence of PDGF, as expected. The subsequent studies of Lee *et al.*[67] supported these results. The effect of the DA on osteogenesis was addressed by Hidaka *et al.*,[68] who implanted subperiosteally over the calvaria of rats membranes prepared from hydroxyapatite and chitosan. DAs of 0, 6, 20, 30, and 35% were used. The authors reported for DAs $\geq$ 20% a marked inflammatory reaction, followed by accumulation of osteocalcin positive cells at the site of implantation, while for lower DAs a mild inflammation with minimal osteogenesis was observed.

2.213.1.6. Chitosan Functionalization

Chitosan has both reactive amino or amido groups at C(2) positions, as well as primary and secondary hydroxyl groups at C(6) and C(3) positions which can be used to prepare derivatives with well-defined structures and biological properties under mild reaction conditions. Two modification reactions were already addressed in this chapter, namely deacetylation and *N*-acetylation. Other chemical modifications often explored to prepare versatile precursors and chitosan derivatives for biomedical applications include other acylation reactions, *N*-phthaloylation, Schiff's base formation, *N*,*O*-carboxymethylation, *N*-carboxyalkylation, and graft copolymerization.[2,9] Graft copolymerization, in particular, has been extensively used to introduce side chains onto chitosan, namely to obtain tailored hybrid materials composed of natural polysaccharides and synthetic polymers.

2.213.2. Processing

Chitosan is extremely versatile in terms of processing. Films, micro- and nanoparticles, porous scaffolds, micro- and nanofibers, and meshes can be produced with chitosan for a wide range of applications.

2.213.2.1. Films and Porous Scaffolds (Freeze-Drying and Freeze-Gelling)

Taking advantage of the solubility of chitosan in mildly acidic conditions, films can be produced by casting the resulting gel on a flat surface and then allowing the solvent to evaporate. Neutralization with an alkaline solution, washing, and drying are often employed to stabilize the films. These can then be used as substrates for cell culture experiments.

Porous scaffolds can be prepared by freeze-drying, also known as lyophilization. Acidic chitosan solutions are frozen to temperatures of −20 to −80 °C, which causes formation of ice crystals. The rate and temperature of freezing influence the size of the ice crystals and consequently the size of the pores formed during the sublimation phase. The latter is carried out in a vacuum at low temperature, in order to avoid melting of the chitosan-rich phase. After elimination of the ice crystals, drying can be continued to eliminate unfrozen water molecules. Pores with dimensions in the range 40–250 mm and porosities of 80% can be obtained. By applying a temperature gradient along a certain direction, preferential orientation of the pores can be obtained to produce structures with aligned porosity. **Figure 3** presents laser scanning confocal and scanning electron microscopy (SEM) images of chitosan sponges with two DAs (4% and 30%), which have been colonized by MG-63 cells.[42] It shows that a better spreading is reached with the lower DA.

In some cases, the freeze-drying method can damage the pore walls during evaporation of the solvent. Also, formation of skin can also occur. To avoid these problems, the method of freeze-gelling has been proposed for producing porous structures of poly(L-lactic acid) (PLLA), poly(lactic-*co*-glycolic acid) (PLGA), chitosan, and alginate.[69] The method is based on the extraction of the solution-rich phase by a nonsolvent for the polymer. Exemplifying for the case of chitosan, the procedure is the following. An acetic acid solution of chitosan is frozen to −20 °C, which causes the formation of ice crystals. To form the pores, the ice crystals are removed by immersing the frozen chitosan solution in an NaOH/ethanol solution at −20 °C. Neutralization of the acid by the sodium hydroxide causes the gelation of chitosan, whereas the ethanol dissolves the ice crystals. Subsequent evaporation of the ethanol at room temperature produces the pores. The method has also been applied to produce composite scaffolds of chitosan and gamma-poly (glutamic acid) (γ-PGA) for the delivery of rhBMP-2.[70] Concentrations of chitosan and γ-PGA were 4% and 1%, respectively, in a 0.2 M acetic acid solution. Freezing was done at −80 °C and gelation was achieved by immersing the frozen chitosan/γ-PGA in a 3-M NaOH/ethanol solution at −20 °C.

2.213.2.2. Nanofibers

Nanofibers of chitosan can be produced by electrospinning. This technique has become extremely useful for the

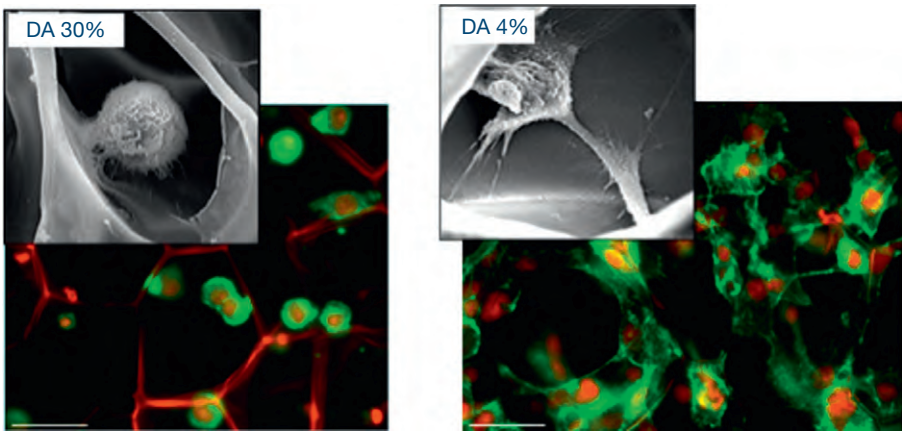

Figure 3 Fluorescence microscopy and scanning electron microscopic images of MG-63 cells cultured in chitosan sponges with different DAs. Red lines: chitosan walls of the pores; nuclei were stained with propidium iodide (red) and actin filaments with Alexa Fluor^{R} 488 phalloidin (green). Adapted from Amaral, I. preparation of nanofibers for tissue engineering, due to the wide range of polymers that can be processed to obtain nanofibers with diameters in the range 20–400 nm. Briefly, the application of a sufficiently high voltage between a needle and a metallic collector overcomes the surface tension holding a drop of liquid at the tip of the needle, resulting in a very thin jet of fluid being projected against the collector. The solvent is evaporated during the trajectory between needle and collector, resulting in a nonwoven structure. One of problems with electrospun meshes is the slow cell infiltration due to the high packing density of the nanofibers. To circumvent this problem fast degrading nanofibers can be combined with slow degrading fibers. This strategy has been developed by,[71] who have co-electrospun poly(epsilon-caprolactone) with poly(ethylene oxide) (PEO) from two separate spinnerets. The former polymer is slowly degradable, whereas the second one is water-soluble, acting as a sacrificial component of the scaffold. Seeding these scaffolds with mesenchymal stem cells (MSCs) has show that cell infiltration improved with the fraction of sacrificial polymer. High porosities (of the order of 95% to 97%) can be obtained also by coating microfibers with nanofibers, as demonstrated by.[72] Scaffolds made from polycaprolactone nanofibers electrospun onto polylactic acid microfibers supported infiltration of human chondrocytes, with higher porosities favoring cell infiltration.

2.213.2.3. Polyelectrolyte Complexes

The self-assembly of polymer chains due to electrostatic interactions is the basis for the formation of PECs. PECs are formed by reacting two oppositely charged polyelectrolytes in an aqueous solution. PECs are generally biocompatible networks and can be easily produced in the lab. PECs between chitosan and many polyanions have been described. Polysaccharides such as alginate, chondroitin sulfate, dextran sulfate and gellum gum form PECs with chitosan. Similarly, polyamino acids (e.g., poly-L-Lysine and poly(aspartic acid)), proteins (e.g., collagen), and glycosoaminoglycans (e.g., hyaluronic acid, HA) also bind electrostatically to chitosan, via anionic carboxylic or sulfate groups. The cationic amino groups of chitosan are responsible for the formation of electrostatic bonds with the anionic groups of the other polyelectrolyte. The formation of PEC hydrogels requires that the two polymers are oppositely charged. Since the pK_a of chitosan is in the vicinity of 6.5, the other polymer must have a lower pK_a for electrostatic aggregation to occur. If attraction is too strong, a precipitate, and not a hydrogel, will form. By modifying the ionic strength of the aqueous solution, for example, by addition of salts such as NaCl, the electrostatic interactions can be modulated so that a homogeneous hydrogel is formed. Functionalization of chitosan with positively charged (e.g., glycol–chitosan[73]), or negatively charged (e.g., sulfate[32,33]) groups expands the range of PECs that can be produced. Since no cross-linkers are required to form the hydrogel, these materials usually have excellent cytocompatibilty.

Using the principles that govern PEC formation, a film can be produced using the layer-by-layer (LbL) method, by alternate immersion of a substrate in solutions of positively and negatively charged polyelectrolytes. LbL films are usually very thin (typically $<1\mu m$). For larger thicknesses, the alternating layer structure becomes progressively disorganized due to interpenetration of the polymers chains. Polyelectrolyte multilayer (PEM) coatings of chitosan (Ch) and HA have shown varying degrees of resistance to enzymatic degradation, depending on whether they were used in the native state or cross-linked with 1-ethyl-3-(3-dimethylamino-propyl)carbodiimide (EDC).[74] The *in vitro* and *in vivo* degradation rate also depended on the molecular weight of chitosan, lower rates being obtained with the higher molecular weight chitosan. The same polymers have been used to produce self-assembled multilayers, by modifying them with DNA base pairs: chitosan with adenine and HA with thymine.[75] No cytotoxicity was reported. Stabilization of LbL films by cross-linking does not appear to always have the same effect on cells. Genipin, which is a nontoxic natural cross-linker, has been used in Ch/HA and Ch/alginate(Alg) films.[76] Cross-linking impaired the adhesion of MC3T3 preosteoblasts and rat fibroblast skin cells to Ch/HA multilayers (3, 5, and 10 bilayers), whereas for Ch/Alg substrates it caused the reverse effect. For high number of

bilayers and using higher concentrations of cross-linker, the effect on adhesion was more pronounced.

2.213.2.4. Micro- and Nanoparticles

Micro- and nanoparticles of chitosan can be prepared by various methods. The most common method consists in ionotropic gelation of chitosan molecules by anions, such as the polyanion tripolyphosphate (TPP)[77] and sulfate.[78] The experimental procedure involves drop-wise addition of the anion to a chitosan solution under agitation. Agitation can be performed mechanically, ultrasonically, or by a combination of both. The rate of agitation controls the size of the particles. Chitosan nanoparticles prepared by gelation with TPP were uptaken by A549 cells in percentages that depended on the molecular weight (M_w) and DA.[79] Uptake decreased by 26% when the M_w decreased from 213 000 to 10 000 and by 41% when the DA increased from 12% to 54%. The nanoparticles cytotoxicity was lower for the higher DA.

Nanoparticles have been produced for incorporating DNA, proteins and therapeutic agents. A complex coacervation method has been often used for incorporating DNA. In complex coacervation, separation of two oppositely charged colloids occurs. Normally, a chitosan solution (e.g., in sodium acetate buffer) and a DNA solution (e.g., in sodium sulfate) are preheated to ~50 °C and then quickly mixed and vortexed to form the chitosan/DNA complex nanoparticles.[80] Chitosan nanoparticles with various ratios of chitosan to plasmid OP-1 were used to transfect chondrocytes.[81] Nanoparticles with a chitosan/plasmid weight ratio of 10:1 entered the cells and resulted in the expression of the plasmid, which maintained its structural integrity. The size of the plasmid did, however, affect the efficiency of transfection to the cells.

2.213.2.5. Cross-linking

Like in other polymers, cross-linking of chitosan molecules is often used to increase the mechanical and chemical stability of chitosan. Cross-linking may involve covalent binding of chitosan molecules to chitosan molecules, or to other polymer chains. A hybrid polymer network is formed in this case. The covalent bonds are formed between the two different molecules, but they may also be established between molecules of the same polymer. Another possibility is to add to the chitosan solution a nonreacting polymer before cross-linking. The chains of this polymer become entangled in the structure of the cross-linked chitosan, contributing to its physical reinforcement. These are called semi-interpenetrating networks (semi-IPN). The reinforcing polymer can be subsequently cross-linked to form a full-IPN. The most common cross-linkers that have been used are dialdehydes, and particularly glutaraldhyde.[82] The aldehyde group forms imine bonds with the amino groups of chitosan and the reaction can be carried out in aqueous medium, without the need for other molecules to initiate the reaction. One of the disadvantages of the method is the toxicity of glutaraldhyde. Removal of residual glutaraldehyde molecules from the hydrogel cannot be guaranteed during washing, which has limited the use of this cross-linker. Genipin, which is a natural product used in traditional Chinese medicine and extracted from gardenia fruit,

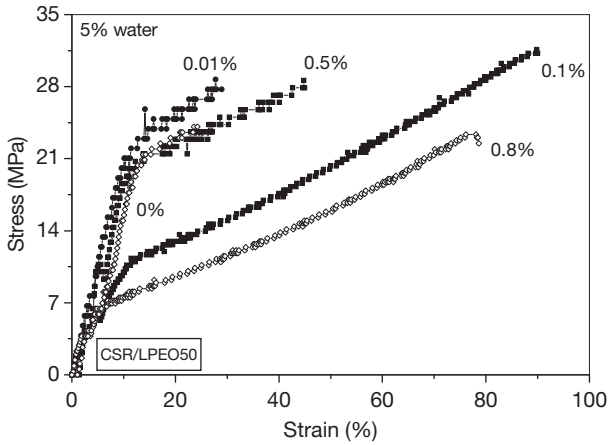

Figure 4 Stress–strain curves of chitosan/poly(ethylene oxide) (PEO) films cross-linked with genipin. The PEO used (LPEO) had a $M_w = 600$. Reproduced from Jin, J.; Song, M.; Hourston, D. J. *Biomacromolecules* **2004**, *5*(1), 162–168, with permission from Elsevier.

has been reported to have no such toxic effects. Cross-linking of chitosan/PEO blends with genipin resulted in more stable and elastic films.[83] Figure 4 shows the stress–strain curves of chitosan/PEO obtained with different concentrations of genipin. 0.1% genipin resulted in films that exhibited a strain to fracture of 90%. Genipin has also been used to stabilize polylectrolyte multilayers of chitosan/hyaluronan and chitosan/alginate.[76] Cell adhesion was markedly influenced by cross-linking. Water-soluble chitosan chlorides (low and high molecular weights) and chitosan glutamates (low and high molecular weights) were cross-linked using various concentrations (5% to 20%) of genipin, to encapsulate cells removed from bovine intervertebral discs.[84] A cell viability of 95% was obtained with the high molecular weight chitosan glutamate cross-linked with 5% genipin.

2.213.3. Biomedical Applications

Because of its well-known biocompability, chitosan is being widely explored for biomedical and pharmaceutical applications. In the following sections the main areas of application and research will be discussed.

2.213.3.1. Wound Management

Chitosan is referenced in the wound management field for its hemostatic properties[85] Furthermore, the biological properties including bacteriostatic and fungistatic[86] properties are particularly useful for wound treatment. It also affects inflammatory cell function that helps in faster wound healing, and has an aptitude to stimulate cell proliferation and histoarchitectural tissue organization.[87]

Chitosan has been explored as a topical hemostatic agent in a variety of forms,[88] reaching the market in recent years. Agents being commercialized include: (1) a dressing, which works by becoming extremely adherent when in contact with blood, sealing the wound and controlling bleeding (HemCon Medical

Technologies, Inc.); (2) high surface area flakes which, when in contact with blood, swell, gel, and stick together to make a gel-like clot (being commercialized by MedTrade Products Ltd.); and (3) a chitosan-coated nonwoven pad used in the management of bleeding wounds (Abbot Vascular, USA). The mechanisms underlying the action of chitosan are not completely understood, but it has been suggested to involve vasoconstriction, and the rapid mobilization of red blood cells, clotting factors and platelets to the site of the injury as a result of the positive charge on the chitosan molecule.[89] This action is reported to occur even in patients on anticoagulants.

Because of its high absorption capacity of fluids, wound-healing properties, adhesiveness, antibacterial activity, and film forming properties, chitosan has been explored for burn and wound dressings.[90] The modification of chitosan properties, either at the structural level or by association with other materials, has been explored[60,61] to potentially improve its biological performance. Despite these efforts, the commercial exploration of a wound dressing material based on chitosan is yet in its infancy.

Although the apparent potential of chitin and chitosan derivatives in the preparation of sutures have long been recognized, there is still no commercial production of chitin-based absorbable suture materials because of insufficient elasticity of chitin threads and certain limitations of their processability into the fiber form.[91,92] Strategies to overcome some of these hurdles have been thoroughly reviewed by Pillai and coworkers.[93]

2.213.3.2. Tissue Repair and Regeneration

Internal medical applications for tissue repair and regeneration include orthopedic implants, such as bone pins and plates, as well as bone fillers, such as cements, adhesives for tissue repair, and scaffolds for tissue engineering. Among the latter, skin, bone, cartilage, and nervous tissues are those where more investigation is taking place, involving the use of chitosan as a scaffolding material or as an extracellular matrix (ECM) analog.[94–96] The popularity of chitosan for tissue repair and regeneration is owing to the fact that it can be readily processed into a variety of forms that include fibers, films, sponges, or hydrogels. This provides the possibility to mimic the shape of target tissue or interfaces. Moreover, the similarity of its chemical structure to some polysaccharide constituents of the ECM and the possibility to chemically modify it to impart desired functionalities add to the great potential of chitosan as a biomaterial for tissue repair and regeneration.

In orthopedics, chitosan has been often used in combination with ceramics, such as hydroxiapatite and other calcium-containing ceramics to produce composites. These have been investigated as bone fillers, and many were found suitable as bone-filling materials.[97,98] The advantage of this approach is to develop bone substitute materials, which combine the biodegradability, strength, and flexibility of chitosan with the osteogenic potential and hardness of the mineral filler. In addition, the chitosan matrix acts as a binder, preventing postoperative migration of the mineral phase.[99] Chitosan has also been explored as an adjuvant additive, to render calcium phosphate cements injectable and to enable their use in minimally invasive surgical procedures.[100] Other bone cements combining chitosan, hydroxiapatite, and poly(methyl methacrylate) were also developed, and reported to provide porous spaces for osteoconduction, after chitosan degradation.[101] Finally, the association of growth factors with chitosan-based bone fillers has also been investigated, as a combinative strategy of controlled local drug delivery and bone regenerative therapy.[49] Besides being used as a filler material, chitosan has also been employed as a coating material, in order to improve titanium and hydroxyapatite implants osteointegration.[102–104] Envisaging to improve the biocompatibility of electrolytically deposited apatite coatings on Ti alloys, Wang *et al.*[105] prepared a hybrid calcium phosphate/chitosan coating. When compared to apatite coatings, this hybrid coating revealed to be more cytocompatible towards bone marrow stromal cells.

There are a wide variety of adhesives available for use in surgery, ranging from cyanoacrylates to fibrin-based mixtures. Chitosan use in the design of new tissue adhesives was motivated by the fact that it can bind to collagen due to hydrogen bonding and polyanionic–polycationic interactions. It is said to overcome some of the limitations of currently available materials. It is not blood-derived, and in light activated applications can be used without significant temperature raise. Lauto and coworkers[106,107] have developed flexible and insoluble strips of chitosan-based adhesives that incorporate indocyanin green dye, for use as a bandage to fix rectangular sections of sheep intestine using a diode laser. The chitosan bandage bonded effectively to tissue without sutures and preserved the ECM structure avoiding irreversible thermal denaturation of imbedded bioactive proteins. A photo-cross-linked chitosan hydrogel showed strong sealing ability when tested in a rabbit animal model of a punctured carotid artery and lung, stopping the bleeding and air leakage, respectively.[108] The sealing ability of the chitosan hydrogel was found to be similar or even stronger than that of fibrin.

Table 1 provides examples of works being developed in the field of tissue engineering using chitosan as a scaffold/matrix material.

Many studies have been reported on the use of chitosan as a scaffold in skin tissue engineering due to its many advantages for wound healing, such as hemostasis, accelerating tissue regeneration, and stimulating the fibroblast synthesis of collagen.[121] The use of chitosan for the preparation of skin substitutes was successfully explored in a blend with bovine collagen types I and III and GAGs, where fibroblast and keratinocytes have been cocultured. The blend-based porous substrate acts as a scaffold for fibroblasts, thereby producing a living dermal equivalent, which once epithelialized results in reconstructed skin.[122] The use of this skin substitute has been proven to lead not only to the reconstruction of surface epithelia for the treatment of pathological conditions of skin, but also as a testing platform for pharmatoxicologic studies, serving as a validated alternative to animal tests.

In articular cartilage tissue engineering, the ideal scaffold should mimic the natural environment in the articular cartilage matrix, which is highly hydrated and rich in ECM components, such as type II collagen and GAGs. These are known to play a key role in the expression of the chondrocytic phenotype and in supporting chondrogenesis *in vitro* as well as *in vivo*. Chitosan has been found particularly interesting for hyaline cartilage tissue engineering, due to its structural similarity with HA, a GAG abundant in the ECM of cartilage.[123] The

Table 1 Current applications of chitosan scaffolds in tissue engineering

Application	*Scaffold*	*DA (%)*	*Scaffold properties*	*Performed biological studies*	*References*
Skin	Asymmetric genepin-cross-linked chitosan membrane containing collagen I nanospheres	15	Asymmetric membrane (porosity 42–58%)	*In vitro* static primary culture of rat skin fibrobasts *In vivo* evaluation of skin regeneration in a rat animal model	109
Cartilage	Chitosan/β-chitin scaffolds	2	Porous (pore size 50–100 μm)	Rabbit chondrocytes (isolated from articular cartilage) culture and ECM production assessment	110
Cartilage	Temperature-responsive chitosan hydrogel (with β-sodium glycerophosphate and hydroxyethyl cellulose)	14	Hydrogel	*In vitro* cultures with adult sheep articular condrocytes *In vivo* implantation in articular cartilage defects in the sheep model	111
Nucleus pulposus of intervertebral discs (IVD)	Chitosan/glycerophosphate gels Chitosan/ glycerophosphate/ hydroxyethyl cellulose gels Chitosan/genipin gels	Chitosan: 5% and 21% Glutamate salt of chitosan: 15%	Hydrogel	*In vitro* primary cultures of peripheral annulus fibrosus and the central nucleus pulposus cells isolated from IVDs from the tails of bovine steers	112
Bone	Chitosan/TCP scaffolds	n.m.	Porous (pore size 100 μm)	Fetal rat calvarial osteoblastic cells proliferation, viability, and differentiation	113
Bone	Chitosan/nonsintered hydroxylapatite particles	12	Bilayered Porous layer (pore size 100–400 μm; porosity 30%)	Cytotoxicity of extracts (fibroblasts) Osteogenic and chondrogenic differentiation studies with mesenchymal stem cell (from human adipose tissue)	114
Bone	Chitosan and PDGF-BB loaded chitosan scaffolds	n.m.	Porous (pore size 100 μm)	Cytotoxicity tests: rat calvarial osteoblastic cells adhesion and proliferation Bone regeneration ability in a rat calvarial defect	66
Bone	Chitosan and chitosan/ chondroitin sulfate scaffolds Chitosan/PLLA scaffolds Chitosan coated PLLA scaffolds (all loaded or not with PDGF-BB)	30	Porous (pore size 100–150 μm) Porous (pore size 150–200 μm) Porous (pore size 100–150 μm)	Rat calvarial osteoblastic cells adhesion and proliferation Bone regeneration ability in a rat calvarial defect	67
Bone	Chitosan/gelatin and chitosan/gelatin/β-TCP macroporous scaffolds	~10	Porous (pore size 322 μm) Porous (pore size 185–420 μm)	Biocompatibility evaluation (subcutaneous implantation in a rabbit model)	115
Bone	Chitosan scaffolds and chitosan scaffolds modified with RGDS or RGES peptides	15	n. m.	Rat osteoblast-like cells (ROS 17/2.8) adhesion, proliferation, and differentiation	45
Nerve	Chitosan conduits containing oriented filaments of polyglycolic acid	7.7	Nonporous chitosan conduit containing oriented filaments of polyglycolic acid	Bridging sciatic nerve across a 30-mm defect in Beagle dogs	116
Nerve	Chitosan	8	Nonporous conduit	Implantation of extramedullary conduits seeded with neural stem and progenitor cells derived from transgenic green fluorescent protein rats after spinal cord transection	117
Ligament	Chitosan-based hyaluronan hybrid polymer fibers	19	Fibers	Rabbit fibroblast adhesion and proliferation; ECM production assessment	118

n. m. – not mentioned.

possibility of using chitosan in the hydrogel form is an added value in such application. In this form it may closely match the natural mechanical properties of hyaline cartilage. Furthermore, its application can be performed by a minimally invasive method. A number of in situ gelling chitosan-based hydrogels are currently under investigation for this purpose.[124,125]

In recent years, considerable attention has been given to the application of chitosan-based materials in the field of orthopedic tissue engineering. Interesting characteristics that render chitosan suitable for this purpose are its biocompatibility/biodegradability, structural similarity to ECM GAGs, intrinsic antibacterial nature, ability to bind anionic molecules such as growth factors, GAGs, and DNA, as well as its ability to be molded into porous structures suitable for cell ingrowth and osteoconduction.[126] In this sense, a wide number of support matrices in the form of injectable gels or porous scaffolds have been developed for bone tissue-engineering applications. Most often, chitosan is used in combination with a variety of materials, such as ceramics, PLLA, gelatin, GAGs, as well as growth factors, in an attempt to improve its mechanical properties, osteoconduction, and ability to induce bone regeneration (see **Table 1**). Binding with cell adhesive motifs has also been explored, in order to promote cell adhesion.

Although chitosan has been used as a scaffold for articular cartilage and bone formation by direct differentiation of mesenchymal cells into chondrocytes and osteoblast, respectively, only recently it has been used as a template for endochondral ossification.[31,127] The endochondral ossification pathway involves an intermediate cartilage stage and is responsible for the formation of long bones, vertebra, and the cranial base during development. Oliveira *et al.* have subcutaneously implanted a transient cartilage scaffold based on chitosan and a permanent cartilage scaffold in nude mice (see **Figure 5**). Only in the former, the deposition of ectopic bone was detected, as early as 1 month after implantation. After 3 months, bone trabeculae and bone marrow cavities were formed inside the scaffolds. The bone deposited was similar to the bone of the mice vertebra. Interestingly, no bone formation was observed in control implants, for the time span of the study.

When the extent of nerve damage prohibits the direct approximation of the two nerve stumps in peripheral nerve repair, autologous nerve grafting is considered the surgical treatment of choice. Artificial nerve guides, where a tube bridges the nerve gap, offer a promising alternative, preventing the sacrifice of a donor nerve and possible neuroma formation at the donor site. Furthermore, the use of synthetic nerve guides reduces operation time and prevents the mismatch between the damaged nerve and the graft. Peripheral nerve correction performed with chitosan-based nerve conduits has been explored with success.[116] Chitosan-based conduits present a number of advantages over other proposed guides, namely, the readiness of tuning their physical properties[38,39] and surface chemistry by changing the DA of chitosan, which in turn influences cell adhesion behavior of the key player cells in the nerve regeneration process.[40] The surface modification of chitosan scaffolds with cell adhesion proteins or motifs, such as the pentapeptides YIGSR and IKVAV, which bind to neural cell membrane receptors, has also been investigated either by physiadsorption[128] or chemical grafting.[129–131] The use of chitosan-based conduits for spinal cord injury treatment is also under study with the first *in vivo* studies showing promising results.[117,132,133] The incorporation into the scaffolds of proteins that can enhance nerve regeneration is being assessed as well.[134] Moreover, the possibility of culturing neural stem cells in these constructs also opens new avenues for addressing nerve lesion treatments.[135]

A transversal problem in the field of tissue engineering has been the vascularization of the tissue-engineered constructs postimplantation. The insufficient supply of oxygen and nutrients to the inner part of the cell–matrix constructs in the initial phases after implantation[136] was found to be contributing to the limited success of many of the proposed tissue regeneration strategies. To overcome this unsolved issue, a number of strategies are being developed to create a vascular network able to deliver oxygen and nutrients throughout an implanted cell–matrix construct. One of the promising approaches has been the precolonization of the scaffolds with vascular cell types, such as ECs or endothelial progenitor cells.[137,138] We have shown that the endothelization of chitosan scaffolds was found to be possible when these were precoated with the ECM protein FN.[46] However, as observed for other cell types, the DA was found to be a key parameter modulating EC adhesion to FN-coated chitosan scaffolds (see **Figure 6**) by influencing the adsorbed protein layer. The selection of suitable DAs will therefore be highly important for the design of new vascularization strategies.

2.213.3.3. Delivery of Therapeutic Agents

The use of chitosan in the pharmaceutical industry spans from its application as an excipient[139] to its application as a vehicle for the controlled delivery of therapeutic agents.

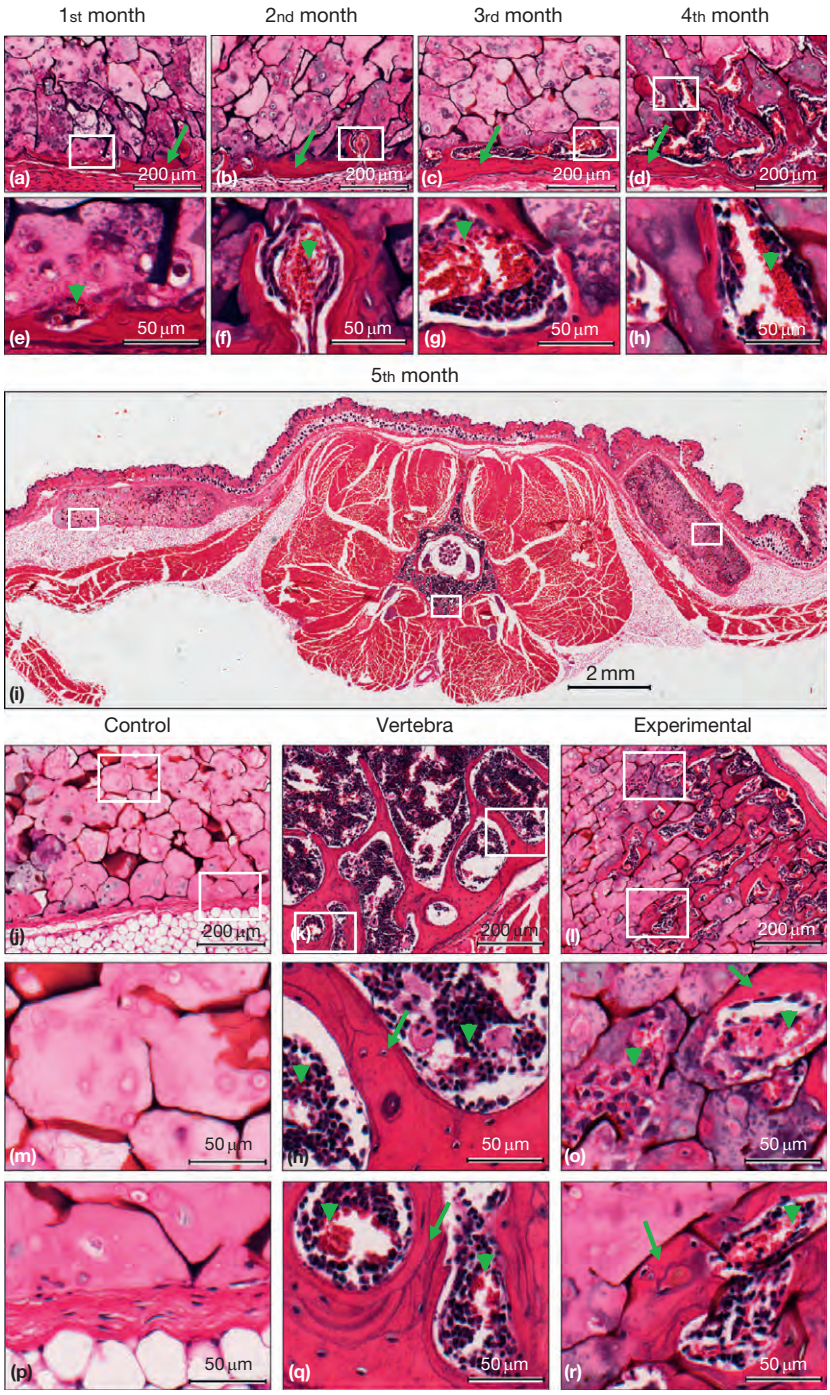

Figure 5 Histological analysis of chondrocyte/chitosan scaffolds implanted in the subcutaneous region of nude mice. Axial paraffin sections were cut through the body of the mouse (I, 5 month time point) to include the experimental and control scaffolds. Sections were stained with H&E and photographed. Details of bone forming in experimental scaffolds during the first 4 months of implantation are shown in images (a) through (d). Images (e), (f), (g), and (h) correspond to high magnifications of (a), (b), (c), and (d), respectively, showing the beginning of vascular invasion (arrow heads). The control scaffolds do not undergo visible changes during the first 5 months of implantation, and therefore only the 5th month is included in this figure. A complete section is shown after 5 months of implantation in image (i). Control scaffold is on the left and experimental is seen on the right side of the image. Details of control scaffold (j), vertebral body (k), and experimental scaffold (l) can be observed. Higher magnifications of control (m, p), mouse vertebra (n, q), and experimental scaffold (o, r) show tissue details. Deep in the control sample (m), only cartilage tissue can be observed. Vascular invasion of cartilage (arrow head in o) and bone deposition (arrow in o) can be observed in the experimental sample. Detail of vertebra (n, q) shows the presence of bone (arrow) and blood vessels (arrow head). Note bone formation deep in the experimental scaffold as well as the presence of blood vessels (r). Adapted from Oliveira, S. M.; Mijares, D. Q.; Turner, G.; Amaral, I. F.; Barbosa, M. A.; Teixeira, C. C. *Tissue Eng.* **2009**, *15*(3): 635–643, with permission from Liebert.

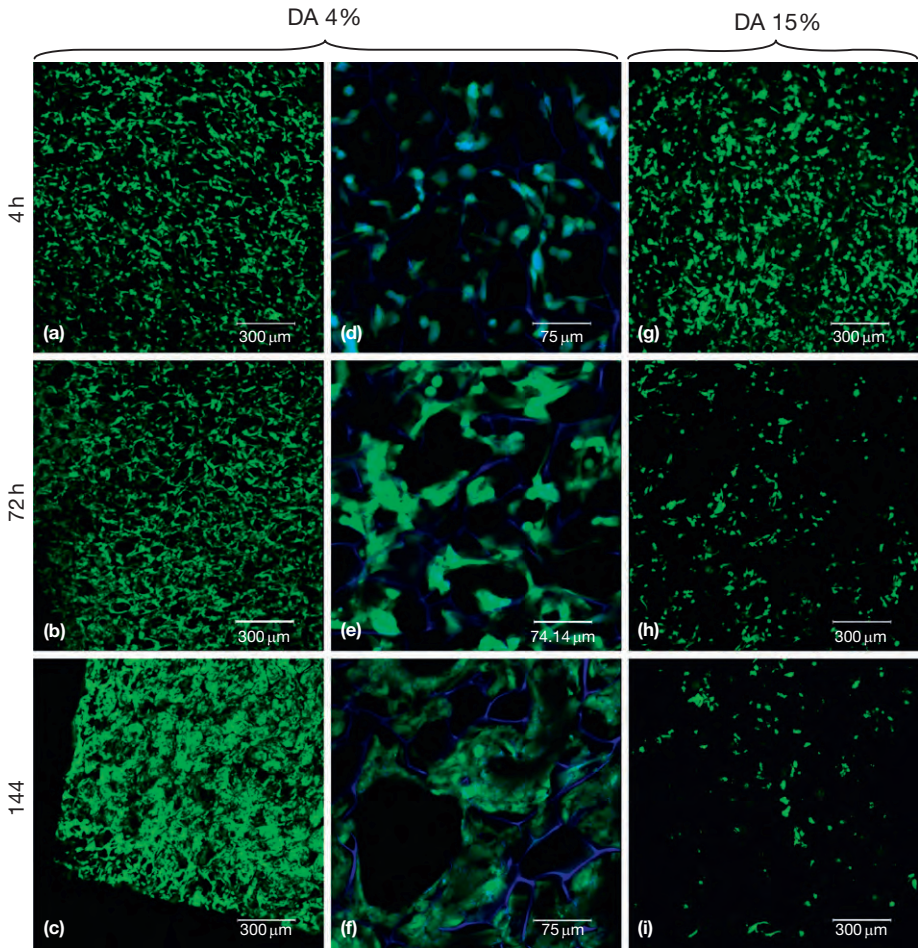

Figure 6 Confocal laser scanning microscopy of human pulmonary microvascular endothelial cells (HPMEC-ST1.6R cell line) grown on chitosan scaffolds previously incubated in a 40 μg ml^{-1} fibronectin solution. Cells were labeled with calcein AM resulting in green fluorescence of viable cells. Images were collected after 4, 72, and 144 h after cell seeding. HPMEC-ST1.6R cells seeded on scaffolds with DA 4% were able to spread and colonize the scaffolds (a) to (f). Cell spreading as well as the cellular layer covering the pore walls after 144 h of cell culture are shown in more detail in the higher magnification images (d) to (f). In these, the 3D scaffold is shown in blue due to chitosan autofluorescence upon excitation by the 405 nm laser. On chitosan scaffolds with DA 15%, very few cells were found after 72 and 144 h of cell culture (h) and (i). Scale bar is 300 μm except for images (d) to (f), for which the same bar corresponds to 75 μm. Adapted from Amaral, I. F.; Unger, R. E.; Fuchs, S. *et al*. *Biomaterials* **2009**, *30*(29), 5465–5475, with permission from Elseiver.

Taking advantage of the fact that positively charged chitosan can bind to negatively charged lipids and bile salt components, interfering with the lipid absorption process in the gut, chitosan has been introduced in the market as a weight and cholesterol control agent. However, the efficacy of its use has been questioned in the field.[140,141] Furthermore, chitosan has been used for the production of controlled release implant systems for delivery of hormones, proteins, and other peptides over extended periods of time.[142–144] The mucoadhesive properties and transmucosal absorption-promoting characteristics of chitosan have been exploited especially for nasal[145,146] and oral delivery[147–151] of polar drugs to include peptides, proteins, and nucleic acids and for vaccine development.[132,133,152] The immune adjuvant behavior of chitosan[153] has also been drawing the attention of the field to its application in vaccine development[154–156] and cancer treatment.[157–159]

Additionally, its cationic nature and high charge density in slightly acidic conditions allow chitosan to form PECs nucleic acids – both DNA and RNA.[94,95,160,161] Although chitosan is able to condense nucleic acids and protect them from nuclease degradation, its main advantage over other nonviral vectors relies on its low cytotoxicty and biodegradability. However, chitosan's poor solubility under physiological conditions and low transfection efficacy has impeded its use as a nucleic acid carrier. To overcome such limitations, a number of strategies for chitosan modification have been proposed by our group and others. These include the increase of chitosan overall positive charge by quaternization,[162] modification of its buffering capacity[163] and functionalization of chitosan with cell-binding molecules for receptor-mediated cell internalization.[164]

2.213.3.4. Other Applications

Other potential applications of chitosan include cosmetics, contact lenses, dialysis membranes, and coatings of the inner lumen of blood-contacting polymeric tubes, onto which an

antithrombotic agent is deposited. Comprehensive reading on these and other applications of chitosan in the biomedical field can be found in Dumitriu.[165]

2.213.4. Future Prospects

Chitosan cationicity and enzymatic degradability associated with structural analogy with ECM glycosaminoglicans (GAGs) contribute together to the increasing interest in its application as a biomaterial. A limitation to its use in clinics is related to the low reproductivity of chitosan physicochemical characteristics among batches as well as the presence of nonexpected contaminants. In this sense, chitosan obtained by biotechnology processes may constitute a better alternative to those presently obtained from marine animal sources. Furthermore, for the development of advanced chitosan-based biomaterials, international standards concerning the range of requirements for chitosan use in medical devices are still missing.

The possibility to covalently and ionically bound proteins and peptides to chitosan, combined with morphologically and mechanically tuned scaffolds for tissue repair/regeneration and targeted delivery of biologically-active entities for cell therapies are fields that remain vastly unexplored. The possibility of producing matrices with various degradation kinetics and inflammatory responses offers ample opportunities to expand the use of chitosan-based materials. In spite of the extensive research that has been carried out with these materials, a lot of clinically useful possibilities have not been tested in depth.

2.214.1. Introduction

2.214.1.1. Biological Origin and Primary Structure of Hyaluronic Acid

In 1934, Meyer and Palmer[1] reported a mucoid-like substance isolated from the bovine vitreous humor under acidic conditions, and it was identified as an acid polysaccharide containing uronic acid and amino sugar but no sulfate. This newly discovered naturally occurring polysaccharide was named hyaluronic acid (HA) after its biological origin, vitreous (hyaloid), and its major structural component, uronic acid. In the following years, HA was successfully isolated from other biological sources such as synovial fluid, skin, umbilical cord, cock's comb, and a bacterial source (streptococci).[2]

HA can be found extracellularly in most human tissues. Skin, lung, and intestine contain more than 50% of the HA in the body. Synovial fluid, skin, umbilical cord, and vitreous body of the eye are rich in HA content.[3] Under physiological conditions, virtually all HA molecules exist in the form of their salts – hyaluronate, such as sodium hyaluronate (NaHA). The generic term, hyaluronan, was introduced, to embrace the free acid and salts of HA, regardless of the degree of dissociation, or identity of the counterion (e.g., sodium, potassium, calcium). The acronym HA now stands for hyaluronic acid, hyaluronate, or hyaluronan, depending on the context in which it is mentioned.[4,5]

Historically, hyaluronidases played a critical role in establishing the structure of the repeating disaccharide units of HA.

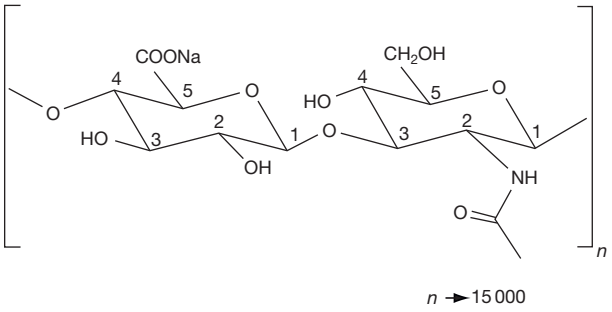

Figure 1 Structure of hyaluronic acid (HA). HA is a linear polysaccharide, with repeating disaccharide units of glucuronic acid–β-1,3-*N*-acetyl glucosamine linked by β-1,4-glycosidic bonds.

The actions of enzymes are specific, and the fragments created as products of hyaluronidase treatment retain the basic structural features. Both testicular and bacterial hyaluronidases hydrolyze only the *N*-acetylglucosaminidic bonds of HA from all sources. The degradation products of HA for both enzymes consistently demonstrated an equimolar ratio of glucuronic acid and *N*-acetylglucosamine. This strongly suggested a linear structure for HA with alternating arrangement of the two sugar units.[6–8]

Based on the study of the detailed structures of the disaccharide building blocks, scientists were able to draw conclusions that polymeric chain of HA is composed of repeat disaccharide units of glucuronic acid and *N*-acetylglucosamine. The linkage from glucuronic acid and *N*-acetylglucosamine is (1→3) and the linkage from *N*-acetylglucosamine to glucuronic acid is (1→4). HA has a wide range of molecular weight, up to several million Daltons (MDa) (**Figure 1**).

2.214.1.2. HA Structure of Higher Orders

The secondary structure of HA is mainly concerned with the spatial relationship of the neighboring functional groups.[9] An exhaustive review of the molecular structure studies of HA describes the history and complexities of this field of study in great detail.[10] Only the basic points will be summarized herein. The molecular structure of HA in **Figure 1** is represented by Haworth conformational formula, which allows visualization of the β-D-anomeric configuration of the C-1 atoms of glucuronic acid and *N*-acetylglucosamine units, as well as visualize the shape of the puckered ring conformations of the monosaccharide units such as the $^4C_1$ conformation of the β-D-glucopyranose.[11] This notation of $^4C_1$ defines a ring conformation with C-4 above the plane described by the oxygen atom and C-2, -3, and -5 carbon atoms; and with C-1 below the plane. The $^4C_1$ conformation of β-D-glucopyranose is favored, because it is more stable than the $^1C_4$ conformation. In the $^4C_1$ conformation, all substituents on the ring are equatorial; in the $^1C_4$ conformation, all substituents on the ring would be axial.[12]

The spatial relations of HA atoms and subunits have great impact on the rigidity of the polysaccharide chain. The degree of rigidity is largely determined by the restriction on the rotation of the glycosidic bonds by the geometry of sugar rings and, as in the case of HA, by the relatively bulky *N*-acetyl group adjacent to the glycosidic bond.

The tertiary structure of HA often refers to its chain conformation, which is partially helical. Such a tertiary structure of HA is possible because of certain characteristics of its primary and secondary structures. The repeating disaccharide building blocks in HA chains provide regularity in sequence and spacing of functional groups. The quaternary structure of a polysaccharide basically involves the aggregation of chains by noncovalent interactions.[11] For example, HA has been reported to form an antiparallel double helix and a honeycomb network at low concentrations of 0.5–1.0 mg ml^{-1}. The honeycomb-like structure of HA in aqueous solution was observed under rotary shadowing electron microscope.[13]

The evidence of ordered structures of HA in solutions first came from the studies of its optical properties using polarized light, providing data indicative of the presence of an ordered conformational structure. These optical properties include optical rotation, circular dichroism (CD),[14] and optical rotary dispersion (ORD).[15,16]

What are the microscopic aspects in solutions that actually cause an extended structure of HA molecules and their aggregation under certain conditions? The classic theory emphasizes the contribution of intramolecular hydrogen bonding, citing evidence from NMR studies that demonstrate the existence of the hydrogen bonding between the functional groups such as C=O, NH, and OH.[17,18] The hydrogen atoms directly involved in hydrogen bonding may show an increased value of chemical shift because of increased electron deficiency caused by such interactions. Furthermore, the NMR studies in aqueous solutions (deuterium oxide) also found that the spectrum of HA sharpens considerably under alkaline conditions. This suggested an enhanced segmental motion as a result of the breaking of hydrogen bonding under alkaline conditions.[18] It was also recognized that the possible hydrogen bonding could represent a fleeting association among the related atoms, that is, 'that the bonding may break and reform in a state of dynamic equilibrium.'[9] Another aspect of the classic theory is related to hydrophobic interaction. By examining the secondary structure of HA using space-filling molecular models, a 'hydrophobic patch' of eight C–H bonds was noticed that stretched across three sugar units. This putative hydrophobic region has been described as a driving force for the formation of the double helix mentioned above.[13,19]

More recently, molecular simulation studies have forced a reevaluation of the classical view. In the newer view, contribution of intrastrand hydrogen bonding is quite limited: 'if an intra-molecular hydrogen bond is present, it cannot exist for more than 5–15% of the time.'[20] It was, therefore, proposed that HA was 'a molecule that has an average local order in its 3D-structure, but with substantial dynamic flexing around this average structure.' The dynamic flexing can even be envisioned in an animation of a few nanoseconds movement of the HA hexa-saccharide model.[20] The dynamic nature appears to explain why even at very high concentrations HA cannot form the so called 'cuttable gels.' As to the driving force of an ordered HA structure in solution, theory supports the notion that this is more likely to be an entropy-driven phenomenon. The maximum entropy for HA plus water, as it so happens, is 'often observed to be consistent with the presence of intramolecular hydrogen bonds.'[21]

2.214.1.3. Biophysical Function of HA

As a major component of the extracellular matrix, biophysically HA serves as a packing material that fills organ space (vitreous, skin), as a biomechanical cushion that absorbs shock (cartilage), and as a lubricant between moving tissues (e.g., joints). Those functions of HA are based on the extraordinary ability of HA to retain water in the extracellular matrix.

The water retention property of HA is often described in terms of intrinsic viscosity (IV), which is a measure of hydrodynamic volume. IV is defined as the volume of water held by unit weight of the material of interest. HA has a very large hydrodynamic volume, which is made possible by the unique structural characteristics of HA and its very high molecular weight as mentioned above. For example, HA with a molecular weight of ~2 MDa has an IV of ~3000 ml g^{-1}.

2.214.1.4. Influence of HA on Cell Behavior

HA plays an important role in the regulation of cell behavior as well. A pattern of strong correlation between HA and the cell cycle has been demonstrated. Cells *in vivo* usually proliferate within an HA-rich extracellular matrix, and HA synthase activity usually peaks during mitosis and declines at confluence.[22,23]

The mechanism of action of HA on cell behavior can be twofold. On the one hand, it can be nonspecific, which is based on its space occupying capability. For cell migration, the presence of HA can create 'hydrated pathways separating cellular or fibrous barriers to penetration by migrating cells.'[22,23] For cell differentiation and morphogenesis, the condensation of mesenchymal cells occurs only after the removal of most of the intercellular HA and along with it the highly hydrated intercellular spaces.

On the other hand, there are specific interactions between HA and cells receptors. The HA receptor for endocytosis (HARE) is found in the liver and is the primary route of clearance of HA from the circulatory system. Blocking HARE with a specific antibody inhibits HA clearance in a perfused liver system.[24] The binding of HA to RHAMM (receptor for hyaluronan-mediated motility) can trigger signal transduction, which directs cell trafficking.[25] CD44, the principal HA receptor, is responsible for the internalization of HA during the development of bone, lung, and hair follicles.[22,23]

In addition to its function in the removal of HA, the cell receptor CD44 and its binding to HA play an intriguing role in maintaining the homeostasis of the cells. Under a relatively quiescent homeostatic state, cells divide only as much to compensate for normal cellular turnover. However, the receptor-mediated effects on cell behavior are molecular weight and viscosity dependent. Under inflammatory conditions, for example, in an arthritic synovium, this homeostasis is disrupted. Reactive oxygen species, particularly free radicals, degrade HA and reduce its molecular weight and viscosity. The binding of the lower viscosity HA with CD44 then sends out mitogenic signals to the mesenchymal cells, which then start the healing process. In this way, HA and CD44 complex regulates the cell behavior by acting as a biological rheostat, which would be a more sensitive and responsive regulatory mechanism than a simple on–off switch.[26]

2.214.2. Production of HA

To exploit the unique properties of HA, significant effort has been devoted to the development of medical products with HA as the major ingredient.[9] Four types of HA-based products are formally commercialized in the United States: (1) a surgical aid and tissue protective agent in ophthalmic surgery, (2) an injectable preparation to alleviate pain of knee osteoarthritis (OA), (3) a barrier in solid or solution form to prevent postsurgical adhesions, and (4) an injectable gel for cosmetic tissue augmentation. In addition, there are a growing number of new applications of HA derivatives and HA composites under development, including the use of HA and its derivatives for drug delivery and as clinical biomaterials. These compositions and uses will be addressed below in Sections 2.214.4 and 2.214.5.

HA can be used either in its native form or in its chemically modified form. In either case, the key step of manufacturing is the production of HA with high purity and a specific molecular weight range. There are three main methods for HA production: isolation from animal tissues, bacterial fermentation (homologous and heterologous), and chemoenzymatic synthesis.

2.214.2.1. Isolation of HA from Cock Combs

In 1949, Boas[27] first identified HA from rooster combs. It was known to stain with certain basic dyes, and therefore was believed to contain mucopolysaccharides. The rich content of HA contributes to the thick layer of connective tissue and the large size of the combs. The isolation and purification procedure can be summarized in the following steps: grinding freshly harvested combs, soaking comb material in acetone to remove fat, extracting HA using sodium acetate solution, adding ethanol to precipitate HA, adding chloroform, and shaking the mixture to remove protein. The final purified dried HA was white and fibrous, with a yield of ~0.1% weight of the combs processed.

Sevag[28] used ~20% chloroform to separate protein content from the carbohydrate content of the egg white. Blix and Snellman[29] adopted Sevag's method with some modifications, including increasing chloroform to 50% of the HA aqueous solution volume. Balazs increased the volume of chloroform to at least equal to the HA aqueous solution during the deproteinizing process.[30] Gently agitating this larger volume of chloroform with the HA solution denatured and separated proteins from HA, while preserving the high molecular weight of HA.

In the method of HA extraction and purification described by Swann,[31] pronase was used to remove protein and cetyl pyridinium chloride (CPC), a quaternary ammonium salt with a long lipophilic chain, was used to isolate the HA. CPC forms a complex with acidic polysaccharides, such as HA, as first described by Scott.[32] The HA-CPC complex precipitates in aqueous media and HA can be recovered in salt solution. In Swann's HA efficient purification method, chloroform was used mainly as a bacteriostatic agent. The amino acid content of the purified fraction of HA was only 0.35% (w/w). A reduction in HA viscosity, however, was observed along with the reduction of protein content.[33] The purified HA still maintained a molecular weight of 1.2 MDa.

2.214.2.2. Bacterial Fermentation with Streptococci

A number of bacterial strains are available to produce HA in good yield such as group A and C streptococci. The presence of HA is a common trait in streptococci,[34] which release cell wall components when grown in complex media. Pathogenic streptococci synthesize HA as the major capsular polysaccharide that serves to evade host defenses. Group A *Streptococcus pyogenes* is a human pathogen,[35] while the group C *Streptococcus* species *S. equi*, *S. equisimilis*, and *S. zooepidemicus* are animal pathogens.[36] Clearly, it makes sense to produce HA for use in human use from strains not related to human disease, and group C streptococci have become the most commonly used strain for HA production.

HA production by fermentation was first reported in 1937 by Kendall *et al.*[35] using group A streptococci. The polysaccharide appeared to be identical with that occurring in bovine vitreous humor. The method by Bracke and Thacker[37] produced HA from streptococcus by fermenting under anaerobic conditions. Glucose was used as the carbon source. Trichloroacetic acid was added to kill the bacteria after fermentation to facilitate the separation of the microorganisms from the HA. The HA prepared as described has an average molecular weight of about 55 000 Da within a range of 10 000 Da to 2 MDa.

Swann *et al.*[38] described an aerobic fermentation process with *S. zooepidemicus*, in which relatively high oxygen concentrations are made available during the initial exponential growth phase of the cultivated microorganism, until a predetermined growth has been reached. This improved overall yields of HA and the highest molecular weight of HA made by this process was slightly above 2.5 MDa. Later, Ellwood *et al.*[39] developed a continuous fermentation method using *S. equi* in a chemostat culture. This gave high yields of high MW HA uncontaminated by toxic impurities. The HA produced by this process had an average MW of 1–3 million.

Expression of the HA-degrading enzyme hyaluronidase and other extracellular protein is a drawback of wild-type streptococci. The application of chemical mutagenesis followed by a serial selection scheme has been exploited to obtain nonhemolytic and hyaluronidase negative mutants[40] and strains producing high MW HA.[36,41]

Nimrod *et al.*[42,43] treated *S. zooepidemicus* with a suitable mutagen, for example, nitrosoguanidine. The mutant derived did not have hemolytic activity and enhanced the HA yield. The method applies vigorous agitation and aeration to the medium. It was claimed to be the first fermentation method of producing HA with high molecular weight that exceeds 3.5 MDa.

Stahl[36,44] has claimed that by selecting supercapsulated mutants of strains of group A and C streptococci, particularly *S. equi* mutants (group C), HA with a molecular weight exceeding 6 MDa can be produced. The process avoided extensive turbulence and agitation and used the type of impeller able to achieve good mixing without generating excessive shear forces that could potentially degrad HA molecules.

2.214.2.3. Bacterial Fermentation with Recombinant *Bacillus subtilis*

In 1993, DeAngelis *et al.*[45] made a breakthrough in the molecular cloning and characterization of the streptococcal gene encoding the protein HasA, known to be in an operon required for bacterial HA synthesis.[46] The *hasA* gene was later used in the fermentation of HA by hosts from a different species (heterologous) such as *Bacillus subtilis*, as a useful alternative to the fermentation by streptococci.[47] *B. subtilis* offers a number of advantages (1) it is free of exotoxins and endotoxins, and therefore many products produced in this organism have been awarded a GRAS (generally recognized as safe) designation, (2) it does not produce hyaluronidase, (3) it is one of the best characterized Gram-positive microorganisms, and (4) its genome has been sequenced.[47,48]

The molecular weight of HA derived from *B. subtilis*-derived measured in the range of 1.1–1.2 MDa, with a polydispersity index of 1.5 (expressed as the ratio of weight/average molecular mass/number/average molecular mass, or M_w/M_n), comparable to what has been reported for commercially available sources.[49]

2.214.2.4. Chemoenzymatic Synthesis

Chemoenzymatic synthesis, a method where chemistry meets biology, combines the utilization of synthetic chemical tools and recombinant natural product enzymes. The chemoenzymatic synthesis of HA was developed by Jing and DeAngelis,[50] which involves an *in vitro* enzymatic reaction using the recombinant HA synthase pmHAS from Gram-negative *Pasteurella* species.

There are two classes of HA synthases. Gram-positive streptococcal, vertebrate, and viral HAS belong to Class I. In contrast, the class II enzyme has its only member, the Gram-negative *Pasteurella*[51] that contains a membrane bound, carboxy-terminal region. Deletion of this c-terminal region results in a soluble, cytoplasmic form of the enzyme.[52] Only the recombinant pmHAS, not streptococcal or vertebrate enzymes, has shown the ability to perform *in vitro* reactions to elongate HA-oligosaccharide acceptors exogenously supplied.

HA synthase pmHAS uses two separate glycosyltransferase sites to add GlcNAc and GlcUA monosaccharides to the nascent HA chain. Technologically, the reaction can be improved by the addition of HA oligosaccharide along with the UDP–sugar substrates, that is, UDP-GlcNAc and UDP-GlcA. The advantages of such methodologies are threefold. First, the rate of reaction can be accelerated 100-fold by the presence of HA oligosaccharide acceptor, which appears to be the result of bypassing the slow initiation stage and effecting the fast elongation from the very start of the reaction. Second, the molecular size of the HA polymer products can be controlled by the size of the added HA oligosaccharide acceptors. The larger the size of the HA oligosaccharides, the fewer reaction sites available, and the longer the final HA polymers become. Third, a narrow distribution of molecular weight of HA polymer product can be achieved by controlling the initial size of added HA acceptors and synchronizing the rapid elongation reactions. The chemoenzymatic method can produce HA polymers with MW of up to 2 MDa and very narrow size distributions with polydispersity value between 1.02 and 1.06.[53]

The dual-action HAS – glycosyltransferases rapidly adds two different sugars, GlcUA and GlcNAc. This would likely

result in long chain HA polymers, and are therefore unsuitable for production of short, defined oligosaccharides. To solve this problem, *Pasteurella multocida* HA synthase (pmHAS) was converted by mutation of one active site aspartate residue, affording two single-action glycosyltransferases (glucuronic acid transferase and *N*-acetylglucosamine transferase). A lesion in one active site leaves the activity of the other unmutated active site relatively unaffected.

When the two resulting transferases, a β-3GlcNAc-transferase and a β-4GlcUA-transferase, are purified and immobilized individually onto solid supports, the enzyme reactors used in an alternating fashion can produce an extremely pure, single-length HA oligosaccharide up to HA20, without purification of the intermediates.[54]

2.214.3. Analysis and Industry Standards

Numerous methods have been developed or adopted to analyze HA both qualitatively and quantitatively.[9] This chapter focuses on those most widely used in the tests of HA products for medical use in humans, especially those related to the chemical properties, rheological properties, and biocompatibility included in a variety of industry standards. Examples of those standards are the monograph of HA in European Pharmacopoeia (EP)[55] and two ISO (International Standards Organization) standards, ISO 15798 (Ophthalmic Implants – Ophthalmic Viscosurgical Devices, OVD[56]) and ISO 10993 (Biocompatibility).

2.214.3.1. Qualitative Analysis

Chemical identification (ID) is performed by infrared spectroscopy (IR) and Na tests as stipulated by EP. In IR analysis the partial assignments of absorptions are as follows: carboxylic acid 1736 cm^{-1} (main) and 1230 cm^{-1} (minor); carboxylate 1610 cm^{-1} (main) and 1410 cm^{-1} (minor); monosubstituted amide 1648, 1560, and 1315 cm^{-1}; and associated methyl group 1375 cm^{-1} (sharp). The IR method has evolved from conventional IR[57] to FTIR (Fourier transform IR),[58,59] from solid film samples[57,58] to HA aqueous solution.[59]

The carbazole assay, a classic, colorimetric assay, is often used as part of the HA identification.[60] The chromogenic reaction of the assay has two steps. The dehydration of hexuronic acid of HA with concentrated sulfuric acid forms a furfural derivative intermediate which reacts with carbazole to yield a distinct red color as an indication of the existence of a class of carbohydrates – uronic acid. Therefore, it is a semiqualitative test method.

Another classic colorimetric assay for HA is the Morgan and Elson[61] assay that measures *N*-acetyl hexosamine which is present at the reducing end of HA. Further studies of the assay by Kuhn and Krüger[62] and Beau *et al.*[63] have concluded that the chromogen generated when HA is treated under mild alkali conditions (Morgan–Elson reaction) was also a furan-type of compound which reacts with Ehrlich reagent DMAB (dimethylaminobenzaldehyde) to form a red color.

The applicability of the above identification tests is predicated on the high purity of the HA samples. Since HA routinely goes through lengthy isolation and purification processes, this level of purity is achieved. Impurities that could interfere with the ID tests of HA, for example, protein, are kept to a minimum (<0.3% of dry weight in EP). When the samples of HA contain significant amount of non-HA impurities, further purification would be necessary prior to ID analysis. If there is uncertainty regarding the nature of the material, additional analytical means such as the use of NMR may be necessary to verify its structure, as mentioned above.

2.214.3.2. Quantitative Analysis

The carbazole assay can also be used as a quantitative method to determine the concentration of HA. This is based on the improvement of carbazole assay by Bitter and Muir[64] using borate that enhances the red color formation and stability and decreases the sensitivity to salts. It also showed a better correlation between uronic acid and hexosamine contents. A solution containing 1 g ml^{-1} of uronic acid can show a positive color reaction. The absorbance at 530 nm is a linear function of concentration between 4 and 40 g ml^{-1}.

Another commonly used assay for HA concentration is the Reissig assay[65] which is a modified form of the Morgan–Elson assay. The Reissig method replaced the sodium carbonate with a concentrated borate buffer, improving the reproducibility of the assay even in the presence of protein or magnesium ions. The maximum absorbance of the red color produced is 520 and 550 nm.[66]

Alternatively, direct measurement of the UV absorbance as quantitative assay for HA concentration constitutes a simple, viable method that can replace or complement carbazole assay, as long as the HA sample is sufficiently pure. In practice, this method of detection is commonly used during high-performance liquid chromatography (HPLC) using an in-line UV detector.

2.214.3.3. Absolute Viscosity

Determination of the rheological properties of HA solutions assumes the utmost importance in the characterization of most HA-based products. At relatively high concentration where intermolecular action of HA becomes significant, its viscosity reflects its bulk properties, which affords HA its broad spectrum of medical uses that include lubrication, space filling, and tissue coating.

The viscosity of a fluid by definition is its resistance to flow. In one protocol, an HA solution is placed between the surfaces of two concentric cylinders of a viscometer. As one cylinder rotates, the ratio of the force per unit area (dyn cm^{-2}) to the velocity gradient (cm s^{-1} over cm = s^{-1}) gives the units of dynamic viscosity, which are expressed as poise (dyn s^{-1} cm^{-2}). Dynamic viscosity can also be expressed as Pascal-second (Pa s). One milli Pascal-second (mPa s) is equal to one centipose (cP). The viscosity of water is ~1 mPa s. A solution with a viscosity of 10 000 mPa s appears viscous, and a viscosity above 100 000 mPa s is characteristic of a gel.[67]

Both dynamic viscosity and kinematic viscosity belong to the category of absolute viscosity. Kinematic viscosity is defined as the quotient of the dynamic viscosity and the density. The numbers of the dynamic viscosity and kinematic viscosity of HA are practically the same as the density of HA solutions in low concentration is virtually one. The unit of kinematic viscosity is Stokes (cm^2 s^{-1}), and is often expressed

as centi-Stoke (cSt). Kinematic viscosity is one of those tests of HA required by ISO-OVD.

2.214.3.4. Pseudoplasticity

Velocity gradient is often referred to as shear rate. For many fluids such as water and mineral oil, viscosity is independent of the shear rate applied. These fluids are called Newtonian fluids. An aqueous solution of HA, however, is non-Newtonian; that is, the viscosity of an HA changes as the shear rate changes. Specifically, as the shear rate increases, the viscosity of an HA solution decreases. This phenomenon is called 'shear-thinning,' or pseudoplasticity (Figure 2).

To properly define the viscosity of HA, one should always cite the shear rate at which the viscosity is measured. A full scan of viscosities within a range of shear rates as show in Figure 2 is more informative of the rheological profile of HA products than a single-point viscosity measurement. For most practical purposes, however, a single low shear rate such as $1\,s^{-1}$ (1 Hz) is often used in comparing the viscosity of HA-based viscoelastic products.[68]

The pseudoplasticity of HA is customarily quantified as the quotient of the viscosity at rest over the viscosity at a shear rate of $100\,s^{-1}$. Note that pseudoplasticity merely reflects the relative effect of the shear force on the viscosity of a material. Pseudoplasticity by itself does not determine the absolute value of viscosity, and a higher pseudoplasticity does not necessarily mean a lower viscosity at the same shear rate. Taking the Healon family of OVD as an example,[69] Healon5 had a zero shear viscosity of 5525 Pa s, with a pseudoplasticity number of 591. This means that at shear rate of 100 Hz, the viscosity of Healon5 should be 9.36 Pa s (5525/591). Likewise, Healon has a viscosity of 243 Pa s at rest, and a pseudoplasticity number of 173, and therefore a viscosity of 1.40 Pa s (243/173) at a shear rate of 100 Hz. Even with a much higher pseudoplasticity, Healon5 is still more viscous than Healon at a shear rate of 100 Hz.

2.214.3.5. IV and Molecular Weight

While dynamic viscosity and kinematic viscosity are considered the physical property of a bulk material in its absolute physical sense, IV reveals many interesting chemical characteristics of the molecules in an isolated state. Measured at much diluted concentrations (normally <0.1%, w/v), IV leads to information related to the molecular weight of HA. IV $[\eta]$ is usually measured by a capillary viscometer, and a series of dilution of the polymer are allowed to pass through the capillary under gravity.

The ratio t/t_0, the efflux time t of the solution over the efflux time t_0 of the solvent, is defined as relative viscosity η_r. Specific viscosity is defined as $\eta_{sp} = \eta_r - 1$. Reduced viscosity η_{red} is η_{sp}/C, in which C is the concentration ($g\,ml^{-1}$). The extrapolation of reduced viscosity to zero concentration gives IV $[\eta]$. The unit of IV is ($ml\,g^{-1}$), the measure of the hydrodynamic volume of polymers (Figure 3).

Staudinger, winner of 1953 Nobel Prize in Chemistry, first proposed that the reduced viscosity of a polymer (η_{red}) is directly proportional to its molecular weight, hence the equation of $\eta_{red} = KM$. Later, Mark *et al.* modified this hypothesis by raising the molecular weight M to a power, and established the following equation $[\eta] = KM^{\alpha}$, where $[\eta]$ is IV and M is molecular weight.[70]

The exponent α and the factor K can be obtained by plotting the molecular weights (by light scattering analysis) and IV data of a certain polymer. Once α and K are established, the molecular weight of a polymer can be calculated by plugging in the measured IV number into Mark's equation.

For high molecular weight HA, the exponent α has been found around 0.8. The exponent α is a parameter that indicates the rigidity of polymer. The larger the exponent α, the more rigid the molecule is. Moreover, the rigidity (extendedness) contributes exponentially to the viscosity (dynamic volume, molecular size) of the molecule.

2.214.3.6. Elasticity

Elasticity goes hand in hand in hand with viscosity with all HA products, that is why HA is often called a viscoelastic fluid. For the use of HA or HA derivatives as dermal fillers (see Section 2.214.5.3), elasticity is especially important, because it is related to the essential feature of a cosmetic dermal filler – the firmness (hardness) of the gel, measured as the elastic modulus G'.

Consider the situation when a gel is placed between two plates. When the upper plate quickly moves horizontally a

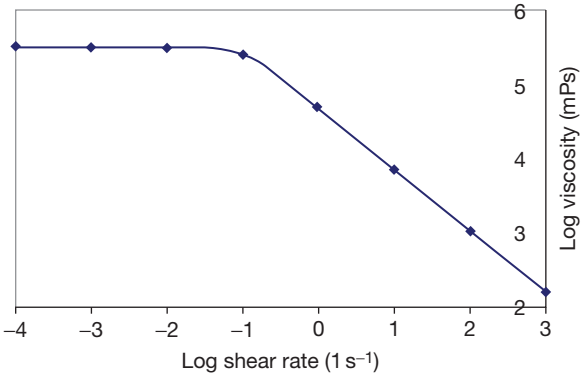

Figure 2 Shear thinning of hyaluronic acid (HA). HA exhibits pseudoplastic behavior, or shear thinning. As shear increases, viscosity decreases.

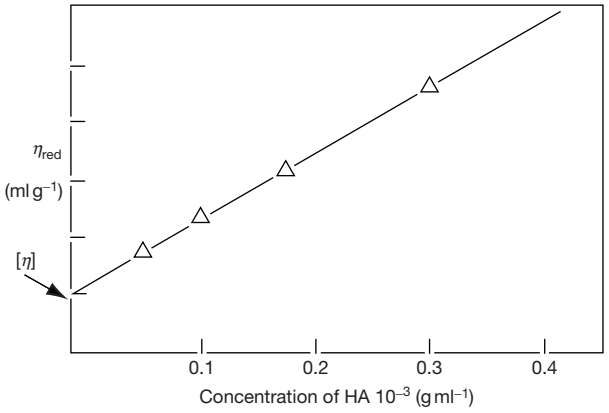

Figure 3 Intrinsic viscosity $[\eta]$ of hyaluronic acid (HA). The intrinsic viscosity of HA is measured by extrapolating reduced viscosity to zero concentration.

small distance, elastic gel tends to resist the change of form. G' is the elastic modulus, defined as the ratio of the shear stress to the shear strain. The unit of G' is (Pa).[71,72]

2.214.3.7. Purity and Biocompatibility

In addition to the qualitative and quantitative analysis mentioned above, for HA-based medical products the tests for purity and biocompatibility are essential for product characterization. HA is by nature compatible with human tissues, the potential toxicity usually come from the impurities. Protein, nucleic acid are routinely tested and their limits set for various applications.

Biocontamination is strictly controlled and closely monitored. During the product development stage, a battery of biocompatibility tests as stipulated by ISO 10993 is normally required by regulatory agencies in EU countries and the United States to establish the safety profile of the products. Examples of those tests are the guinea pig maximization method[73] for a sensitization study, the Ames mutagenicity assay,[74] the chromosomal aberration assay,[75] and the sister chromatid exchange assay[75] for genotoxicity (mutagenicity). For routine tests, sterility and endotoxin level are usually required. The endotoxin limits may vary, and for ophthalmic use ISO-OVD has set the limit at ≤ 0.5 EU ml^{-1}. This very low limit is justified by the highly sensitive nature of the eye tissues supported by the clinical data from the application of OVD.[76]

2.214.4. Chemical Modification of HA

2.214.4.1. Rationale for HA Derivatization

Native HA has several shortcomings for implementation in regenerative medicine, for applications that go beyond viscoelastic supplementation, and providing a moisturizing environment. These limitations include its relatively short residence time *in vivo*, its poor mechanical strength, the inability of most cells to attach to HA, and the inability to form stable structures. A vast array of chemical modifications of HA[77,78] have been developed to make materials more suited for regenerative and reparative medicine.[79] Many of these biomaterials have involved chemical cross-linking. Furthermore, chemical modification techniques have allowed the modification of the surfaces of implantable devices and biomaterials with HA.[80] In this section, we summarize the two main categories of HA modifications and list the principal modification employed. In the following section, we illustrate the use of HA and modified HA in human and veterinary medicine. The practical aspects of these HA-based medical products are the summary of a recent monograph.[9]

We recently categorized chemically modified HA derivatives into two major categories.[81] In *monolithic* derivatives, the modification results in a final form that cannot form new chemical bonds in the presence of cells or tissues, and can only be manipulated by fabrication into different physical forms. *In situ* cross-linking *in vivo* is not possible due to the harsh chemical conditions. However, in *living* derivatives, the modification permits the formation of new covalent bonds *in vivo* or *ex vivo*, enabling a change in physical form – from solution to hydrogel – during cell encapsulation or injection in a clinical procedure. This section presents the basic features of monolithic and living HA technologies and products, but earlier reviews should be consulted for details of using these materials for drug delivery,[82,83] for wound repair, and tissue engineering,[77,84] or for the production of clinically useful extracellular matrices.[85,86] The focus of this section is to highlight results since 2000 that are relevant to the preparation of monolithic and living HA derivatives.

2.214.4.2. Monolithic HA Derivatives

2.214.4.2.1. Carbodiimide-mediated reaction products

2.214.4.2.1.1. N-acylureas

The carboxylic acid moeities of the glucuronic acid units in HA readily react with water-soluble carbodiimides such as N-ethyl, N,N-dimethylaminopropylcarbodiimide (EDCI) to form an intermediate *O*-acylurea that can rearrange to produce the more stable *N*-acylurea adducts.[87,88] The interaction of the cationic acylurea moiety of the EDCI-modified HA and the remaining anionic carboxyl group forms an internal polyelectrolyte complex in the form of a water-insoluble gel. Seprafilm, a reaction product of EDCI with HA and carboxymethyl cellulose (CMC), is a bioabsorbable material used to prevent surgical adhesions that is an example of this type of modification. In addition, biscarbodiimides (BCDIs) can chemically cross-link HA to make bis-*N*-acylurea derivatives of HA which form stable hydrogels.[87]

2.214.4.2.1.2. Carbodiimide-mediated hydrazide chemistry

The reactive *O*-acylurea can undergo further reaction with nucleophiles. Because high molecular weight HA is viscous and diffusion in HA solutions is slow, reactions with amines are unpredictable, and often unproductive. [87] This problem is largely overcome by trapping the intermediate *O*-acylurea with *N*-hydroxysuccinimide, followed by subsequent reaction with the desired amine nucelophile.[89] Yet more efficient and versatile is the use of hydrazide chemistry. Hydrazides are effective nucleophiles at pH 4–6 because of the lower pK_a values (usually 2–4) rather than the higher values for simple amines (p$K_a \sim 12$).[90] The use of bishydrazide or polyvalent hydrazides can make cross-linked HA gels with a wide range of physicochemical properties, from being soft, pourable to more rigid and brittle, by varying reaction conditions and the molar ratios of the reagents.[91,92] Using multivalent hydrazides or hydrazides containing disulfide linkages, as discussed below, affords highly versatile living HA derivatives. One of these living thiolated HA derivatives, HA-DTPH(3,3′-dithiolpropionyl bishydrazide), has also been converted into a monolithic nanofibrous network by dual-syringe reactive electrospinning using polyethylene glycol dialdehyde as the cross-linker.[93] The cross-linking occurs rapidly during electrospinning, and polyethylene oxide (PEO) was present (and later dissolved out) to facilitate fiber formation. Fibroblasts migrated into HA nanomesh scaffolds coated with fibronectin.

The hydrazide chemistry has been adopted to make alkyl-modified HA. Thus, condensation of the adipic dihydrazide adduct of HA, HA-ADH, with aldehydes from octanal to hexadecanal afforded water-soluble but amphiphilic HA derivatives.[94] These alkylated HA-ADH derivatives self-assembled to form hydrophobic domains, affording viscous solutions that exhibited shear-thinning behavior. Compounds of this nature

have promise for viscosupplementation in medicine as discussed in more detail below.

HA-ADH has also been cross-linked into microgels with partially oxidized HA-dialdehyde. These microgels were further set into double-cross-linked networks (DXNs) to obtain an advanced biomaterial with properties desirable for restoring the viscoelastic properties of damaged vocal folds.[95] These HA-based DXNs were biocompatible and had elastic moduli similar to those of human vocal fold lamina propria. A second use of the partially oxidized HA dialdehyde involved forming a covalent network by condensation with gelatin in the presence of a pH 9.4 borax solution, giving, after removal of byproducts, a biocompatible hydrogel suitable for subsequent cell culture.[96]

2.214.4.2.1.3. Carbodiimide-mediated aminooxy chemistry

The reactive *O*-acylurea can also react with aminooxy compounds, which also retain their nucleophilicity at pH 4.75 used during carbodiimide coupling. Recently, aminooxy derivatives of the triblock polyethylene oxide–polypropylene oxide–polyethylene oxide (PEO–PPO–PEO) copolymers known as Pluronics were synthesized and coupled to HA carboxylates using EDCI.[97] Pluronics were prepared with a single AO group or with homobifunctional bis-AO groups. The bis-AOP-HA derivatives formed gels will all three Pluronics, regardless of the length of the hydrophobic segment, consistent with inter- and intramolecular gelation by both covalent cross-linking and noncovalent association of the hydrophobic PPO segments. The mono-AOP-HA also formed gels, but in this case the gelation was the result of hydrophobic–hydrophobic interactions driving self-assembly of the mono-AOP-HA derivatives.

2.214.4.2.2. Divinylsulfone cross-linking

Hylans[98] are chemically cross-linked through the hydroxyl groups of HA, leaving the carboxyl groups unchanged. Hylan A links the HA hydroxyl groups with residual protein by using formaldehyde, and the reaction product retains many of the bulk properties of linear HA, but with increased molecular weight. Hylan B is produced by the reaction of divinylsulfone with HA hydroxyl groups under alkaline conditions. This cross-linked HA network forms a highly swollen gel. The cross-linking and increased elasticity of Hylan B extend its half-life in the knee from 12 h for HA to 9 days for Hylan B. These properties make the Hylan A and B useful as injectable materials for OA, as dermal fillers, and as space-filling dressing in sinus surgery.

2.214.4.2.3. Esterification

2.214.4.2.3.1. Hydrophobic esters

A family of HA ester derivatives has been prepared by the reaction of a quaternary ammonium salt of HA and an alcohol in a polar aprotic solvent. These materials, known as HYAFFs, have increased hydrophobicity of esterified HA resulting from both masking the carboxyl as well as introduction of the hydrophobic side chains.[99] The HYAFFs can still absorb water as a function of degree of esterification. For example, the 100% benzyl ester (HYAFF 11) and 100% ethyl ester (HYAFF 7) hydrated in water at 37 °C by 48% and 259%, respectively; the 75% benzyl ester (HYAFF 11p75) was hydrated by 1250%. HYAFFs are only slowly degraded by hyaluronidases. Scaffolds made of the monolithic HYAFF 11 are cell adhesive and are sufficiently stable in aqueous solution to allow incubation with cells for over 3 weeks. A variety of cell types, including keratinocytes, fibroblasts, chondrocytes, and mesenchymal stem cells, can proliferate on the surface of a nonwoven HYAFF mesh. The monolithic HYAFF also has the potential as a drug delivery vehicle as described below.

2.214.4.2.3.2. Autocrosslinked HA

The HA carboxyl groups can be activated to form inter- and intrastrand esters with HA hydroxyl groups. An effective activating agent is 2-chloro-1-methylpyridinium iodide (CMPI).[100,101] autocrosslinked polymer (ACP) is the brand name of cross-linked HA products of Fidia based on such autocrosslinking technology. ACP gels have been used in preclinical studies for adhesion prevention.

2.214.4.2.3.3. Melt-processable esters

The cetyltrimethylammonium salts of HA containing different levels of silylation of the hydroxyl groups was reacted with acid chlorides to give are series of melt-processable HA esters.[102] Thermoplastic materials were obtained with multiple esters in which the alkyl chains were greater than ten atoms, with longer chains producing materials with lower melting points. These materials have medical applications in hot molding with thermoplastic ultra high molecular weight polyethylene for total joint replacements.

2.214.4.2.3.4. Physically and chemically cross-linked HA esters

The loose physically associated hydrogels arising from HA partially esterified with dodecyl chains were further cross-linked by a second partial esterification using tetraethylene glycol ditosylate.[103] Even at low levels of modification, the physically and chemically dual cross-linked gels would shear thin and showed potential utility for cartilage repair.

2.214.4.2.4. Bis-epoxide cross-linked HA and epoxide-modified HA

Under alkaline conditions, HA can be cross-linked by bisepoxides such as butane 1,4-diol diglycidyl ether or 1,2,7,8-diepoxyoctane (DEO).[78] Such hydrogels can be brittle, and may require reformulation with native HA as a carrier injection as cosmetic dermal fillers and in arthritic knees. Under acidic conditions, the reaction product of diepoxides with the carboxyl group of HA is an ester.[104] HA can be cross-linked twice with the same diepoxide, first under basic conditions and then under acidic conditions. Double cross-linking decreased the water absorbing capacity of the HA derivative and increased its resistance to hyaluronidase degradation when compared to the single cross-linked intermediate.[105]

Another type of bis-epoxide cross-linking was recently performed using polyethylene glycol bisepoxide.[106] Reaction with HA alone or HA plus collagen gave degradable HA hydrogels that were degradable by hyaluronidase and collagenase and had potential utility for tissue engineering.

The reactivity of HA with monoepoxides has been exploited to produce alkylated HA derivatives. Reaction of the primary 6-hydroxy group of the *N*-acetylglucosamine residue with glycidyl ethers (butyl, hexyl, octyl, decyl, and tetradecyl) under basic conditions afforded biocompatible amphiphilic derivatives.[107]

2.214.4.2.5. Ionic cross-linking and polyelectrolyte complexes

Several ionically gelled forms of HA have been produced. First, Intergel is a viscous formulation of HA formed by chelation with ferric chloride.[108] This reddish gel was approved for reduction of postsurgical adhesions in gynecological surgery, but was withdrawn from the market in 2003.

Second, HA can also be used to prepare multilayered polyelectrolyte films, such as the poly(L-lysine) (PLL)-HA films formed by an exponential growth regime.[109] Using fluorescently tagged polymers, it was found that PLL diffused throughout the film after each new PLL injection. As the PLL reached the outer layer of the film, it interacted with the incoming HA, forming the new HA-PLL layer, the thickness of which was proportional to the amount of PLL that diffused out of the film during the buildup step.

Third, HA has been combined with chitosan and ionically cross-linked with sodium tripolyphosphate (TPP) to give nanoparticles that could be loaded with proteins (albumin) or drugs (cyclosporine A).[110] The size and zeta potentials of these nanocarriers could be customized to a given need, and the nanoparticles were stable as freeze-dried powders and could be resuspended in biological media.

A fourth example that is related to ionic cross-linking, but which in fact likely includes covalent phosphate ester formation, involves the use of trisodium trimetaphosphate (STMP) to synthesize HA hydrogel particles.[111] The authors found a linear relationship between cross-linking density and methylene blue absorption.

2.214.4.2.6. Monolithic photocrosslinked hydrogels

There have been at least two reports of HA modified with photocrosslinkable groups, followed by high-energy irradiation to effect cross-linking (which would be incompatible with *in situ* cross-linking as discussed below). First, a postsurgical adhesion barrier was prepared by modification of HA first using EDCI and *N*-hydroxysuccinimide (NHS) chemistry as described above, followed by coupling with 3-aminopropyl cinnamate.[112] The resulting 20% modified compound was irradiated at 3000 W for 2 h to produce the cyclobutane-containing dimeric truxillic/truxinic acid derivatives. The degree of cross-linking was selected to obtain an injectable, biocompatible material. In a different study, styrenated HA was produced by coupling 4-vinylalanine under carbodiimide-coupling conditions.[113] Irradiation with other vinylated proteins and polysaccharides with initiators at 200 mW cm^{-2} produced hydrogels in a variety of physical forms for potential use as tissue engineering scaffolds.

2.214.4.3. Living HA Derivatives

2.214.4.3.1. Thiol-modified HA

The motivation to create living HA derivatives was the need to create an *in situ* cross-linkable equivalent of the extracellular matrix. HA was selected as the basic building block for this covalently cross-linked synthetic extracellular matrix (sECM).[86,114] To create a modular, clinically versatile and readily manufactured sECM, we developed a thiol-introduction chemistry[115] based upon the modification of the carboxylate groups of glycosaminoglycans (GAGs), proteins, and other synthetic polymers by hydrazide formation (**Figure 4**).[116] These mild aqueous conditions do not alter other chemical groups required for biological function of the GAG. Moreover, when the hydrazide reagent contains a disulfide bond,[91,115] thiol-modified HA, sulfated GAGs, even proteins such as gelatin[117,118] could be prepared and cross-linked into hydrogels

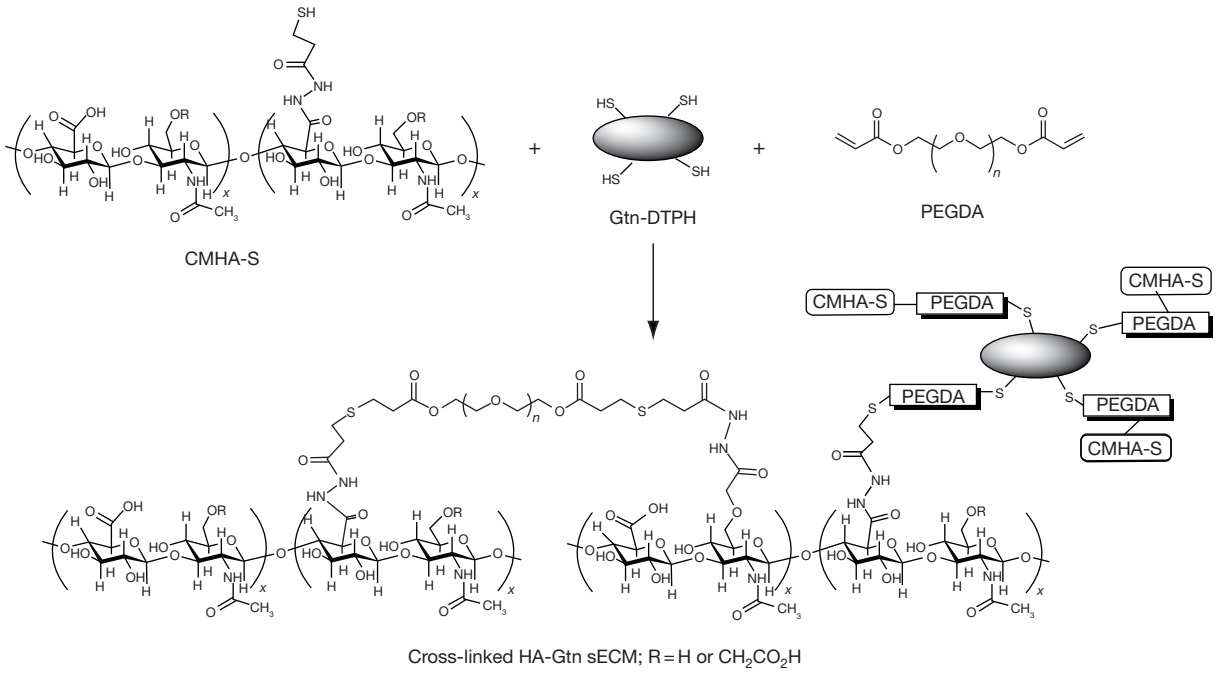

Figure 4 Chemical structure of CMHA-S and PEGDA-cross-linked synthetic extracellular matrix composed of CMHA-S and gelatin-DTPH.

under cytocompatible physiological conditions. For example, thiol-modified macromonomers spontaneously, but slowly, cross-linked in air only to a hydrogel; this gel could be dried to give a thin film or lyophilized to produce a porous sponge.[119] Alternatively, cross-linking with difunctional electrophiles can be accomplished, in the presence or absence of cells, to give injectable and biocompatible hydrogels.[114,118]

Different physical properties and rates of biodegradation can be obtained by controlling several parameters for the biocompatible HA hydrogels[119]: (1) molecular weight of starting HA employed; (2) percentage DTPH modification; (3) concentration of HA-DTPH; (4) molecular weight of poly(ethylene glycol) diacrylate (PEGDA); and (5) ratio of thiols to acrylates. We have also investigated polyfunctional acrylates, acrylamides, and additional thiol-reactive groups, for example, PEG divinyl sulfone, PEG bis-haloacetates, and PEG bis-haloamides.[120,121]

2.214.4.3.2. Haloacetate-modified HA

HA derivatives containing thiol-reactive electrophilic esters were prepared to react with thiol-modified macromolecules to give 'cross-linker-free' hydrogels. Specifically, an aqueous solution of HA was converted to HA bromoacetate (HABA) with a degree of substitution of 18% using ten equivalents of bromoacetic anhydride. Reaction occurs almost exclusively on the more reactive and less sterically hindered primary 6-hydroxy group of the *N*-acetylglucosamine residue. HA iodoacetate (HAIA) was prepared by displacement of bromide with excess iodide. Cross-linker-free hydrogels were then prepared by thiol alkylation using HAIA and HABA as polyvalent electrophiles and thiol-modified HA (CMHA-S) as the polyvalent nucleophiles.

2.214.4.3.3. Methacrylated HA

Photopolymerization offers many attractive opportunities for biocompatible hydrogel formation *in situ* with a range of natural and synthetic polymers, including HA.[122] Three methacrylate derivatized HA macromonomers have been prepared. This extremely useful living modification allows solutions to be seeded with cells and photocrosslinked into hydrogels using either UV or visible light in conjunction with a photoinitiator.[123] The most commonly used method involves the direct methyacrylation of HA with methacrylic anhydride in a pH 8.5 solution,[124] in analogy to the haloacetylation. Similarly, the methacrylation occurs on the primary 6-hydroxy group of the *N*-acetylglucosamine residue. Conditions can be adjusted to give low (~5%) to high (over 30%) modification.

Alternatively, several researchers have used the glycidyl ether methacrylate (GMA) method, which requires a stronger base.[125] The 6-hydroxyl group acts as a nucelophile to open the epoxide of the GMA, analogous to the diepoxide cross-linking described above. A large excess of GMA is required, because the basic conditions also lead to hydrolysis of GMA to glycidol, as well as hydrolysis of the methacrylated HA.

One problem with the photocrosslinked gels, as with the thioether cross-linked gels, was the inability to hydrolyze the gels and recover cells from culture. To solve this problem, a hydrolysable methacrylated HA was synthesized, in which a lactate spacer was introduced between the HA and the methacrylate group.[126]

2.214.4.3.4. Tyramine-modified HA

A new approach to creating a living hydrogel capable of *in situ* cross-linking was recently described, in which carbodiimide chemistry is used in step 1 to add controlled levels of tyramine to HA carboxylates, leaving most carboxylates unmodified.[127] In step 2, either in the presence or absence of cells, cross-linking is induced by the addition of small amounts of hydrogen peroxide to solutions of tyramine-based HA to which horseradish peroxidase has been added. The resulting peroxidase reaction forms phenolate radicals which isomerize and dimerize to form C–C bonded and fluorescent dityramine adducts.

2.214.4.3.5. Alkynylated and azidoalkylated HA

The now well-known Staudinger reaction of azides with alkynes to produce triazoles, or 'click chemistry,' has been applied in nearly every area of chemical biology. Recently, HA hydrogels were produced using this approach, and yeast cells were encapsulated during cross-linking.[128] Briefly, HA carboxylates were modified with proparygyl amine using carbodiimide chemistry to give the alkynyl HA component, and separately modified with 11-azido-triethyleneglycol amine linker to give the azido HA component. The hydrogel was formed at room temperature overnight in the presence of ~0.01% CuCl as a catalyst. While this is an interesting way to make an HA hydrogel, it is unlikely that such a protocol would be approvable or biologically robust in tissue engineering constructs either *ex vivo* or *in vivo*.

2.214.5. Medical Applications of HA

HA and its derivatives have an ever-expanding number of clinical and preclinical applications, including drug targeting and drug delivery.[82,129] Discussion of targeted drug delivery exceeds the scope of this chapter, and in the five sections below we summarize selected medical applications of HA in ophthalmic surgery, intraarticular injections in joints, dermal fillers, acute and chronic wound repair (including surgical adhesion prevention) and 3D cell culture and tissue engineering.

2.214.5.1. Ophthalmic Surgeries

The first HA-based medical products were developed for tissue protection for ophthalmic surgeries. Two rooster comb HA products, Healon (MW 3 MDa, HA 10 mg ml^{-1}) and Amvisc (MW 2 MDa, HA 12 mg ml^{-1}), received approval from the Food and Drug Administration (FDA) in 1983. Viscosity and transparency were critical characteristics for such applications, which included cataract extraction surgery. The viscosity of the HA products helped maintain a deep anterior chamber and retinal attachment surgery, and the HA aided in holding the retina against the sclera for reattachment. The transparency was critically important, since a material used as a surgical aid should neither obscure the vision of the ophthalmic surgeon during the surgery nor the patient postsurgery. The clearness of natural HA has rarely been a problem, unless contaminated by impurities, including particulates.

In the products as ophthalmic surgical aids, the HA ingredient normally has a molecular weight (MW) at or above

1 MDa, and a range of concentration around or above 1% (w/v). The viscous property of the products can be observed by the naked eye. Over the last three decades, HA-containing products have gained wide acceptance and even become a preferred choice for many ophthalmic applications especially in anterior segment surgeries. Here, we will use HA application in the procedures of cataract removal and insertion of intraocular lens as examples to explain the relationship between the product features and their functions.

2.214.5.1.1. Viscosity and lubricity

A certain degree of viscosity is required for HA to remain in the anterior chamber to prevent tissue–tissue contact. Lang *et al.* studied the viscosity of HA preparations under the shear rate of 10 Hz, a close approximation to the shear rate under many surgical conditions and concluded that a threshold of 80 P was needed for the surgery. Healon (1% w/v) has a viscosity of 270 P at such a shear rate. It is gel-like and remains in the eye even when external pressure is applied to the cornea. At rest, Healon's viscosity (zero shear rate viscosity) can reach 1000 P. This prevents the egress of HA from the surgically opened eye under the nonshear, compressive forces of the cornea and the iris–lens–vitreous diaphragm. The viscosity of the same HA material, however, can be reduced to 1 P when it passes through a thin cannula (e.g., 27-gauge) under a high shear rate of 1000 Hz. This is a typical example of shear-thinning phenomenon and the underlying pseudoplasticity of HA as discussed above.[67] This also explains why the same HA product can be both a good space filler and lubricant. Conceivably, pseudoplasticity enables the HA layer not in immediate contact with the tissue surface to move under shear force with less resistance than a Newtonian fluid such as a chondroitin sulfate (CS) solution. This reduces the abrasion such movement might impose on the tissue that the viscous material is supposed to protect.

2.214.5.1.2. Thickness of coating and easiness of the removal of HA

Cataract removal and the implantation of intraocular lens are the ophthalmic procedures where HA-based OVD is most widely used. Here, the viscosity and lubricity of the OVD only partially reflect the desired features of the OVD. The other important factors influencing product performance in such procedures are the thickness of the coating formed and the easiness of the removal of the OVD during postsurgical irrigation and aspiration.

First, the protective effect of a viscous layer depends in large part on the thickness of the layer present at the tissue surface. The bovine cornea abrasion studies by Hammer and Burch[130] indicated that an overly thin layer of high viscous material could cause damage to endothelial cells. This is consistent with the equation by which the viscosity η is defined ($\eta = f\, dy/A\, dv$). For a certain material with certain viscosity (η), the force f (so the damage to cells) is inversely proportional to the distance y (so the thickness).

The thickness of the HA layer that remains after cataract surgery (such as phacoemulsification) and during the insertion of intraocular lens is critical for the protection of cornea. Glasser *et al.*[131] found that a less viscous but more sticky Viscoat provided better corneal protection (~20% cell damage) than the more viscous but less sticky Healon (>40% cell damage) after the traumatic intraocular lens implantation. McDermott *et al.*[132] conducted a rabbit study to quantify the adherence of OVDs to the corneal endothelium after phacoemulsification, and found that the thickness of Viscoat was the highest among the group of Viscoat, Amvisc Plus, and Healon GV. This appears to support the notion that a thin layer of highly viscous material may be responsible for extra endothelial cell loss.

Second, the amount of the remaining HA residue postsurgery can affect the intraocular pressure (IOP), which is a safety related issue. The increase of IOP in the eye is caused by the net influx of the liquid and driven by osmotic pressure. A significant amount of exogenous HA residue in the eye can cause osmosis of liquid from outside, leading to the rise of IOP. Fry compared the IOP increase of four OVDs at 4 and 8 h after surgery.[133] The group of Viscoat without aspiration had the highest IOP increase, followed in decreasing order by the Viscoat group (with aspiration), the Amvisc group (with aspiration), and the Healon group (with aspiration). Viscoat contains HA and CS at high-concentrations (~30 mg NaHA per ml, 40 mg NaCS per ml) and low MW (HA >500 000, CS ~55 000). For the same amount of OVD, Viscoat has more molecules than any other OVDs in the study (Amvisc and Healon) and is therefore attributable to the larger increase of osmotic pressure.

2.214.5.1.3. Cohesiveness and dispersiveness

Another set of properties of OVDs related to the coating thickness during the phacoemulsification procedure: cohesiveness and dispersiveness. Arshinoff explained[134] that 'cohesion allows a viscoelastic to be removed as a single mass, by aspiration or irrigation at the end of the surgical procedure.' The opposite of cohesiveness is dispersiveness.

Cohesiveness can be measured by dynamic aspiration method[135] and the cornea retention method.[136] In the dynamic aspiration method, the percentage of viscoelastic samples aspirated was plotted against vacuum pressure. The slopes of these curves indicate the relative cohesion. The results of the cohesiveness were found in the following descending order: Healon GV (72.3), Provisc (46.0), Healon (31.2), Amvisc Plus (21.4), and Viscoat (3.4). It is noteworthy that the high cohesiveness of Healon GV is related to its very high MW (5 MDa) and medium HA concentration (10 mg ml^{-1}). Materials with higher cohesiveness are easier to remove than materials that are more dispersive.

The second method was the measurement of the retention of viscoelastic agents on corneal endothelial cells after the colored rabbit corneal endothelial cells covered with OVDs underwent irrigation and aspiration, with fluid turbulence similar to that encountered in phacoemulsification surgery.[136] The retention values (the percentage of cells with viscoelastic retained on the surface) were found as follows: Healon, 7; Provisc, 16; Amvisc Plus, 17; Formulation A (a synthetic dispersive preparation), 55; and Viscoat, 90. The results of this experiment also indicated that cohesive viscoelastics were readily removed from the cells, whereas dispersive viscoelastics were highly retained.

High MW contributes a great deal to the networking of HA, and therefore the cohesiveness of the viscoelastics, whereas low-MW materials such as Viscoat, composed of CS (55 kDa) and low-MW NaHA (0.5 MDa), have weaker intermolecular interactions. The lower MW polymer solutions have to be

more concentrated to be viscous. This is why dispersiveness of an OVD relates to its low MW and a high concentration.

The optimum function of an OVD should come from the careful design of its composition and formulation that strives to strike a proper balance between viscosity and ease of removal. There have been many different approaches toward this goal.

1. Amvisc Plus appears to be somewhere near the center in the full spectrum from being cohesive to dispersive, and related to that observation is the fact that Amvisc Plus also has both middle range of HA molecular weight ($1.5\,mg\,ml^{-1}$) and middle range of HA concentration ($\sim 16\,mg\,ml^{-1}$).
2. DuoVisc is an example of putting a typical dispersive product (Viscoat) and a typical cohesive product (ProVisc) in the same package. While Viscoat may provide better protection to the cornea during the cataract removal, Provisc (MW > 1 MDa, HA $10\,mg\,ml^{-1}$) can do a better job reducing the trauma during the insertion of the intraocular lens and is easier to remove afterwards.
3. DisCoVisc is an example of mixing a dispersive ingredient (high concentration of low molecular weight (LMW) OVD CS) and a more cohesive ingredient (an HA formulation very close to that of Amvisc Plus). The CDI (cohesive/dispersive index) of DisCoVisc is 12, as compared to the dispersive Viscoat (3.4) and cohesive Healon (40).
4. Healon5, a high molecular weight (4 MDa) and high concentration ($23\,mg\,ml^{-1}$) formulation of HA is highly viscoelastic and can become dispersive by being fragmented under high shear rates and turbulence generated during phacoemulsification. This property is called adaptiveness. In addition, the fragmentation of the OVD facilitates the forming of a cavity with an outer retentive shell, which is also protective.[69]

2.214.5.2. Injections for Osteoarthritic Joints

The effectiveness of injections of HA for the OA joints to alleviate local pain has been widely investigated. Reviews and analysis of human clinical trials of HA injections for the knee,[137] hip,[138] shoulder,[139] ankle,[140] and temporal mandibular joint (TMJ)[141] are available. However, to date only the knee indication has gained regulatory approval for marketing in the United States by the FDA after many controlled human clinical studies, and along with them a large body of data, which will be our focus in the following analysis.

2.214.5.2.1. Effectiveness of HA injected in the knee

As of the end of 2009, five HA-based injection products on the US market for the treatment of pain of OA of the knee were Hyalgan, Synvisc, Supartz, Orthovisc, and Nuflexxa (Euflexxa). Synvisc is the only chemically cross-linked HA product (cross-linked with divinylsulfone), and the others contain of native HA. Nuflexxa is the only product with HA from fermentation; the other four products use rooster comb HA. Unlike the use of HA in ophthalmic surgery, which has gained universal acceptance, the clinical value as well as the mechanism of action of HA-based formulations for the knee remain unclear.

How effective is HA as local injection into the OA knee? To answer the question objectively, one needs to examine the universe of clinical evidence in its entirety. A meta-analysis by Lo *et al.*[137] reviewed the data of the clinical studies of HA for knee injection from 1966 to 2003. The effectiveness data pertaining to pain relief were extracted from measures of change from baseline at 1–4 months after the first intraarticular injection. An analysis was considered intent-to-treat if there were no dropouts.

The key effectiveness parameter used by Lo *et al.* in their meta-analysis is *effect size*, defined as the pain improvement (Pain HA/Pain placebo) divided by the pooled standard deviation (SD). The effective size in the range of 0.2–0.5 was considered small, equivalent to the effect of nonsteroidal anti-inflammatory drugs.[142] A large effect size was deemed to be at or above 1.0, benchmarked against the effect of a total knee replacement.[143] The pooled effect size for the treatment of knee OA with HA injection versus buffered saline was 0.32, indicative of a small effect. In addition, the study has concluded that injection of saline control contributes ~80% of the treatment effect.

Another meta-analysis conducted by Arrich using data from inception to 2004 reached similar conclusion. Patients who received the HA injection experienced a reduction in pain during movement. The mean difference was from -3.8 to -7.1 mm on a 100-mm visual analogue scale and during the period from 2 to 30 weeks. However, a clinically meaningful difference would expected to be about 15 mm.[144]

As a whole, the intervention of knee OA by HA injection is only marginally effective. There may be subgroups of patients who react more favorably to the treatment than the population in general. But such particular subgroups, if they exist, have not been consistently identified across multiple trials.[137] In clinical practice, it is recommended only for those patients who have attempted other conservative therapies with no appreciable positive results.

2.214.5.2.2. Clinical performance of native and chemically cross-linked HA

To compare the effectiveness and safety of chemically cross-linked Hylan-based product (Synvisc) and native HA products for OA knee injection, Reichenbach *et al.*[145] performed a systematic review and meta-analysis of the pain related outcome of randomized controlled human clinical trials up till 2006. Thirteen trials with a pooled total of 2085 patients contributed to the meta-analysis.

The pooled effect size of all trials slightly favored Synvisc, but between-trial heterogeneity was high. For those trials with blinded patients and in an intent-to-treat analysis, the effect sizes were near zero. The meta-analyses on safety revealed an increased risk associated with the cross-linked Hylan product for any local adverse events including flares.

2.214.5.2.3. Mechanism of action for exogenous HA in the knee

There are two different schools of thought on the mechanism of action of exogenous HA in the OA knees. One theory (viscosupplementation) emphasizes local and physical effect, while the other maintains that the main effect is systemic. The local effect proponents argue that HA with high viscosity restores the physiological homeostasis of the joint characterized by the rheological property of healthy, viscous synovial fluid. Critics often point to the lack of strong clinical evidence of the efficacy of local

injection of HA over placebo, or the evidence of high viscosity formulations being superior to the lower viscosity ones. Proponents of systemic effect of HA on joints point to the fact that HA administered intravenously (i.v.) in horses actually works just as well as the HA injected intraarticularly (i.a.).

One of the products (Legend) for racehorses is approved for both i.v. and i.a. routes of administration. In the controlled trials, i.v. injection of Legend was shown to be as effective as i.a. injection, according to the Freedom of Information for Legend (NADA 140–883). The Legend injectable solution was 1% of sodium hyaluronate. In principle, a systemic effect can arise from either i.a. or i.v. injection. It is conceivable that a significant portion of the effect of locally injected HA may occur systemically.

What could be the scientific rationale behind such phenomena? Kawcak *et al.*[146] found that horses treated i.v. with HA had better (lower) lameness scores and synovial membrane histologic scores. In addition, the HA-treated group had a significantly lower concentration of total protein and prostaglandin E2 within synovial fluid 72 days after the surgery. It was postulated that i.v. administered HA may 'alleviate signs of lameness by interacting with synoviocytes, and by decreasing production and release of inflammatory mediators.'[146]

2.214.5.3. Cosmetic Tissue Augmentation

HA-based dermal fillers for cosmetic tissue augmentation are gaining increased popularity. The cross-linked HA products Restylane (cross-linked with BDDE, butanediol diglycidyl ether) and Hylaform (cross-linked with divinyl sulfone (DVS)) were first commercialized in the United States for the temporary correction of facial wrinkles in early 2000s. In the controlled clinical trials of Restylane (6 months) and Hylaform (12 weeks), both products were as effective as collagen-based product Zyplast in the correction of moderate to severe facial wrinkles and folds (such as nasolabial folds). In general, HA-based products offer more discernable results than facial creams and chemical peels, yet are less invasive than facial surgery. Since then, Juvederm (also BDDE cross-linked) and Elevess (BCDI cross-linked) also gained FDA approval and entered the US market. Puragen uses DEO as cross-linker and is often called double-cross-linked HA because epoxide can form an ether bond with the hydroxyl groups of HA under basic conditions, but form an ester bond under acidic conditions. FDA approval is pending as of 2009.[147]

2.214.5.3.1. Residence time

It is not accidental that all those HA dermal fillers use cross-linked HA as their major ingredients. In its native form, HA can only produce a cosmetic effect for the duration of only 1–2 days.[148] In contrast, cross-linked HA dermal fillers have residence time in skin from 4 months to a year.[149]

There is little doubt that the residence time of HA dermal fillers is a key parameter because HA has to be able to stay in the injected site long enough to be effective. This is unlike ophthalmic surgery, where HA is meant to be removed after its function as surgical aid is accomplished, or in the case of knee injection where the importance of residence time of exogenous HA has not been proven.

2.214.5.3.2. Elasticity

If viscosity is the predominant feature of HA products for ophthalmic use, elasticity may be considered as the most important parameter for HA-based dermal fillers. Elasticity is the resistance to deformation and in the case of a polymeric gel it is displayed and observed as its firmness. HA products with high elastic modulus G', such as Restylane and Perlane ($\sim$600 Pa) are more elastic than those with low G' values such as Hylaform (140–220 Pa) and Juvederm 30 HV (105 Pa).[72] In general, fillers with high G' can better resist forces during facial muscle movement and provide better lift for areas like nasolabial folds, whereas fillers with low G' are perhaps better suited to areas like lips where volume and softness of the filler are critical.[72]

The elasticity displayed by different HA fillers is determined by multiple factors. The degree of cross-linking is the first determinant for the firmness of an HA gel. The more the cross-linkers are chemically bonded to the HA molecules, the more structural support to the HA network and therefore the more physical force the gel can sustain. The second determinant has to do with HA concentration, which relates to the amount of HA that was cross-linked. Naturally, the more HA in the gel, the firmer the filler would become. Combining factors one and two can at least partially explain why Hylaform (5.5 mg ml^{-1} HA, 12% cross-linking) and Juvederm 30 HV (24 mg ml^{-1}, 2% cross-linking) have similar elasticity.

The third factor is the gel/sol ratio of the filler. Note that there is always a portion of the HA molecules in the filler that are either uncross-linked or very lightly cross-linked. That part of the filler is basically liquid in nature, which does not contribute to the firmness, but acts a lubricant to soften the gel. This soluble part of the filler is added by the manufacturer to improve injectability. The fourth factor is the post-cross-linking processing steps, such as sizing and homogenization. Sizing largely maintains the granular feature of the particles and elasticity, whereas homogenization reduces the particle sizes dramatically to make the filler smooth and in doing so also changes its elasticity.[71]

2.214.5.3.3. Safety and reversibility

As a biodegradable polymer, the safety profile of HA-based dermal fillers is generally acceptable, but serious adverse events do occur, whether the source of HA is avian or bacterial. Batch-to-batch quality consistency is also a challenge. Excessively large sizes of particles in the gel are the suspects for causing some granular tissue reactions. HA-based fillers, however, have the advantage of being reversible in the presence of its degrading enzyme hyaluronidase, which the clinicians may option to use if clinically necessary.[150]

2.214.5.4. Acute and Chronic Wound Healing

Modified HA products are used clinically in veterinary practice for wound healing and have potential for use in human patients as well. We present only a few highlights below and refer to web-based information and published literature for details.

2.214.5.4.1. Acute cutaneous wounds

Adipic hydrazide-modified HA and CS (HA-ADH and CS-ADH) were cross-linked with PEG-dialdehyde and the resulting

hydrogels were dried in air and sterilized with ethylene oxide.[151] The resulting films were used in two cutaneous injury models. First, full-thickness wounds were created on the dorsal side of Balb/c mice and were dressed with a GAG film plus Tegaderm or Tegaderm alone. A significant increase in reepithelialization was observed at day 5 and day 7 for the wounds treated with GAG films versus the controls. In addtion, wounds treated with either HA or CS films showed more fibro-vascular tissue by day 10. The GAG films, which rehydrated in the wound bed, provided a highly hydrated, pericellular environment in which assembly of other matrix components, presentation of growth and differentiation factors, and cell migration could occur.[151]

The second model for these GAG films was a pig model for the treatment of autograft sites of burn patients.[152] Multiple shallow (5 cm × 5 cm × 0.03 cm) wounds were created on the backs of pigs. Half of the wounds were treated with a GAG film (cross-linked CS-ADH or HA-ADH) plus an occlusive dressing (Tegaderm™), whereas the other half were treated with Tegaderm™ alone. At 3, 5, or 7 days after surgery, the partially healed wounds were excised and evaluated histologically for three animals at each time point. By day 3, epithelial cells had proliferated and migrated from wound edges and from epithelial islands associated with residual hair follicles to begin to cover the wound bed. A statistically significant increase in coverage was observed for GAG treated wounds over controls at day 3 and day 5 postsurgery. Both the HA and CS hydrogels accelerated wound healing by enhancing reepithelialization.[152]

Thiol modified HA (see **Section 2.214.4.3.1**), was first known as HA-DTPH, but was then replaced with an improved carboxymethylated HA derivative known as CMHA-S. The thiolated HA derivatives readily formed biocompatible hydrogels that did not support cell attachment and proliferation. Cross-linking was accomplished slowly via disulfide bond formation in air, or with better control of cross-linking time and hydrogel stiffness using cytocompatible bivalent cross-linkers. Using a murine full-thickness wound repair model, we evaluated the PEGDA-cross-linked CMHA-S derivative.[85] Bilateral injuries were formed on the flanks of each animal, allowing each animal to act as its own control. One site was left untreated, while a cross-linked HA film was applied to the contralateral wound; Tegaderm used for both sites to prevent dessication and reduce microbial invasion. After 6 days, the treated wounds were over 45% reepithelialized after 6 days, while the untreated wounds were only 12% healed. Moreover, wound filling, epidermal thickness, dermal thickness, and vascularization were also significantly enhanced in treated animals. Similarly, in a pilot study in horses, excisional wounds were more than 75% healed after 26 days without detectable proud flesh formation (**Figure 5**). These studies have now been repeated numerous times in clinical veterinary practice for dogs, cats, horses, ferrets, hawks, and other animals (www.sentrxanimalcare.com).

2.214.5.4.2. Acute surgical wounds

2.214.5.4.2.1. Seprafilm

Seprafilm was described above as a partially co-cross-linked formulation of HA and carboxymethylcellulose. It is indicated for use in abdominal surgery to reduce postsurgical adhesions (*Summary of Safety and Effectiveness Data of Seprafilm P950034*). Seprafilm can remain at surgical sites for up to a week, the critical time needed to prevent adhesion formation. However, it is brittle when dry and sticky when moist and is therefore difficult for surgeons to handle. A more pliable Seprafilm II has been developed which contains glycerol, in addition to the components of Seprafilm.[9] A BCDI cross-linked HA, Incert (Anika Therapeutics) was developed for the prevention of postsurgical adhesions.[87] Incert was effective in reducing tissue adhesions in a uterine horn model.[153]

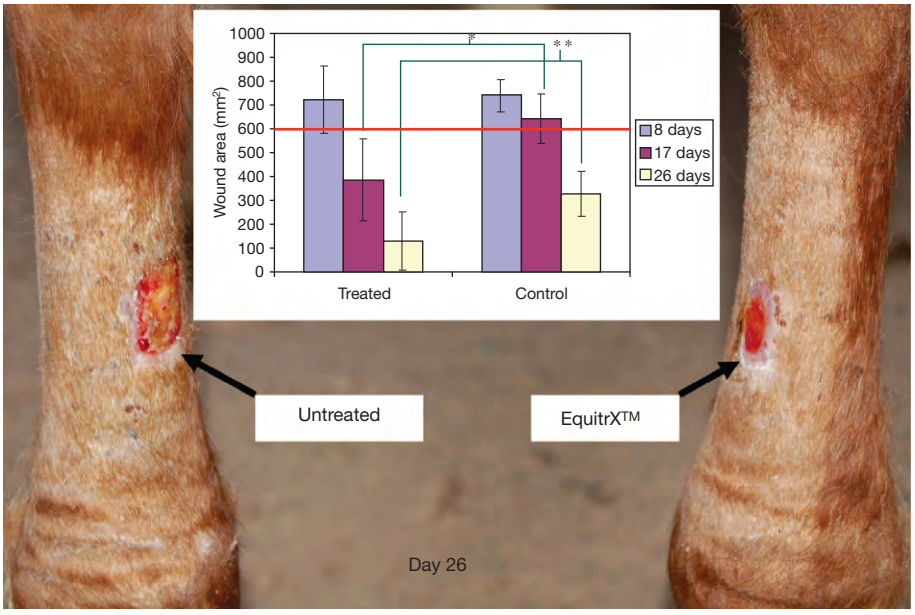

Figure 5 Pilot study for treatment of 1 × 2 cm excisional injuries in horses ($n = 8$) with cross-linked CMHA-S films (EquitrX) compared with untreated controls. Wounds were exposed and redressed at 8 and 17 days and photographed and quantified at 8, 17, and 26 days. The inset shows statistically significant healing at 17 days (*, $p < 0.004$) and 26 days (**, $p < 0.003$) and a complete lack of proud flesh formation.

2.214.5.4.2.2. Autocrosslinked HA products

Controlled human clinical studies have been conducted to investigate the effectiveness of internal ester cross-linked ACP gel (Hyalobarrier) in the prevention of intrauterine adhesions. Ultrasonographic data indicated that ACP gel kept uterine walls separated for at least 72 h. The group of patients receiving ACP gel during adhesiolysis showed significant decrease in incidence and severity of adhesion reformation than the control group (without gel) 3 months after the procedure.[154] Similarly, Hyalobarrier reduced *de-novo* adhesions after hysteroscopic surgical procedures to remove myomas and polyps.[155] An ACP formulation known as Hyaloglide also reduced adhesions after knee surgery in a rabbit model.[156]

2.214.5.4.2.3. Ionically cross-linked HA

The reddish ferric hydroxide cross-linked HA gel Intergel was approved by the FDA in 2001 to reduce postsurgical adhesions in patients undergoing open, conservative gynecological surgery (*Summary of Safety and Effectiveness Data of PMA P990015 of Intergel*). After about a week, the tissues absorbed the gel and the metabolites were excreted. However, in 2003, this product was withdrawn from the market, due to adverse events associated with off-label use in laparoscopy and nonconservative surgical procedures such as hysterectomy. A recent study documents the unacceptably high rates of postoperative morbidity following colorectal resection.[157]

2.214.5.4.2.4. Thiol-modified HA

The cross-linked thiol-modified CMHA-S and HA-DTPH materials have shown remarkable preclinical success in preclinical models for postsurgical adhesion prevention. Reduction of scarring following vocal fold injury *in vivo* was facilitated by the cross-linked HA-DTPH hydrogel[158] and the CMHA-S hydrogel.[159] Postoperative pericardial adhesions were dramatically reduced by the CMHA-S hydrogel in a rabbit cardiac abrasion model.[160] In rat uterine horn model, PEGDA-cross-linked HA-DTPH with or without mitomycin C as an antiproliferative agent significantly reduced the area and severity of adhesions.[161] Even more effective were the CMHA-S-PEGDA materials. In both a rat uterine horn model and a rat cecal abrasion model, the CMHA-S (Carbylan-SX) films were statistically superior to Seprafilm in reducing the extent and area of adhesions.[162] Importantly, the use of an *in-situ* gelling formulation of Carbylan-SX reduced adhesions to near zero in the cecal abrasion model.[162] In contrast, the Carbylan-SX films outperformed the hydrogels for the prevention of peritendinous adhesions following partial-thickness flexor tendon injury in rabbits.[163] Both treatments were superior to Seprafilm in reducing the severity of adhesions; the Carbylan-SX films actually reduced the force required to remove the tendon from the paw to the same value required for an unoperated control (**Figure 6**). The Carbylan-SX gels have also been used to reduce stenosis after tracheal injury,[164] to improve healing following endoscopic sinus surgery,[165] and to promote healing following middle ear injury.[166]

2.214.5.4.3. Chronic wounds

2.214.5.4.3.1. Esterified HA

The TissueTech autograft system comprises a dermal replacement (Hyalograft 3D) made of a 3D matrix of HYAFF 11 with autologous fibroblast *and* an epidermal replacement (Laserskin) made of a microperforated HYAFF 11 membrane containing autologous keratinocytes. A clinical study[167] of patients with chronic wounds such as diabetic or pressures

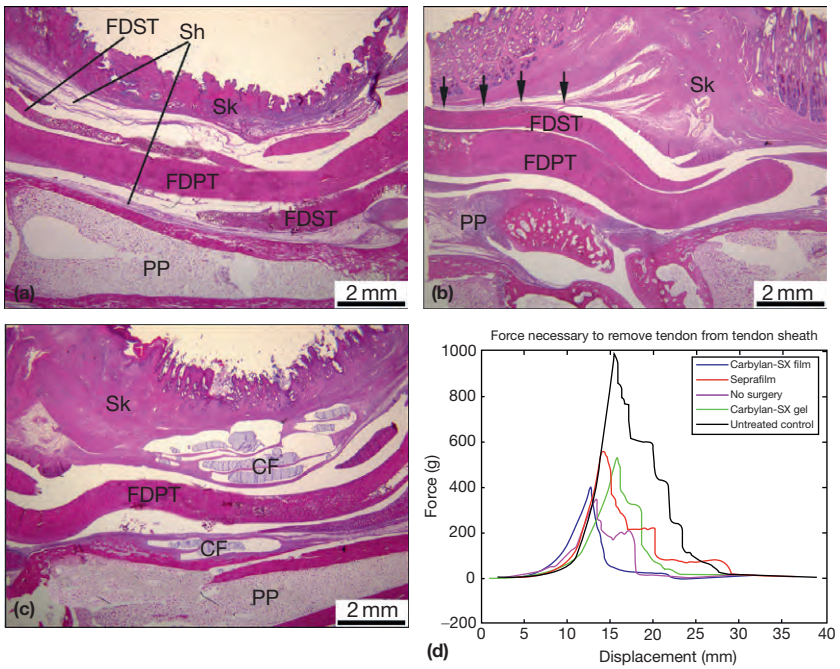

Figure 6 Tendon repair in rabbit flexor tendon model. (a) Unoperated tendon; (b) operated and untreated adhesion, with arrowheads showing adhesions; (c) CMHA-SX film wrapped tendon, showing absence of adhesions. H&E staining, scale bar = 2 mm. ulcers indicated that 59% of the treated ulcers reached complete closure in <4 months.

2.214.5.4.3.2. Thiol-modified GAGs and growth factors

Using a blend of HA-DTPH with a thiolated heparin (HP-DTPH) macromonomer, basic fibroblast growth factor (bFGF) was released from an HA-based sECM *in vitro* with a half-life of 1 month[168] when released from a CS-based sECM *in vivo*, bFGF showed dose-dependent acceleration of reepithelialization and improved formation of vascularized dermal tissue in the repair of large acute wounds in diabetic mice.[169]

2.214.5.5. Selected Uses in Tissue Engineering and 3D Cell Culture

2.214.5.5.1. 3D cell culture

2.214.5.5.1.1. Modular sECMs[170]

The use of modular sECMs for reparative medicine and for drug discovery in three dimensions[171] has been recently reviewed, with an emphasis on clinically useful materials.[85] Only illustrative examples are presented below. Incorporation of attachment factors to an HA-based hydrogel provides an sECM that supports cell attachment, growth, and proliferation in 3D. By co-cross-linking the thiol-modified gelatin (Gtn-DTPH) with HA-DTPH, we obtained materials to which cells readily attached and spread.[172] This can be accomplished with lyophilized macroporous sponges based on disulfide co-cross-linking, or with injectable materials using PEGDA cross-linking.[118] Alternatively, gelatin can be replaced by either an Arg-Gly-Asp (RGD) peptide[84] or selected domains of fibronectin.[173] These materials have been also be used centrifugal casting of endothelial cells[174] and have promise as biopaper in bioprinting strategies.[175] To further enhance cell growth and simultaneously enhance the rate of neovascularization, an HA-based sECM containing co-cross-linked thiol-modified heparin (HP-DTPH) was found to give a half-life for bFGF release of over 1 month *in vitro*.[168] Varying the GAG-DTPH composition regulates release of vascular endothelial growth factor (VEGF) and keratinocyte growth factor (KGF), with dual release[176] further enhancing vascularization and vascular maturation *in vivo*.[177]

2.214.5.5.1.2. Human embryonic stem cells (hESCs)

When encapsulated in a photocrosslinked HA methacrylate hydrogel, hESCs maintained their undifferentiated state, preserved their normal karyotype, and maintained their full differentiation capacity as indicated by embryoid body formation. Differentiation could be induced within the HA hydrogel by altering the soluble factors present in the medium. Living HA hydrogels, with their developmentally relevant composition and tunable physical properties, thus provide a unique microenvironment for the self-renewal and differentiation of hESCs.

2.214.5.5.2. Cartilage and bone repair models

2.214.5.5.2.1. Osteochondral defect repair with esterified HA

Two esterified HA products were tested for their ability to enhance the natural healing response in osteochondral defects on the femoral condyles of 4-month-old rabbits. Defects were filled with an autocrosslinked ACP sponge, or HYAFF-11 sponge, made of benzylated hyaluronan. While untreated defects filled with bone tissue up to or beyond the tidemark, at 12 weeks, the ACP-treated and HYAFF-11 treated defects had bone beyond the tidemark that was covered with a thin layer of hyaline cartilage. ACP-treated defects scored significantly higher than HYAFF-11-treated defects. The HA-based polymers provided an appropriate scaffolding and favorable microenvironment for the reparative process.[178]

More recently, this protocol has been translated to the clinic. Hyalograft C, consisting of autologous chondrocytes grown on a HYAFF 11 scaffold, used to treat cartilage defects of the knee. A clinical study[179] demonstrated that the functions and symptoms of the patients continued to improve for at least 3 years, suggesting that Hyalograft can be a valid alternative to autologous chondrocyte transplantation (ACT).

2.214.5.5.2.2. Defect repair with living HA

Chondrocytes encapsulated in photocrosslinkable HA methacrylate retained the chondrocytic phenotype and synthesized cartilage matrix *in vitro*, and accelerated healing in an osteochondral defect model *in vivo*.[180] The poor cell attachment to these *in situ* photopolymerized HA hydrogels can be significantly enhanced by RGD modification.[181] When human mesenchymal stem cells (MSCs) were encapsulated in the photocrosslinked HA methacrylate hydrogels, a significant upregulation in chondrogenic genes (type II collagen, aggrecan) was observed compared to MSCs in inert poly(ethylene glycol) (PEG) gels. Blocking CD44 receptors reduced the chondrogenic gene expression profile induced by HA gels, and microarray analysis identified a range of genes involved in this improved chondrogenesis, including specific matrix interactions that are only found with HA. This is an important example of biomaterial chemistry controlling stem cell differentiation and again emphasizes the importance of the microenvironment to provide cues to control MSC behavior.[182]

An sECM hydrogel using thiolated HA (CMHA-S) was also examined for repair of an osteochondral defect in a rabbit patellar groove.[183] In untreated control defects, extensive scar tissue accumulated after 12 weeks. However, simply filling the defect with the HA-gelatin-based sECM hydrogel resulted in regeneration of both new osteal and chondral tissues. More robust remodeling was accomplished by the addition of autologous MSCs to the sECM hydrogel, suggesting that localized cell delivery and retention can add an important dimension to the regenerative process. Nonetheless, the fundamental role of the sECM is to enhance the natural biological repair processes mediated by endogenous cells.

The stiffness and porosity of the ECM substitute were also important. In a rat femoral defect model, using either a hydrogel or a lyophilized sponge form of the cell-free two component sECM Extracel[184] to deliver human demineralized bone (DBM) enhanced bone repair (**Figure 7**). While untreated controls showed little new bone formation after 8 weeks, the sECM sponge treatments generated more new bone at all time points than the softer sECM hydrogels (**Figure 8**). In addition, the addition of DBM to either material gave a statistically significant improvement in healing, reaching over 85% repair at 4 weeks postinjury.

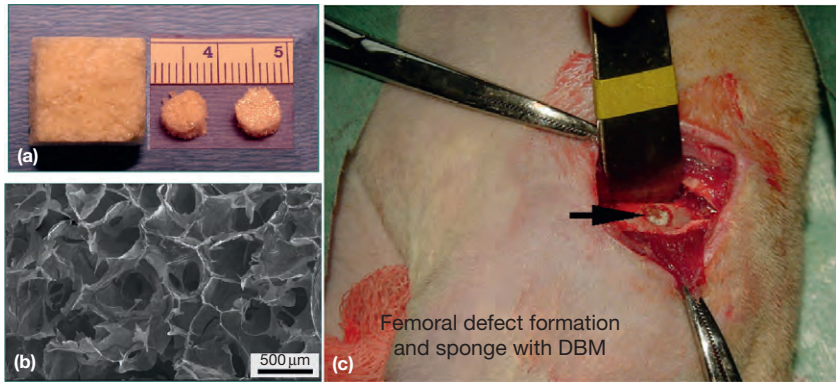

Figure 7 Paradigm for rat femoral defect model. (a) Lyophilized sponge block of PEGDA-cross-linked synthetic extracellular matrix composed of CMHA-S and gelatin-DTPH, and biopsy punch generated press-in cylinders. (b) Scanning electron microscope (SEM) of sponge containing 20% (w/w) demineralized bone matrix. (c) Insertion of sponge plug into defect site.

2.214.6. Future Perspectives and Conclusions

2.214.6.1. The Future of HA Science

Three important resources exist for understanding both the historical perspectives and tracking the very dynamic research in hyaluronan science. The first is an online review series, entitled 'Hyaluronan Today,' which is hosted by the Seikagaku Company. This resource (http://www.glycoforum.gr.jp/science/hyaluronan/hyaluronanE.html) encompasses diverse subject areas, from the physical and synthetic chemistry of HA to HA–protein interactions and medical applications of HA.

The second is the International Society for Hyaluronan Research (ISHAS), which can be found at http://www.ishas.org/. The mission of ISHAS is to advance knowledge on the

structure, function, and therapeutic application of hyaluronan and its role in the structure and function of the extracellular matrix and cells. The ISHAS meets every 3–4 years and the proceedings are often published in monograph form.

The third is the Matrix Biology Institute (MBI) (http://www.matrixbiologyinstitute.org) which aims to further knowledge on the structure, function, and therapeutic applications of hyaluronan by supporting conferences with the primary objective of promoting communication between scientists and clinical investigators whose interest is hyaluronan or the intercellular matrix. MBI conducts and supports a project of collecting all scientific papers and books (basic research and clinically oriented) on hyaluronan since the late nineteenth century. This library is continually updated and references will be available at the website. In addition, since 2002 the MBI has been constructing an encyclopedia on hyaluronan. In 2010, MBI will post a definitive document for the characterization and analysis of HA from natural sources.

2.214.6.2. Concluding Remarks

Native HA has grown from laboratory curiosity to an essential player in clinical medicine over the past 40 years. In the last two decades, we have witnessed growing importance of the first generation of chemically modified HA derivatives, the so-called 'monolithic' materials, that can be injected, molded, shaped, spun, or woven for a variety of clinical uses. While these monolithic materials will continue to enjoy commercial and clinical success, the past 10 years has seen the emergence of an important second generation of 'living' HA derivatives. The living polymers offer many new opportunities for 3D cell culture, injectable tissue engineering, wound repair, scar-free healing, drug delivery, and toxicology testing. The applications of the living HA technology for therapeutic, veterinary, and laboratory research uses will continue to grow and mature during the decades to come.

Acknowledgments

The authors thank the NIH, the NSF, The Center for Biotechnology at the University at Stony Brook, Med Chem Products, Inc., Anika Therapeutics, Inc., Clear Solutions Biotech, Inc., Sentrx Surgical, Inc., the University of Utah, and The Center for Therapeutic Biomaterials, for financial funding over the past two decades that facilitated the author's activities with HA. Commercialization of the living sECM technology is currently pursued by Carbylan Biosurgery, Inc. (human therapeutics), Sentrx Animal Care, Inc. (veterinary products), and Glycosan BioSystems, Inc. (3D cell culture systems for research and toxicology).

Glossary

Collagen cross-links Covalent bond formation between α chains within a triple helix (intramolecular) or between α chains of neighboring triple helices (intermolecular). Cross-links are enzymatically initiated and are formed spontaneously over the lifetime of an organism. Cross-linking constitutes a crucial mechanism that stabilizes the tissues and provides resistance to wear and tear.

Collagen type Up to now, 29 different collagen types have been identified. All collagens are composed of polypeptide subunits called α chains. Three α chains make up each molecule (γ-component).

Collagen type I The most abundant collagen in mammalian body. It is used extensively for tissue-engineering applications.

Extracellular matrix (ECM) By definition, secreted molecules that become immobilized around a cell.

Gelatin Heat-denatured collagen whereby the α chains have been disassociated or separated from each other. In solution, these α chains do not come into proper register anymore and form random coil structures instead of triple helices.

Gly-X-Y repeat The classical amino acid sequence that characterizes the primary structure of collagen and represents it triple-helical domain. The X-position is often occupied by proline (Pro) while the Y-position is often occupied by hydroxyproline (Hyp).

Abbreviations

AGE	Advanced glycation endproduct
ECM	Extracellular matrix
FBS	Fetal bovine serum
Gly	Glycine
HFP	Hexafluoropropanol
HPLC	High performance liquid chromatography
Hyl	Hydroxylysine
Hyp	Hydroxyproline
kDa	Kilo Dalton
Lys	Lysine
mTGase	Microbial transglutaminase
PAGE	Polyacrylamide gel electrophoresis
PAMAM	Polyamidoamine
PEG	Polyethylene glycol
PEO	Polyethylene oxide
Pro	Proline
SCA	Sircol dye assay
SDS	Sodium dodecyl sulfate
SHG	Second harmonics generation
TGase	Transglutaminase

2.215.1. Origins of Collagen and Role in Animal Physiology

2.215.1.1. Collagen: A Component of the Extracellular Matrix

Collagen represents the major structural extracellular matrix (ECM) component of vertebrates. It is the most abundant mammalian protein accounting for about 20–30% of total body proteins.[1] About 700 My, collagen made its appearance in the oldest metazoan of the animal kingdom on earth, the sponges, and was found subsequently also in other invertebrates such as jellyfish, coral, and sea anemones (reviewed in Huxley-Jones *et al.*[2]). Starting from a prototypic collagen we now have evidence for an evolutionary branching into currently 29 different collagens in vertebrates.[3] Vertebrate ECM genes have mainly arisen through duplication of preexisting genes and modification of preexisting matrix molecules all of which were tested fiercely for their usefulness.[2] The collagen types that have survived the test of time are very sensitive to even point mutations. Single amino acid changes, mostly glycine substitutions in the collagenous or triple-helical region, lead to tissue pathology and disorder. Collagens, in particular the major class of fibrillar collagens, are often referred to scaffolds that hold cells in place and provide them with anchorage while lending tensile strength or stiffness to a tissue. Often overlooked are the ligands that bind to these collagenous aggregates and add function. Nonfibrillar collagens are to be mentioned here along with proteoglycans, growth factor-binding proteins, and growth factors themselves.[4] Cells therefore gather complex information from their microenvironment that induces them to spread, migrate, divide, regulate metabolic functions, or differentiate. This is accomplished not only via recognition of extracellular matrices with integrin receptors, but also via discoidin domain receptors that have recently emerged as nonintegrin-type receptors for collagen.[5] It is even speculated that cells can recognize a suprastructural collagen assembly as a whole, even different collagen types.[6] We have listed the currently known collagen types in **Table 1**. It is conspicuous from this table that dermis alone contains some ten different collagen types, and tendon at least eight. While collagen I amounts for roughly 70% of skin proteins, it is the almost, but not exclusive, component of tendons with 97–98%.[7] As animal dermis (e.g., bovine hides) and tendons (e.g., bovine or equine Achilles tendon) are a major source for acidic extracts and slurries for freeze-dried collagen sponges for biomedical uses, it becomes obvious that a substantial fraction of these biological functions that are created by the multitude of collagens and other ECM proteins might become lost during industrial processing, but some of them might be retained. It is therefore essential to know the basic composition of the connective tissue of the tissue unit used for manufacturing biomaterials and to envision the interaction of cells with it. This alone decides the fate integration, remodeling or inflammatory destruction of this biological biomaterial in a host.

2.215.1.2. General Characteristics of Collagen

Collagens are synthesized by a variety of mesenchymal and epithelial cells and details of their biosynthesis are reviewed extensively in Kielty and Grant.[8] All members of the collagen family have a common and unique signature, namely the [Gly-X-Y]*n* sequence in which the X- and Y-positions are frequently occupied by proline (Pro) and hydroxyproline (Hyp). The latter represents a significant posttranslational modification that occurs intracellular and is dependent on vitamin C. This unique primary structure translates into a unique secondary structure, the collagen α chain. It is not to be confused with the α-helix of a normal protein which is a right-handed structure stabilized by hydrogen bonds that bridge the turns of the helix. These hydrogen bonds –C=O:–H–N– occur between the α carbon atoms of the partnering amino acids. In contrast, the collagen α chain forms a left-handed helix that is stretched due to the abundance of prolyl residues acting as helix breakers. This increases the distance between turns (pitch) which precludes hydrogen bond formation. In addition, Pro is an unusual amino acid as the amino nitrogen is part of a secondary amino group (N–H) instead of the usual primary amino group ($-NH_2$). This means that after the dipeptide bond formation between Pro and another amino acid the α carbon atom of Pro has no further hydrogen to offer. Therefore, the collagen α chain is not stabilized by hydrogen bonds. Pro renders the collagen α chain stretched and stiff, therefore this secondary structure cannot fold into a superstructure. Thus, we have to consider secondary and tertiary structure of the collagen α chain as identical. (This aspect is often not discussed in textbooks. The triple helix is often given as the tertiary structure of collagen, which in fact it is not.) The quaternary structure, however, is unique again, represented by the association of three α chains forming a triple helix. The three pro-α chains are tightly wound around each other and form a three-stranded rod-like molecule with the glycyl residues representing the central core of this molecule. For this reason, Gly-X-Y repeats are also addressed as 'collagenous' or 'triple-helical' domains as they are a predictor for the formation of such a unique quaternary structure.

The Hyp residues are derived from posttranslational modification of a substantial number of abundant prolyl residues and they stabilize the triple-helical domain (not the single α chain) by interchain hydrogen bonding along the helix. Collagenous domains vary in length from as short as 30 to in excess of 1500 amino acid residues and are either uninterrupted or contain imperfections in the Gly-X-Y repeat that result in flexible regions within the relatively stiff, rod-like triple helix. With the exception of collagens XXIV and XXVII, the major triple-helical domain is slightly longer than 1000 amino acid residues and has a perfect Gly-X-Y triplet structure. All nonfibrillar collagens have at least one imperfection or interruption in their triple helices. The amino end of a fibrillar collagen, the *N*-propeptide, usually contains at least one small triple-helical domain, designated the minor helix. Once the major triple helix has formed, the amino and carboxyl ends are proteolytically removed from the central molecule by specialized enzymes in the extracellular space. These processed molecules align themselves in a quarter stagger arrangement in the growing fibril (reviewed in Kielty and Grant[8]). In transmission electron micrographs, collagen fibrils have an alternating light and dark pattern, which has led to them being termed 'banded' or 'cross-striated fibrils' – a typical signature feature shown in countless textbooks and publications, including this chapter. This banding pattern is also evident from

Table 1 The collagen family, types, forms, and tissue distribution

Collagen type	*Chains*	*Molecular assembly*	*Supramolecular structure*	*Mr × 10^{-3} α chain*	*Examples of tissue location*
I	$[\alpha1(I)]_2\alpha2(I)$	Monomers staggered by 67 nm	Large diameter 67 nm banded fibrils	95	Bone, cornea, dermis, tendon
I trimer	$[\alpha1(I)]_3$		67-nm banded fibrils		Tumors, dermis, bone
II	$[\alpha1(II)]_3$	Monomers staggered by 67 nm	67-nm banded fibrils	95	Cartilage, vitreous, cartilaginous zones of tendon
III	$[\alpha1(III)]_3$	Monomers staggered by 67 nm	Small-diameter, 67-nm banded fibrils	95	Dermis, aorta, uterus, admixture in tendon, intestine, blood vessels
IV	$[\alpha1(IV)]_2\alpha2(IV)$; also $\alpha3(IV)$, $\alpha4(IV)$, $\alpha5(IV)$, $\alpha6(IV)$	Association of 4N- and 2C-termini	Nonfibrillar meshwork	170–180	Basement membranes

X	$[\alpha1(X)]_3$	?	Nonfibrillar, hexagonal lattice?	59	Calcifying cartilage (incl parts of tendons)
XI	$[\alpha1(XI)\alpha2(XI)\alpha3(XI)]$	Monomers staggered by 67 nm	Fine fibrils similar to those of collagen V	110–145	Cartilage, intervertebral disk
XII	$[\alpha1(XII)]_3$	Associates with surface of collagen fibrils?	FACIT; nonfibrillar	220, 340	Dermis, tendon, cartilage
XIII	$\alpha1(XIII)$	?	Membrane-intercalated	62–67	Endothelial cells, epidermis
XIV	$[\alpha1(XIV)]_3$	?	FACIT; nonfibrillar	220	Dermis, tendon, cartilage
XV	$\alpha1(XV)$	?	MULTIPLEXIN; nonfibrillar	125	Placenta, kidney, heart, ovary, testis
XVI	$\alpha1(XVI)$	?	FACIT; nonfibrillar	150–160	Heart, kidney, muscle
XVII	$[\alpha1\ (XVII)]_3$	?	Membrane-intercalated	180	Hemidesmosomes (skin) specialized epithelia
XVIII	$\alpha1(XVIII)$	?	MULTIPLEXIN; non fibrillar	200	Kidney, liver
XIX	$\alpha1(XIX)$	Aggregates	FACIT; nonfibrillar	165	Transitory embryonic expression, interneurons and formation of hippocampal synapses, basement membranes, muscle cell, rhabdomyosarcoma
XX	$\alpha1(XX)$	?	FACIT	185, 170, and 135	Corneal epithelium, embryonic skin, sternal cartilage, tendon
XXI	$\alpha1(XXI)$	?	FACIT	?	Blood vessel walls, secreted by smooth muscle cells
XXII	$\alpha1(XXII)$		FACIT	200	Tissue junctions
XXIII	$\alpha1(XXIII)$		Membrane-intercalated		Tumors (prostate)
XXIV	$\alpha1(XXIV)$		Fibrillar, fibril associated?		Regulation of collagen I fibrillogenesis, osteoblast differentiation marker
XXV	$\alpha1(XXV)$		Membrane-intercalated		Interaction with β amyloid plaques in Alzheimer's disease
XXVI	$\alpha1(XXVI)$		FACIT(?)	~80	Ovary and testis
XXVII	$\alpha1(XXVII)$	Network	Thin fibrils nonstriated		Hypertrophic cartilage
XXVIII	$\alpha1(XXVIII)$			~50	Basement membrane of Schwann cells
XXIX	$\alpha1(XXIX)$	?	Nonfibrillar?		Suprabasal cells in epidermis

images taken from the surface of fibrils as obtained via atomic force microscopy. What is not evident from these pictures is that these fibrils can be composed of a variety of collagen types and which isoform of a particular collagen type might be forming these fibrils.

2.215.1.3. The Collagen Family: Types and Forms

The difference between different pro-α chains within one collagen type allows compositional changes within one collagen type. For example, collagen I can exist as a heterotrimer of two α1 chains and one α2 chain, or as a homotrimer of three α1 chains. A series of collagens exist only as homotrimers (see Table 1). In contrast, six genes coding for six different α(4) chains create considerably diverse isoforms of collagen IV that have histologically distinct distribution in different types of basement membranes. Hence, different collagen types are necessary to confer distinct biological features to the various types of connective tissues in the body. For example, collagen type I is predominant in higher-order animals especially in the skin, tendon, and bone where extreme forces are transmitted. Type III is found in limited quantities (~10%) in association with type I. Thus, type III is a minor component of type I collagen from skin (reviewed in Friess[9]). In addition, blood vessels predominantly contain type III. This means that a typical cross-striated fiber in TEM might be in reality a heterotypic fiber, a composite of different collagen types.

Collagen III has been addressed previously as 'contaminant'[9] from the industrial point of view. We feel that with increasing knowledge about the diversity of the collagen family and the multiple collagenous composites found in vertebrate tissue it would be preferable to accept it as a given biological admixture that plays an important biological role (This explains the difficulty to obtain pure collagen III preparations. In several commercially available collagen III preparations we found mostly collagen I, truly much more than a mere contaminant in this case.) and to acknowledge that *in vivo* 'pure' collagen populations exist only on the microscale.

Currently, 29 collagen types have been identified, some of them with highly unique features, many with interrelated features, but often with specific localization in specific tissues. This variety points to crucial biological functions and is reflected by a multitude of physical structures. Currently, the collagen family falls into four divisions that are largely based on their primary structure and the respective sizes of their triple-helical domains.

Group 1 consists of the fibril-forming collagens I–III, V, XI, XXIV, and XXVII, as they have triple helices with uninterrupted Gly-X-Y stretches of approximately 300 nm in length. However, XXI and XXVII show imperfections in the triple-helical stretches as seen in invertebrates. The classical fibril-forming collagen triple helices act as monomers that form supramolecular assemblies by associating in parallel, but staggered by one-quarter of their length. This quarter staggered array leads to the typical cross-striation with a 67-nm banding pattern as seen after contrasting with heavy metals in transmission electron microscopy. This feature is absolutely typical for collagen. Collagen fibrils in the dermis, the source of leather and many types of collagen sponges, are often alloys of different collagen types, usually types I, III, and V. These fibers are referred to as heterotypic as opposed to homotypic fibrils that would be composed of only one collagen type, for example, collagen VII in anchoring fibrils of the dermoepidermal junction.

Group 2 hosts the basement membrane collagens IV, VII, and XXVIII. While collagen IV forms a fibrillar meshwork, collagen VII forms cross-striated fibrils, albeit with a different banding pattern and created by antiparallel dimer association.

Group 3 contains the short-chain collagens VI, VIII, and X. They are named after their triple-helical regions which extend to 100 and 150 nm, respectively. Collagen VI forms beaded microfilaments, while collagens VIII and X form most likely hexagonal lattices. The recently discovered collagen XXIX has a short uninterrupted triple-helical region that is flanked by several von Willebrand factor A domains.

Group 4 contains a collection of collagens that show multiple interruptions of the triple-helical Gly-X-Y stretches. These *f*ibril-*a*ssociated *c*ollagens with *i*nterrupted *t*riple helices are known as FACIT collagens and comprise types IX, XII, XIV, XVI, XIX–XXII. Taking the number of interruptions to the extreme are collagens XV and XVII which have been subsumed under the term MULTIPLEXINs. Finally, a remarkable subgroup are collagens XIII, XVII, XXIII, and XXV for they contain transmembrane domains that allow these molecules to be inserted in cell membranes while projecting the (interrupted) triple-helical domains outward into the extracellular space. A synopsis on current collagen types, their structure and tissue distribution are given in Table 1. The current collagens have been reviewed very recently,[3] further data on tissue distribution, and biochemical features of collagens I–XIX are discussed in Kielty and Grant,[8] while current references on collagens XX–XIX are given elsewhere.[10–19] Important to know is that the proteolytic breakdown products of collagens can have a biological life on their own. For example, the carboxyl terminal domains of collagens XV and XVIII can be cleaved to generate antiangiogenic peptides. These are called either endostatin and restin, or endostatin-XVIII and endostatin-XV.[20,21]

2.215.2. The Biochemical Fingerprint of Collagen

2.215.2.1. Primary Structure

Keeping in mind that any given tissue preparation can naturally contain half a dozen and more collagen types we can nevertheless focus on the most predominant collagen type, collagen I, as it presents the materials scientist with the typical analytical issues related to collagen and allows us to understand the biochemistry of all collagens in principle. Collagen I is a glycoprotein with a carbohydrate content of less than 1%. The sugar components are either a single galactose unit or a disaccharide of galactose and glucose *O*-glycosidically attached via hydroxylysine (Hyl) residues. The basic collagen I molecule contains three polypeptide pro-α chains, each consisting of more than 1000 amino acids. The triple-helical Gly-X-Y domain is uninterrupted. Thirty-three percent of the amino acids are Gly residues, 35% of the nonglycine positions are occupied by Pro, found almost exclusively in the X-position, and 4-Hyp, predominantly in the Y-position. Hyp and Pro account for approximately 22% of the total amino acid residues. Hyp is derived from Pro by catalytic activity of prolyl hydroxylase, an enzyme resident in the lumen of the

endoplasmic reticulum of fibrogenic cells. Limited amounts of Hyp can be found in elastin and collagen-like molecules, but their presence in any given tissue that is not extremely rich in elastic fibers is negligible. Hyp comprises approximately 10% of the amino acid composition of collagen and therefore is a molecular fingerprint for collagen or its breakdown products. Hyp can be quantified via HPLC or colorimetric assays after total hydrolysis (see Section 2.215.4). Collagen also contains the unusual amino acid Hyl, a posttranslational modification of lysine via lysyl hydroxylase. The formation of Hyl residues and subsequent attachment of sugar components appear to be important modulators of fibrillogenesis and further cross-linking and fibril stabilization.[8]

2.215.2.2. Secondary to Quaternary Structure of Collagen

Compared with most synthetic polymers, collagen shows considerable structural complexity. The α-chains form left-handed helices with 3.3 residues per turn and a pitch of 0.94 nm as identified by X-ray analysis. In comparison, common peptides form right-handed α-helices (or β-pleated sheets or mixtures of α-helices and β-sheets) with a pitch of 0.54 nm and 3.6 residues per turn. This means that the collagen α chain is stretched (larger pitch), but narrowly twisted (less amino residues per turn). The rod-shaped triple helix of collagen I has an average molecular weight of approximately 300 kDa, a length of 300 nm with a diameter of 1.5 nm. This extreme ratio of the dimensions gives rise to high viscosity in solutions and high mobility in electrical fields (reviewed in Friess[9]). Collagens are secreted as oversized molecules, procollagens. Specialized enzymes remove the N- and C-terminal propeptides leaving a triple helix with short nontriple helical stubs measuring 9–26 amino acids in length at the amino and carboxyl terminal chain ends. These nonhelical regions are denoted as telopeptides, they play a role in the registering of collagen α chains and cross-linking (see Section 2.215.2.4.1).[8]

2.215.2.3. Supramolecular Assembly of Collagen

Collagen triple helices are able to form supramolecular aggregates only after the enzymatic removal of the propeptides. The triple helices are staggered by 67 nm with an additional gap of 40 nm between succeeding molecules. The triple-helical molecules stagger longitudinally and bilaterally into fibrils with distinct periodicity. Fibrillogenesis starts with microfibrils consisting of four to eight collagen molecules that grow further into fibrils. Those fibrils reach from 10 to 500 nm in diameter depending on tissue type and stage of development. These collagen fibrils organize into fibers, which on their part can form even larger fiber bundles. Ultrastructurally, microfibrils, fibrils, and bundles exhibit the typical banding pattern; however, the absence of cross-striation does not signify absence of collagens, but merely absence of fibrillar collagens (see Table 1). Another particular physical feature of collagen fibers is their ability to be optically imaged in multiphoton microscopy through second harmonics generation (SHG).[22] The reason for this lies in the physical properties of the triple helix which – in crystallographic terms – is defined as a noncentrosymmetric structure, which after self-assembly into higher-order fibers provides an 'ordered nonlinear medium with a cross-sectional path length comparable to near infrared wavelengths.'[23] SHG has been used in multiphoton microscopy for specific optical imaging of collagen in tissues. In skin, the heterotypic interwoven collagen fibers and bundles (collagen types I≫III>V) give strong SHG signals, whereas the dermoepidermal junction (collagen IV, VII, XVII) does not. Thus, the SHG signal is strongly dependent on the material order, making it highly sensitive to structural changes such as go along with denaturation.[24]

2.215.2.4. Natural Cross-Links of Collagen Aggregates

2.215.2.4.1. Classical collagen cross-links

The systematic packaging of the triple helices lends strength and resilience to the collagen fibers. Additional mechanical and chemical stability is derived from intra- and intermolecular cross-links. The cross-linking occurs enzymatically and nonenzymatically. Initially, the formation of cross-links is initiated indirectly by lysyl oxidase during fibril formation (reviewed in Kielty and Grant[8]). The enzyme can only work on the surface of forming fibrils and paves the path for subsequent spontaneous cross-linking processes rather than creating the cross-linking itself. Its activity is limited to the nonhelical telopeptides and leads to the conversion of selective Lys and Hyl residues to the corresponding aldehydes allysine and hydroxylallysine. While the fibrils associate, these aldehydes can react spontaneously. Intramolecular cross-links form between two α chains in the nonhelical (telopeptide) section of the same molecule by aldol condensation of two aldehydes, for example, two allysines, resulting in α chain dimers that are evident in sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE) gels as β component (see Figures 1 and 2). Intermolecular cross-links occur between the telopeptides of one collagen molecule and the helical region of a quarterly staggered adjacent molecule. These bridges between two different triple helices result from aldimine between aldehyde residues and ε-amino groups presented by Lys and Hyl. The interchain bifunctional cross-links are still reactive and continue to form multifunctional cross-links through multiple condensations with His, Lys, or Hyl residues. These aldimine cross-links are acid labile and their detection depends on their prior reduction with sodium borohydride ($NaBH_4$), after which they can be recovered from acid hydrolysates of collagen and subsequent chromatography. Details of collagen cross-link formation are reviewed in Kielty and Grant.[8]

Quantification of the individual cross-links in collagen is performed currently in highly specialized laboratories and is complicated by the fact that in most tissues the number of borohydride-reducible cross-links decreases with age because they most probably mature into stable, nonreducible cross-links, the nature and number of which remain to be fully defined. In the case of the Hyl aldehyde pathway, the more mature cross-links appear to be based on trivalent 3-hydroxypyridinium residues – Hyl-pyridinoline (3Hyl) and Lys-pyridinoline (2Hyl and 1Lys). These two cross-links are naturally fluorescent and can be assayed directly in tissue hydrolysates (reviewed in Kielty and Grant[8]). The pyridinoline cross-links are stable and can be detected in urine by HPLC[25] or specific enzyme-linked immunosorbent assays.[26] Measurement of the excretion of these cross-links is gaining interest for the monitoring of osteoporosis and its treatment.

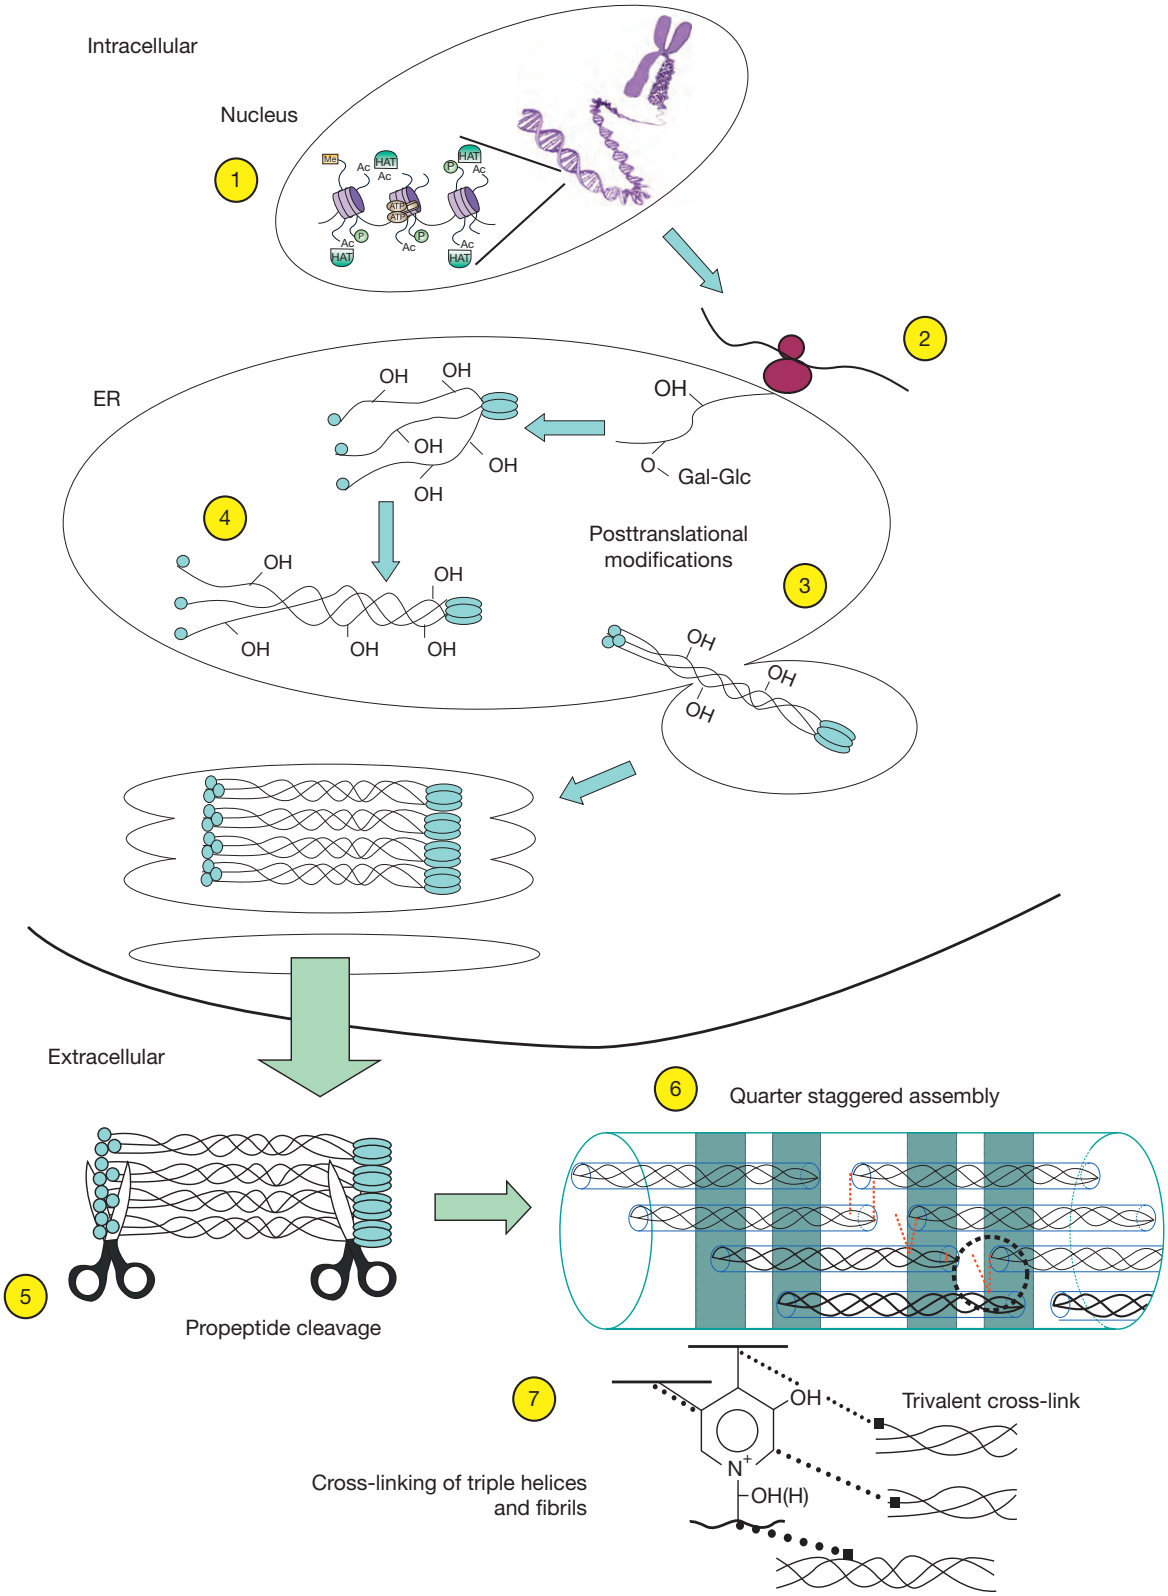

Figure 1 Cartoon of the intracellular and extracellular pathway of collagen biosynthesis, ranging from transcription/translation (1,2), posttranslational modification ((3) O-glycosylation. (4) hydroxylation), the extracellular trimming of procollagen to collagen (5) and its subsequent supramolecular assembly (6). The dotted lines in the quarter staggered assembly (6) represent di- and trivalent cross-links. The trivalent cross-link shown here (7) is a hydroxyl-pyridinoline cross-link. The position of the cross-links is given schematically and is not drawn to scale or in exact position. 2.215.2.4.2. Sugar-based collagen cross-links

Collagen cross-links can also be formed by sugars. Since the discovery of nonenzymatic glycation of hemoglobin molecules in patients with diabetes mellitus, the role of sugars in modifying tissues has been of great interest. The prolonged exposure of collagens to reducing sugars produces glycation end-products that are implicated as factors in aging and diabetic complications. Indeed, glycation is a major cause of dysfunction of collagenous tissues in old age, and the process is accelerated in diabetic subjects due to the higher levels of glucose. Glycation can affect a number of properties of collagen including its biomechanical features and the formation of supramolecular aggregates. The most damaging effects, however, are caused by glucose-mediated intermolecular cross-links which decrease flexibility and permeability and reduce turnover. Almost all extracellular proteins can react nonenzymatically with a sugar group (frequently glucose) via a free ε-amino group of a Lys or Hyl. This form of glycation (Maillard reaction) involves the chemical reaction of a sugar aldehyde or ketone with a free amino group to form a Schiff base, which may undergo a rearrangement to form a fairly stable ketoimine (Amadori product). These structures go on to form advanced glycation end-products (AGEs) or are degraded into reactive α-dicarbonyl groups that react with other free amino groups to form cross-linked adducts. The occurrence and accumulation of these groups on stable low-turnover macromolecules such as collagen is receiving considerable attraction because these cross-links potentially influence the resistance of collagen to being broken down or remodeled[27–30] (reviewed in Kielty and Grant[8]).

2.215.2.4.3. Other enzymatic cross-links

The role of tissue-type transglutaminase (TGase 2) as a cross-linker of collagen matrices is not firmly anchored in textbooks on collagen and derived biomaterials yet. TGases belong to a family of enzymes that catalyze the formation of isodipeptide bonds between proteins (reviewed in Iismaa *et al.*[31]). The vertebrate TGases all require calcium for their catalytic activity. A few ECM targets of TGase 2 have been biochemically characterized. Fibronectin has been known for some time to be a target, but with regards to the collagens information exist only on collagen III, collagen V/XI in cell culture, and collagen VII in human skin. This has inspired us and other groups to explore the opportunities of enzymatic cross-linking of collagen-based biomaterials TGase 2 as the cross-links created would be biologically acceptable by the host organism (reviewed in Collighan and Griffin,[32] Zeugolis *et al.*,[33] and Orban *et al.*[34]). Data on TGase 2 treatment of collagen I derived from shark skin, gelatin from skin or bone suggests collagen I as a target; however, there is surprisingly little information as to the precise target sites. It cannot be ruled out that those reactive sites in collagen gels are provided by collagen III or V, which are, as mentioned above, admixtures of collagen preparations from skin. Microbial TGases (mTGases), in particular from *Streptoverticillium mobaraense* (also *Streptomyces mobaraensis*) are widely used in commercial food processing as glue for processed meat and fish products and to improve the texture of protein-rich foods. mTGases are ideal for industrial purposes since they do not require calcium and are active across a range of temperatures and pHs. In fact, mTGases have been used as cross-linkers for collagen type I gels,[35–38] but we would like to point out that this enzyme is biochemically very different from a mammalian protein. Our unpublished data suggest that TGase 2 is still present in considerable amounts after the cross-linking procedure. If the same holds true for mTGases, this might represent an immunogenic threat for implanted material. It might therefore be advisable to use mammalian, better even, human recombinant TGase 2 for cross-linked biomaterials that are to go into the body. Fingerprints of effected transamidation are the presence of ε-(glutamyl)-lysine isodipeptide that can be detected via specific antibodies or by HPLC.

2.215.3. Sources of Collagen

Although collagen is encountered almost everywhere in the mammalian body, skin and tendons are primarily used to extract collagen type I, and cartilaginous tissues are used to extract collagen type II due to their abundance in these tissues.[39–43] Fins, scales and bones, and waste materials of the fish industry have also been used to extract collagen for biomaterials applications.[44–47] Although different methods (neutral salt, alkali, acid, and enzyme) have been investigated over the years to isolate and purify different types and amounts of collagen from different tissues and species, the acid and enzyme extractions are the most preferred.[48–52] Dilute acidic solutions although effectively disassociate intermolecular cross-links of the aldimine type; they are ineffective against less labile cross-links such as ketoimine bonds. To this end, proteolytic enzymes-based approaches are used to cleave additional cross-links and to solubilize/extract more collagen.[9,40,42,48,49,53,54] The efficacy of enzymatic treatment arises from selective cleavage in the nonhelical N- and C-terminal telopeptides that allows dissection of essentially intact helices[55–57] unless the collagen molecule is partially unfolded, molten, or broken.[58] The resulting monomolecular collagen or atelocollagen benefits from the removal of the antigenic P-determinant located on the telopeptides and as a consequence the host immune response can be greatly reduced and a

more competitive biomaterial can be produced[59–67] that it is expected to become more widely used in clinical settings.[67–69]

Despite advances in extraction and purification procedures, collagen is a biopolymer derived from animals and thus there is the issue of interspecies transmission of disease.[70–75] For example, the recent concern about the transmission of bovine spongiform encephalopathy across species barriers has proven to be a significant drawback for manufacturing bovine-derived biomaterials despite reports stating that the transmission of this disease to humans, if it occurs at all, requires an effective dose for a sufficiently prolonged period of time.[76] For this reason, collagen-like synthetic peptides[77,78] and human recombinant collagens[79–81] have been investigated for scaffold fabrication.

Design and synthesis of synthetic peptides mimicking the structural, biological, and mechanical properties of native collagen has been the subject of research for several decades. The basic constituent of the collagen helix is the repeating triple-helical sequence of Glycine-X-Y, where X is often Pro and Y is frequently Hyp.[8,82–88] Data have revealed that five triplets are required to form a stable triple helix and for this reason 5–15 triplets are frequently used to mimic the primary and tertiary structures of collagen.[77,89] Several sequences have been investigated over the years,[90–95] including a synthetic peptide system able to self-assemble into a fibrous collagen-like homotrimeric helical structure with well-defined periodicity evident by transmission electron microscopy.[96] Studies using collagen-biomimetic peptides have provided invaluable insights into physiological[97,98] and pathophysiological[99] collagen-folding pathways as well as information about the triple helix stability[100–102] and biological functions including cell adhesion and cross-linking sites.[103–106] Despite the significant strides that have been achieved, the recent years in medicine, and nanotechnology using synthetic collagen-like peptides, it is still very difficult to mimic the higher-order supramolecular structures of native collagens.

The use of genetically engineered cells, microorganisms, animals, and plants appeared to be a cost-effective, scalable, and reproducible technology for the production of recombinant human collagens that avoids problems related with variations between batches, interspecies transmission of disease and possible xenogenic immuno-responses induced by animal-extracted collagens.[107–109] Several expression systems including transfected mammalian cells,[110,111] insect cells,[112,113] yeast,[114,115] bacteria,[116–118] transgenic mice,[119] transgenic plants such as tobacco,[120,121] corn,[122] and silkworms[123] have successfully been employed to produce human recombinant procollagens. However, expression of fully functional molecules has been difficult due to the complex nature of procollagen synthesis.[124] Moreover, in all cases, the procollagen expression levels have been low ranging from 15 mg ml^{-1} for mammalian cell culture[125] and yeast[126] to 60 mg ml^{-1} in baculovirus[113] and therefore limiting broad commercialization potential. Additionally, while recombinant collagens have been expressed in a thermostable triple-helical form, they lack specific domains otherwise present in native fibrillar collagens,[127,128] which further compromises their biological function and further reduce their use.

Recently, our laboratory has developed a novel biotechnological approach that involves the *in vitro* deposition of large amounts of collagen from fibrogenic human cell lines under conditions of macromolecular crowding which entails the addition of macromolecules >50 kDa in the culture media.[129–132] The principal of the approach is based on the fact that the deposition of a collagen matrix depends on the conversion of *de novo* synthesized procollagen to collagen in the extracellular space or immediately before its release into the same.[133] The rate-limiting step of collagen I deposition is the proteolytic conversion of procollagen to collagen. This step is catalyzed by procollagen C-proteinase and proteolytic modification of its allosteric regulator. We have recently demonstrated that this key step can be dramatically accelerated in the presence of high concentrations of macromolecules (e.g., polystyrene sulfonate, dextran sulphate, Ficoll) in the culture media.[134,135] In fact, under noncrowding conditions, lung fibroblasts produce approximately 6×10^5 collagen chains per hour per cell,[136] while the crowding system enables 10–30 times greater collagen deposition (**Figure 2**). To further increase the collagen production, transforming growth factor-β has been used, which has been shown to increase further collagen type I deposition *in vitro* under crowded and noncrowded conditions.[137,138] It has also been shown in cultured fibroblasts that the fibrogenic factor can cause a three- to sixfold increase of the rate of type I collagen synthesis by stimulating the transcription of type I procollagen genes.[139] It was postulated that this agent acts by modulating the synthesis of specific macromolecules rather than a general increase in cellular metabolism and proliferation.

2.215.4. Collagen: Purification and Analysis

Following collagen production, it is essential to purify the final collagen solution. All methods of purification are a compromise between removing as much impurity as possible without denaturating the collagen, particularly by heat, from its native form.[140] Soluble collagen is purified mainly by salt/polyelectrolyte precipitation, followed by centrifugation and dialysis. Precipitation has long been used as an early step in the process of purifying proteins from complex solutions.[141–146] Protein precipitation has been described as equilibrium between the protein phase (precipitate) and the saturated liquid phase (supernatant).[143] It has been reported that proteins precipitate through the formation of protein–polyelectrolyte complexes and the formation of particles from these complexes.[147] Electrostatic attraction and hydrogen and hydrophobic bonding have been recognized as the driving forces.[148] At low concentration of the additive, the protein solubility is increased and this is called the salting-in zone, while at higher concentrations, solubility decreases giving rise to the salting-out effect.[149] Different collagen types can be precipitated by differential salt/polyelectrolyte fractionation. Insoluble precipitates can be redissolved in dilute acidic solutions and proteolytic enzymes, followed by salt/polyelectrolyte fractionation. Collagen solutions contain varying proportions of monomer and higher molecular weight covalently linked aggregates, depending on the source and method of preparation and purification. It has been postulated that it is near impossible to obtain a truly monomeric collagen solution; however, pepsin-extracted collagen usually contains higher proportions of monomer than salt- or acid-extracted material.[9,56] Soluble collagen can be stored in solution, frozen or lyophilized. In any case, it is

essential to determine the level of purity of the collagen preparation as well as the collagen concentration.

The purity of collagen solutions has been evaluated over the years using numerous methods with variable level of complexity. Although mass spectroscopy has been used extensively in collagen research,[150–153] complication arising either due to the high molecular mass of collagen or due to the low molecular mass of collagen telopeptides, provide significant challenges in purity assessment of collagen with mass spectroscopy.[154] Amino acid analysis has also been employed as a very sensitive method to evaluate the collagen purity[155–162]; however the complexity of the method, the costs, and the requirement for specific columns limits its use. SDS-PAGE is the most commonly used method to assess the purity of collagen preparations as has been described previously.[163] The electrophoresis is based on the principle that charged molecules migrate through a semisolid medium (gel) when subjected to an electric field, during which proteins are separated from a complex mixture into distinct bands at a characteristic rate depending on charge, size, and other physical characteristics. Protein bands are customarily visualized by staining with Coomassie Brilliant Blue, although more sensitive stains (20–50-fold increased sensitivity) have been developed using silver for both proteins and carbohydrates. The heat-denaturated collagen sample binds to the SDS molecule that confers a net negative charge on each molecule and consequently the polypeptides migrate on the polyacrylamide gel proportionally to their molecular weight.[42,56,164] Delayed reduced electrophoresis has also been introduced to separate different collagen types from tissues; for example, the α1(III) chains can be resolved from the α1(I) chains by interrupted electrophoresis with delayed reduction of the disulfide bonds of the type III collagen.[165] **Figure 3** demonstrates that under nonreduced conditions, type I and III collagens comigrate, while under delayed reduction, separation of α1(III) and α1 (I) can be achieved. Subsequent densitometric analysis allows detection of samples on the nanogram scale,[40,166] while complementary Western blots can be used to assess the specificity of collagen type using monoclonal antibodies.[167,168]

To fabricate reproducible scaffolds with controllable properties, it is essential to be able to accurately determine the collagen concentration.[169–172] Moreover, collagen represents a crucial metabolic biomarker of cellular activity and phenotype, such as collagen type I and III production in dermal/keloid fibroblast culture[173] or the ratio of collagen type I and III to collagen II in chondrocyte culture, respectively.[167,174] Accurate determination of collagen content in pathophysiologies (e.g., fibrosis) is also crucial.[175–177] It is therefore essential to develop assays that will allow accurate determination of collagen synthesis or degradation. Collagen and elastin contain the unusual amino acids Hyl and Hyp.[178] Hyl is formed from lysine via enzymatic hydroxylation by lysyl hydroxylase, while Hyp is formed from Pro, by the enzyme 4-prolyl hydroxylase to form 4-Hyp in the endoplasmic reticulum.[9,179–181] Since the percentage of Hyp remains relatively constant throughout the various genetic forms, the amount of Hyp is used to calculate the total collagen content in collagen-based biomaterials, in tissue-engineering assays, and in tissue pathophysiologies with very little error.[56,182,183] Several methods have been introduced over the years to determine the collagen concentration through Hyp, but still there is no ideal one. Problems associated with endogenous synthesis and reutilization of Pro[184] have limited the use of the *in vivo* and metabolic labeling with radioactive amino acids.[185–189] High-performance liquid chromatography[187,190,191] and colorimetric assays based on the oxidation of free Hyp with chloramine-T reagent have been used for precise quantification of collagen to nanogram scale;[9,56,181–183,192–199] however, these approaches are time-consuming and not suitable for routine estimation of collagen content. Recently, the Sircol Collagen Assay (SCA; Biocolor Ltd., Northern Ireland) has been introduced as a more convenient colorimetric assay for the quantification of collagen in cell and tissue culture.[200–207] The SCA is based on the amino acid-binding property of sirius red (SR), an anionic dye with sulphonated acid side-chain groups that react with the side-chain groups of basic amino acids[208–212] and is also used as a selective histochemical stain for collagen in normal and pathological tissue.[213–219] During

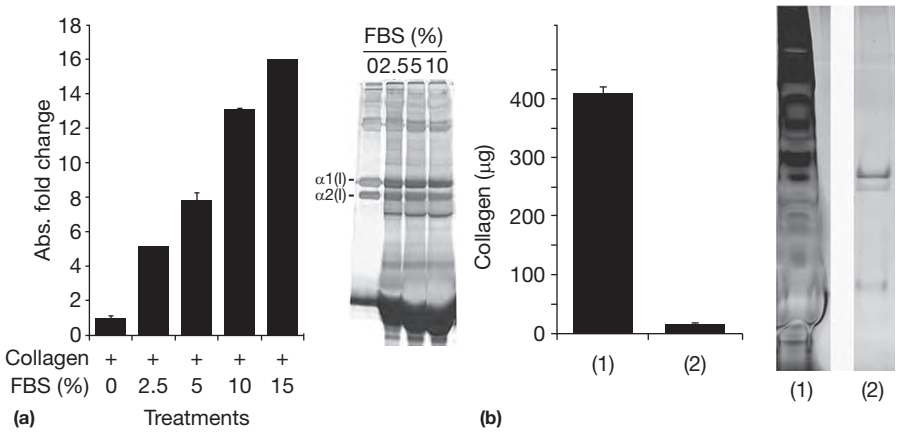

Figure 3 Using the SCA according to the manufacturer's protocol, the addition of increasing amounts of FBS into a collagen I solution (100 μg/ml^{-1}) lead to an erroneously increased apparent collagen content was detected (a, left). Large-format SDS-PAGE proves that all samples contain the same collagen concentration (a, right). Quantification of collagen using the unmodified SCA protocol (1) revealed a 24-fold overestimation of collagen content in culture media in comparison to the modified (2) protocol (b, left). Complementary SDS-PAGE demonstrates the low in collagen content culture media solution (b, right). Adapted with modification from Lareu, R.; Zeugolis, D. I.; Abu-Rub, M.; Pandit, A.; Raghunath, M. *Acta Biomater.* **2010**, *6*(8), 3146–3151.

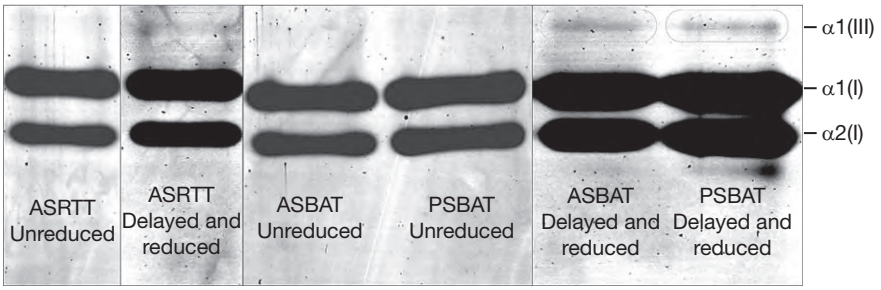

Figure 4 SDS-PAGE analysis of acid soluble rat tail tendon (ASRTT), acid-soluble bovine Achilles tendon (ASBAT), and pepsin-soluble bovine Achilles tendon (PSBAT) collagens. Reduction of disulfide bonds directly from the start of the gel electrophoretic run causes the single α1(III) chains to comigrate with the α1(I) chains. Delayed reduction disassembles the disulfide-linked collagen III trimer at a later stage of the run, so that they migrate above the α1 (I) chains and thus can be distinguished.

our attempts to quantify collagen content using SCA, we found that the presence of noncollagenous proteins in cell culture medium and tissue hydrolysates result in a dramatic overestimation of collagen content by 3–24-fold (Figure 4). To remedy this deficit, we have introduced a simple pepsin digestion followed by column ultrafiltration purification step that not only allows the removal of noncollagenous proteins, but also enables the accurate determination of collagen in complex protein solutions.[220]

If the collagen is to be freeze-dried, special attention should be paid during the process. Although it has been reported that the freeze-drying process does not alter the structure of the collagen molecule, at least with regard to its polypeptide composition,[221] incorrect application of heat could lead to irreversible dehydrothermal cross-linking and therefore increase the amount of insoluble collagen. We[166] and others[154] have recently evaluated a number of lyophilized collagen type I samples available from different commercial vendors and we found great variability in solubility among the samples (Figure 5). For this reason, we introduced a simple quality control step to evaluate the solubility of freeze-dried collagen preparations prior to use for biomedical applications.[166]

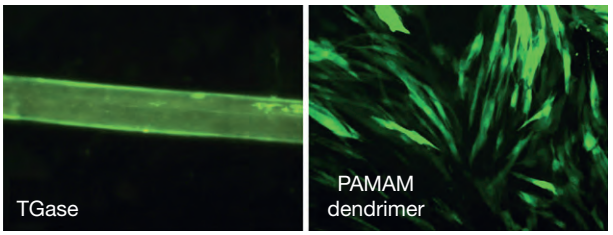

Figure 5 Using TGase, we have been able to incorporate fluorescent peptide in collagenous structures (left panel), while functionalization strategies based on PAMAM dendrimers allow transfection of cells (right panel). Left panel adapted with modification from Zeugolis, D. I.; Panengad, P. P.; Yew, E. S. Y. *et al. Journal of Biomed. Mat. Res. A* 2010, *92A*, 1310–1320.

2.215.5. Biomedical Applications of Collagen

Collagen-based materials have found applications in several aspects of our lives. Humans have been using skin from animals for several millennia. In Genesis (Genesis 3.21), it is mentioned that "the Lord God made garments of skin for Adam and his wife and clothed them." As early as 2000 BC animal sinew was used for suturing.[222,223] The Romans, as early as AD 1150, were using collagen to produce glue.[180] In the nineteenth century, collagen was used to describe 'the constituent of connective tissue that yields gelatin on boiling.'[86] Both collagen and gelatin have found numerous applications in the food industry (edible coatings, emulsifying, foaming, and gelling agents).[224] With the development of tissue engineering, several collagen-containing tissues have been used for biomedical applications.[225–228] Their use has been advocated because they closely match the tissue to be replaced. Early drawbacks of tissue grafts[229–232] have now been addressed[233,234] and recent data demonstrate normal tissue ingrowth in several animal models.[235–238] However, allografts and xenografts still face the risk of potential transmission of infectious diseases,[239–242] and autografts present the disadvantages of creating a donor site defect from harvesting. To this end, collagen-based biomaterials (fibers, films, sponges, hydrogels, and particles) have been developed for soft and hard tissue repair.[9,243–245] The attractiveness of collagen as a raw material for scaffold fabrication rests largely on its inherent properties such as cell recognition signals that promote cell attachment and growth and consequently tissue healing and regeneration, ability to form scaffolds of different conformation, high tensile strength, low antigenicity, and association with bioactive or therapeutic molecules.[8,246–252]

When designing a construct for tissue-engineering applications, it is essential for the scaffold material to provide mechanical stability, integrity, and thus a template for the three-dimensional organization for the developing tissue.[69,253–255] *In vivo*, native cross-linking takes place to impart desired mechanical stability and proteolytic resistance on collagen fibers in connective tissues.[9,88,179,256] As mentioned above, lysyl oxidase is secreted from fibrogenic cells as a 50-kDa proenzyme that is proteolytically processed to the mature enzyme in the extracellular space. Inhibition of lysyl oxidase action toward collagen molecules results in the accumulation and ultimate proteolytic degradation of soluble collagen monomers, thus preventing the formation of insoluble collagen fibers.[257] The participation of this enzyme is therefore critical to the development and repair of connective tissues.[258] However, the lysyl oxidase-mediated cross-linking does not

occur *in vitro*, and consequently, reconstituted forms of collagen lack sufficient strength and may disintegrate upon handling or collapse under the pressure from surrounding tissue *in vivo*. Thus, it is often necessary to introduce exogenous cross-links (chemical, biological, or physical) into the molecular structure, in order to control mechanical and thermal properties, biological stability, the residence time in the body and to some extent the immunogenicity and antigenicity of the device.[9,68,247,259–265]

However, biomaterials design has evolved from basic constructs that match the mechanical properties of the target body site, to biofunctional materials with incorporated instructive signals for the modulation of cellular functions such as proliferation, differentiation, and morphogenesis and therefore encourage functional tissue regeneration.[69,254,266–268] Indeed, biomaterials concepts provide the exciting possibility for the local and specific delivery of bioactive niche components that may inhibit or promote molecules or drugs that control biological functions. At present, there is no commonly accepted ideal cross-linking treatment for collagen-derived biomaterials and among them only TGase and polyamidoamine (PAMAM) dendrimeric systems offer opportunities of functionalization. Tissue TGase belongs to a family of enzymes that catalyze several posttranslational modifications of proteins by forming inter- and intramolecular bonds; the process results in the formation of stable covalently cross-linked proteins in the ECM in a Ca^{2+}-dependent manner.[269–273] We have recently demonstrated that TGase can be used to stabilize collagen scaffolds,[36,37] albeit limited.[33,265] We have, however, been able to use the resultant covalent γ-glutamyl-ε-lysine isopeptide bond to incorporate peptides into the molecular structure,[33] which indicates the functionalization potential of TGase in the biomaterials field (**Figure 6**, left panel). The limited stabilizing effect of TGase in addition to its single molecule functionality can limit its use in tissue-engineering applications. For these reasons, we[274,275] and others[276,277] have developed a multifunctional approach based on PAMAM dendrimers that not only enhance the mechanical properties of the produced scaffolds, but also offer multiple opportunities of functionalization (**Figure 6**, right panel). However, cytotoxicity complications of PAMAM dendrimers as a function of generation, independent of the surface charge, have caused concerns with regard to their use in the biomaterials field.[278–282] Polyethylene glycol (PEG) dendrimeric systems have been recently introduced as an alternative approach to PAMAM dendrimers. PEG-based polymers have a multifunctional dendrimeric core conjugated to PEG (or polyethylene oxide – PEO) chains. PEG has been shown to facilitate cell infiltration, tissue ingrowth, and enzyme degradation with improved blood compatibility and ability to resist protein adsorption.[283,284] Moreover, we have demonstrated that linear PEGs can significantly increase the mechanical stability of extruded collagen fibers[40,170,285] and collagen films. The use of PEG–dendrimer hybrids has been advocated due to the high ratio of multivalent surface moieties to molecular volume, low toxicity and haemolytic properties, long blood circulation times, low organ accumulation, and high accumulation in tumor tissue due to the enhanced permeation and retention effect.[286–295]

Many biological processes such as cell migration, axon extension, angiogenesis, bone formation, and development are regulated by the position and distribution of local signals.[296,297] Therefore, control of the spatial orientation of molecules on a surface or throughout a material using structural, biological, or biochemical cues is expected to imitate the native ECM environment and ultimately enhance functional neotissue formation. Numerous micro- and nanofabrication technologies have been developed over the years to achieve topographical, spatial, biochemical, biophysical, biological, and immunological control over cellular functions.[254,266,268,282,298–315] However, not all fabrication methods are applicable to natural biopolymers, such as collagen. For example, electrospinning has been recently introduced as the most promising technique to manufacture *in vitro* fibrous scaffolds for tissue-engineering application with fiber diameter ranging from less than 100 nm to a few microns.[316–320] Such materials mimic ECM components, such as collagen fibrils with an *in vivo* diameter range from 20 nm to 40 μm.[321–323] However, we[24] and others[324] have demonstrated that this nanofabrication process irreversibly denaturates collagen into gelatin and as such defeats its purpose, that is, to preserve the typical biological properties of collagen and imitate native ECM assemblies (**Figure 7**).

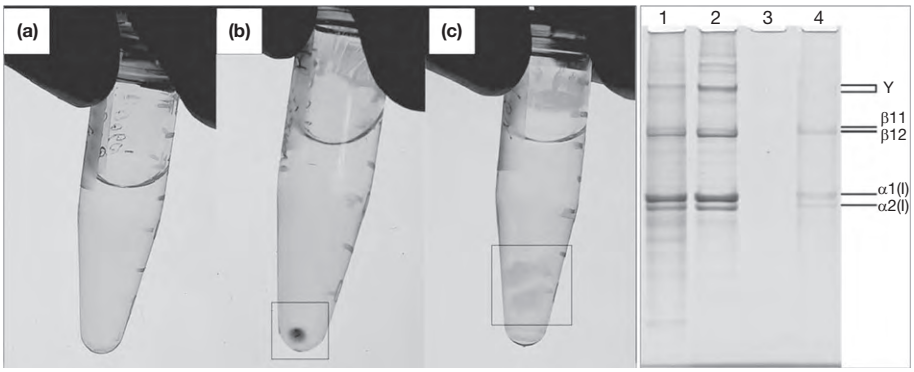

Figure 6 Visual impression of solubility in 0.5M acetic acid of 1mg ml^{-1} collagen suspensions from (a) Koken, (b) Sigma, and (c) Yi Erkang. Supplementary SDS-PAGE analyses of 1mg ml^{-1} in 0.5M acetic acid collagen samples from (1) Sigma, (2) Koken, (3) Yi Erkang, and (4) Fluka demonstrate that certain preparations are highly insoluble. Adapted with modification from Zeugolis, D. I.; Li, B.; Lareu, R. R.; Chan, C. K.; Raghunath, M. *J. Biomater. Sci. Polym. Ed.* **2008**, *19*, 1307–1317.

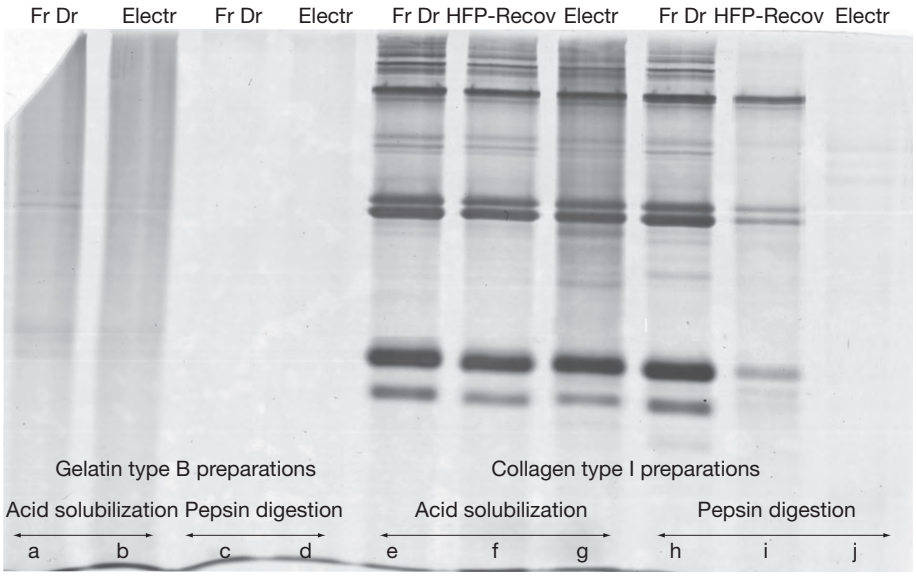

Figure 7 SDS-PAGE analysis of acid-solubilized and corresponding pepsin-digested materials: (a and c) freeze-dried Sigma gelatin type B; (b and d) Sigma gelatin type B electrospun nanofibers; (e and h) freeze-dried Symatese type I collagen; (f and i) Symatese type I collagen dissolved in hexafluoropropanol and subsequently freeze-dried (HFP-recovered); (g and j) Symatese collagen type I electrospun nanofibers. The results demonstrate reduction in collagen content after disassociation in HFP and even greater losses after electrospinning (up to 99%). Adapted with modification from Zeugolis, D. I.; Khew, S. T.; Yew, E. S. Y.; *et al*. *Biomaterials* **2008**, *29*, 2293–2305.

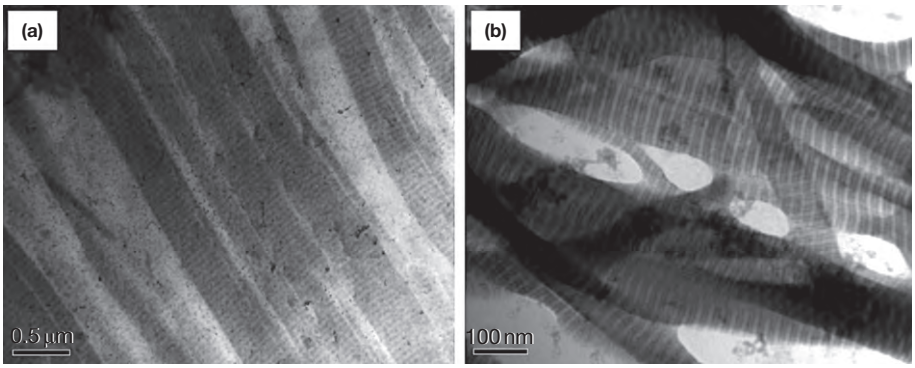

Figure 8 Cross-striated (a) native rat tail tendon collagen fiber and (b) self-assembled collagen fiber from pepsin-extracted rat tail tendon. Adapted with modification from Zeugolis, D. I.; Khew, S. T.; Yew, E. S. Y.; *et al*. *Biomaterials* **2008**, *29*, 2293–2305.

Despite the drawback of electrospun collagen-originated nanofibers, collagen-based biomaterials of different physical form have been used extensively for numerous tissue-engineering applications since they are closely imitating native ECM assemblies.[325,326] The use of collagen sponges has been proposed for the treatment of severe burns, drug-delivery and hemostatic applications, scaffold for tissue-guided regeneration, cerebral, peripheral nerve, pulmonary, vascular, and hepatic implants, and biodegradable composites.[261,327–335] Collagen films have been developed for clinical use as burn and wound dressings, abdominal wall repair, dura matter replacement, hemostatic/control bleeding agent, enhancer of healing of open dermal wounds, organ replacement, surgical tampons, and bone/skin reinforcements.[336–344] Collagen hydrogels have a long history in biomedical applications (corneal shields, hard and soft tissue implants, drug-delivery matrices, injectable suspensions).[65,345–351] Collagen fibers have been extensively used as substrate for several tissue regeneration applications due to their unique properties such as high surface area, softness, absorbency, and ease of fabrication into many product forms.[352–362] Collagen, under ideal conditions of concentration, temperature, pH, and ionic strength collagen solutions will spontaneously self-assemble *in vitro* into microscopic fibrils, fibril bundles, and macroscopic fibers that exhibit D periodic banding patterns and that are virtually indistinguishable from native fibers when examined by electron microscopy (**Figure 8**).[355,357,358,363–375]

The principle of self-assembly has been employed to fabricate collagen fibers with wet diameter range from 50 to 650 μm that have found great potential in tendon and nerve regeneration.[24,265,355,357,376–380] Furthermore, recent optical analysis using transmission electron microscopy and SHG microscopy demonstrated that such fibers possess high level of crystallinity and structural alignment that is characterized by

strong SHG signals in the presence of intense laser light.[24] In addition, the unique nanotextured surface topography of these fibers has been shown to facilitate directional cell migration and enhance spatially guided axonal growth that is essential for functional neotissue formation (Figure 9).[40,311,381]

One of the most interesting applications of collagen is the fabrication of hollow spheres.[309,382–384] The emerging field of tissue engineering requires accurate delivery of bioactive and/or therapeutic molecules to a specific location; this is a key issue in modern biotechnology and molecular biology. Glycosaminoglycans and proteoglycans[385–387] or bioactive molecules such as growth factors or hormones are traditionally used to enhance biological functions of biomaterials.[388–391] However, the biological half-life of growth factors is very limited; it is 2, 3, and 50 min for platelet-derived growth factor, basic fibroblast growth factor, and vascular endothelial growth factor, respectively.[392] As a result, the use of polymeric drug-delivery vehicles in the form of micro- or nanospheres to encapsulate the active molecules and maintain a sustained localized delivery to the target site is attractive (Figure 10).[292,389,393–400] This approach is benefited by tight regulation of release by controlling the shell material and protection of the active molecules until their delivery is required.[266,267] Moreover, loading hollow collagen microspheres with active molecules and embedding them within the fibrous structure would enable us to create gradients using the fibrous structure.[24] Gradients in the concentration of growth factors has been shown to enable directional cell migration, create patterns of cellular differentiation, and direct tissue organization into complex structures, such as branching networks of vascular or nervous systems.[298,342,401–403]

2.215.6. Outlook and Future for Collagen Materials

The existence of collagen as a biomaterial since the dawn of the animal kingdom commands respect as this implies that it has survived a fierce and rigorous material testing over the last 700 My. In fact the prototype not only survived but it flourished into the currently known successful 29 isoforms and

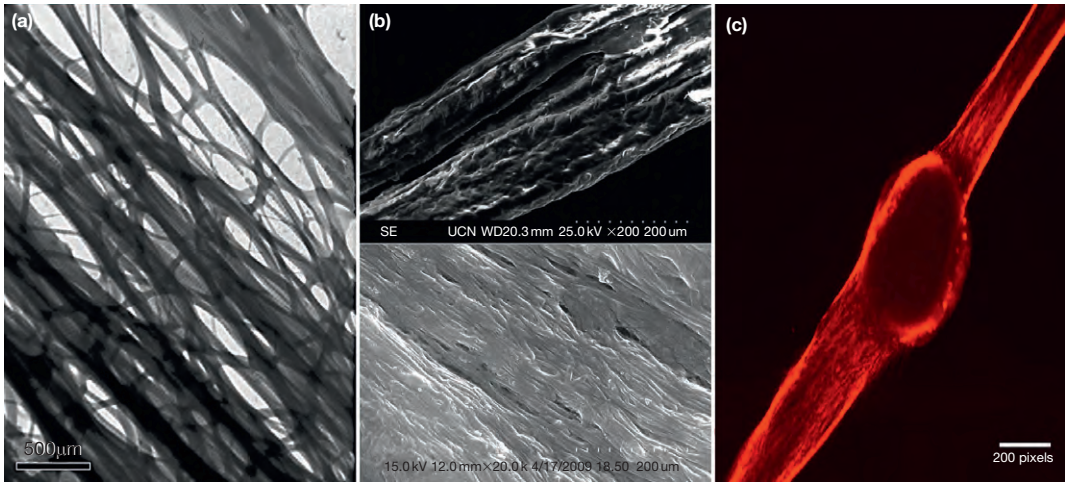

Figure 9 Transmission electron micrographs of self-assembled collagen fibers reveal an aligned collagen sub-fibrillar structure (a) that give rise to unique morphological features (e.g., grooves) apparent from scanning electron micrographs (b, top). Isoelectrically focused collagen solutions assemble into aligned supramolecular fibrillar hydrogels (b, bottom) that facilitate bidirectional neurite outgrowth along the axes of aligned hydrogels (c). (b, bottom) and (c) adapted with modification from Abu-Rub, M. T.; Billiar, K. L.; van Es, M. H.; *et al*. *Soft Matter*. **2011**, *7*, 2770–2781.

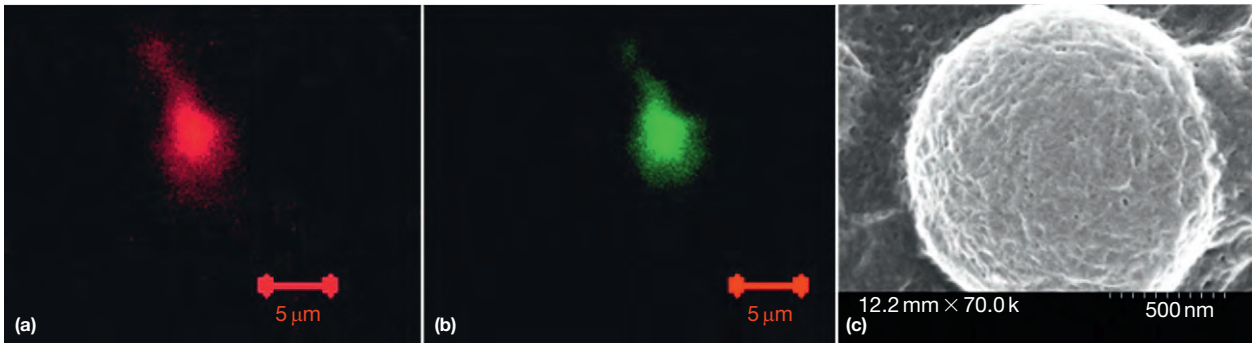

Figure 10 Encapsulation of therapeutic or bioactive molecules provides means of controlled delivery at the side of the injury. Confocal micrograph of ethidium-bromide-labeled pDNA (a) encapsulated into FITC-labeled shells (b). Hollow collagen spheres (c). Adapted with modification from Réthoré, G., Naik, H., Pandit, A. Hollow Biodegradable Nanospheres and Nanoshells for Delivery of Therapeutic and/or Imaging Molecules. (Preliminary US Continuation-in-part (CIP) Patent filed Mar 20, 2010 Patent 12/886492 (derived from PCT/EP2009/053258)).

variants as a major tissue constituent of the total protein in animals. This would predict that collagen-based materials will retain a firm place in consumer markets and biomedical applications. Driven by a strong interest in the food, leather, and pharmaceutical industry, six decades of modern research – not all of it published – have been dedicated to study the materials properties of collagen and ways to manufacture it into various biomedical products. The intrinsic task of all extracellular matrices is to be insoluble and cross-linked. This poses challenges in extracting and handling collagen and the subsequent manufacturing of biomaterials from it. It is comparably easy to completely denature collagen, melt its triple helices and thus to create gelatin, a product without which the food and pharmaceutical industry would be unthinkable today. But putting native collagen materials together again in the form of gels (from extracts derived from acidic or combined peptic/acidic extraction) or via freeze-drying from homogenized (as far as this is possible) slurry containing fibril fragments is much more demanding and complex. The intrinsic difficulty to work with collagen has spurned biomaterials scientists to search for synthetic materials that would be more amenable to handling, and pose less of a biohazard. This also is in keeping with an engineer's desire to control and to interfere. Materials were therefore sought that are better soluble, malleable, pure and defined, and can be subjected to a number of procedures. However, when we look at the implants and advanced wound care products in clinical use, we realize that this represents a very small selection of the vast number of novel biomaterials that have been developed and published in the last 30 years. This small selection represents that group of biomaterials that work within this group of collagen-based materials figure prominently. There is a good reason for this. Collagen has an undisputed excellent biocompatibility and a well-characterized low immunogenicity; it degrades into well-tolerated physiological compounds; it can be processed on an aqueous base; and enhances cellular penetration and wound repair.

Collagen is a very old biological component of animal tissues, and the over 213 cell types that build the human body are ancient biological entities that have coevolved with it and recognition systems for it. In contrast, cells have no receptors for polyethylene-based polymers or acrylic polymers, metals, ceramics, and the many more novel biomaterials that have been developed recently. Therefore, the best case scenario is often that these materials are ignored by the host tissue and do not elicit an attack by the immune system. Collagen therefore literally appears to be a natural choice. The uses of collagen biomaterials range from advanced wound care products to implantable drug-delivery devices and it is not difficult to see that this work will continue. Without any doubt, the recombinant expression of collagen represents a huge scientific feat that took some 15 years to come to fruition, but the amounts that can be produced to date are nowhere near the needs of the biomedical market, and it appears questionable whether the costs of recombinant human collagen will become cost-competitive in the near future. The reality of the market forces might defeat forecasts here. While fully synthetic collagen triple helices are technically not feasible currently, mini-triple helices can play a role in the creation of novel biomimetic biomaterials or at least surface modifications. However, looking into collagen from traditional sources, recent advances in wet spinning of collagen derived from tissue extract slurry look promising[404] for industrial scale and demonstrate that collagen-based biomaterials have not even reached their zenith.

Abbreviations

CFD	Computational fluid dynamics
CFM	Culture force monitor
CG	Collagen–glycosaminoglycan coprecipitate
CGCaP	Collagen–glycosaminoglycan–calcium phosphate triple coprecipitate
COL*x*A*y*	Family of genes that encode for synthesizing distinct collagen subunit chains; *x*, *y* correspond to collagen type and subunit chain, respectively (e.g., COL1A2, COL3A2, COL2A1, COL4A4, COL4A5)
COX-2	Cyclooxygenase-2; key enzyme for the production of early bone formation marker prostaglandin E_2
DHT	Dehydrothermal crosslinking
DRT	Dermal regeneration template
ECM	Extracellular matrix
EDAC	1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride
EDX	Energy-dispersive X-ray spectroscopy
ESEM	Environmental scanning electron microscopy
FGF	Fibroblast growth factor

GAGs	Glycosaminoglycans
GDNF	Glial cell line-derived neurotrophic factor
HA	Hyaluronic acid
HGF	Hepatocyte growth factor; a paracrine signaling factor involved in cellular growth, motility, morphogenesis, and angiogenesis
HMOX	Heme oxygenase; an enzyme that catalyzes the degradation of heme and is critically involved in angiogenesis
IPN	Interpenetrating network
MC3T3-E1	Mouse preosteoblast cell line
MMP	Matrix metalloproteinase; a family of enzymes that degrades extracellular matrix proteins. Key MMPs include: MMP-2, MMP-12, MMP-19
MSC	Mesenchymal stem cell or marrow stromal cell
NHS	*N*-Hydroxysulfosuccinimide
NRT	Nerve regeneration template
OPN	Osteopontin; late marker of bone formation
PGE_2	Prostaglandin E_2; early bone formation marker
SA/*V*	Specific surface area; total surface area per unit volume for a given unit cell
TC	Tropocollagen; the fundamental organizational unit of collagen
TGF-β1	Transforming growth factor-β1;
TIMP	Tissue inhibitor of metalloproteinase. Key MMP inhibitors include: TIMP1, TIMP3
UC	Unit cell
μCT	Microcomputed tomography
VEGF	Vascular endothelial growth factor; a chemical signal produced by cells that stimulates the growth of new blood vessels (angiogenesis)

Symbols

D_{jxn}	Strut junction spacing; defines the distance between points in the scaffold where multiple struts meet
d	Scaffold pore size
E_s	Elastic modulus of individual scaffold strut
E^*	Elastic modulus of the entire cellular material
E_sI	Scaffold strut flexural rigidity
ε	Compressive strain
F_c	Average contractile force generated by an individual cells within a 3D scaffold
I	Second moment of inertia
k	Scaffold permeability (m^2)
l	Edge length of unit cell
l_s	Scaffold strut length
σ^*_{el}	Compressive plateau stress
ρ_{jxn}	Strut junction density; the number of strut junctions per unit cell divided by the volume of the unit cell in a cellular material
ρ^*/ρ_s	Relative density (1 – porosity)

2.216.1. Introduction

The extracellular matrix (ECM) is a complex macromolecular structure composed of a fibrillar network of structural proteins (collagens, elastin, etc.), proteoglycans (polypeptide core with attached polysaccharide chains called glycosaminoglycans (GAGs)), specialized proteins for cell adhesion (fibronectin, laminin, etc.), and other tissue-specific materials such as apatite in bone. The ECM defines the physical morphology of tissues and the local environment in which cells reside. In addition to serving as a physical support structure and insoluble regulator of cell activity, the ECM is a reservoir of numerous soluble regulators of cell behavior.

Tissue engineering scaffolds are utilized as ECM analogs to heal or modify tissues in a defined manner. In order to be successful, these scaffolds must be able to mimic key aspects of the native ECM and support normal cell behaviors. As an analog of the native ECM, collagen–glycosaminoglycan (collagen–GAG) materials possess several vital characteristics that aid in the making of successful tissue engineering scaffolds, including three dimensionality with interconnected pores, tunable degradation and resorption rates, surface ligands for cell adhesion, and mechanical integrity.[1,2] Since their inception, these materials have been utilized in a variety of tissue engineering studies, both *in vivo* as regenerative templates for skin, peripheral nerves, conjunctiva, and cartilage[3–6] and *in vitro* as 3D microenvironments to probe more fundamental questions about cell behaviors and cell–matrix interactions. Scaffold microstructure characteristics, such as porosity, mean pore size, pore shape, interconnectivity, specific surface area,[4,5,7–15] and mechanical properties (Young's modulus, yield stress),[16–25] have been shown to be key factors that can influence cell behaviors such as adhesion, motility, contraction, stem cell differentiation, gene expression, and overall bioactivity.[4]

This chapter will provide an introduction to, and an overview of, the development and application of collagen–GAG (CG) materials. We begin with an overview of the structure and biochemistry of both collagen and GAGs and will consider questions concerning the immunogenicity, antigenicity, and regulatory compliance of CG biomaterials. We will continue with a summary of the fabrication techniques used to make a wide range of CG materials, including mineralized and nonmineralized (type I and II) scaffolds as well as membranes and hydrogels. Characterization of CG materials, notably microstructural, mechanical, and chemical properties, and the use of modeling approaches to describe these features will then be covered. We will detail *in vitro* applications of CG scaffolds for the investigation of cell adhesion, motility, contraction, stem cell differentiation, gene expression, and mechanotransduction. Finally, *in vivo* applications of CG materials as ECM

analogs for the regeneration of a wide variety of tissues, notably skin, peripheral nerves, conjunctiva, cartilage, and bone will be reviewed.

2.216.1.1. Collagen

Collagen is the major organic component of the natural ECM.[26–29] To date, 29 types of collagen have been identified,[26,28] although 90% of collagen in the human body is fibrillar (main types: I, II, III, and V). Type I collagen is the major structural component of the ECM in a wide variety of tissues such as skin, tendon, ligament, and bone. Type II collagen is found principally in cartilage; type III is found in skin, blood vessels, and intestines; and type V is a component of bone, skin, cornea, and other tissues.[28]

Like all biological proteins, collagen is defined by four levels of organization: primary, secondary, tertiary, and quaternary. The primary structure of the collagen is highly conserved among mammals and follows a Gly-X-Y pattern characterized by the presence of a glycine every third residue with X and Y representing other amino acids (**Figure 1(a)**). Common residues in these X and Y positions are proline (28% of total residues) and hydroxyproline (38%), respectively.[26–30] These amino acids form left-handed, polyproline II-type polypeptide chains that define the secondary structure. Three of these polypeptide chains come together in a coiled, helical manner to form a right-handed triple helix termed tropocollagen (TC). The TC molecule is the fundamental organizational unit of the collagen and defines its tertiary structure[26,28,30] (**Figure 1(b)**), with dimensions of approximately 280 nm in length and 1.5 nm in diameter.[28,30] Each of the three polypeptide units, or alpha units, contains 1050 amino acids.[27] Typically, two of these units have very similar sequences and are termed α1 chains while the dissimilar third chain is denoted as α2. Glycine is the only amino acid with a side group (single hydrogen) small enough to fit within the tight packing of the triple helix, thereby necessitating its presence at every third residue. While the glycines face inward because of steric constraints, the proline and hydroxyproline groups face outwards and help stabilize the overall triple helix structure via hydrogen bonding.[27,28]

For tissues composed of type I collagen (bone, tendon, ligament, etc.), TC molecules assemble into fibrils up to 500 nm in diameter and 1 cm in length (quaternary structure). Fibrillogenesis, and subsequent crosslinking, is aided by the presence of nonhelical residues on each end of the TC molecules called collagen telopeptides.[27,28] These ends contain lysyl residues that promote covalent crosslinking between opposing ends of adjacent TC molecules. This crosslinking insures the stability of the fibrillar structure. Each TC molecule is displaced from its laterally adjacent partner by 67 nm. This periodic organization is the key feature of the quaternary structure (**Figure 1(c)**).[27,28] Fibrils band together to form higher order fiber bundles that are tissue specific. For example, tendon is composed of uniaxially aligned, crimped fiber bundles. It is important to note that the banding (quaternary structure) of collagen is abolished as a result of acid coprecipitation during fabrication of CG materials, limiting platelet aggregation *in vivo*.[4,31] The destruction of the quaternary structure is accomplished without denaturing the collagen to gelatin. Gelatin is the amorphous form of collagen, having the same amino acid sequence but lacking the triple helical character of collagen. Gelatin can be formed by heating hydrated collagen past a critical temperature of 75–105 °C. The temperature varies according to collagen type, species, and hydration level. Dry collagen is denatured when heated over 150 °C.[30,31]

2.216.1.2. Glycosaminoglycans

GAGs are long, repeating disaccharide units that are linked to protein cores to form proteoglycans (**Figure 2**).[32] GAGs serve as

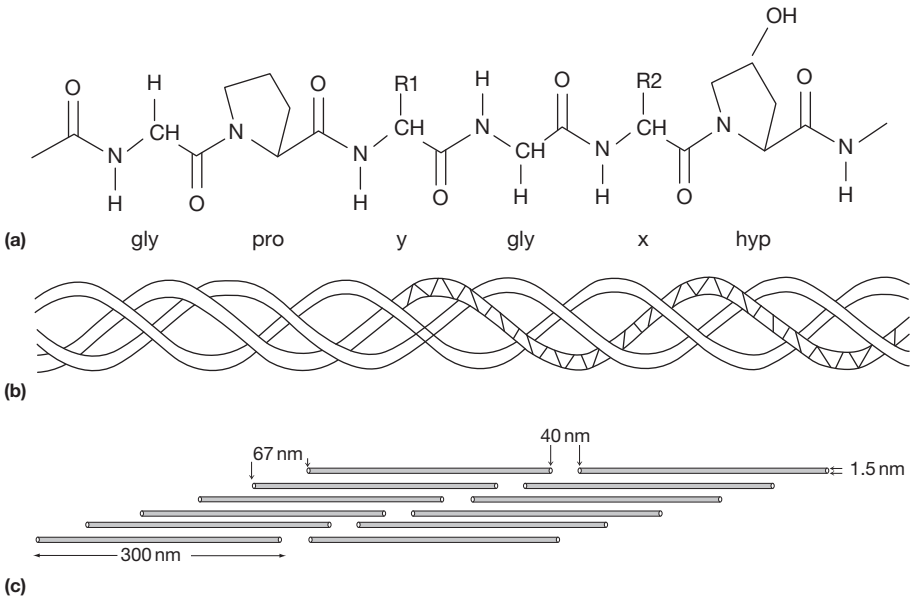

Figure 1 Structural and chemical overview of collagen type I. (a) Typical primary amino acid sequence. (b) Secondary left-handed helix and tertiary right-handed triple-helix structure. a crucial component of the native ECM and influence various biological functions including cell migration, division, angiogenesis, collagen fibrillogenesis, and the presentation of soluble factors.[27,32–34] These macromolecules are strongly negatively charged because of the presence of sulfate groups, resulting in large associated osmotic pressures and allowing them to significantly swell in water. These properties are responsible for the high compressive modulus and excellent resistance to repeated deformation seen in GAG-rich tissues such as articular cartilage.[35] The main GAG component of aggrecan, the chief proteoglycan in articular cartilage, is chondroitin sulfate, the most common GAG found in humans and also in CG materials.[27,31,36] Other common classes of GAGs include dermatan sulfate (a derivative of chondroitin sulfate), heparin sulfate and heparin, keratan sulfate, and hyaluronic acid (HA).[27,34,37] Chondroitin sulfate, like other GAGs, is composed of a disaccharide repeat unit consisting of a acidic sugar-like molecule and a sulfated amino sugar (the exception is HA, which is not sulfated).[32] For chondroitin sulfate, these sugars are D-glucuronic acid and *N*-acetyl galactosamine respectively.[27]

2.216.1.3. Collagen–GAG Material Development

CG materials were developed in the 1970s by a collaboration between Ioannis Yannas, a professor at Massachusetts Institute of Technology, and John F. Burke, a surgeon at Massachusetts General Hospital. Burke's search for a treatment for traumatic burns coupled with Yannas' background in collagen biochemistry led to the development of a CG membrane that was one of the first bioactive materials designed for a tissue engineering application, in this case the regeneration of full-thickness skin wounds. Collagen is a well characterized biopolymer and was chosen as a model material in part because of its controllable biodegradability, relative weak antigenicity/immunogenicity, and overall history in clinical applications (see **Chapter 2.215, Collagen: Materials Analysis and Implant Uses**).[31,38] GAGs were incorporated into the collagen material for several reasons beyond that of ECM chemistry and biomimicry. First, although the biodegradation rate of collagen can be adjusted over a wide range of values via crosslinking, heavy crosslinking leaves the material brittle and stiff. The copolymerization of collagen with GAG results in a material more resistant to degradation, thereby reducing the need for heavy crosslinking.[31] The addition of GAG was shown to significantly improve material mechanics, including elastic modulus and fracture energy.[31] SEM imaging also showed that scaffolds made with collagen and GAG exhibit a more open pore structure than scaffolds made from collagen alone, a critical design requirement to insure adequate cell migration and permeability throughout the entire construct. The addition

of GAG also gives CG materials their unique hemostatic properties discussed earlier, limiting platelet aggregation normally associated with collagen.[31]

2.216.1.4. Antigenicity and Immunogenicity of Collagen–GAG Materials

Collagen has been used in a variety of medical capacities, including sutures, skin and bone grafts, and for cosmetic purposes.[5,38–40] The collagen source for these applications as well as that used for CG biomaterials has typically been bovine skin or tendon. Collagens from these sources have consistently displayed low antigenicity (ability to interact with antibodies) and immunogenicity (ability to induce immune response), with adverse immune responses occurring even less frequently than nickel or latex allergies.[38] The majority of adverse responses arise from preexisting allergies (only 2–4% of population), but even in these cases, local inflammation and granulation subsides after several months to 1 year.[38,41,42] GAGs on their own have been utilized in orthopedic implants and more recently as dietary supplements to improve joint health. They are weak antigens and break down into oligosaccharides that can be cleared by native biological processes.[31] In addition, there is little evidence that the copolymerization of collagen and GAG increases antigenicity or immunogenicity of collagen on its own.[38] With over 1500 human cases, CG skin grafts have not had an adverse response to date.[5,38] With their long clinical history, CG materials are regulatory compliant in both the United States and Europe.

2.216.2. Fabrication of Collagen–GAG Materials

2.216.2.1. CG Scaffold Fabrication: Lyophilization

CG scaffolds are typically created via freeze-drying of a suspension consisting of coprecipitated type I collagen and the glycosaminoglycan chondroitin 6-sulfate in a solution of weak acetic acid.[4] HA has been used as an alternative to chondroitin 6-sulfate in CG scaffolds for cartilage tissue engineering.[43] Typical solids concentration for these suspensions are 0.5–1% (w/v) collagen and 0.05–0.1% (w/v) GAG. These values have been traditionally selected not only because the resultant scaffolds have high porosities to enable rapid cellular infiltration and diffusive transport processes, but also because of the inherent difficulty in processing CG suspensions with higher solids content without denaturing the collagen which occurs due to the increased temperature and shear stresses required for complete mixing of the CG content at high weight or volume percentages. The suspension is homogenized at 4 °C to prevent collagen gelatinization, degassed under vacuum to remove air bubbles introduced during mixing, and then freeze-dried to produce the porous CG scaffold.[1] During lyophilization, the CG suspension is frozen at a specified temperature,[44] resulting in a continuous, interpenetrating network of ice crystals intertwined with CG coprecipitate. Sublimation of the ice crystals produces a highly porous scaffold whose microstructure is formed by individual fibers of CG called struts (**Figure 3**). These scaffolds resemble low-density, open-cell foams, with an interconnected network of struts and relative densities (ρ^*/ρ_s) typically significantly less than 10%. Relative density is calculated as the ratio of the density of the porous material (ρ^*) to the density of the solid it is constructed from (ρ_s). Porosity, another key parameter used to describe porous biomaterials, can be calculated from scaffold relative density: porosity $= 1 - \rho^*/\rho_s$.

2.216.2.2. Modifications to CG Scaffold During Fabrication

2.216.2.2.1. Relative density

Scaffolds for certain applications, such as peripheral nerve and bone regeneration, have been created from CG suspension with considerably higher solids content (5–10%, w/v). Peripheral nerve scaffolds have been fabricated from high solids content CG suspension produced using plasticating extruders to homogenize the CG suspension.[3] Vacuum filtration has also been used to remove solvent from homogenized CG (both mineralized and nonmineralized) suspensions, thus increasing scaffold relative density. Nonmineralized CG suspensions were created with relative densities as high as 2.5% (w/v) while still enabling fabrication of bioactive, porous CG scaffold structure;[45] mineralized CG suspensions with relative densities as high as 18% (w/v) were also created in this manner.[46] These densified scaffolds have been created in order to improve mechanical properties and slow biodegradation rates relative to nondensified suspensions.[45,46]

2.216.2.2.2. Pore size and shape

During the freeze-drying process, modifying CG suspension thermal profiles enables fabrication of CG scaffolds with a wide range of pore sizes and shapes. Pore size is governed by the final freezing temperature, where lower temperatures lead to smaller pores.[44,47] Final freezing temperature and degree of undercooling control the rate of ice crystal nucleation in the suspension. Longer solidification times lead to more significant coarsening, where ice crystals aggregate to reduce their surface energy, resulting in larger pores.[9,10] Scaffolds with equiaxed pores can be fabricated using a constant cooling rate technique that results in homogenous cooling, solidification, and pore formation throughout the CG suspension.[44] Using this method in combination with final freezing temperatures ranging from −10 to −60 °C, CG scaffolds have been fabricated with pore sizes

from 85 to 325 μm but with constant relative density ($\rho^*/\rho_s = 0.006$) (Table 1).[9,10] More heterogeneous solidification processes at lower temperatures (−80 °C) have also been used to fabricate CG scaffolds with pore sizes as low as 10–20 μm.[5,47,48]

Scaffold microstructure can be further tuned by altering other aspects of the freezing profile. For example, the alignment and elongation of pores is controlled by the directionality of heat transfer during the freezing process. While the constant cooling method results in isotropic polyhedral pores by cooling the entire CG suspension homogenously, aligned tracks of ellipsoidal pores can be created using a thermally mismatched mold (polysulfone mold, copper base); the mismatch in thermal conductivity promotes unidirectional heat transfer through the copper bottom, resulting in aligned pores.[49] Forthcoming work modifying this technique has allowed fabrication of CG scaffolds with pore anisotropies as great as 1.5:1 (aligned:unaligned direction) (Caliari and Harley, unpublished). Aligned features are a critical design criterion for scaffolds aimed towards regenerating directional tissues such as peripheral nerves,[50] myocardium,[51] and tendon.[52] Rapid, unidirectional cooling has also been used to create aligned CG scaffolds for peripheral nerve regeneration.[47,48] CG scaffolds with pore size and alignment gradients have been used to entubulate the transected ends of peripheral nerves and induce regeneration.[3,48,53]

Tubular CG scaffolds with uniform pore microstructures have been fabricated by injecting high solids content CG suspension into a tubular mold with a rotating mandrel. Recently, a spinning technique to create radially patterned CG scaffold tubes has been developed.[54] The CG suspension is placed into a cylindrical copper mold and spun at high angular velocities (> 5000 rpm), resulting in radial sedimentation of the CG solids. The suspension is then flash frozen in liquid nitrogen, resulting in the creation of small ice crystals within the CG suspension that do not interrupt the sedimentation. By varying the angular velocity and spinning time, solid cylinders or hollow tubes of variable inner diameter and tube wall microstructure can be created. These tubes display a radially aligned pore structure and a gradient of porosity along the tube radius (Figure 4). A modeling framework that describes this sedimentation process using Lamm differential equations for collagen concentration and balances sedimentation and diffusion forces to determine scaffold tube geometry as a function of spinning conditions has also been recently developed.[55] These scaffolds are currently being investigated as substrates to limit the inward migration of exogenous contractile cells into and through the tube wall for a peripheral nerve regeneration application.

Table 1 Mean pore size of isotropic, equiaxed CG scaffolds produced using a variety of thermal treatments

[b]Initial freezing temperature followed by 24 h anneal at −10 °C.

2.216.2.2.3. Crosslinking

Crosslinking improves the mechanical competence (e.g., Young's modulus, yield stress) and decreases the degradation rate of CG scaffolds independent of the chemical and microstructural characteristics.[3,56,57] The three most common crosslinking techniques are the physically based dehydrothermal (DHT) and ultraviolet (UV) processes and the chemically based carbodiimide (EDAC) process. DHT and EDAC in particular have been used extensively for *in vitro* and *in vivo* applications.[5,56] DHT processing involves heating of the CG material under vacuum for a specified amount of time (typically 105–120 °C, <50 mTorr, 24–48 h) to remove residual moisture and introduce covalent crosslinks within the CG struts. Increasing the DHT crosslinking temperature and duration has been shown to increase compressive modulus by up to twofold and tensile modulus by up to 3.8-fold.[56,58] While increased crosslink density was correlated with increasing compressive modulus, higher denaturation levels led to higher tensile modulus, but also led to reduced ultimate stress and strain to failure.[58] EDAC processing utilizes carbodiimide chemistry to translate carboxyl (COOH) groups into unstable amine-reactive esters. This intermediate can be stabilized by *N*-hydroxysulfosuccinimide

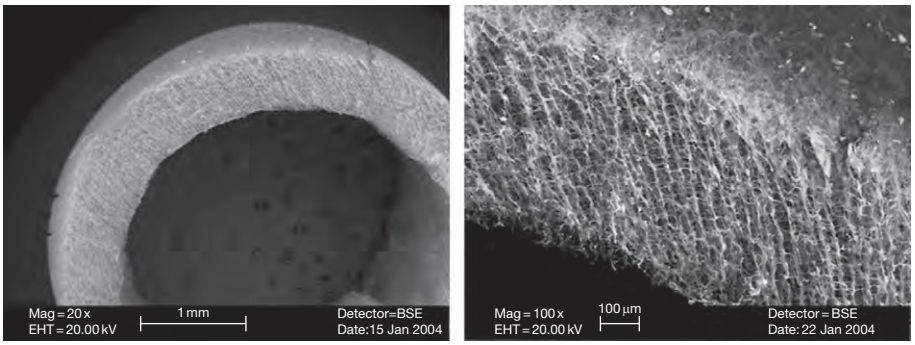

Figure 4 ESEM image of the pore structure of the tubular CG scaffold fabricated via spinning method. Scale bars: 1 mm (tube), 100 μm (wall). Reprinted with permission from Harley, B. A.; Hastings, A. Z.; Yannas, I. V.; Sannino, A. *Biomaterials* **2006**, *27*, 866–874.

(NHS), leading to the formation of stable amide crosslinks.[59] Increasing the ratio of EDAC and NHS to COOH increases the degree of crosslinking.[56,59] Both DHT and EDAC methods maintain the integrity of the open pore structure of the material by introducing crosslinks within the CG struts only.[56]

2.216.2.3. CGCaP Scaffold Fabrication

In addition to solidification-induced structural modifications, the CG construct can be chemically modified to create collagen composites for specific regenerative medicine applications. Mineralized CG scaffolds are of particular interest for orthopedic applications because of their potential to mimic the native biochemistry of bone: interpenetrating collagenous matrix (organic) and CaP (mineral) content. The addition of a mineral phase to the classic CG scaffold archetype allows for the development of materials with the requisite biochemical and biomechanical properties for bone and osteochondral tissue engineering. Mineralized CG scaffolds have been created via two distinct mechanisms: coating a fully formed CG scaffold with a mineral shell, or synthesizing a mineralized CG chemistry in liquid phase prior to freeze drying.

Mineralized CG materials have been fabricated via a surface coating process.[60] Here, CG scaffolds were initially synthesized using conventional freeze-drying and then sequentially soaked in phosphate ($NaNH_4HPO_4$) and calcium ($CaCl_2$) solutions. This treatment improved construct compressive modulus nearly 70-fold, from 0.3 to 31 kPa, while maintaining high porosity (95%).[60]

Mineralized CG (CGCaP) materials for bone and osteochondral tissue engineering can also be fabricated from a triple coprecipitate of collagen, GAG, and calcium phosphate (CaP). These scaffolds are synthesized from a suspension produced via a concurrent mapping technique that allows for simultaneous modulation of CG suspension pH as well as the CaP mass fraction (0–80 wt%), a range that covers a host of physiologically relevant tissues including subchondral bone (75%) and cartilage. This method is particularly powerful because it does not require the use of harmful titrants or additives that would be difficult to dissociate from the freeze-dried matrix.[61–63] Concurrent mapping uses 3D maps of pH and CaP mass yield derived from experimental data to determine the concentration of CaP needed to achieve a specific mass fraction, given the concentrations of collagen and GAG as well as the pH of the suspension.[62] This method yields nanocrystallite CaP content, precipitated within the CG struts, rather than coating the CaP on the CG content. This approach also enables the phase of the CaP mineral to be adjusted via hydrolytic conversion from the original brushite phase to either octacalcium phosphate or apatite, two biologically relevant CaP phases, without altering the pore structure of the scaffold.[61] Conversion from brushite to apatite results in a scaffold that is less soluble and has altered bone-bonding effectiveness.[64–66] Modified freeze-drying profiles have been developed to enable fabrication of CGCaP scaffolds with homogeneous microstructure (85 ± 3% porosity), highly interconnected pores, and tunable mean pore sizes from 56 to 1085 μm (**Figure 5**).[61] Mineralized CG scaffolds, produced by coating the CG scaffold with a mineral component or by precipitating nanocrystallites of CaP mineral into the CG content prior to fabrication, successfully mesh the advantageous microstructural and biochemical properties of standard CG scaffolds with the mechanical integrity and bone-bonding properties of calcium phosphate mineral in a manner reminiscent of the chemical composition of native bone[67] to produce a promising class of scaffolds for orthopedic application.

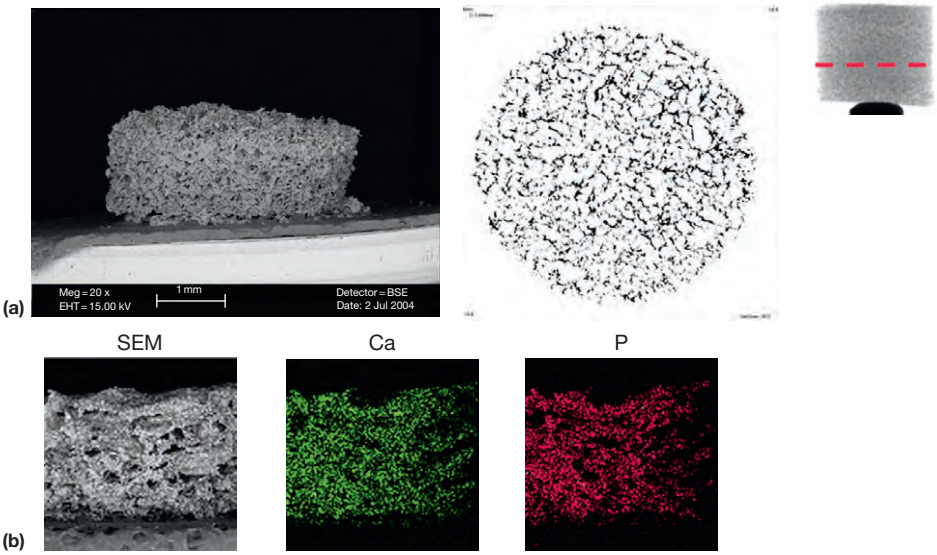

Figure 5 (a) SEM and μCT micrographs of CGCaP scaffold microstructure displaying an open pore structure with interconnected pores. (b) EDX analysis of CGCaP scaffold shows uniform distribution of both calcium (Ca) and phosphorous (P) throughout the scaffold. Scale bars: 1 mm. Reprinted with permission from Harley, B. A.; Lynn, A. K.; Wissner-Gross, Z.; Bonfield, W.; Yannas, I. V.; Gibson, L. J. *J. Biomed. Mater. Res. A* **2010**, *92*, 1066–1077.

2.216.2.4. Multicompartment CG Scaffold Fabrication

The CGCaP scaffold technology has been used as the basis for creating multiphase collagen scaffolds for the repair of interfacial tissues, notably osteochondral defects. A liquid phase cosynthesis method was created to fabricate multicompartment CG scaffolds. The multicompartment scaffold was designed to be a single biomaterial construct containing multiple regions ('compartments'), each with distinct microstructural, chemical, and mechanical properties that are connected via a continuous interface between regions. The initial multiphase scaffold developed via this approach contains an osseous compartment for subchondral bone regeneration (type I collagen, chondroitin 6-sulfate, and CaP) and a cartilagenous compartment for cartilage regeneration (type II collagen and chondroitin 6-sulfate). A key feature of this design is that by avoiding discrete interfaces between scaffold compartments that would require external fixation (sutures, glue, etc.) these materials reduce the potential for stress concentrations and resultant delamination at the interface.[68] The continuous interface is created by layering the cartilaginous compartment and the osseous compartment suspensions in a conventional freeze-drying mold, but then incorporating a processing step to enable partial diffusive mixing between the two suspensions near their interface. Once the region of interdiffusion was created between the suspension layers, freeze-drying was used to form the final multicompartment scaffold microstructure (Figure 6).[69] The continuous interface between scaffold regions is critical for the recapitulation of native interfacial physiology for tissues such as cartilage and tendon.[69] The differential chemistry, microstructure, and mechanics of the osseous and cartilaginous compartments enable these layered scaffolds to exhibit compressive deformation behavior that mimics behavior observed in natural articular joints.[69] These layered scaffolds are currently the subject of numerous *in vitro* and *in vivo* experiments for various orthopedic tissue engineering applications.

2.216.2.5. CG Hydrogels

CG hydrogels have been developed as alternative matrices for soft tissue engineering. CG hydrogels are typically composed of type I collagen, GAG, acetic acid, sodium hydroxide, and cell

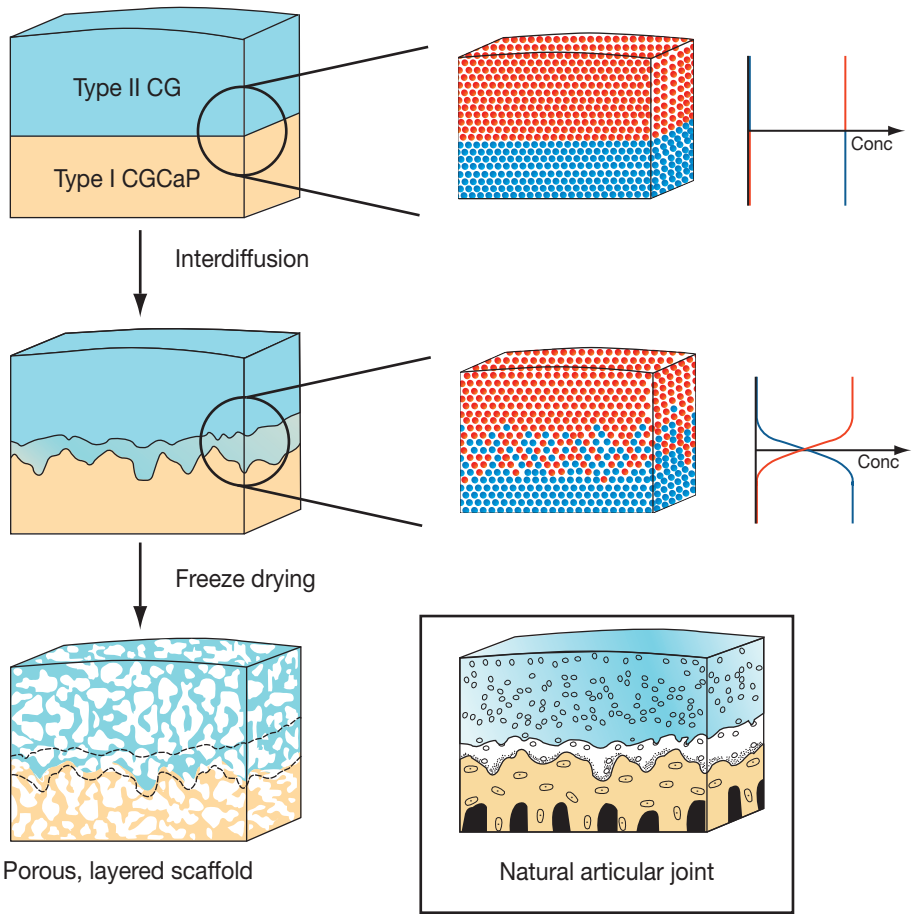

Figure 6 Schematic of liquid phase cosynthesis method used to produce layered osteochondral CG scaffold with soft, continuous interface. Nonmineralized, type II collagen–glycosaminoglycan (Type II CG) suspension is layered on top of mineralized, type I collagen–glycosaminoglycan (CGCaP) suspension, allowed to interdiffuse, and then freeze-dried to produce a porous, layered scaffold that mimics natural articular joint physiology. Reprinted with permission from Harley, B. A.; Lynn, A. K.; Wissner-Gross, Z.; Bonfield, W.; Yannas, I. V.; Gibson, L. J. *J. Biomed. Mater. Res. A* **2010**, *92*, 1078–1093.

culture media.[70,71] As collagen fibers are more dispersed within a gel compared to a porous scaffold, the addition of GAG imparts additional mechanical strength, significantly increasing tensile modulus (56 kPa vs. 40 kPa) and maximum stress (7 kPa vs. 5 kPa).[70] Other work has combined methacrylated HA hydrogels with semi-interpenetrating networks (semi-IPN) of collagen (see **Chapter 2.214, Hyaluronic Acid**).[72,73] Both methacrylation of HA and addition of collagen significantly improve mechanical properties (compressive modulus and fracture stress) and bioactivity (fibroblast adhesion). In addition, these hydrogels can be modified with microscale features using lithographic techniques, demonstrating their potential as tissue engineering constructs.[72] This type of hydrogel has also been explored as a neural tissue engineering template. Schwann cells remained viable in a collagen–HA hydrogel for 2 weeks and secreted nerve growth factor as well as brain-derived neurotrophic factor. The addition of laminin to the hydrogel increased secretion of these factors.[73]

2.216.2.6. CG Membranes

Nanoporous CG membranes have recently been developed as a bioactive, mechanically robust 2D substrate. CG membranes are synthesized by filtering and drying the classic type I CG suspension[74] (**Figure 7**). CG membranes have been created with a range of thicknesses (25–240 μm) but with relatively consistent relative densities (0.68 ± 0.06–0.91 ± 0.09). These membranes have been found to be mechanically isotropic (in plane) and have demonstrated tensile moduli as high as 47 MPa (hydrated) (Caliari, Ramirez, and Harley, Unpublished data). Ongoing work is looking to improve fabrication processes to enable enhanced control over membrane thickness, isotropy/anisotropy, relative density, mechanical properties, and metabolite permeability.

2.216.3. Characterization of Collagen–GAG Materials

Experimental characterization of properties such as chemistry, pore morphology (size/shape), relative density, permeability, and mechanics of a number of CG scaffold variants has been undertaken; such experimental characterization has also been supplemented by modeling approaches allowing for a more complete understanding of the microenvironmental cues presented within the CG structure to distinct cells or populations of cells.

2.216.3.1. Microstructure: Experimental Measurement and Modeling

CG microstructure (pore size and morphology) is typically assessed using a stereological approach. Longitudinally and transversely oriented scaffold samples are embedded in glycol-methacrylate, sectioned, stained, and observed using optical microscopy. Using a linear intercept approach in any standard image analysis software package, a best-fit ellipse representative of the mean pore morphology is created. Dimensions of the ellipse (major and minor axis) are used to calculate an equivalent mean diameter and aspect ratio.[10,44,75] Microcomputed tomography (μCT) has also been utilized to analyze pore microstructure,[10,44,75] though often requires significant use of contrast agents to allow sufficient visualization of the nonmineralized CG content. Most recently, μCT analysis has been used to create a computational model of the CG microstructure for use in analysis of shear stresses on cells in dynamic culture conditions (**Figure 8**).[76]

Cellular solids modeling approaches have proven to be a useful tool in the description and characterization of CG scaffold pore geometry and microstructural properties (pore shape and specific surface area).[77] The complex geometry of foams (and scaffolds) is difficult to model exactly; instead, dimensional arguments can be used to model salient microstructural features without incorporating exact cell geometries using the cellular solids modeling framework. CG scaffolds have been primarily modeled as a low density, open-cell foam using a

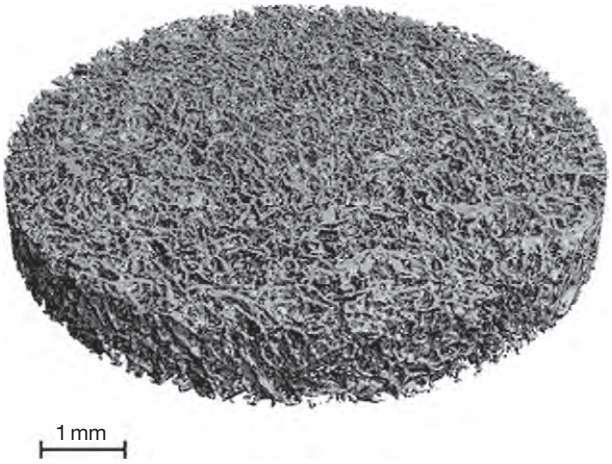

Figure 8 μCT scan of CG scaffold utilized in CFD simulations. Scale bar: 1 mm. Reprinted with permission from Jungreuthmayer, C.; Jaasma, M. J.; Al-Munajjed, A. A.; Zanghellini, J.; Kelly, D. J.; O'Brien, F. J. *Med. Eng. Phys.* **2009**, *31*, 420–427.

tetrakaidecahedral (14-sided polyhedron) unit cell. Modeling microstructural features of CG scaffolds in this manner is possible because the mean pore structure of it and a variety of other low-density, open-cell foams has been observed to have a number of consistent features, notably approximately 14 faces per unit cell, 5.1 edges per face, and vertices that are nearly tetrahedral.[77,78] The tetrakaidecahedron packs to fill space, nearly satisfies minimum surface energy requirements, and approximates the structural features of many experimentally characterized low density, open-cell foams (Figure 9).[77,79] Application of modeling approaches using the tetrakaidecahedral unit cell with CG scaffolds has led to estimations of a number of key microstructural features of the CG scaffolds, many of which will be discussed throughout this chapter. The first microstructural element described using cellular solids approaches was the scaffold specific surface area (SA/V), the total surface area divided by the volume of the scaffold. Specific surface area describes the relative amount of surface available for cells to attach, and has been shown to be an integral factor affecting overall scaffold bioactivity.[9,10] For a low density, open-cell foam with an interconnected pore structure and edges of circular cross-section modeled using the discussed approaches, specific surface area is related to the mean pore size (d) and the relative density (ρ^*/ρ_s):[10,77]

$$\frac{SA}{V} = \frac{10.15}{d}\left(\frac{\rho^*}{\rho_s}\right)^{1/2} \quad [1]$$

2.216.3.2. Permeability: Experimental Measurement and Modeling

Permeability of tissue engineering scaffolds is a critical design parameter to be controlled as it influences the diffusion of cytokines, nutrients, and waste throughout the scaffold prior to material vascularization; further, biomaterial permeability has also been shown to significant impact cell migration processes and scaffold biodegradation rates, among others.[80] Material permeability also affects fluid pressure fields and shear stresses within the construct, additional potential stimuli for functional adaptation.[81] Permeability of tissue engineering scaffolds is dictated by a variety of microstructural characteristics including porosity, pore size and orientation, pore interconnectivity, fenestration size and shape, specific surface area, and applied strain. Permeability of low porosity foams (porosity <90%) has previously been modeled and measured experimentally.[82] However, such models are not applicable to highly porous materials that are typically used in tissue engineering, such as CG scaffolds (porosity >99%); here, material permeability has been conventionally measured empirically with no associated modeling framework to describe the results. A series of CG scaffolds with constant relative density ($\rho^*/\rho_s = 0.006$) were used not only to characterize both CG scaffold permeability as a function of pore size (96–151 μm) and applied compressive strain (0–40%), but also to calibrate a cellular solids-based model of the permeability of low-density, open-cell foams. As with specific surface area, a low density, open-cell foam cellular solids model was successfully created to describe the permeability (k) of the entire class of CG scaffolds as a function of the scaffold mean pore size (d), percent compression (applied strain: ε), relative density (ρ^*/ρ_s), and a single dimensionless system constant (A'):[83]

$$k = A'\left(\frac{d}{2.785}\right)^2(1-\varepsilon)\left(\frac{1-\rho^*}{\rho_s}\right)^{3/2} \quad [2]$$

Experimental and modeling analyses showed that CG scaffold permeability increases with increasing pore size and decreases with increasing compressive strain (Figure 10). The experimentally measured and theoretically predicted scaffold permeability values showed excellent agreement with the need for only a single fitting constant (A') to describe the entire class of scaffolds, again validating the use of the model tetrakaidecahedral unit cell for describing microstructural features of CG scaffolds.[83] These results also suggested that cellular solids modeling techniques can be used to predict scaffold permeability under a wide range of physiological loading conditions and experimentally relevant pore microstructures (size and relative density).

2.216.3.3. Mechanical Properties: Experimental Measurement and Modeling

The mechanical properties of a range of biomaterials have been shown to significantly impact cell behaviors including adhesion, proliferation, differentiation, and overall bioactivity.[4,7,16–25] The mechanical properties of a number of CG scaffold variants have been tested in tension and compression; further, the elastic modulus of the individual struts that define the scaffold network has also been characterized[56] (Table 2). The mechanical behavior of CGCaP scaffolds under compression as well as the modulus of the individual mineralized struts has also been evaluated[61,84] (Tables 2 and 3). These results offer insight to the mechanical properties of a standardized set of CG materials.

Cellular solids modeling has been shown to be a powerful tool to aid the analysis of the mechanical properties of CG biomaterials. The cellular nature of CG scaffolds requires that

materials mechanical characterization must be performed at multiple scales: at the level of the whole material (macro) as well as at the level of the individual struts that define the scaffold structure (micro). The significant porosity of the CG scaffolds often results in multiple orders of magnitude difference in these mechanical properties. The theory predicts that stress–strain curves for low-density, elastomeric open cell foams in compression are characterized by three distinct regimes: a *linear elastic regime* (strut bending), a *collapse plateau regime* (struts buckling and pore collapse), and a *densification regime* (complete pore collapse) (Figure 11).[77] In tension, the initial linear elastic response is typically the same as is observed in compression for small strains; however, as the strain increases, the struts become increasingly oriented in the direction of applied tension, increasing the material stiffness until tensile failure.[77] Experimentally, the CG scaffold variants exhibited the theoretically predicted stress–strain behavior with distinct linear elastic, collapse plateau, and densification regimes (Figure 12). Experimental results show that CG scaffolds with equiaxed pores (mean pore sizes: 96–151 μm) as well as CGCaP scaffolds (50 wt% CaP) are microstructurally and mechanically isotropic.[56,84] CG materials demonstrated compressive moduli of order 30 kPa (dry) and 200 Pa (hydrated), independent of pore size, while CGCaP scaffold demonstrated compressive moduli of order 750 kPa (dry). The independent effects of variables including hydration level, pore size, and crosslink density on the mechanical properties were also determined (Tables 2 and 3).[56,84] The Young's modulus of the individual (CG and CGCaP) scaffold struts (E_s) that define the scaffold microstructure was measured via AFM (Figure 13).[56,84]

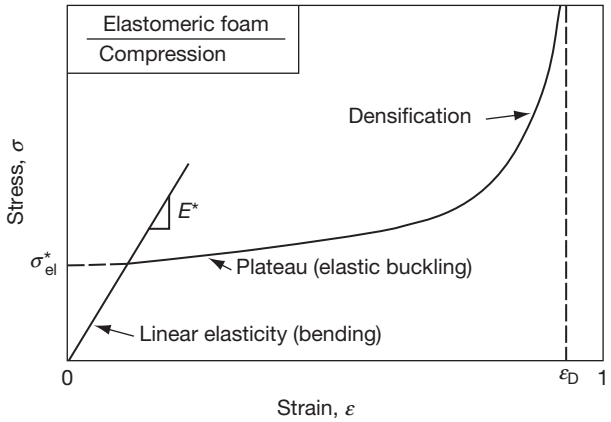

Figure 11 Uniaxial stress–strain curve for an elastomeric cellular solid in compression showing linear elastic, collapse plateau, and densification regions as well as the linear elastic modulus (E^*) and elastic collapse stress (σ^*_{el}). Reprinted with permission Gibson, L. J.; Ashby, M. F.; Harley, B. A. *Cellular Materials in Nature and in Medicine*; Cambridge University Press: Cambridge, 2010.

Using cellular solids theory, the Young's modulus (E^*) and elastic compressive strength (σ^*_{el}, also called the compressive plateau stress) of low density, open-cell foams such as CG scaffolds are predicted to depend on the foam relative density, ρ^*/ρ_s, the Young's modulus of the solid from which the foam is made, E_s (termed the strut modulus), and a constant of proportionality (C_1 and C_2) related to the cell geometry:[77] For elastomeric cellular solids, E^* and σ^*_{el} are

$$E^* = C_1 \left(\frac{\rho^*}{\rho_s}\right)^2 E_s \quad [3]$$

$$\sigma^*_{el} = C_2 \left(\frac{\rho^*}{\rho_s}\right)^2 E_s \quad [4]$$

Data for a wide variety of open-cell foams give approximate values as $C_1 \sim 1$ and $C_2 \sim 0.05$.[77] Interestingly, these equations show that the strain at which cell collapse by buckling occurs, ε^*_{el} is a constant value equal to $C_2/C_1 = 0.05$ and that both E^* and σ^*_{el} are expected to be independent of the pore size.[77]

Experimental results of scaffold mechanical characterization and low density, open-cell foam model predictions for the scaffold E^* and σ^*_{el} (eqns [3] and [4]) for the standard series of isotropic CG scaffold variants (ρ^*/ρ_s: 0.006; mean pore size: 96–151 μm) showed good agreement. Notably, CG scaffolds showed distinct *linear elastic*, *collapse plateau*, and *densification regimes*, and CG scaffold modulus was found to be independent of scaffold pore size, but highly dependent on scaffold ρ^*/ρ_s.[56] The effect of relative density on the mechanical properties of both mineralized and nonmineralized CG scaffolds has recently been evaluated.[45,46,56,84] Nonmineralized CG scaffolds over a range of relative densities (0.0062–0.0239) showed significant increases in compressive modulus and strength as well as tensile modulus with increasing relative density (Table 4).[45,56] While the model correctly predicted the relationship between E_s and E^*, it over-predicted E^* at higher relative densities. This is likely due to difficulties in fabricating CG scaffolds with high solids content, which often leads to areas of microstructural heterogeneities.[56]

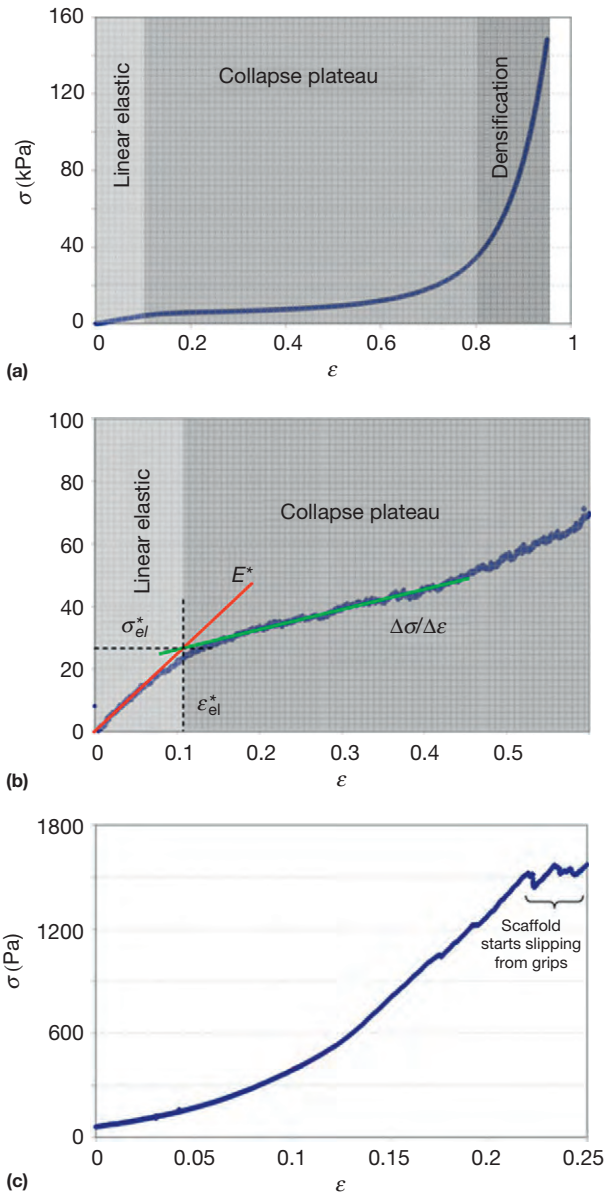

Figure 12 Characteristic stress–strain curves observed for the CG scaffold under compression for the entire tested strain range (a) ε: 0–0.95, and for a subregion of a hydrated CG scaffold (b) ε: 0–0.60. Linear regressions of the linear elastic and collapse plateau regimes are used to calculate the linear elastic modulus (E^*) and the collapse plateau modulus ($\Delta\sigma/\Delta\varepsilon$).The elastic collapse stress and strain are σ^*_{el}, ε^*_{el}. (c) Characteristic stress–strain curve observed for the (hydrated) CG scaffold variants under uniaxial tensile testing in the plane of the scaffold sheet. Reprinted with permission from Harley, B. A.; Leung, J. H.; Silva, E.; Gibson, L. J. *Acta Biomater.* **2007**, *3*, 463–474.

Likewise, mineralized CG scaffolds with relative densities from 0.045 to 0.187 had significantly increased compressive modulus and strength (both dry and hydrated) with increasing relative density (Table 4).[46] Meanwhile, modeling consistently over-predicted E^* and σ^*_{el} for the mineralized CG scaffolds. These discrepancies can be explained by the presence of voids, cracks, and disconnections within the scaffold microstructure.[84] Experimentally, CGCaP scaffolds with higher

Table 4 Mechanical properties (mean ± standard deviation) of CG (relative density 0.0062–0.0239) and CGCaP (0.045–0.187) scaffolds in the dry state

Scaffold	ρ^*/ρ_s	E* *(kPa)*	σ* *(kPa)*	ε* *(%)*	*Δσ/Δε (kPa)*

mineral content (75 wt% CaP) displayed inferior mechanical properties to the 50 wt% CaP scaffolds.[84] This behavior is possibly caused by the retention of residual moisture, even after extensive freeze-drying, due to the dehydration of 33% of the CaP mineral content from brushite to monetite in the 75 wt% CaP scaffold.[84]

2.216.3.4. CG Scaffold Degradation Kinetics and Byproducts

The degradation kinetics of tissue engineering scaffolds must be carefully tuned so that the scaffold structure remains intact throughout the duration of the regenerative process to prevent wound contraction, while degrading rapidly enough so as not to impede the healing process.[1,2,4,85] This optimization has been termed the isomorphous tissue replacement model, where the biomaterial degradation half life of the scaffold (t_d) must equal the healing half life of the tissue (t_h) in which it is implanted. Scaffold degradation that happens too quickly ($t_d > t_h$) or too slowly ($t_d < t_h$) is detrimental to the tissue regeneration process.[4] In addition to degradation kinetics, byproducts must also be carefully considered in scaffold design. Many synthetic scaffolds degrade to cytotoxic byproducts, limiting their *in vivo* applicability.[1,2] However, CG scaffolds, like most scaffolds made of natural materials, break down into harmless byproducts already found in abundance in the body.[31]

The degradation kinetics of CG scaffolds can be tuned by altering chemical composition (collagen to GAG ratio), relative density, or most commonly through differential crosslinking (see previous section for more details), where increasing crosslinking densities are used to slow scaffold degradation.[1,86] Pek *et al.* have evaluated the degradative process of CG scaffolds treated with one of four conventional crosslinking techniques: noncrosslinked (Nx), DHT (Dx), EDAC (Ex), and DHT/EDAC (DEx) in real time.[86] Here, scaffolds displayed an inverse relationship between swelling ratio and crosslink density, as is characteristic of random polymeric materials. ESEM observation of Nx and Dx scaffolds degraded with collagenase showed micropitting and eventual collapse of scaffold struts, leading to complete loss of mechanical integrity after a week while Ex and DEx samples maintained their structure and showed only minor micropitting.[86] Degradation by chondroitinase led to distinct structural (but not mechanical) changes for the Nx and

Dx scaffolds that were predicted to be more prone to GAG removal: scaffold struts were observed to swell and thereby reduce the open pore interconnectivity of the microstructure. This effect was not nearly so pronounced for the Ex and DEx variants.[86]

2.216.4. *In Vitro* Applications

2.216.4.1. Cell Attachment and Viability

CG tissue engineering scaffolds must have a mean pore size that is large enough for efficient metabolite exchange and cell infiltration, but small enough to provide ample surface area (ligands) to achieve adequate cell attachment. Distinct optimal pore sizes have been hypothesized for different cells, biomaterial chemistries, and clinical applications. CG scaffolds with uniform, well characterized microstructures (pore sizes 85–325 μm) have been used as a platform to begin to investigate the relationship of pore microstructure and scaffold-specific surface area with cell attachment, viability, and the uniformity of their distribution throughout the material.[9,10,45] These scaffolds were seeded with MC3T3-E1 mouse clonal osteogenic cells and then cultured for anywhere between 1 and 7 days to determine viable cell number and distribution. Increased early cell adhesion (24–48 h) was correlated with increased scaffold specific surface area (**Figure 14**).[10] Modulating scaffold relative density (0.0062–0.0239) to alter scaffold SA/*V* also gave a linear relationship between scaffold specific area and MC3T3-E1 cell attachment ($R^2 = 0.97$ at 24 h).[45] These results indicate a strong correlation between specific surface area and early MC3T3-E1 cell attachment for this set of CG scaffolds. However, for longer culture periods (7 days), a higher number of cells are observed in scaffolds with larger pores (>300 μm). This result has been hypothesized to be due to the competing influence of scaffold proliferation and metabolic support via diffusion, both of which increase with increased scaffold pore size: larger pore sizes allow for easier cell proliferation and migration throughout the entire scaffold, especially at later time points (7 days). These results have helped confirm that scaffolds with larger pore sizes, 325 μm, may be more optimal for long-term bone tissue engineering applications.[9]

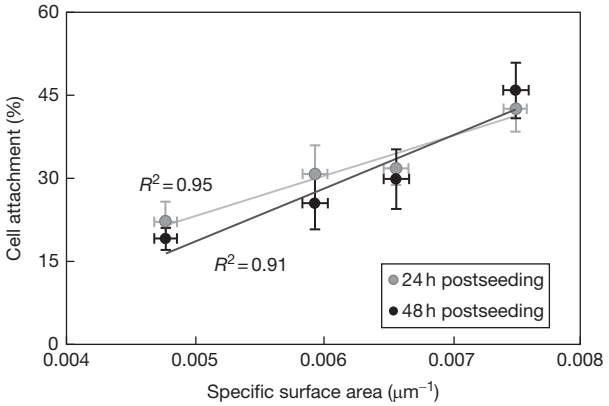

Figure 14 MC3T3-E1 cell attachment plotted against specific surface area showing a strong linear relationship at 24 (gray line) and 48 h (black line) postseeding. Reprinted with permission from O'Brien, F. J.; Harley, B. A.; Yannas, I. V.; Gibson, L. J. *Biomaterials* **2005**, *26*, 433–441.

Fabrication flexibility also has enabled investigation of the effect of CG scaffold chemical composition on initial cell attachment and viability. MC3T3-E1 attachment and viability have been shown to depend on scaffold chemical composition (collagen and GAG concentration)[12] and mechanical properties.[11] Here, scaffolds were fabricated over a range of concentrations of collagen (0.25–1%, w/v) and GAG (0–0.088%, w/v), seeded with cells, and cultured for 6 h to 7 days. Lower concentrations of collagen and GAG showed high initial cell attachment, likely because of a temporary increase in surface area due to loss of structural integrity (pore collapse).[12] However, the higher concentration of surface ligands on the 1% collagen scaffolds supported the highest cell attachment after 7 days; 0.088% GAG scaffolds also had better cell infiltration than their counterparts.

2.216.4.2. Cell Contraction

Cell-mediated contraction plays an integral role in many physiological and pathological processes, notably organized contraction and scar formation during wound healing. One of the key functions of CG and other tissue engineering scaffolds is to block wound contraction to prevent scar tissue proliferation, instead allowing for regeneration of functional tissue.[4] This objective requires a comprehensive understanding of the forces and kinetics associated with cell contractile processes within the scaffold microstructure so that scaffolds can be designed with the requisite mechanical integrity to withstand contraction for a critical period of time. Most studies of cell contraction *in vitro* have used 2D substrates. Here, contractile force is calculated as a function of substrate deformation due to a population of cells and the elastic modulus of the substrate.[87–93] This technique has been used to show that substrate elastic modulus significantly affects cell behaviors such as proliferation, differentiation, migration speed, directional persistence, and applied traction forces.[21,87,93–102] These methods yield estimates of fibroblast contractile forces on the order of hundreds of nanoNewtons.[90,93,95] However, these results are not likely comparable to *in vivo* contractile forces, given the fact that the shape and cytoskeletal organization of cells on these 2D substrates (amorphous, spread) are significantly different than that of fibroblasts observed in wound sites within the natural ECM (elongated spindle-shaped).[75,103–105]

CG scaffolds have been used in a number of investigations to quantify the macroscopic (bulk construct) and microscale (individual strut) contractile behavior of cell populations as well as the relationship between distinct integrin–ligand interactions, cytoskeletal organization, and cell contraction. Macroscopically, the average contractile force generated by a known cell population can be calculated as a function of the gross deformation of the CG scaffold by that cell population and the scaffold's elastic modulus. Total contractile force generated by a population of dermal fibroblasts within the CG scaffold was observed to reach an asymptote of 1.0 ± 0.2 nN, independent of the number of cells seeded, with an associated time constant of 5.2 ± 0.5 h.[17] When the stiffness of the scaffold system was changed, fibroblasts were observed to apply differential levels of strain but a constant average force to the CG scaffold, suggesting that dermal fibroblasts apply contractile forces independent of the local microenvironment (**Figure 15**).[106]

Similar analysis has been performed for chondrocytes[107] and Schwann cells.[108] Fibroblasts displayed significant cytoskeletal reorganization during contraction within the CG scaffold; initially rounded after seeding, they were observed to form attachments to single struts as well as between multiple CG struts and elongated over time into spindle-shaped cells. The average aspect ratio (maximal cell length/maximal cell thickness) of the cells increased asymptotically from 1.4 to 2.8 during the first 15 h in the scaffold (**Figure 15**) with a time constant similar to that observed for contractile force generation.[17,109] In addition, the role of integrin–ligand complexes in the contraction of CG scaffolds has been examined using a culture force monitor (CFM) via specific inhibition of integrins and distinct cell adhesion proteins (fibronectin, vitronectin, and collagen).[110] Initial dermal fibroblast attachment and force generation (0–5 h) was found to be sequentially mediated primarily by fibronectin followed by vitronectin. Attachment and force profiles at later time points (6–20 h) were shown to be dominated by cell–collagen interactions.[110]

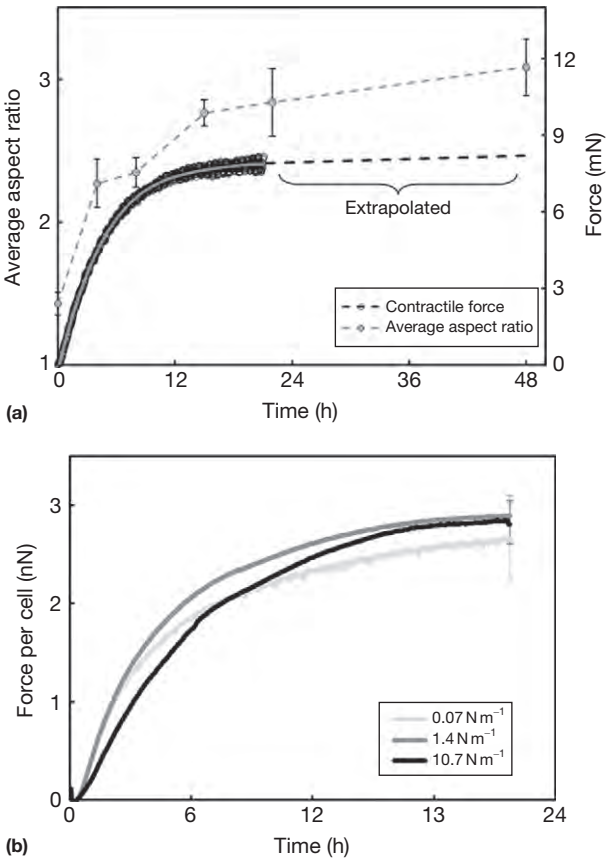

Figure 15 (a) Plot of the fibroblast aspect ratio and generated contractile force with time in the CG scaffold. The average cell aspect ratio increased up to 15 h postseeding in a manner similar to the total force generated by the cell population. (b) Plot of force per cell over time for different system stiffnesses. The displacement developed per cell increased as the system stiffness decreased but the force developed per cell was independent of the system stiffness. Reprinted with permission from Gibson, L. J.; Ashby, M. F.; Harley, B. A. *Cellular Materials in Nature and in Medicine*; Cambridge University Press: Cambridge, 2010.

However, two significant assumptions are made with this analysis. First, the deformation of the cell-seeded, rectangular CG scaffold sample was measured in only one direction. Second, the fraction of contractile cells versus the total cell population within the scaffold was not characterized. As the average force per cell was calculated using the assumptions that all cells were contracting in a single direction and that all cells were contracting at the same time, the calculated average contractile force of 1.0 ± 0.2 nN is a lower bound.

CG scaffolds have also been used to quantify the contractile forces generated by individual cells within a 3D ECM analog. Phase contrast microscopy has been used to generate time-lapse images of dermal fibroblasts differentially migrating through the scaffold, or contracting the local scaffold microstructure, resulting in buckling of the strut(s) to which the cell was attached (**Figure 16**).[17,106,109] Improved mechanical and

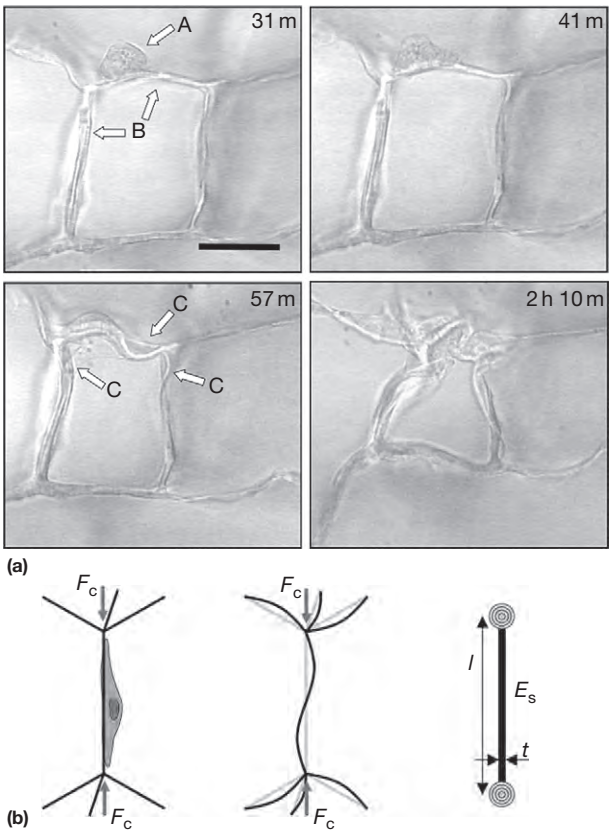

Figure 16 (a) Time lapse images of an individual dermal fibroblast within the CG scaffold. The sequence of images shows a dermal fibroblast (arrow A) elongating and deforming the surrounding scaffold struts (arrows B). Several struts are deformed over time (arrows C). Time, in hours and minutes, after cell seeding is indicated in the top right of corner of each image. Scale bar: 50 μm. (b) Schematic of a single cell applying a critical buckling load (F_c) to a scaffold strut within an idealized CG scaffold network (left). microstructural characterization of the individual CG scaffold struts[75] and the application of cellular solids theory enabled the use of modified Euler column buckling relationships in order to quantify the magnitude of individual cell contractile forces within the CG scaffold.[75] The magnitude of the cell-mediated contraction forces generated by individual dermal fibroblasts within the CG scaffold was calculated from the observed strut deformation by individual dermal fibroblasts, strut dimensions and mechanical properties, and previous experimental and theoretical work describing the mechanics and collapse of open cell foams.[77] The critical load (F_c) at which a scaffold strut of length l_s, average pore size d, Young's modulus E_s, and second moment of area I (strut geometry was approximated as a cylindrical fiber, $I = \pi d^4/64$) buckles can be calculated by Euler's formula and the hydrostatic compression end restraint ($n^2 = 0.34$):[75,77,111]

$$F_c = \frac{n^2 \pi^2 E_s I}{l_s^2} \quad [5]$$

The contractile force generated by individual dermal fibroblasts that were able to buckle a CG scaffold strut was calculated to range between 11 and 41 nN, with an average contractile force (F_c) of 26 ± 13 nN.[75] The upper limit of fibroblast contractile capacity in CG scaffolds was established from data on a cell that was unable to buckle the strut it was attached to because that strut was significantly thicker than the average strut, thereby increasing its flexural rigidity (E_sI) and buckling load (F_c). Analysis of this strut's microstructure indicates that the force required to buckle the strut was approximately 450 nN. These results suggest that while dermal fibroblasts can easily develop the ~25 nN force required to buckle conventional CG scaffold struts, they are unable to develop contractile forces at the level of 450 nN.[75] While developed with a well-characterized CG scaffold system, this technique can be used to study individual cell contraction and cell–scaffold interactions within a wide variety of tissue engineering scaffolds.

2.216.4.3. Cell Motility

Cell motility plays an integral role in many physiologic and pathologic processes, notably organized wound contraction and fibroblast and vascular endothelial cell migration during wound healing,[4] metastatic tumor cell migration,[112] stem cell mobilization and homing,[113,114] and tissue remodeling.[4] Cell migration is a complex process modulated by a range of spatiotemporally presented biochemical and biophysical signals, both extracellular and intracellular.[115,116] Studies of cell motility on 2D substrates have led to an improved understanding of how surface features, particularly substrate stiffness, affect migration through changes in cytoskeletal organization and applied traction forces.[98–100] However, 3D biomaterials enable the investigation of the complex set of biophysical and biochemical signals that can affect motility in a 3D environment that better resembles physiologically and pathologically relevant conditions. Understanding of the microenvironmental factors that govern cell motility is also critical for acellular biomaterials (like CG scaffolds) because they must be able to induce rapid cellular invasion.

Cell motility in CG scaffolds relies on a phenomenon known as contact guidance. As CG scaffold pore sizes are significantly larger than the characteristic length of the fibroblasts, cells are forced to migrate along scaffold struts. External microstructural and mechanical stimuli from the scaffold provide physical cues (contact guidance) to regulate cell motility and other cell behaviors.[2] NR6 mouse fibroblasts were seeded into CG scaffolds with pore sizes ranging from 96 to 151 μm but with constant mechanical properties ($E^* = 208 \pm 41$ Pa), and single cell migration paths were tracked using 3D time-lapse confocal microscopy.[7] Cell dispersion (Wind-Rose plot, **Figure 17(a)**) and motile fraction (**Figure 17(b)**) significantly decrease with increasing pore size.[7] Cell speed was also shown to significantly decrease with increasing scaffold pore size (**Figure 17(b)**); cell speed is reduced almost by half over the range from 96 to 151 μm, from about 12 to 6 μm h^{-1}. Further, as cell speed was calculated for only the motile population, which also decreased significantly with mean pore size, scaffold pore size has an even more significant influence on overall cell motility than is suggested by **Figure 17(b)** alone. The effect of scaffold stiffness on NR6 fibroblast motility was assessed in a series of DHT- and EDAC-crosslinked CG scaffolds of constant pore size (96 μm) but variable strut modulus (E_s: 5.3–38 MPa). Cell migration speed exhibited a subtle biphasic behavior with strut modulus increasing (significantly) from 11 to 15 μm h^{-1} for strut moduli between 5 and 12 MPa and then decreasing (significantly) back to 12 μm h^{-1} for strut moduli of 38 MPa (**Figure 17(b)**). The effects of pore size and scaffold stiffness on cell migration speed correlated well with previous experimental and computational studies of cell motility in dense, 3D materials.[25,117] Unlike with the dense materials used in those studies, cells were not exposed to significant steric hindrances in these porous, CG scaffolds, so the strong dependence of cell motility on pore size was not expected.

In addition to satisfying the practical need to better understand cell motility in CG scaffolds to enable more efficient cellular invasion, the fabrication, characterization, and modeling tools recently developed for CG scaffolds enabled a rigorous analysis of the independent effect of microstructural and mechanical scaffold features on cell motility. Modeling techniques were then used in an attempt to better explain the initially inexplicable effect of pore size on cell motility. Cellular solids modeling suggested that while the strut moduli (E_s) and scaffold relative density (ρ^*/ρ_s) are constant for the scaffolds of different pore size, scaffolds with a larger pore size have longer and thicker struts (**Figure 9**). So, while the moduli (E_s) of these struts are identical, the second moment of inertia (I) increases with increasing pore size, translating to a larger strut flexural rigidity (E_sI) with increasing pore size. Cells are known to apply a constant contractile force to the CG scaffold regardless of the system stiffness[106] which suggests that cells probe their local mechanical environment by applying a constant traction force and measuring the resultant substrate deformation.[118] These results suggested that strut flexural rigidity, not stiffness, is the more relevant mechanical signal to cells. So even though the struts have a constant elastic modulus, they may 'feel' stiffer in scaffolds with larger pore sizes because of an increased resistance to buckling. The 'apparent' stiffness, or flexural rigidity (E_sI), of the scaffold with the largest pore size (151 μm) was calculated to be greater than that of the scaffold with the

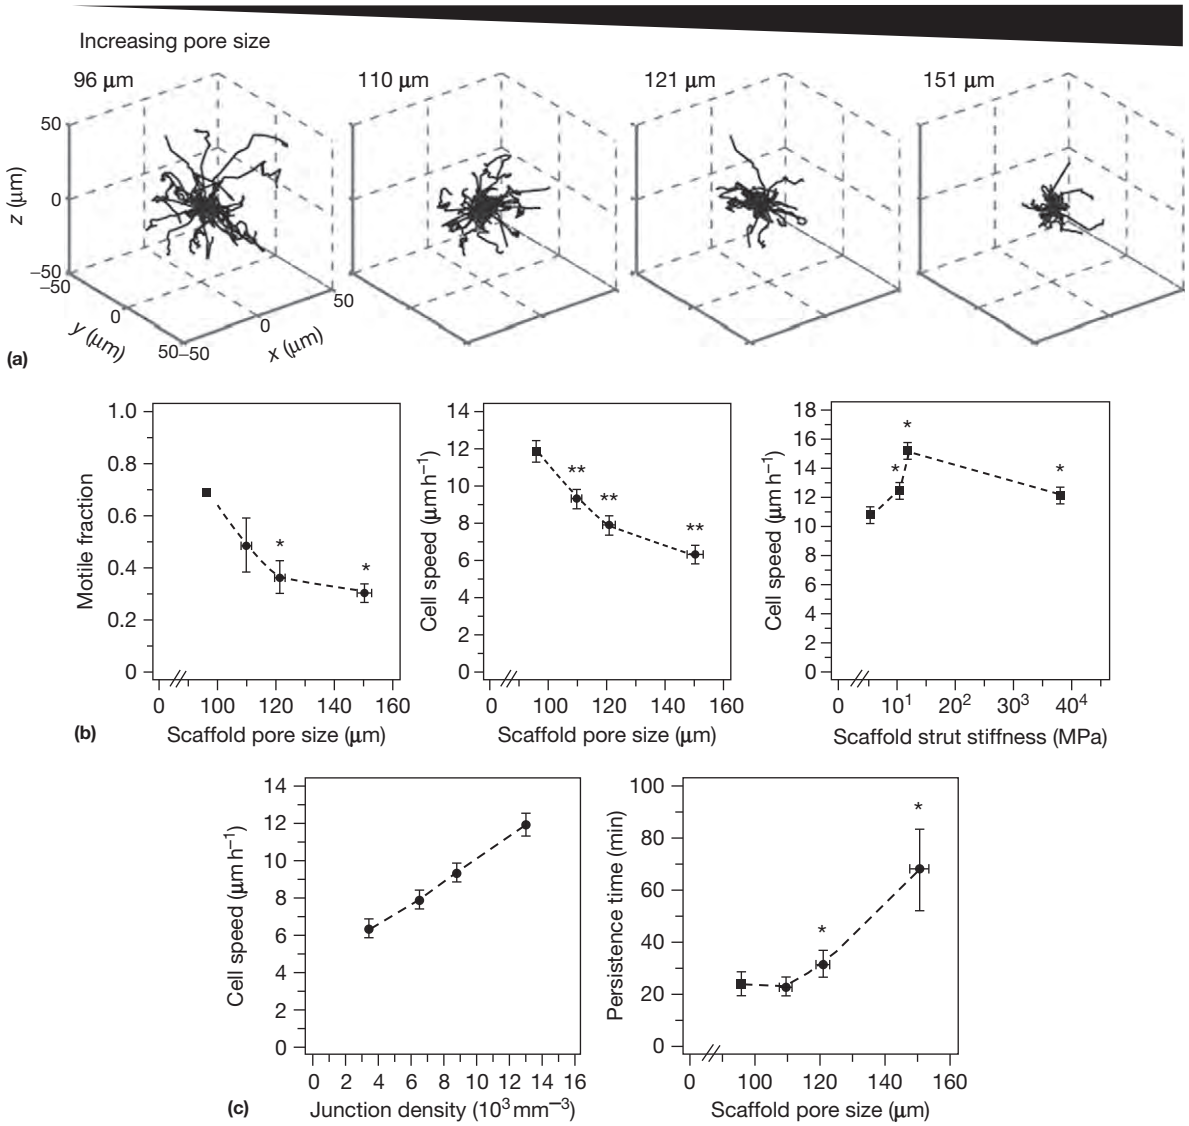

Figure 17 (a) 3D Wind-Rose plots of randomly chosen cell tracks showing cell dispersion; cell dispersion decreases as scaffold mean pore size increases. (b) Motile fraction and mean cell speed decrease as scaffold pore size increases. Cell speed shows a subtle biphasic relationship with scaffold strut modulus. (c) Cell speed increases proportionally with scaffold strut junction density. Cell persistence time increases with pore size (increasing distance between strut junctions). Reprinted with permission from Harley, B. A. C.; Kim, H. D.; Zaman, M. H.; Yannas, I. V.; Lauffenburger, D. A.; Gibson, L. J. *Biophys. J.* **2008**, *95*, 4013–4024.

smallest (96 μm) pore size by a factor of 6.1. Thus, if strut flexural rigidity was the mechanism by which pore size affected cell motility, cell motility would be expected to decrease for the series of scaffolds of constant pore size but increasing scaffold modulus (changing E_s in the flexural rigidity term (E_sI)). However, when strut modulus (E_s) was increased over a range (between 5.3 and 38.0 MPa; Factor: 7.2; Table 3) that closely approximated the change in strut flexural rigidity with mean pore size (Factor: 6.1), motility did not decrease but instead displayed subtle biphasic behavior (Figure 17(b)).[7]

After attempting to explain the significant influence of CG scaffold pore size on cell motility using predictions made by the cellular solids modeling regarding local scaffold mechanics, geometric insights from the cellular solids model regarding strut junctions (points in the scaffold where two or more struts meet) were investigated. The geometry of strut junctions within the scaffold was described as the mean spacing between junctions (D_{jxn}) or the mean junction density (ρ_{jxn}, the number of strut junctions per unit cell divided by the volume of a unit cell). D_{jxn} and ρ_{jxn} were calculated from the scaffold mean pore size (d) assuming a tetrakaidecahedral unit cell:[7]

$$D_{jxn} = \frac{d}{2.785} \quad [6]$$

$$\rho_{jxn} = \frac{11.459}{d^3} \quad [7]$$

Replotting the pore-size-dependent cell speed data against strut junction density, an exceptionally strong correlation

between cell speed and strut junction density was observed (Figure 17(c)). Further, cells migrating in scaffolds with larger pore sizes, and therefore larger D_{jxn} and lower ρ_{jxn}, were observed to exhibit greater persistence times, indicating more directional motion along a scaffold strut (Figure 17(c)). In contrast, persistence times of cells migrating in scaffolds with smaller pore sizes and greater ρ_{jxn} are significantly lower, representative of erratic movement (time turning) that likely occurs more often at junctions when cells encounter higher surface ligand densities and can therefore move with increased speed. These results provided a mechanistic explanation for the initially counter-intuitive observation that cell motility decreases as scaffold pore size increases,[7] as well as an excellent example of the types of mechanistic questions that can be answered using the CG scaffold system because of the capacity to create uniform scaffold variants with independently controlled microstructural and mechanical properties and to integrate rigorous characterization and modeling techniques.

2.216.4.4. Growth Factor and Gene Delivery

Tissue engineering scaffolds are frequently enhanced through the addition of exogenous factors including growth factors, drugs, and genes. CG scaffolds have been used as a platform to study the combined effects of the scaffold and delivery of growth factors and genes. Recently, marrow stromal cells (MSCs) were transfected with a plasmid encoding for glial cell line-derived neurotrophic factor (pGDNF) and seeded onto standard type I CG scaffolds.[119] For optimal plasmid loading, the level of GDNF remained six to seven times higher than a control after 2 weeks of culture, reaching previously described therapeutic levels.[120] These results show promise for future brain tissue engineering studies with CG scaffolds.

The potential for CG materials as cartilage and meniscus scaffolds has been enhanced using gene delivery. EDAC crosslinking of as little as 10 μg of IGF-1 plasmid to type II CG scaffolds resulted in sustained plasmid release that was controlled by the degradation rate of the scaffold. IGF-1 was overexpressed over a 2-week culture period, resulting in significantly higher amounts of chondrocyte-like cells, GAG, and type II collagen production compared to controls.[121] Another study transfected MSCs with a plasmid encoding endostatin, a potent antiangiogenic factor that could potentially prevent unwanted vascularization of cartilage, and cultured on CG scaffolds.[122] Endostatin levels, while negligible in control cultures, reached a peak of 13 ng ml^{-1} after 3 days and approached therapeutic levels after 2 weeks.[122] MSCs and meniscal cells have also been transfected with a vector for TGF-β1 and cultured *in vitro* on type I CG scaffolds. Implantation of transfected, cell-seeded constructs following culture led to increased matrix synthesis and meniscal gene expression over controls.[123]

2.216.4.5. Modifying Gene Expression

CG scaffolds have been used to compare gene expression profiles of fibroblasts cultured on 2D and 3D constructs. The gene expression profiles investigated focused on genes involved in angiogenesis (VEGF, HMOX, and HGF) and matrix remodeling (matrix metalloproteinases and their inhibitors, ECM components), two critical processes that must be understood for rational scaffold design. Genes for some matrix metalloproteinases (MMP-2, MMP-12, MMP-19), ECM protein synthesis (COL1A2, COL3A2, COL2A1, COL4A4, COL4A5), and proangiogenic factors were upregulated while some MMP inhibitors (TIMP1, TIMP3) were downregulated in the 3D CG scaffolds compared to the 2D CG surfaces.[8] These results indicate that the geometric and topographical differences between 2D and 3D CG substrates can critically affect gene expression and possibly matrix remodeling.

2.216.4.6. Mechanical Stimulation

Mechanical stimuli, derived from both physical extracellular binding sites and the movement of fluids within the ECM, is known to influence critical cell behaviors such as proliferation, differentiation, and gene expression.[124–126] Experimental, computational, and modeling techniques have all been used with the CG scaffold system to improve our understanding of how these mechanical forces affect cell behavior. For example, the effects of pore size and mechanical stimulation on gene expression profiles for MSCs in CG scaffolds have recently been evaluated. Osteogenic markers collagen type I, osteocalcin, and osteopatin were all upregulated in MSCs seeded into CG scaffolds with larger pores (151 μm vs. 96 μm),[127] indicating that larger pore sizes may be more optimal for bone tissue engineering. Also, scaffolds that were mechanically constrained to prevent contraction showed lower MSC RNA levels of osteocalcin, osteopatin, and bone sialoprotein, suggesting that prevention of cell-mediated contraction may be detrimental to osteogenesis.[127]

CG scaffolds have also been used to investigate the role of direct mechanical stimulation on osteoblastic activity. Mechanical loading of MC3T3-E1 cells in culture is known to improve bone morphogenic activity within scaffolds. In addition, mechanical stimulation during *in vitro* culture improves nutrient and waste transport within the scaffold while promoting cellular infiltration, which should lead to more uniform tissue engineering constructs compared to static culture. Dynamic culture was shown to upregulate the gene for cyclooxygenase-2 (COX-2), a key enzyme for the production of early bone formation marker prostaglandin E_2 (PGE_2). The gene for osteopontin (OPN), a later marker of bone formation, was also upregulated.[128] In addition, incorporation of rest periods during dynamic culture has been shown to significantly increase OPN expression over both static and dynamic conditions.[129] This suggests that mechanical stimulation via flow perfusion could be a useful technique for encouraging osteoblastic activity and bone formation in CG scaffolds (see **Chapter 5.501, Scaffolds: Flow Perfusion Bioreactor Design**).

3D computational fluid dynamics (CFD) modeling has further been utilized to estimate shear stress forces on cells seeded within CG scaffolds for bone tissue engineering during *in vitro* culture in perfusion bioreactors.[76,130] For bone, it is understood that applied wall shear stresses on cells are critical in activating matrix production and mineralization.[81] Accurate simulations of applied shear stresses on cells would allow the selection of an optimal perfusion rate that correlates to physiologic shear stress levels. CFD showed that cells in CG scaffolds were exposed to a wide range of shear stresses while conventional analytical methods to estimate shear stress report a mean shear stress value only. The analytical methods also

predicted shear stress values 10–20% higher than CFD and do not take into account the type of secondary cell deformation that can take place on the basis of cell orientation within the scaffold.[130] CFD analysis of fluid velocity, hydrostatic pressure, and wall shear stress on common cell attachment profiles within CG scaffolds (stretched along one strut or spread between two struts) shows that low wall shear stresses (~20 mPa) are sufficient to activate bone growth mechanisms.[76]

While computational methods can be useful, the above analysis focused on small scaffold sections only as it was impractical to analyze an entire scaffold area.[76,130,131] Recent work by Stops *et al.* has developed a finite element approach to predict cellular strains within CG scaffold systems (see **Chapter 3.307, Finite Element Analysis in Bone Research: A Computational Method Relating Structure to Mechanical Function**). Utilizing the tetrakaidecahedron unit cell and experimental data regarding scaffold deformation, cell attachment profiles, and cell sizes, a model was developed to predict individual cell strain as a function of pore size, cell length, and applied scaffold strain. This model correctly predicts individual cell strain within two standard deviations for 72% of cells.[131] This approach has also been applied to predict the differentiation of MSCs in CG scaffolds as a function of Young's modulus.[132] The model takes into account pore size, cell proliferation, angiogenesis, and shear stress/strain among other factors. Results over a range of 0.001–1000 MPa show that higher Young's modulus should lead to higher numbers of osteoblasts, indicating that stiffer CG scaffolds could be ideal for bone tissue engineering (**Figure 18**).[132] All of these tools highlight the multi-scale experimental and analytical tools available when utilizing the CG scaffold system for studies of cellular mechanotransduction.

2.216.4.7. Stem Cell Differentiation

CG scaffolds have recently been started to be used to explore extrinsic modulation of stem cell fate decisions (differentiation, quiescence, and self-renewal) (see **Chapter 2.209, Materials as Artificial Stem Cell Microenvironments**). Adult mesenchymal stem cells (MSCs) can differentiate into a myriad of tissues, including bone, cartilage, and tendon, making them a powerful tool for orthopedic tissue engineering. Farrell *et al.* has recently shown that adult MSCs in CG scaffolds could be induced to differentiate along osteogenic or chondrogenic lineages in the presence of osteogenic (dexamethasone, ascorbic acid, and β-glycerophosphate) and chondrogenic (dexamethasone and TGF-β1) factors, respectively.[133] The CG scaffold's demonstrated ability to support both bone and cartilage growth makes it a promising material for the treatment of osteochondral defects. Subsequent work has compared the osteogenic potential of MSCs on 2D substrates versus 3D CG constructs. While MSCs initially expressed collagen type I quicker on 3D substrates, the delayed expression of osteocalcin indicates that osteogenic differentiation is slower in CG scaffolds compared to that in 2D substrates.[134] MSCs cultured in CG materials have also shown variable differentiation and gene expression profiles under mechanical strain. High strains (15%) led to enhanced α-smooth muscle actin expression but poorer differentiation into type I collagen positive cells compared to lower strain levels (5%).[135] Ongoing work is examining the utility of CG scaffolds to influence fate decisions of hematopoietic and cardiac stem cells.

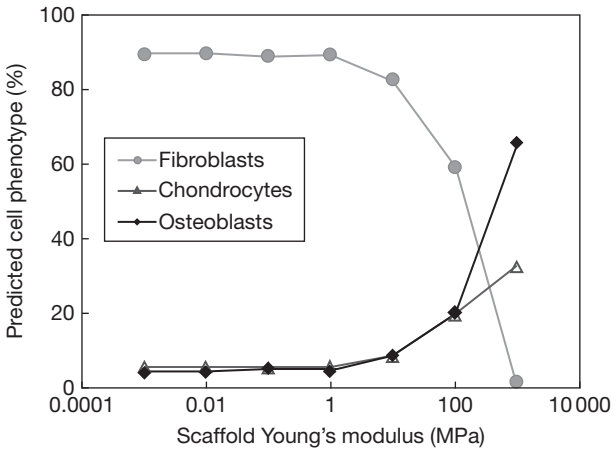

Figure 18 Percentage of MSC-derived cell phenotypes inside CG scaffold as a function of Young's modulus as predicted by finite element modeling. The fraction of osteoblasts compared to fibroblasts increases with increasing modulus, suggesting that stiffer CG scaffolds may be preferred for bone tissue engineering. 2.216.5. *In Vivo* Applications

Since the development of the first clinically viable artificial skin,[5] CG scaffolds have been used *in vivo* to regenerate a wide variety of chronic and acute injuries involving skin (see **Chapter 5.534, Skin Tissue Engineering**), peripheral nerves (see **Chapter 5.531, Peripheral Nerve Regeneration**), conjunctiva, cartilage (see **Chapter 5.515, Cartilage Tissue Engineering**), and other tissues.[4] CG scaffolds, like other tissue engineering scaffolds, serve a multitude of functions *in vivo* including physical inhibition of wound contraction, mechanical support for cells and neo-tissue growth, and carrier of biochemical ligands and signaling molecules. CG scaffold mechanical, chemical, and microstructural properties have been rigorously characterized *in vitro*, leading to independent control of pore size and shape, elastic moduli, biodegradation rate, chemical composition, and other scaffold parameters. These variables can be tuned to create scaffolds optimized for the regeneration of specific tissues.

2.216.5.1. Dermal Regeneration Applications

The CG scaffold is found to optimize skin regeneration as a monolithic, uniform structure (termed the dermal regeneration template (DRT)) that is fabricated from a CG copolymer with a 98:2 ratio of type I collagen to GAG (chondroitin 6-sulfate). This chemistry was developed in part because of the additional mechanical stability afforded by the GAG content as well as the processing to the collagen fibrils that allowed platelet attachment but prevented activation of platelet degranulation processes.[5,136] The DRT has isotropic pores with a 20–125 μm size range and a degradation time of 5–15 days. The DRT is typically implanted acellularly (without cells) along

with a thin silicone coating to control moisture loss and bacterial infection at the wound site. This bioactive scaffold recruits epidermal cells from the wound site and encourages spontaneous regeneration of skin tissue layer by layer. Sequential regeneration results in a mature epidermis and basement membrane as well as near physiologic dermis that lacks hair follicles. This scaffold has regenerated full-thickness skin wounds in animal models and human burn victims.[4,5]

2.216.5.2. Peripheral Nerve Regeneration Applications

Peripheral nerve injuries are typically treated by entubulating transected nerve ends. Tubes made of type I collagen have been the most successful as defined by morphological and electrophysiological methods.[3,4,48,137–139] While a tube is sufficient to induce regeneration across a gap of several millimeters, the addition of a porous material into the tube lumen can enhance the quality of regeneration and has been proven superior to other nonporous, nonpermeable lumen designs (**Figure 19**).[4,139] This porous core acts as a physical support for the growing nerve while allowing migration of cells and cytokines across the nerve gap. In addition, this central scaffold core has also been shown to organize wound contraction and scar proliferation.[54] The CG scaffold optimized for peripheral nerve regeneration, termed the nerve regeneration template (NRT), has axially elongated pores on the order of 10–20 μm that provide contact guidance for Schwann cell migration and axon formation between nerve stumps.[137] These scaffolds, with an optimal degradation half life of 6 weeks,[4,47] were found to regenerate peripheral nerves at the same level as autografts, the current gold standard in the industry.[137]

2.216.5.3. Conjunctiva and Corneal Regeneration Applications

CG scaffolds have demonstrated the ability to alter the typical contraction and scar synthesis healing mechanisms associated with full thickness lesions of the conjunctiva in a rabbit animal model. Scaffolds were able to significantly reduce wound contraction ($6.8 \pm 3.2\%$ fornix shortening vs. $26.4 \pm 5.0\%$ for ungrafted wound sites) and promote the synthesis of a nearly physiologic stroma layer.[140] CG scaffolds have also been shown to be promising substrates for the development of artificial corneas (see **Chapter 6.631, Keratoprostheses**). *In vitro* characterization of these scaffolds showed that stromal keratocytes, epithelial cells, and endothelial cells could be successively cocultured over a period of 12 weeks.[141] The cells produced a new ECM, complete with an epithelium, basement membrane, and endothelial cell monolayer.[141]

2.216.5.4. Cartilage and Fibrocartilage Disk Tissue Engineering Applications

CG scaffolds have been applied to the regeneration of a range of other orthopedic tissues including articular cartilage, meniscus, and the intervertebral disk (see **Chapters 5.524, Biomaterials for Replacement and Repair of the Meniscus and Annulus Fibrosus** and **6.615, Intervertebral Disc**). The effects of crosslinking density, chemical composition, and pore size of CG scaffolds, as well as the use of gene and growth factor seeded CG scaffolds, have been studied extensively in the context of articular cartilage regeneration.[121,142–146] Recently, CG scaffolds populated with TGF-β1 transfected meniscus cells

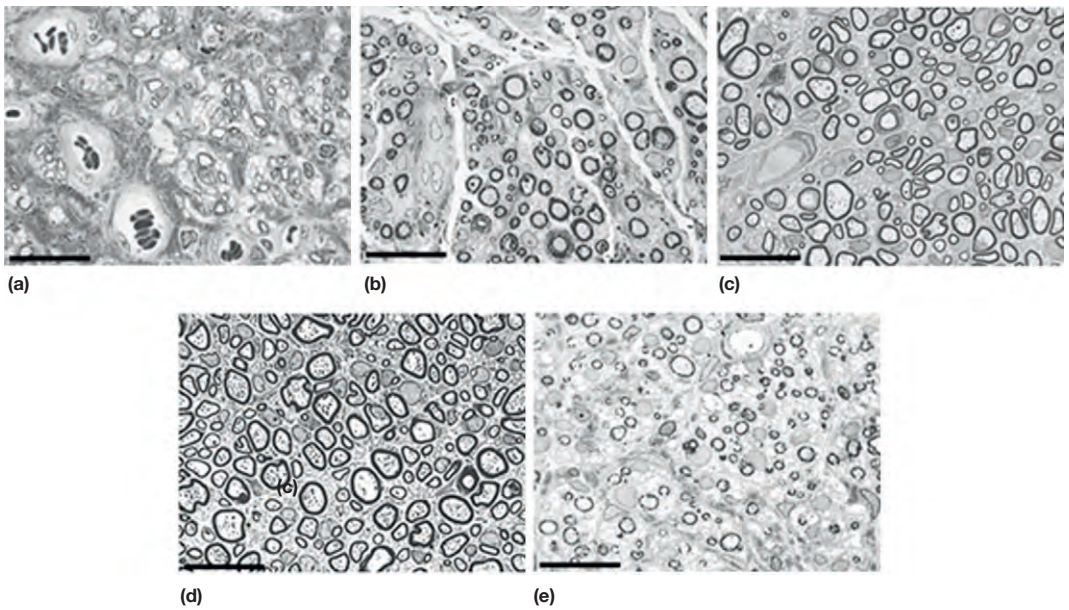

Figure 19 Histomorphometic, cross-sectional images of the nerve trunk regenerated using collagen tubes with tailored biodegradation rates. The images are arranged in order of lowest to highest crosslink density, or fastest to slowest degradation rate from (a) to (e). Nerves trunks regenerated in devices (c) and (d), characterized by intermediate levels of the crosslink density and degradation rate (device half life: 2–3 weeks), showed superior morphology, with significantly larger axons, a more well-defined myelin sheath, and a significantly larger *N* ratio. Scale bar: 25 μm. Reprinted with permission from Harley, B. A.; Spilker, M. H.; Wu, J. W.; *et al*. *Cells Tissues Organs* **2004**, *176*, 153–165, S. Karger AG, Basel, Switzerland.

were used to successfully fill avascular zone meniscus lesions with repair tissue.[123] Other work has compared type I and type II CG scaffolds for intervertebral disk tissue engineering applications, finding that type II CG scaffolds were preferential to type I on the basis of cell number as well as protein and GAG synthesis after 8 weeks.[147]

2.216.5.5. Bone, Osteochondral Regeneration Applications

Single phase and layered, multiphase CGCaP scaffolds have recently been developed for *in vivo* bone and osteochondral tissue engineering applications, respectively (see **Chapter 6.617, Bone Tissue Grafting and Tissue Engineering Concepts**).[61–63,69,148] These materials are currently undergoing *in vivo* examination as both bone scaffolds (single phase CGCaP form) and as full osteochondral scaffolds. CGCaP bone regeneration scaffolds are composed of type I collagen, chondroitin 6-sulfate, and calcium phosphate. Initial *in vitro* and *in vivo* experiments have demonstrated that these scaffolds can successfully integrate into bone defects and show preliminary bony substitution and mineralization as early as 6 weeks post implantation.[149]

The biphasic layered, gradient scaffold developed for the treatment of osteochondral defects has been shown to mimic aspects of the natural structure of articular joints,[69] notably a continuous boundary that should induce the formation of interfacial tissue as seen in healthy joints between articular cartilage and subchondral bone (**Figure 20**). Utilization of this fabrication method also prevents complications often observed in layered scaffolds with abrupt interfaces including delamination, foreign body contamination (from glue or other adhesives), and inefficient cellular transport between scaffold phases.[69] Under mechanical loading, the osteochondral scaffolds perform as expected for a biphasic material, with the

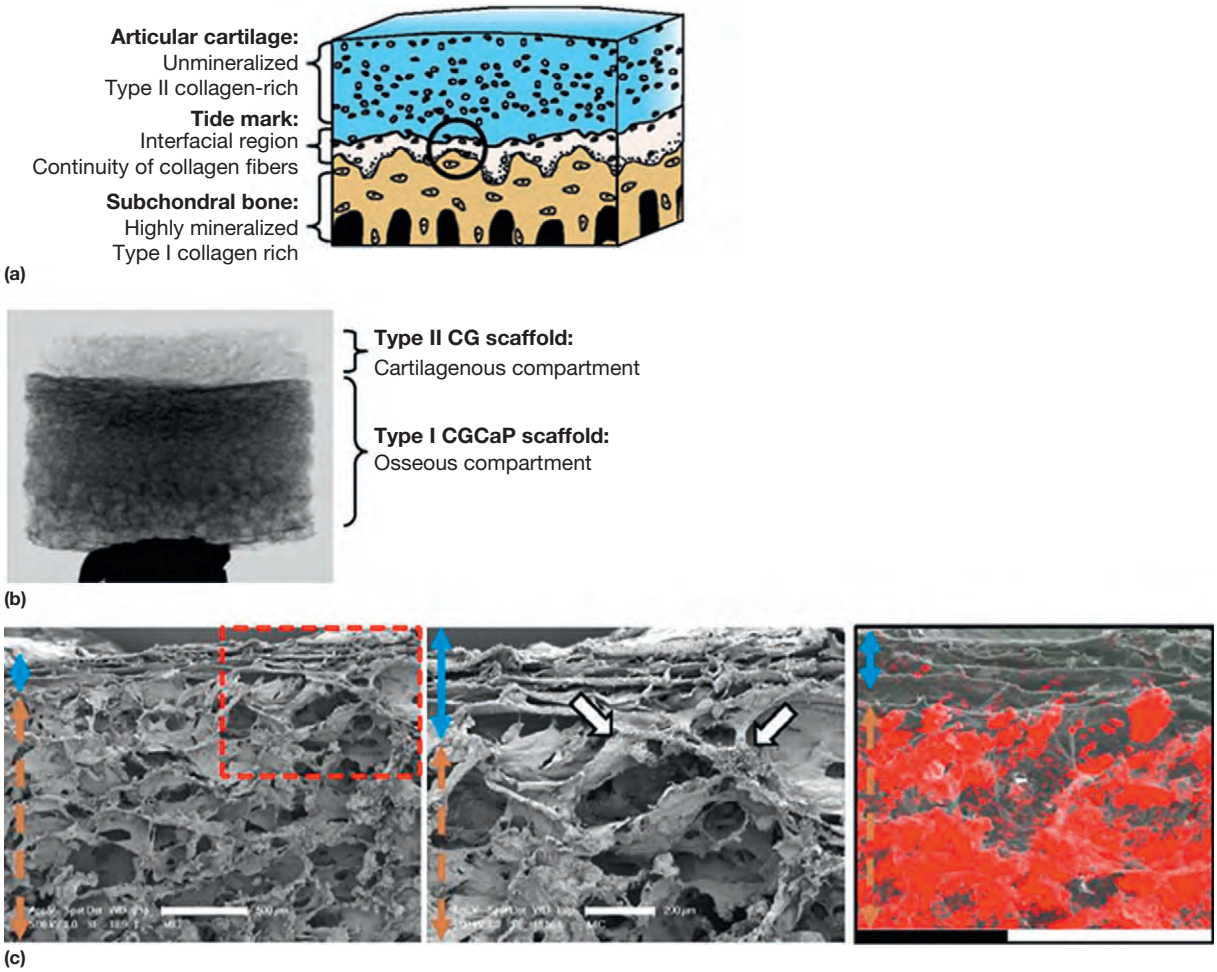

Figure 20 (a) Structure of the natural articular joint showing articular cartilage and subchondral bone joined by a continuous interfacial region. (b) X-ray μCT image of the layered osteochondral scaffold showing distinct cartilaginous and osseous compartments (scale bar 1 mm). (c) SEM images of the osteochondral scaffold showing the complete scaffold microstructure (left; scale bar 500 μm), and the interfacial region (middle; scale bar 200 μm) showing continuity between the osseous (tan dashed arrow) and cartilaginous (blue solid arrow) compartments including collagen struts extending across the transition (white arrows). No regional areas of delamination or debonding are observed between the compartments. Distribution of Ca mineral (P similar but not shown) content (red shading) superimposed over an SEM image of the osteochondral scaffold showed distinct mineralized (high CaP content, tan dashed arrow) and nonmineralized (low/zero CaP content, blue solid arrow) layers (right; black scale bar 400 μm). Reprinted with permission from Harley, B. A.; Lynn, A. K.; Wissner-Gross, Z.; Bonfield, W.; Yannas, I. V.; Gibson, L. J. *J. Biomed. Mater. Res. A* **2010**, *92*, 1078–1093.

majority of deformation confined to the cartilagenous compartment and no evidence of delamination between the scaffold compartments during or following loading.[69] This scaffold is currently being developed as a clinical product that can be implanted using a mosaicplasty approach without the use of sutures, glue, or screws.[69] This scaffold system is currently undergoing Phase I clinical trials for primary and secondary (backfill of traditional mosaicplasty harvest sites) osteochondral defects in the knee. The developed technologies and techniques hold promise for the regeneration of not only osteochondral defects, but also other physiological interfaces such as the tendon to bone insertion site.

2.216.5.6. Brain Tissue Engineering Applications

CG scaffolds are currently being explored as substrates for neural defects in the brain. These scaffolds are fabricated via the conventional freeze-drying approach from type I or type II collagen and HA, a GAG that is the chief component of the brain ECM.[150] Although the brain is almost entirely composed of HA, the collagen component of these CG scaffolds allows additional control of mechanical properties and biodegradation rates.[151] Altering the ratio of collagen to HA allowed manipulation of porosity over a wide range (75–91%, brain = 76%) and compressive modulus (1.33–6.31 kPa, brain = 1.06 kPa).[151] Neuronal stem cells showed the capacity to differentiate into neuronal cells in these HA–collagen scaffolds,[151] and ongoing studies are continuing to optimize scaffold properties via a series of *in vitro* and *in vivo* experiments.

2.216.5.7. Lung Tissue Engineering Applications

The cellular nature of CG scaffolds and the ability to modify scaffold porosity and pore size have made them candidate materials for regenerative medicine studies in the lung. CG scaffolds have been utilized as prospective materials to investigate design parameters for *in vivo* healing of lung tissue damage. Lung cells from Sprague-Dawley rats were seeded onto standard CG scaffolds (type I collagen and chondroitin 6-sulfate) and cultured for 2–21 days. This *in vitro* culture led to the development of alveolar-like structures as well as cell-mediated contraction, possibly as a result of expression of α-smooth muscle actin.[152] These results suggest that CG scaffolds hold promise as an *in vivo* treatment for lung defects and that they also might be interesting model systems for *ex vivo* culture of cells associated with a wide range of lung-tissue abnormalities and diseases.

2.216.6. Conclusions

Porous, 3D biomaterials have been used extensively for a variety of tissue engineering applications, primarily as analogs of the ECM capable of inducing regeneration of damaged tissues and organs. An important evolving application is their use as constructs to quantitatively study cell behavior and cell–scaffold interactions. Scaffold material, microstructural, and mechanical properties have all been observed to significantly affect individual cell behavior as well as overall scaffold bioactivity and regenerative capacity. CG scaffolds are comprised of naturally derived ECM and allow investigations of highly porous and fibrous ECM systems relevant to physiology and tissue engineering applications. Fabricating CG scaffolds via freeze-drying allows independent modulation of scaffold mean pore size, pore shape and orientation, relative density, mechanical properties, chemical composition, and available ligands. CG scaffolds and triple coprecipitated CGCaP nanocomposite scaffolds have been utilized as regenerative templates for a wide range of tissues following injury, notably of skin, peripheral nerves, brain, lung, cartilage, bone, fibrocartilage disks, and the conjunctiva. CG scaffolds have been shown to not only be a bioactive substrate for regenerative medicine applications, but are also well-suited to answer biologically relevant questions regarding cell–material interactions. As CG scaffolds as well as many other tissue engineering scaffolds resemble low-density, open-cell foams, with an interconnected network of struts, they can be modeled as cellular solids. Models for cellular solids contribute to our understanding of cell–scaffold interactions and hold promise for future studies of *in vitro* cell mechanobiology and *in vivo* tissue engineering.[153,154]

Glossary

Anastomosis Network of blood vessels that both branch out and reconnect.

Durotomy Incursion of the dura, especially during spinal surgery.

Ecchymosis Passage of blood from ruptured blood vessels into subcutaneous tissue, marked by a purple discoloration of the skin.

Electrocauterization Process of heating tissue with electricity. Procedure frequently used to stop bleeding.

Epididymis Narrow, tightly coiled tube connecting the efferent ducts from the rear of each testicle to its vas deferens (sperm 'carry-away vessel').

Fistula Abnormal connection or passageway between two epithelium-lined organs or vessels that normally do not connect.

Genitourinary injuries Injuries related to the genital organs.

Laparoscopic partial nephrectomy Procedure to remove a small renal tumor, while preserving the remainder of the kidney.

Necrosectomy Surgery excision of necrotic tissue.

Nephrectomy Surgical procedure to remove a kidney or a kidney section.

Oozing Exudation of fluid.

Rhynophyma Descriptive term for a large, bulbous, ruddy appearance of the nose caused by granulomatous infiltration, commonly because of untreated rosacea.

Sternotomy Surgical procedure in which a vertical inline incision is made along the sternum, after which the sternum itself is divided. This procedure provides access to the heart and lungs for surgical procedures.
Vasectomy Minor surgical procedure wherein the vasa deferentia of a male are severed, and then tied or sealed in a manner such as to prevent sperm from entering the seminal stream.
Vasoepididymostomy Surgical creation of a passage between the vas deferens and the epididymis.
Vasovasostomy Procedure to reconnect the vas deferens tubes that were cut during a vasectomy.

Abbreviations

ACL	Anterior cruciate ligament
BMP-2	Bone morphogenetic protein-2
EGF	Epidermal growth factor
FGF	Fibroblast growth factor
GAG	Glycosaminoglycan
GDNF	Glial-derived neurotrophic factor
GFAP	Glial fibrillary acidic protein
IGF	Insulin-like growth factor
IGFBP	Insulin-like growth factor-binding protein
K1	Kringle1
KGF	Keratinocyte growth factor
MALP-2	Macrophage activator lipoprotein peptide-2
MCL	Medial collateral ligament
MSC	Mesenchymal stem cell
NGF	Nerve growth factor
NRK	Normal Rattusnorvegicus kidney
NT-3	Neurotrophin-3
PBS	Phosphate-buffered saline
PDGF	Platelet-derived growth factor
PEG	Polyethylene glycol
PEI	Polyethylenimine
PGA	Polyglycolic acid
PLGA	Polylactic-*co*-glycolic acid
PRP	Platelet-rich-plasma
PTFE	Polytetrafluoroethylene
PTH	Parathyroid hormone
PTN	Pleiotrophin
SDMSC	Skin-derived mesenchymal stem cell-like cells
β-TCP	β-Tricalcium phosphate
TGF-β	Transforming growth factor-β
VEGF	Vascular endothelial growth factor

2.217.1. Historical Perspective

The first scientific concepts of the blood coagulation process were developed only at the beginning of the nineteenth century,[1] and it is only in 1909 that the fibrin was first used for clinical applications by Bergel.[2] A few years later, and during the First World War, fibrin tampons and patches were used as parenchymal tissue dressings to control bleeding and for hemostasis in cerebral surgery.[3] In the 1940s, human fibrinogen and thrombin were produced in large quantities in a laboratory at Harvard led by Cohen, and in 1943, human plasminogen and thrombin were used by Tidrick and Warner as a biological adhesive for the fixation of skin grafts in humans.[4] These events constituted a significant step in the development of fibrin sealants. However, they were neglected for about three decades because of a rather poor clinical outcome of their early generation, mainly because of poor adhesive strength and poor durability, probably related to the absence of fractionation technologies to provide concentrated fibrinogen solutions and the lack of knowledge on fibrinolysis inhibitor.[4,5] It is only in the early 1970s that the use of fibrin sealants reappeared when Matras *et al.* successfully used a highly concentrated human plasma-derived fibrinogen solution in combination with factor XIII, thrombin, and calcium chloride to seal nerves in animal experiments.[6] The risk of viral transmission, which had also caused some issues in the 1940s, was reduced through careful donor selection, followed by a heat treatment.[7] The successes observed during the early 1970s led to the first commercial fibrin sealant in 1978 (Fibrinkleber Human Immuno®). Since then, improved versions of the product and other fibrin sealants have been introduced on the market. Newer developments have focused on the enhancement of viral safety profiles as well as improvement of handling properties and delivery methods without compromising the product properties. In addition to their initial intended use as a sealant for hemostasis, fibrin sealants have now become a growing platform for various other applications in the tissue engineering and regenerative medicine arenas.

2.217.2. Composition, Structure, and Properties

2.217.2.1. Composition and Polymerization

Fibrin is a natural biopolymer involved in the coagulation cascade and results from the conversion of fibrinogen to cross-linked fibrin by thrombin (Figure 1).

The fibrinogen molecule, a 340 000 Da hexamer, is a plasma protein, approximately 45 nm long. It consists of two outer D domains, each connected by a coiled-coil segment to the central E domain. The molecule is composed of two sets of three polypeptide chains termed Aα, Bβ, and γ, which are joined together in the N-terminal E domain by five symmetrical disulfide bridges[3,8–12] (Figure 2). The Aα, Bβ, and γ chains consist of 610, 461, and 411 residues, respectively.[13,14]

The conversion of fibrinogen to fibrin is catalyzed by the serine protease thrombin, which is generated by the blood coagulation cascade from the activation of prothrombin. Thrombin

cleavage of two sets of small N-terminal fibrinopeptides (fibrinopeptide A (FpA) and fibrinopeptide B (FpB)) from the Aα and Bβ chains exposes binding sites E_A and E_B and initiates fibrin polymerization[12,15] (Figure 2). Each E_A-site combines with a constitutive complementary-binding pocket (Da) in the D domain of neighboring molecules.[16–18] The initial E_A:Da associations cause fibrin molecules (or fibrin monomers) to align in a staggered overlapping end-to-middle domain arrangement to form double-stranded twisting protofibrils with a periodicity of 22.5 nm (i.e., with a 22.5-nm repeat spacing of the individual fibrin monomers)[11,12] (Figure 3). These protofibrils further self-assemble laterally and into branched fiber bundles (Figure 3), resulting in the formation of a characteristic biopolymer gel material with an open three-dimensional (3D) porous network structure,[1] as depicted in Figure 4.

2.217.2.2. Structure and Mechanical Properties

Although the mechanical properties of *in vivo* fibrin clots are still largely unknown, there is no doubt that these properties are critical in clinical scenarios. For example, the viscoelastic properties of a thrombus in a blood vessel will determine whether the blood flow will rupture or embolize the clot. In the case of hemostasis, the structure must be strong enough to withstand the pressure of arterial blood flow.[19]

The properties of the fibrin clots vary greatly depending on the conditions of polymerization, which influence the clot structure. Negatively contrasted fibrin studies using transmission electron microscopy revealed the substructure of the fibers forming the fibrin clot and the presence of branch points[19] (Figure 5). During polymerization, two types of branching occur, and they both account for fibrin network.[12,20,21] Bilateral (or tetramolecular) branch junctions (i.e., lateral aggregation) occur when double-stranded protofibrils converge side to side, whereas equilateral (or trimolecular) branch points form by coalescence of three fibrin molecules that connect three double-stranded protofibrils of equal widths[12,20,21] (Figure 3). Hence, trimolecular branch points seem to be formed when protofibrils diverge instead of aggregating only laterally, and may therefore be formed early during the polymerization process while protofibrils are added to the network. Polymerization conditions that favor lateral aggregation would then tend to produce clots made of rather thick fibers with few branch points, whereas polymerization conditions that would inhibit lateral aggregation would tend to produce clots made of rather thin fibers with many branch points.[19,22] The rate of release of the fibrinopeptides FpA and FpB as well as other factors influencing the lateral association of the fibers during polymerization will regulate fiber thickness, degree of branching, and clot porosity, which, all together, influence the overall clot structure.

Some of the factors influencing the rate and extent of polymerization and the fiber formation include the fibrinogen and thrombin concentrations, the ionic strength, the presence of certain other plasma proteins (such as albumin), the pH, and the temperature. For example, when comparing the structure of fibrin clots prepared with different thrombin concentrations, Helgerson *et al.*[1] reported that the fiber structure formed was much finer with less porosity and many more branch points with a higher thrombin concentration compared to a structure with thicker and more laterally associated fibers with lower thrombin concentrations (Figure 6). The authors also reported that, similarly, increasing salt concentration produced thinner fibers with more branch points and lower porosity,[1] forming 'fine gels' as described earlier by Sierra,[3] in comparison to the 'coarse gels' presenting larger diameter fibers and higher porosity, observed with lower salt concentrations (Figure 7). Factor XIII, which, when activated, is responsible for cross-linking fibrin monomers that make up the fiber bundles and catalyses the formation of covalent bonds between fibrin chains, has been reported to have no effect on gel porosity[3] and fiber thickness.[23] Finally, the eventual presence of fibronectin also does not seem to influence the porosity, but it increases fiber diameter of the clots.[24]

The different constituents of the fibrin clot influencing its structure will also affect its mechanical properties. Fibrin is a viscoelastic polymer, and therefore, its properties may be characterized by stiffness (representing its elastic properties) and creep compliance (representing its inelastic properties).[25] As mentioned before, these properties will determine how the clot will respond to the stress to which it is subjected. A very stiff clot will not deform as much as a less stiff one under the same applied stress. As a consequence, under flowing blood pressure, for example, a clot with a greater elastic component will return to its original shape, whereas a clot with a greater inelastic component will incur more permanent deformation[19] and may be less subject to embolization.[19,22] In a review on mechanical characteristics of fibrin sealants, Sierra[3] reported that the compliance was dictated by the number of contacts and

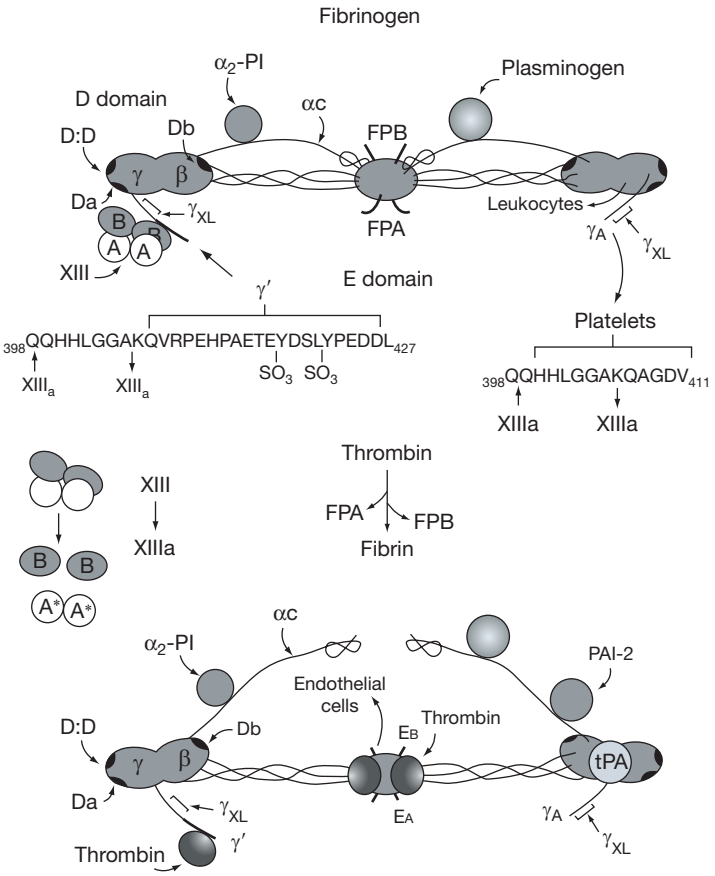

Figure 2 Schematic diagram of fibrinogen and fibrin showing the major structural domains, the association sites that participate in fibrin polymerization and cross-linking, and other molecular and cellular binding interactions. Bottom half of the figure: Thrombin cleavage of two sets of fibrinopeptides (fibrinopeptide A (FpA) and fibrinopeptide B (FpB)) from the Aα and Bβ chains of the fibrinogen molecules exposes sites E_A and E_B (initiation of the polymerization). Images from Mosesson, M. W.; Siebenlist, K. R.; Meh, D. A. *Ann. N. Y. Acad. Sci.* **2001**, *936*, 11–30, reproduced with permission.

interactions between the fibers. When comparing gels with or without fibronectin under shear loading, the author reported that coarse gels with added fibronectin (which has been reported to increase the diameter of the fibers) demonstrated a large increase in their modulus and a decrease in creep compliance, whereas fine gels exhibited a decrease in their modulus and a corresponding increase in creep compliance.

Other parameters commonly reported are the breaking strength and the adhesiveness. Some studies and reviews on fibrin mechanical properties reported an increase of the elastic modulus, tensile strength, and adhesive strength with increasing fibrinogen concentrations.[3,23,26,27] With regard to the effects of thrombin, a study from Rowe *et al.* reported that the elastic modulus and ultimate tensile strength of the clots increased with decreasing thrombin concentrations.[28] It is worth noting that in this latter study, fibrin gels were seeded with vascular smooth muscle cells. However, the authors attributed the changes in mechanical properties to the differences in thrombin concentration as they did not observe these changes in similar constructs made of collagen type I. A recent study by Akpalo and Larreta-Garde,[29] looking at the effects of varying concentrations of both thrombin and transglutaminase on the fibrin network and mechanical strength, reported that thrombin concentration influenced the kinetics of gelation (or polymerization), but not the evolution of the mechanical properties. The authors also showed an indirect relationship between the gel elasticity and thrombin concentration upon covalent binding. Finally, although factor XIII content does not seem to influence the clot structure, at least in terms of porosity[3] and fiber thickness,[23] some studies and reviews have reported that increasing the clot content of factor XIII increases the elastic modulus by enhancing clot rigidity and decreasing inelastic deformation.[22,30] This would be primarily explained by the stabilization of the interactions between preassembled protofibrils by cross-linking.[22] Such increase can be up to fivefold under physiological conditions.[30] The effects of cross-linking on the mechanical stability of clots are an important part of blood clotting that may be responsible for the serious bleeding problems of patients lacking factor XIII.[22]

2.217.2.3. Degradation Process: Fibrinolytic Properties

As described above, the viscoelastic properties of the fibrin clot are very important as the clot needs to fulfill a mechanical function and its stability will be greatly influenced by these properties. However, the clot stability will also be directly influenced by its fibrinolytic properties as in physiological

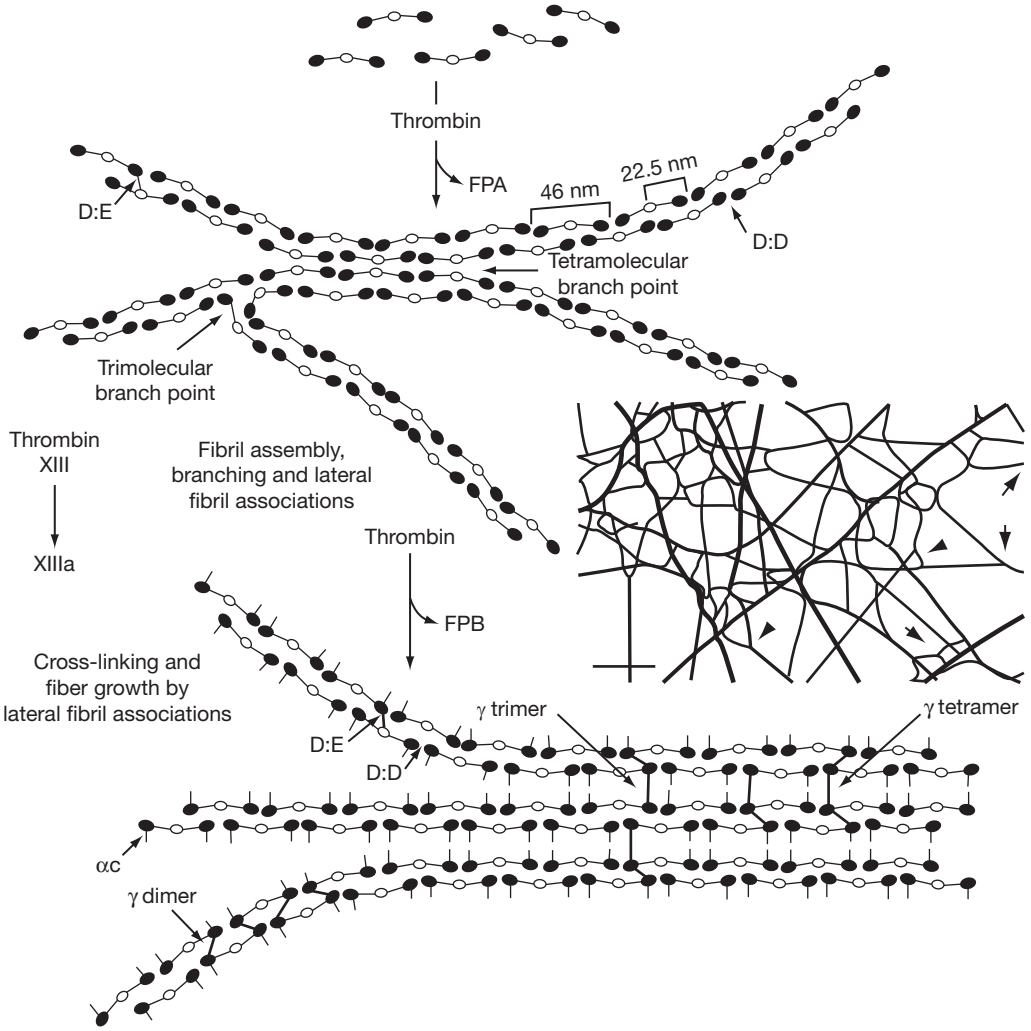

Figure 3 Schematic diagram of fibrin assembly and cross-linking. Thrombin cleavage of two sets of fibrinopeptides (fibrinopeptide A (FpA) (top half of the figure) and fibrinopeptide B (FpB) (bottom half of the figure)) from the Aα and Bβ chains of the fibrinogen molecules, respectively, exposes sites E_A and E_B and initiates fibrin polymerization. Each E_A site combines with a constitutive complementary-binding pocket (Da) (D:E on the diagram) in the D domain of neighboring molecules. These associations cause fibrin monomers to align in a staggered overlapping end-to-middle domain arrangement to form a double-stranded twisting protofibrils. The protofibrils further self-assemble laterally and into branched fiber bundles. Inset shows a critical point dried fiber matrix containing bilateral (arrowheads) and equilateral (arrows) branch junctions. Note: Bilateral (or tetramolecular) branch junction (i.e., lateral aggregation) occurs when double-stranded protofibrils converge side to side. Equilateral (or trimolecular) branch point (i.e., formation of branch point) forms by coalescence of three fibrin molecules that connect three double-stranded protofibrils of equal widths. Images from Mosesson, M. W.; Siebenlist, K. R.; Meh, D. A. *Ann. N. Y. Acad. Sci.* **2001**, *936*, 11–30, reproduced with permission.

conditions, the clot must be efficiently dissolved in a timely manner to avoid thrombosis.

Fibrinolysis under physiological conditions involves the binding of circulating plasminogen to fibrin, and the activation of plasminogen to the protease plasmin by tissue-type plasminogen activator (tPA), also bound to fibrin.[22,25] The activation of plasminogen is further stimulated by the initial cleavage of fibrin. Plasmin then cleaves fibrin at specific sites, creating new binding sites and leading to identifiable soluble, large, and complex fragments with portions of individual fibers and protofibrils.[22,25] A study by Veklich *et al.* using scanning electron microscopy imaging of clot surfaces being digested demonstrated that fibrinolysis proceeded by transverse cutting of fibrils and fibers, with the creation of gaps in the fiber continuity and free transected fiber segments that associate laterally within the matrix fiber structure to form thicker fiber bundles.[31] Similarly, a study by Collet *et al.*[32] using confocal electron microscopy to characterize the morphological changes at the fibrin network and fiber levels showed a progressive disaggregation of the fibrin fibers, also suggesting that fibrinolysis proceeded by transverse cutting rather than by progressive cleavage uniformly around the fibers. Finally, in a recent review, authors from the same group reported that fibrinolysis would involve the movement of plasmin laterally across fibers, binding to sites created by its own proteolytic activity.[33]

Numerous approaches have been used to measure the rate of fibrin degradation, including enzyme-linked immunosorbent assay to detect soluble cross-linked D dimers, measuring

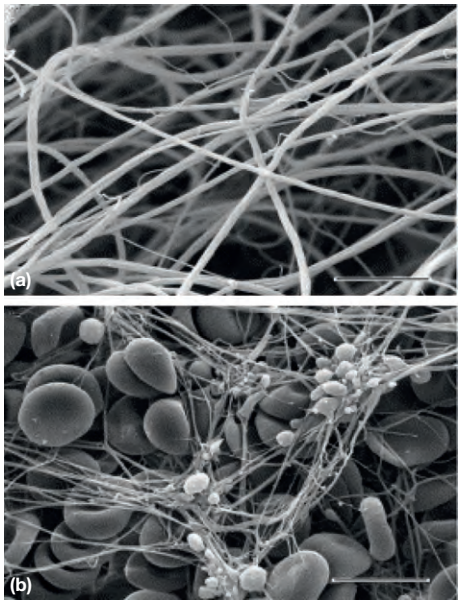

Figure 4 Scanning electron microscope images of fibrin clots. (a) Scanning electron micrograph of a clot formed by the addition of thrombin to purified fibrinogen. Magnification bar: 5 μm. Note the visible twisting of protofibrils making up the fibers on the surface of some fibers. (b) Electron micrograph of whole blood clot, made from freshly drawn blood with no addition. Figure 5 Transmission electron micrographs of negatively contrasted fibrin fibers showing the substructure of the fibers and the presence of branch points. Most branch points consist of three fiber segments that join at a small acute angle with band patterns aligned. The band pattern depicts the fiber repeat of 22.5 nm. Such pattern arises because areas with high protein density exclude stain and appear bright while areas with lower protein density allow more stain to penetrate and appear darker. Magnification bar = 200 nm. Images from Weisel, J. W. *Biophys. Chem.* **2004**, *112*, 267–276, reproduced with permission.

the absorbance of the clot supernate at 280 nm or the release of [^{125}I]-labeled fibrin degradation products to assess the release of soluble degradation products, analyzing changes in turbidity, or using thromboelastographic measurements of lysing clots.[34]

Overall, it appears that although the lysis rate is influenced by the structural properties of the clot, other physical and chemical properties of the clot also influence its dynamic changes and therefore its lysis. These properties and the fibrinolysis process of a natural clot need to be considered when using fibrin for clinical applications. In fact, in bleeding situations or in tissue regeneration applications where fibrin is used as a delivery system and/or as a free scaffold for tissue growth as detailed later in the chapter, a challenge is to keep the fibrin clot stable long enough to reach hemostasis or allow tissue regeneration. Fibrinolysis of the clots will highly depend not only on the surgery site but also on the fibrin composition. The presence of preseeded cells in the fibrin clots in some tissue engineering applications will also accelerate the clot lysis.

Strategies have been explored to prolong the life of fibrin matrices, including their reinforcement through the use of synthetic polymers such as polyethylene glycol (PEG) and the addition of protease inhibitors.[35] For example, the use of calcium chloride and/or a fibrinolysis inhibitor such as aprotinin in fibrin sealant mixtures will increase the retention of the clot and is essential for its efficacy. However, although aprotinin is an efficient inhibitor of fibrin degradation, it rapidly diffuses out of fibrin matrices. Methods have been developed to prevent this diffusion. For example, Smith *et al.* showed prolonged presence of fibrin in a chick chorioallantoic

membrane invasion assay by chemically conjugating aprotinin to fibrinogen using a cysteine-based trifunctional cross-linker prior to gel formation.[36] Recently, Lorentz *et al.* reported an engineered aprotinin variant that could be immobilized within fibrin.[35] The authors showed that by recombinantly fusing aprotinin to a transglutaminase substrate domain from α2-plasmin inhibitor, the resulting variant (aprotinin-α2-plasmin inhibitor) could be covalently crosslinked into fibrin matrices during normal thrombin/factor XIIIa-mediated polymerization, leading to a 78% mass retention of the fibrin matrices submitted to physiological plasmin concentrations for 3 weeks *in vitro*. Fibrin matrices containing wild type aprotinin degraded completely within 1 week. These strategies constitute useful tools for possibly extending the applicability of fibrin-based biomaterials in tissue engineering as well as clinically.

2.217.2.4. Inherent Biological Properties

The first function of fibrin(ogen) in the blood coagulation process and wound healing is to rapidly control bleeding at the injury site. Once hemostasis is achieved, the fibrin clot serves as the basis of a complex matrix both to initiate and to support subsequent tissue repair[1,37] by providing a structural scaffold for the adhesion, proliferation, and migration of cells important in wound healing.

The exact mechanisms by which the different cell types interact with fibrin(ogen) are still not fully understood. However, some mechanisms have been proposed. Indeed, fibrin has peptide domains that facilitate cell adhesion to the clot, serving as binding sites for integrin receptors on cells involved in tissue repair.[1] The most established one is through the platelet integrin αIIbβ3 through the γ-chain C-terminal epitope containing Ala-Gly-Asp-Val (AGDV).[38] A number of cell attachment and adhesion epitopes have been proposed for fibrin(ogen). For example, RGD sequences found on the α-chains in human fibrinogen have been regarded as candidates for integrin-mediated cell binding to fibrinogen.[38,39] Another possible cell-interacting mechanism to fibrin may be based on the group of membrane proteins of the family of the cell marker CD44, which has been reported to be involved in cell proliferation, differentiation, migration, and signaling for cell survival.[38,40,41] In addition, the release of FpB from the β-chain of fibrinogen during fibrin polymerization results in the exposure of a new N-terminal peptide domain that will serve as a binding site for vascular endothelial cell surface receptor VE-cadherin, itself causing the vascular endothelial cells in injured blood vessels to migrate, proliferate, and differentiate to form new blood capillaries.[1] This angiogenesis process resulting in neovascularization is critical for the tissue regeneration, and will therefore also be critical for most tissue engineering applications.

The biological properties inherent to fibrin clots are not just limited to fibrin(ogen) but also include a complex mixture of other proteins that bind to fibrin matrix.[1,42] For example, factor XIIIa, which stabilizes the clot by covalently cross-linking fibrin monomers, also cross-links other plasma proteins to fibrin, such as plasma-derived proteins fibronectin, α2-antiplasmin, and plasmin activator inhibitor 2 (PAI-2), which help to control subsequent fibrinolysis of the clot. Residual fibronectin in fibrinogen, usually present in clots made of fibrin sealant preparations, as well as cross-linked plasma fibronectin might be responsible for cell-binding activity of the fibrin clot by providing specific receptor-binding sites for cells involved in wound healing, such as keratinocytes, fibroblasts, and vascular endothelial cells.[43]

Therefore, in addition to its favorable 3D structure as illustrated in previous paragraphs, fibrin also presents inherent biological properties that will be important for successful tissue regeneration. Moreover, these inherent biological properties can be enhanced by the addition of cells or bioactive molecules, for which fibrin can be used as a delivery system, as explained in the following section and summarized by Figure 8.

2.217.3. Fibrin Use as a Delivery System

2.217.3.1. Cell Delivery System

Fibrin sealants have been used for years to deliver autologous cells to various skin defects.[44] A study by Horch *et al.*[45] showed that the transplantation of actively proliferating and dividing human keratinocytes in a fibrin sealant matrix could be used in clinics for the treatment of chronic ulcers. A study by Kopp *et al.*[46] also showed the potential of a fibrin sealant matrix for delivering cultured human autologous keratinocytes and

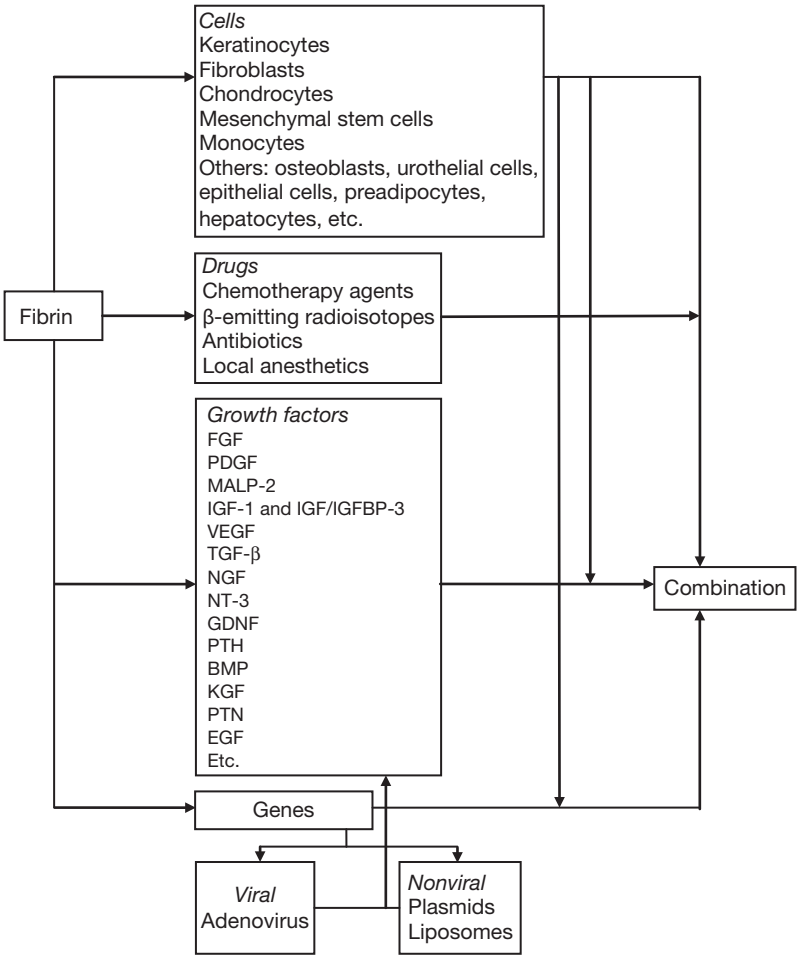

Figure 8 Schematic of the common cells and bioactive molecules delivered by fibrin scaffolds. Although the list is not exhaustive, all cells and bioactive molecules listed on this figure have been reported in the literature and illustrated in paragraph 3. Adapted from Breen, A.; O'Brien, T.; Pandit, A. *Tissue Eng. Part B* **2009**, *15*(2), 201–214.

leading to the reepithelialization of acute and chronic wounds. In an *in vitro* study, Tuan *et al.*[47] showed that fibroblasts seeded in fibrin gels synthesized collagen and remodeled the matrix into a collagen-rich granulation tissue-like matrix. When used as a delivery system for cultured keratinocytes and fibroblasts, fibrin sealants may actually provide similar advantages to those proven with conventional skin grafts,[48] and, at the same time, at least partially overcome some of the common disadvantages of standard sheet grafts such as uncertain attachment rate of cultured cells to the wound ground and difficulty in handling the grafts.[45]

Several groups have also reported on the use of fibrin as a delivery system for chondrocytes.[49–54] For example, a study by Homminga *et al.*[52] demonstrated that chondrocytes encapsulated in a fibrin sealant retained their morphology and synthesized matrix. Ameer *et al.*[49] showed a 2.6 times higher retention of synthesized glycosaminoglycans (GAG) when seeding pig chondrocytes in a biodegradable composite scaffold made of fibrin gel and polyglycolic acid (PGA) nonwoven mesh compared to a scaffold made of PGA only. Kirilak *et al.*[53] showed that fibrin sealant could promote the migration and proliferation of human articular chondrocytes, possibly via thrombin-induced protease-activated receptors-1 signaling. Dare *et al.*[51] showed that, when cultured in chondrogenic medium, fibrin-encapsulated C5.18 cells (a chondrogenic precursor cell line) elaborated an extracellular matrix containing type II collagen, as well as aggrecan, components of hyaline cartilage. A study by Pettersson *et al.*[54] showed that human autologous chondrocytes seeded in biodegradable macroporous gelatin microcarriers embedded in fibrin glue led to chondrocyte adhesion and expansion as well as extracellular matrix synthesis. However, this study also showed that the presence of the microcarriers was essential for the fibrin glue to support the structural takeover of extracellular matrix proteins produced by the embedded chondrocytes, as exclusion of the microcarriers resulted in unstable structures that dissolved before matrix formation could occur. In a study investigating whether a fibrin sealant could provide a suitable scaffold for *in vitro* generation of cartilage transplants using human mesenchymal stem cells (MSC), Baumgartner *et al.*[50] demonstrated that under chondrogenic differentiation conditions, especially under hypoxic conditions, stem cells seeded in the fibrin sealant differentiated into rounded chondrocyte-like cells with a chondrogenic phenotype.

Other studies investigated the use of fibrin for the delivery of other cell types such as osteoblasts,[55] urothelial cells,[56–58] tracheal epithelial cells,[57] preadipocytes,[57] and hepatocytes.[59] Those studies showed the potential of fibrin as a cell delivery vehicle for successful reimplantation of these different cells to reconstruct the tissue in which they are implanted.

Interestingly, some *in vitro* studies have shown that by simply varying the concentration of fibrinogen and thrombin, one could optimize the environment for delivering various cell types such as fibroblasts, keratinocytes, monocytes, and MSC.[60–64] For example, Cox *et al.*[61] reported that fibroblasts proliferated well within fibrin clots containing fibrinogen concentrations ranging from 5 to 17 mg ml^{-1} and thrombin concentrations from 1 to 167 IU ml^{-1}. In addition, the cells retained their morphology and growth characteristics after migrating out of the gels. When looking at the delivery of skin keratinocytes in fibrin, Harkin *et al.*[62] showed optimized keratinocyte cell growth in fibrin containing 1–3 mg ml^{-1} fibrinogen and 2–5 IU ml^{-1} thrombin. Mana *et al.*[64] reported that while all fibrin formulations analyzed supported monocyte proliferation, the highest cell proliferation was reached with a fibrinogen concentration between 26 and 50 mg ml^{-1} and a thrombin concentration of 250 IU ml^{-1} (final concentrations in the clots). The profiles of cell proliferation and cell adhesion were similar. Investigations of MSC proliferation within various fibrin formulations showed that lower fibrinogen concentrations favored a higher proliferation.[60,63,65] For example, Bensaid *et al.*[65] reported that a concentration of 18 mg ml^{-1} for the fibrinogen component and that of 100 IU ml^{-1} for thrombin were optimal for human MSC spreading and proliferation. The authors also showed that MSC were able to migrate out of the fibrin gels and invade a calcium carbonate-based ceramic scaffold (coral) implanted within the peritoneal cavity of nude mice, supporting the concept of using fibrin sealant as a delivery system for human MSC.[65] When looking at the osteogenic differentiation of the seeded MSC with no additional osteogenic agent in the culture medium, Catelas *et al.*[60] reported that increasing the concentration of fibrinogen component favored early osteogenic differentiation of the cells, as demonstrated by a higher expression of alkaline phosphatase activity. However, the rather small size of calcium phosphate nodules and low expression of specific osteogenic genes revealed that the cells were not fully differentiated. A study from Trombi *et al.*[66] also analyzed the capability of fibrin gels to support osteogenic differentiation of MSC. The authors reported an increase in alkaline phosphatase activity, calcium phosphate deposition, and osteopontin expression in samples cultured with osteogenic medium and concluded on the potential of fibrin gels to support osteogenic differentiation. A study from Zhang *et al.*[67] showed that PEGylation of fibrin patch made of 10 mg ml^{-1} fibrinogen and 100 IU ml^{-1} thrombin (final concentrations in the clots) could increase the viability and differentiation of MSC isolated from the sternum of healthy pigs. More recently, the same group also showed that modifying fibrinogen with various PEG derivatives, which resulted in different physical and mechanical characteristics of the fibrin matrix, affected the differentiation of MSC towards the endothelial phenotype.[68] Finally, a recent study by Huang *et al.*[69] demonstrated that fibrin could regulate MSC gene expression of phenotypic markers across multiple lineages. However, the effect of fibrin appeared to be limited as MSC did not differentiate into fully mature cells considering the absence of distinctive immunofluorescence expression of mature lineage-specific markers after 12 days.

Despite differences in the cell and/or fibrin sources that have been reported to affect the results,[70] all these studies support the capability of fibrin to be used as a cell delivery system and show the potential of fibrin as a biomaterial for various cell-based therapy or tissue engineering applications, which will be detailed later in this chapter.

2.217.3.2. Drug and Growth Factor Delivery System

2.217.3.2.1. Drug delivery system

Systemic administration of antibiotics is generally adequate but in some situations, such as severe trauma and large-area burns, local delivery of high levels of antibiotics may be desirable or necessary.[7] Fibrin has been used as a delivery system for chemotherapy agents and antibiotics for some years, but the challenge has always been to sustain the delivery of the drug for adequate periods of time.[7] Therefore, different forms of fibrin have been investigated, such as microparticles, fibrin-coated drug particulates, fibrin discs, drug-containing beads embedded within fibrin gels, or fibrin sheets with the entrapped drug.

In the oncology arena, fibrin gels have been used for the delivery of chemotherapy agents such as carboplatin to the retina,[71,72] or for delivery of beta-emitting radioisotopes in microspheres in the treatment of brain tumor.[73] A study by Yoshida *et al.*[74] also demonstrated the importance of the hydrophobicity of the anticancer drugs influencing their release from fibrin gels. The release rate of various drugs, such as mitomycin C, fluorouracil, and enocitabine, was evaluated. While the first two were quickly released from fibrin gels, whether or not they contained aprotinin, the last one was gradually released from fibrin-containing aprotinin. The authors concluded that the release rate of each drug from fibrin containing aprotinin correlated with the drug hydrophobicity and that lipophilic anticancer drugs should be used to favor a sustained release from fibrin.

With regard to the treatment of localized infections, various studies have been looking at the use of fibrin to deliver tetracycline, erythromycin, cefazolin, ciprofloxacin, aminoglycoside, cefotaxim, mezlocillin, or even vancomycin alginate beads. For example, Woolverton *et al.*[75] evaluated the use of fibrin discs to deliver tetracycline for the treatment of peritoneal infection initiated with *Staphylococcus aureus (S. aureus)* in rats and mice. Results showed that the mice prophylactically treated with fibrin sealant-tetracycline 2 days prior to an infection with *S. aureus* cleared the infection, resulting in 100% survival. In addition, the same treatment in rats showed no detectable serum tetracycline levels. A study by Kumar *et al.*[76] also evaluated the release of soluble tetracycline, but using a freeze-dried fibrin disc. The *in vitro* release kinetics of the drug in phosphate, buffered saline (PBS) solution and serum were compared. Results showed that the release rate of tetracycline from the fibrin disc into serum remained steady from day 1 to 12, whereas the delivery of the drug from the discs into PBS was found to be high for up to the third day, followed by a sharp decline. The authors concluded that fibrin disc may be a suitable candidate as a drug delivery implant for short-term use.

A study by Tredwell *et al.*[77] evaluated the encapsulation, stability, and controlled release of erythromycin and cefazolin from fibrin sealants. Results showed that erythromycin was released slowly from the fibrin clots over the first 2 h and then degraded rapidly. Cefazolin, however, appeared to be very stable over a period of 2 days, suggesting the potential use of cefazolin-loaded fibrin sealants as an antibiotic delivery system postoperatively. A recent study by Tsouvakas *et al.*[78] investigated the *in vitro* release of ciprofloxacin from acrylic bone cement and fibrin clot for the treatment of bone infections. Results revealed that the diffusion of ciprofloxacin from bone cement was rapid at first and decreased gradually over a period of 365 days. The release from fibrin clots was high up to 65 days, that is, enough time to treat a bone infection. It is, however, surprising that the authors were able to maintain the fibrin clots *in vitro* for such a long time. In a previous study, the same authors had reported that ciprofloxaxin–fibrin clot complexes usually disintegrated after 60 days,[79] which was already surprisingly long. Also in the context of bone infection treatment, Hou *et al.*[80] evaluated the *in vitro* use of fibrin for the simultaneous codelivery of vancomycin alginate beads to treat the infection and MSC to promote bone formation. Results showed that cell behavior was affected by the addition of the vancomycin beads. Interestingly, the addition of the beads seemed to increase the osteogenic differentiation of the MSC, as depicted by a higher ALP activity, and higher osteogenic gene expression. With regard to the antibiotic release kinetics, results revealed that vancomycin concentrations remained above the breakpoint sensitivity for 22 days.

Finally, Zhibo and Miaobo[81] recently reported on the use of fibrin to deliver lidocaine as a local anesthetic to reduce pain after subpectoral breast augmentation. The positive results of this study suggested the possibility of using fibrin for local anesthetic delivery. However, the study only included a limited number of patients, and therefore, results need to be confirmed through a larger randomized, double-blind study.

2.217.3.2.2. Growth factor delivery system

Although fibrin possesses inherent biological properties that make it particularly attractive as a cell delivery system for tissue regeneration, the incorporation of an exogenous growth factor can enhance and accelerate tissue repair through a synergistic effect. Many studies have been reported on the use of fibrin for the delivery of growth factors. A comprehensive review detailing some of these key studies has been provided by Breen *et al.*[15]

For example, a study by Pandit *et al.*[82] looking at the effects of the addition of fibroblast growth factor (FGF)-1 in fibrin for wound healing in a rabbit model showed that the combination of FGF-1 and fibrin improved the mechanical properties of the healed tissue compared to fibrin alone or growth factor alone. Mogford *et al.*[83] showed that the combination of fibroblasts and platelet-derived growth factor (PDGF)-BB delivered using fibrin sealant enhanced ear cutaneous wound healing in the rabbit. Ucuzian *et al.*[84] showed that the delivery of PDGF-BB and FGF-2 (also known as basic FGF (bFGF)) could promote smooth muscle cell invasion into fibrin gels *in vitro*. In a study on bone regeneration, Park *et al.*[85] showed that fibrin delivery of bFGF and osteoblasts resulted in two and nine times more bone formation and calcium content, respectively, than fibrin delivery of osteoblasts alone. A study by Cole *et al.*[86] showed that monocytes seeded on fibrin containing macrophage activator lipoprotein peptide-2 (MALP-2) secreted more cytokines such as interleukin-6 and tumor necrosis factor-α, as well as chemoattractants such as macrophage inflammatory protein-1α and monocyte chemoattractant protein-1, than monocytes seeded on fibrin with no added MALP-2. Finally, a study by Bhang *et al.*[87] using fibrin gel as a delivery vehicle to release bFGF and human bone marrow stromal cells in rat traumatic brain injury showed that the addition of bFGF enhanced neural tissue regeneration compared to the control group (fibrin with human bone marrow stromal cells alone).

Some of the growth factors used for tissue regeneration applications, including bFGF,[88] the insulin-like growth factor-1 (IGF-1)/IGF-binding protein-3 complex (IGFBP-3) (IGF-1/IGFBP-3),[89] and vascular endothelial growth factor (VEGF) isoform 165[90] specifically bind to fibrin(ogen). Therefore, fibrin acts as a natural reservoir for such growth factors.[1,91] The natural fibrin(ogen)-binding affinity of these growth factors allows for their controlled release and delivery from fibrin-based gels as demonstrated both *in vitro*[91,92] and *in vivo*.[93] In this case, the growth factors are released primarily upon cellular infiltration of the scaffold and subsequent scaffold degradation. For example, a study by Wong *et al.*[91] showed a slower release of bFGF and VEGF-165 (added prior to the formation of the fibrin sealant clots) compared to VEGF-121 that is not binding to fibrin(ogen), or at least not binding to the same extent, and that is readily released from the clots by free diffusion. The authors suggested that VEGF-165 binding to fibrin(ogen) and to fibronectin contained in fibrin may be associated with the 44-residue C-terminal domain that was previously shown to contain the heparin-binding site to VEGF-165. This study suggested a controlled release of bFGF and VEGF-165 from fibrin clots. Catelas *et al.*[92] also reported the possibility of controlling the release of transforming growth factor-β1 (TGF-β1) by varying the concentrations of fibrinogen component and thrombin. The authors showed that increasing the concentration of the fibrinogen component decreased TGF-β1 release. Indeed, the cumulative release reached 75% of the initially added amount after 10 days *in vitro* when using 5 mg ml^{-1} of fibrinogen component and 2 IU ml^{-1} of thrombin. On the other hand, it only reached approximately 50% when using a fibrin gel formulation containing 25 mg ml^{-1} of fibrinogen component and the same amount (2 IU ml^{-1}) of thrombin. These results suggested a binding affinity of TGF-β1 with fibrin(ogen), possibly related to factor XIII content. The released TGF-β1 remained biologically active as demonstrated by its chondrogenic effects on human MSC cultured in 2D with fibrin gel supernatants containing the released TGF-β1.

Several linkage approaches have been studied to enhance the retention of growth factors. As described by Bhang *et al.*,[94] a possible approach is to incorporate free heparin into the fibrin matrix to sequester and protect the growth factors, mimicking the natural extracellular matrix.[15] Indeed, the authors showed that the rate and duration of nerve growth factor (NGF) release were controlled by heparin and by the concentration of fibrinogen and thrombin in the gels.[94] The authors also showed that the release was lower when adding heparin or increasing fibrinogen and thrombin concentrations, with fibrinogen concentration having the largest effect.

Released NGF was biologically active as depicted by a higher viability and differentiation of pheochromocytoma (PC12) cells cultured with medium containing released NGF. Other strategies have been carried out to attach heparin-binding domains to the fibrin matrix through the use of factor XIIIa substrate as explained later in this section. Another linkage approach was recently reported by Zhao *et al.*[95] Aiming to improve therapeutic neovascularization and wound repair, the authors fused bFGF with the fibrin-peptide Kringle1 (K1), derived from human plasminogen. The resulting recombinant K1bFGF showed high fibrin and plasma-clot-binding affinity. It also induced neovascularization and improved wound healing when applied in wound sites. The authors then developed a fibrin-scaffold/K1bFGF system, which promoted localized neovascularization and tissue regeneration when implanted subcutaneously. The same authors recently reported similar results when using the Kringle4 domain (K4).[96] Finally, Drinnan *et al.*[97] reported on a multimodal release system of PDGF-BB and TGF-β1 using PEGylated fibrin gels to potentially stabilize neovascularization in the treatment of ischemic tissue. While PDGF-BB was entrapped during thrombin-mediated crosslinking leading to a diffusion-controlled release, TGF-β1 was conjugated through a homobifunctional amine reactive PEG linker as well as physical affinity with the fibrin matrix. The authors showed that by modulating the molar ratio of PEG to fibrinogen, the release rate of TGF-β1 could be controlled without affecting the release of PDGF-BB.

In the case of VEGF, the protein domain of the VEGF-165 isoform responsible for conferring the binding affinity to fibrin(ogen) has been identified by Helgerson and coworkers.[98] The VEGF gene consists of eight exons that give rise to different protein isoforms (VEGF-121, VEGF-145, VEGF-165, VEGF-183, VEGF-189, VEGF-206) as a result of alternative splicing of the pre-mRNA transcript.[99,100] The activity of these VEGF isoforms is associated with the N-terminal domain common to all the isoforms, that is, the VEGF-121 protein sequence. The alternate domain sequences contained in the other VEGF isoforms confer increasing binding affinity of the proteins for extracellular matrix proteins as evidenced for heparin and heparin sulfate *in vitro*.[101] The observation that VEGF-165 was released more slowly from fibrin-based clots compared to VEGF-121[91] led to the hypothesis that the C-terminal domain sequence of VEGF-165 coded by the VEGF gene Exon 7 was responsible for fibrin(ogen) binding. Subsequently, a recombinant fusion protein that added the C-terminal domain of VEGF-165 to leptin, a protein with no significant heparin or fibrin(ogen)-binding affinity, was designed and expressed.[98] This engineered protein was shown to have binding affinity for heparin, and also, to be released from fibrin-based clots with a controlled release kinetic.

Additional methods have been developed to modify the fibrin-based matrix with the intent to control the time and extent of delivery of growth factors that do not naturally bind to fibrin(ogen), or at least not strongly. In particular, covalent linkages between the growth factors and fibrin gels have been used extensively to control the growth factor release.[102] Some of these methods include the design of a bi-domain peptide with a factor XIIIa substrate in one domain and a bioactive peptide in another domain, both covalently incorporated into fibrin gels during coagulation through the action of the transglutaminase factor XIIIa as described by Schense and Hubbell.[103] In this study, the authors determined the cross-linking characteristics for two bi-domain peptides with factor XIIIa substrates based on fibrinogen, as well as one bi-domain peptide with a substrate sequence based on α2-plasmin inhibitor, and another one with a nonbiological oligolysine substrate. Results showed that each of these peptides was able to cross-link into the fibrin gels during coagulation, without changing the structural characteristics of the resulting gels. The bioactivity of the incorporated active factors was tested in a neuronal culture model using two bioactive sequences (RGD and DGEA) and one inactive control sequence (RDG). Results showed that each of the tested peptides influenced the extension of neurites from chicken dorsal root ganglia. Further use of this approach has been reported for covalent incorporation of other molecules such as lamin peptides, VEGF-121, and ephrin B2.[104–106]

Utilizing this method of covalently cross-linking bi-domain peptides to fibrin matrices using the transglutaminase activity of factor XIIIa, Sakiyama-Elbert and Hubbell[107] created an affinity-based delivery system sequesting growth factors inside the matrix through the use of a bi-domain heparin-binding peptide. One domain within this heparin-binding peptide consists of a transglutaminase substrate to facilitate peptide cross-linking into fibrin matrices, while the other domain consists of a heparin-binding domain that allows non-covalent immobilization of heparin to the peptide. The authors used bFGF as an example of a heparin-binding growth factor, and showed enhanced neurite extension relative to unmodified fibrin. The use of this system was further tested for other growth factors with heparin affinity, such as neurotrophin-3 (NT-3) in the context of spinal cord injury.[108] However, although such scaffolds allowed growth factor control delivery thereby enhancing the initial regenerative response by increasing neuronal fiber sprouting and cell migration into the lesion, they were not sufficient to produce functional motor recovery.[109] In a more recent study using a subacute rat model, Johnson *et al.*[110] showed promising results for functional recovery following spinal cord injury by demonstrating enhanced survival of embryonic stem-cell derived neural progenitor cells as well as differentiation of the cells into neurons when embedding them in fibrin scaffolds containing NT-3, PDGF and the heparin-binding delivery system. Sakiyama-Elbert and Hubbell[111] also reported on the controlled release of NGF from their fibrin-based heparin-binding delivery system. Surprisingly, in that study, the release rate of NGF reported by the authors showed a higher initial burst release and was not lower than that found by Bhang *et al.*[94] using free heparin. However, it is likely that the difference in the concentrations of fibrinogen and thrombin (3.5 vs. 94.3 mg ml^{-1} fibrinogen for Sakiyama-Elbert and Bhang *et al.*, respectively; and 2 vs. 33.3 IU ml^{-1} thrombin for Sakiyama-Elbert and Bhang *et al.*, respectively) accounted for the differences in the release kinetic profiles between the two studies. More recent studies from Sakiyama-Elbert's group showed that the delivery of NGF and glial-derived neurotrophic factor (GDNF) from fibrin matrices containing the bi-domain heparin-binding peptide could promote peripheral nerve regeneration[112,113] and selectively promote motor neuron regeneration as well as functional recovery in a rat sciatic nerve model.[114]

Finally, utilizing the multidomain peptide technology, Sakiyama-Elbert *et al.* designed a fusion protein system consisting of a factor XIIIa substrate and a β-NGF sequence, but with the addition of a plasmin substrate sequence linker.[115] The theory behind the incorporation of a plasmin substrate sequence linker was that such a linker would enable cleavage by endogenous plasmin, resulting in a release on cell demand of the bioactive molecules *in situ*.[115,116] Such modified fibrin system incorporating β-NGF enhanced neurite extension from embryonic chick dorsal root ganglia by 50% compared to the use of soluble native β-NGF alone. In the bone regeneration field, a fusion protein system was also used to deliver bone morphogenetic protein (BMP)-2 and parathyroid hormone (PTH)1–34.[116–118] In a study comparing the retention of the engineered human recombinant nonglycosylated BMP-2 fusion protein (referred as TG-pl-BMP-2 with TG denoting a transglutaminase-sensitive binding domain and pl the plasmin-sensitive linking domain) with the retention of glycosylated BMP-2 without using the fusion protein technology, Schmoekel *et al.*[118] reported that the retention of the TG-pl-BMP-2 was higher than that of the glycosylated BMP-2 alone (60% ± 5% vs. 27 ± 1% after 60 h and 50 wash volumes). The authors also showed a higher healing at 3 weeks in the rat calvaria model when using 1 μg of TG-pl-BMP-2 (81 ± 5%) compared to the healing observed when using 1 μg of glycosylated BMP-2 (46 ± 14%). Interestingly, however, in a previous separate study, the same authors had reported a retention rate of 83 ± 6% after 60 h and 50 wash volumes, and a bone healing of 74 ± 4% in the rat model at 3 weeks with nonglycosylated BMP-2 without the use of the fusion protein technology.[117] Therefore, the comparison of the two separate studies shows that the retention rate of nonglycosylated BMP-2 without using the fusion technology was higher than that using the fusion technology (83 ± 6% vs. 60 ± 5%, respectively), while the induced bone healing at 3 weeks in the rat model was comparable (74 ± 4% vs. 81 ± 5%, respectively). This would mean that using the fusion protein technology was, in the case of nonglycosylated BMP-2, not increasing the retention of the protein, nor significantly improving bone healing in rat calvaria. Results reported by the authors in a canine pancarpal arthrodesis were also similar, with 100% of the dogs demonstrating clinical bridging within 12 weeks when using the TG-pl-BMP-2,[118] versus 88% when not using the fusion protein technology.[117]

Other methods aiming to control the time and extent of growth factor delivery are looking into modifying the bioactive substance itself, be it therapeutic proteins, drugs, or DNA as explained in the following section.

2.217.3.3. Gene Delivery System

As described above, fibrin constitutes an attractive carrier system for recombinant growth factors that have been used successfully to promote and improve tissue healing in various clinical applications. However, growth factor applicability remains restricted by their limited commercial availability, high costs, as well as their limited half-lives *in vivo*, requiring high and repeated doses that are associated with undesired systemic side effects.[119] Some studies have been looking at the use of fibrin-encapsulated liposomes as a protein delivery system.[120,121] In general, such studies revealed that the protein-filled liposomes protect the protein during fibrin polymerization process and are retained in fibrin until its degradation by plasmin. Therefore, such technology helps in keeping the protein stable and prolonging its biological activity.

As gene therapy represents an alternative to protein-based therapies, an alternative method to deliver growth factors consists of transfecting or transducing their respective cDNAs under the control of suitable promoters in target cells *ex vivo* or *in vivo*.[119] Recent studies have been reported on fibrin scaffold efficacy for gene vector delivery, either viral or nonviral. A comprehensive review of some of those studies has been provided by Breen *et al.*[15]

2.217.3.3.1. Viral delivery

Of all the viruses developed for use in gene therapy, recombinant adenoviruses represent an appealing gene delivery method, when considering viral systems. However, some limitations of their use include an inflammatory response to the vector and the transient nature of transgene expression,[122] which can be overcome, at least to some extent, by the use of an appropriate scaffold. Fibrin has recently been evaluated for its use as such a scaffold. Applications that have been evaluated include bone, esophagus, vasculature, and dermal ulcer,[15] all showing promising results. For example, a study by Teraishi *et al.*[124] evaluated the endoscopic local delivery of recombinant adenoviruses in aerosolized fibrin glues through a multiluminal catheter. Results showed that such technique could be optimal for gene transfer into epithelial cells in the mucosal surface. A study by Schek *et al.*[123] showed that the bioactivity of an adenovirus expressing β-galactosidase and suspended in medium or collagen decreased to half-maximal activity after 15 h incubation, whereas the virus suspended in fibrin exhibited a threefold extension of bioactivity and did not reach half-maximal activity for 45 h. The study also reported bone formation after 4 weeks following intramuscular implantation of BMP-7 expressing adenovirus in collagen, fibrin, or liquid in nude mice. However, bone formation occurred in 80% of muscles with the adenovirus implanted with collagen or fibrin, compared to 50% of muscles with the adenovirus implanted with liquid. Fibrin also led to significantly larger ossicles. A study by Breen *et al.*[125] investigating the use of fibrin to enhance the delivery of adenovirus encoding endothelial nitric oxide (NO) synthase (eNOS), one of the enzymes responsible for NO production, showed more NO production and enhanced healing of diabetic wound sites, normally characterized by NO deficiency, when using fibrin containing the adenovirus encoding eNOS. Another study by the same authors analyzed whether fibrin could deliver a low single dose of a viral vector to a wound site, without compromising transfection efficiency.[126] Groups with fibrin containing adenovirus encoding β-galactosidase, fibrin alone, adenovirus alone, and no treatment were studied using the rabbit ear ulcer model. Results showed that fibrin helped in the delivery of a low-dose viral vector, thereby avoiding a chronic inflammation response and allowing superior transfection than the viral vector alone.

Another study of Breen *et al.*[122] showed that fibrinogen and thrombin concentrations could affect the release of the adenovirus. Different fibrin formulations were analyzed incorporating an adenoviral vector encoding β-galactosidase.

Results showed that the optimum concentrations of fibrinogen and thrombin were 60 mg ml^{-1} and 4 IU ml^{-1}, respectively, in order to sustain a release of the adenovirus up to 192 h.

Finally, in order to avoid direct exposure to viral vectors, some studies have been reported on the combined use of cell and gene therapy. In this case, cells are manipulated with the vector and are embedded within the fibrin scaffold. For example, in the attempt to promote skin wound healing, Escamez *et al.*[127] compared the efficacy of keratinocyte growth factor (KGF)-adenoviral gene-transferred human fibroblasts embedded in fibrin, with KGF gene transfer by adenoviral vector immobilized in fibrin with no cells, and with KGF gene transfer by intradermal adenoviral injection. Results showed that the use of genetically modified fibroblast-containing matrix as an *in situ* protein bioreactor was highly reproducible and was leading to a significant improvement of the overall healing process.

2.217.3.3.2. Nonviral delivery

In terms of nonviral delivery, various studies have been reported on plasmid delivery and liposome-based vector delivery from fibrin. Indeed, because of low transfection efficiency of naked plasmid injections, polymer matrix such as fibrin has been examined.[128] By encapsulating the plasmid in the fibrin matrix, the DNA would be released more slowly as the matrix degrades, thus increasing chances of plasmid–cell interaction and transfection efficiency.[129] Using such technology in a rabbit hind-limb ischemia model, Jozkowicz *et al.*[130] tested the angiogenic potency of plasmid encoding human VEGF-165 (pSG5-VEGF165) entrapped in fibrin sealant or dissolved in PBS. Results showed that injection of pSG5-VEGF165 into ischemic adductor muscle led to synthesis of human VEGF and increased the number of capillaries, but, surprisingly, the mode of delivery did not influence the results. A study by Michlits *et al.*[131] also reported on the topical fibrin-mediated administration of a VEGF-A plasmid to the wound bed of rat abdominal skin flaps to evaluate if such a method could protect the tissue from necrosis. Results showed that flaps treated with fibrin-mediated VEGF plasmids in the presence of uptake-enhancing Lipofectamine transfection reagent increased significantly the flap survival 7 days postoperatively, with markedly elevated tissue perfusion and enhanced tissue VEGF-A protein expression. Fibrin delivery of plasmid VEGF-A without Lipofectamine, however, was not beneficial. A study by Christman *et al.*[129] examined the use of pleiotrophin (PTN) plasmid in fibrin for the treatment of ischemic myocardium. The authors demonstrated that delivery of PTN plasmid in fibrin increased neovasculature formation compared to injection of the naked plasmid in saline solution.

Nonviral delivery studies have also been conducted using cells as the gene vector. For example, Andree *et al.*[132] inoculated a fibrin matrix with human epidermal growth factor (EGF) expression plasmid and human keratinocytes. Transfection rates were reported to be up to 100-fold higher compared to controls containing no EGF expression plasmid. Transplantation of such constructs to full-thickness wounds in athymic mice led to a 180-fold increase in EGF concentration compared to controls for up to 7 days. A study by Lee *et al.*[133] analyzed the feasibility of using fibrin as a scaffold for normal Rattusnorvegicus kidney (NRK) cells carrying BMP-2 for rabbit spinal fusion. Cells were first transfected with plasmid cytomegalovirus (pCMV)-BMP-2 vectors by FuGENE6, a multicomponent nonviral reagent that forms a complex with DNA and can then be used to transport the complex into mammalian cells. They were then encapsulated and evenly suspended in the fibrin scaffold before being implanted. Results showed prominent new bone formation in 67% animals and moderate new bone formation in the remaining 33%, compared to no new bone formation in the control group (gelatine sponge). The authors concluded that fibrin gel could encapsulate pCMV-BMP-2 transfected NRK cells and deliver them successfully in lumbar spine spaces in rabbits, with no sign of rejection. Hence, fibrin gel appeared to be a promising scaffold for future gene therapy applications.

In a study looking at generating a lyophilized gene-vector-doted fibrin glue, Schillinger *et al.*[119] examined clotting parameters, vector release, and structural characteristics after formulating a copolymer-protected polyethylenimine (PEI)–DNA vector, naked DNA, and PEI–DNA with the lyophilized fibrinogen component of a fibrin sealant. Reporter and growth factor gene delivery to primary keratinocytes and chondrocytes was examined *in vitro*. Results showed that the material containing copolymer-protected PEI–DNA vector was suitable to mediate growth factor gene delivery to primary keratinocytes and chondrocytes admixed before fibrin clotting. Copolymer-protected PEI–DNA vectors also remained tightly immobilized over extended periods of time (0.29% release per day) compared to naked DNA that was rapidly released from fibrin clots (>70% within the first 7 days). *In situ* BMP-2 gene transfection and subsequent expression in chondrocytes grown in fibrin clots containing BMP-2-copolymer-protected PEI–DNA vectors also resulted in alkaline phosphatase expression as well as in an increased extracellular matrix formation when the chondrocyte-colonized clots were cultured in medium supplemented with 50 μg ml^{-1} ascorbic acid *in vitro*. This study showed that fibrinogen could possibly be used in clinics as the gene vector carrier that could be lyophilized and mixed with thrombin to form a fibrin clot containing a gene vector.

Finally, using lipoplexes, NIH-3T3 cells, and plasmids encoding for luciferase, des Rieux *et al.*[134] analyzed the effects of two different *in vitro* models on cell transfection: encapsulating the cells in the fibrin gels versus seeding the cells onto the fibrin gels. Results showed that transfection was dependent on fibrinogen and DNA concentrations. In the case of encapsulated cells, all cells had intracellular plasmid and transgene expression persisting for at least 10 days, with greatest levels at day 1. When seeding cells onto the fibrin gels, the expression levels were less, but increased throughout the culture period.

2.217.4. Fibrin in Tissue Engineering Applications

An appropriate biomatrix is a key structural element for tissue regeneration since a provisional extracellular matrix is required to support the highly organized remodeling and repair processes involved in forming new tissue.[1] As explained earlier in this chapter, fibrin provides a biocompatible physical structure and many of the important

biological properties needed for successful tissue regeneration. It can, therefore, be used as a biocompatible matrix in addition to being used as a delivery system for cells or bioactive molecules. Fibrin matrix also allows a uniform distribution of the cells and nutrients throughout the scaffold, which remains a critical challenge in many tissue engineering applications that require cell seeding of the scaffolds. Finally, fibrin matrix is readily remodeled and resorbed through normal fibrinolytic processes as cells deposit the tissue-specific extracellular matrix components during the regeneration of functional tissues, making it an attractive platform for tissue engineering applications.

Some of the tissue engineering applications using fibrin as a starting matrix include vascular grafts and cardiovascular tissues, bone, cartilage, neurite regeneration, and others, as detailed below.

2.217.4.1. Vascular Tissue Engineering

Examples of studies using cell, growth factor, and/or gene delivery to induce angiogenesis and neovascularization have been presented when reviewing fibrin as a delivery system (Section 2.217.3). The present section illustrates some examples of the use of fibrin for vascular tissue engineering (i.e., vascular grafts and engineered tissues).

2.217.4.1.1. Vascular grafts

Small-caliber vessels constructed from synthetic materials for coronary bypass or peripheral vascular repair have been reported to have poor intermediate and long-term patency rates, probably because of thrombogenic occlusion of the lumen caused by the blood-contacting surface.[135] Autologous grafts remain the standard for small-caliber vessel replacement procedures, but they are not an option for some patients with severe pathological conditions. The development of tissue-engineered grafts is therefore promising. Aper *et al.*[136] reported on the use of fibrin and a polyglactin mesh seeded with endothelial cells and myofibroblasts for engineering a vascular graft. Results showed that a hierarchically organized vessel wall structure could be achieved with this combination. However, the layer thickness of the viable vascular structure was limited and remained to be investigated. Tschoeke *et al.*[135] recently developed a small-caliber vascular graft made of a bioabsorbable, macroporous poly(L/D) lactide 96/4 [P(L/D)LA 96/4] mesh combined with fibrin. The authors tested the graft seeded with arterial smooth muscle cells/fibroblasts and lined with endothelial cells in a bioreactor. After 21 days in culture, cells deposited extracellular matrix proteins into the graft wall, with a significant increase in both cell number and collagen content. A luminal endothelial cell lining was also evidenced by Von Willebrand factor staining. The same group then reported promising results in a sheep carotid artery model for up to 6 months using such vascular composite graft seeded with autologous arterial-derived cells and submitted to mechanical conditioning in a bioreactor prior to implantation.[137]

Some studies demonstrated the importance of mechanical stimulation when developing small-diameter vascular grafts. For example, a study by Cummings *et al.*[138] analyzed the mechanical properties of constructs made of collagen, fibrin, and 1:1 mixtures of collagen and fibrin in order to evaluate the use of fibrin as an alternative, or additional matrix for engineered blood vessels. The authors showed that the properties of engineered vessels could be modulated by the application of mechanical stimulation. Pure collagen had the highest linear modulus and pure fibrin had the lowest. The ultimate tensile stress was strongly dependent on the degree of gel compaction, which was increased by the application of cyclic mechanical strain. Collagen–fibrin mixtures at $2\,mg\,ml^{-1}$ total protein content showed the highest values. A study by Stekelenburg *et al.*[139] also showed that dynamic conditioning enhanced the mechanical properties of the grafts engineered using a fast-degrading PGA scaffold coated with poly-4-hydroxybutyrate combined with fibrin gel and seeded with myofibroblasts. Finally, using a pulsed flow-stretch bioreactor in which fibrin-based grafts seeded with fibroblasts were subjected to cyclic distension and transmural flow, Syedain *et al.*[140] showed extensive remodeling of the grafts into circumferentially-aligned tubes of collagen and other extracellular matrix, with a compliance comparable to native arteries.

2.217.4.1.2. Engineered cardiovascular tissues

Some *in vivo* animal studies have shown promising results when using fibrin as a carrier system for cell delivery and/or growth factors to restore injured heart muscles. For example, transplanted skeletal myoblasts or cardiomyocytes using fibrin sealant have been shown to survive in myocardial infarction area and improve heart function in rats with myocardial ischemia.[141,142] Using a porcine model of post-infarction left ventricular remodeling, Xiong *et al.*[143] recently showed that a fibrin patch-based transplantation of human embryonic stem cell-derived vascular cells (endothelial cells and smooth muscle cells) led to a significant cell engraftment, accompanied by a significant increase of neovascularization and left ventricular contractile functional improvement, which in turn resulted in a significant reduction of regional wall stress and infarct size.

Other studies have been exploring the use of fibrin to generate a tissue construct *in vitro*. For example, a recent study by Divya and Krishnan[144] showed that the combination of fibrin with GAG, hyaluronic acid, and heparin sulphate induced endothelial cell growth and extracellular matrix remodeling, with simultaneous degradation of the fibrin matrix and deposition of collagen IV and elastin. The authors concluded that this combination may be suitable for generating a cardiovascular tissue *in vitro*. A study by Montano *et al.*[145] also showed promising results for engineering prevascularized matrices. Using a 3D culture system consisting of human microvascular endothelial cells seeded into fibrin-based hydrogels, the authors were able to demonstrate capillary lumen formation, followed by the generation of intracellular vacuoles, successive fusion of these vacuoles, and finally the formation of a continuous lumen. The transplanted prevascularized matrices onto the back of immunoincompetent rats showed that mural cells recruited from the underlying recipient mesenchyme stabilized the newly formed vessels. However, to be used for reconstruction of tissue defects, engineered grafts need to be axially vascularized to enable transplantation without graft loss due to hypoxia.[146] Promising results in generating such a tissue have been reported using an

arteriovenous loop (AV-loop) embedded in an isolation chamber filled with fibrin matrix in the rat,[147] and more recently in larger animal models such as the sheep.[146]

2.217.4.2. Bone Tissue Engineering

Although some studies reported no direct osteoinductive property of fibrin sealant when implanted alone in dogs[148] or in rats,[149] other studies reported a stimulation of osseous repair in osteochondral fractures sealed with fibrin sealant in dogs[150] compared to fractures fixed with pins.

The suitability of fibrin as a cell delivery system as described earlier in this chapter represents a great potential for bone formation if fibrin is seeded with osteoprogenitor cells and induces their differentiation before their release. By injecting cultured periosteal cells with fibrin glue into the subcutaneous space on the dorsum of athymic nude mice, Isogai *et al.*[151] showed the feasibility of initiating site-directed formation of bone structures at heterotopic tissue sites. The fibrin carrier contained 64 mg ml^{-1} of fibrinogen and 50 IU ml^{-1} of thrombin (final concentrations in the gels). When injected alone, fibrin did not initiate any bone formation. By using a combination of fibrin with MSC and platelet-rich plasma (PRP) to fill bone defects after placing dental implants in dogs, Ito *et al.*[152] showed more bone–implant contact in the group containing cells, PRP and fibrin, compared to the group containing only cells and fibrin (no PRP) for up to 4 weeks. In a recent study, Kang *et al.*[153] reported on the *in vitro* and *in vivo* osteogenenesis of skin-derived mesenchymal stem cell-like cells (SDMSC) with a demineralized bone and fibrin glue scaffold. Scaffolds seeded with autologous SDMSC were grafted into the maxillary sinus of adult miniature pigs and compared with scaffolds alone. Results showed that trabecular bone formation and osteocalcin expression were more pronounced around the grafted material containing cells than around the scaffolds alone, with also new bone formation from the periphery to the center. The authors concluded that autologous SDMSC with a demineralized bone matrix and fibrin glue scaffold could serve as a predictable alternative to bone grafting in the maxillary sinus floor.

Because of its suitability for delivering exogenous growth factors, fibrin can also be used as a delivery system of BMP or angiogenic growth factors for bone tissue engineering applications. For example, when combining fibrin with BMP, Kawamura and Urist[154] reported a potential immunochemical function of fibrin clot, with the observation of more new bone formation than in the control group (BMP alone). Schmoeke *et al.*[117,118] also reported similar bone healing at 3 weeks in rat calvaria when using BMP-2 and fibrin compared to autograft. In addition, the authors reported bone bridging in a canine pancarpal arthrodesis within 12 weeks.

In addition to cells and growth factors, fibrin has also been combined with other biomaterials for bone regeneration applications. For example, despite some mixed results in the past, bioceramic-derived fibrin composites have been widely used,[155] possibly because of the improved surgical handling of such combination. While some studies showed negative effects of bioceramic–fibrin composites,[156,157] others showed osteogenic properties of these composites.[158,159] For example, Carmagnola *et al.*[156] showed a negative impact on bone colonization in alveolar bone defects in dogs when using a composite made of a bone graft (Bio-Oss®) and a fibrin sealant.[156] On the other hand, Le Guéhennec *et al.*[158] reported newly formed bone at a distance from the surface of Micro-macroporous Biphasic Calcium Phosphate (MBCP®) granules in rabbit femoral defects, suggesting an osteoinductive phenomenon, compared to the commonly described osteoconduction effect of calcium phosphate materials depicted by bone formation directly on the surface of the granules when not mixed with fibrin. To gain insight into the role of fibrin structural properties on bone wound healing *in vivo*, Karp *et al.*[160] conducted an experiment comparing bone healing in rat distal femur defects, filled with either poly(lactic-*co*-glycolic acid) (PLGA) scaffolds alone, PLGA scaffolds combined with a fibrin sealant (TISSEEL™) prepared with a low thrombin concentration (i.e., thick fibers and large pores), PLGA scaffolds combined with the fibrin sealant prepared with a high thrombin concentration (i.e., thin fibers and small pores), or nontreated (controls). Results showed that after 5 days, fibrin-filled PLGA scaffolds were infiltrated with less bone than empty scaffold, and after 11 days, they showed significantly delayed bony wound healing. The authors concluded that fibrin sealants in their present state were not ideal for enhancing bone-tissue invasion into PLGA scaffolds. However, they still observed a more rapid bone-tissue invasion during the first 5 days of healing within PLGA scaffolds filled with fibrin containing a low thrombin concentration compared to fibrin containing a high thrombin concentration. They also reported more disorganized thin collagen fibrils within scaffolds filled with fibrin containing a high thrombin concentration at early time points, and concluded that the structural properties of fibrin matrices may be an important design parameter for maximizing host-tissue invasion during wound healing. Indeed, large pores in fibrin containing a low thrombin concentration may have permitted deeper penetration of cell processes compared to smaller pores in fibrin containing a high thrombin concentration. Fibrin properties and retention on the surface of an endosseous implant are also expected to affect peri-implant bone healing. The influence of the microroughened surface of a titanium implant on the initial interactions of blood/cells has been investigated by Park and Davies.[161] The authors showed that these interactions influenced fibrin clot formation and thereby the migration and differentiation of osteogenic cells in the healing compartment,[161] which has been considered as the hallmark of osteoconduction.[162] Considering that osteogenic cells exert tractional forces while migrating through the fibrin covering the implant surface, the strength of fibrin adhesion (initially attached on the implant surface because of fibrin-adhesive properties) should be strong enough to withstand these tractional forces (http://www.ecf.utoronto.ca/~bonehead/). Davies defined the concept of effective fibrin retention versus inadequate fibrin retention by the implant surface and showed that an effective fibrin retention will allow the cells to migrate toward and stay on the implant surface where they will polarize and secrete bony matrix, thereby providing a good osteointegration. Davies also showed that fibrin retention on the implant surface is a function of the implant microtopography, which will therefore largely influence the implant fixation and its clinical outcome.

Studies described above have been looking at mixing fibrin with cells, growth factors, or biomaterials. Additional studies

investigated other types of combinations. For example, the mixture of fibrin glue with natural coral and TGF-β1 has proven effective in repairing rabbit skull defects.[163] In a recent study, Arkudas *et al.*[164] showed early improvement of vascularization by mixing VEGF-165 and bFGF with fibrin, used to fill a particulated porous hydroxyapatite and beta-tricalcium phosphate matrix in which an arteriovenous loop was created in the medial thigh of rats. The same group also showed successful axial vascularization in a large volume of the same construct but without the growth factors, when creating such arteriovenous loop in a large animal model (sheep).[165] Using a combination of fibrin, MSC and β-tricalcium phosphate (β-TCP), Yamada *et al.*[166] demonstrated that MSC/β-TCP fibrin glue admixtures (containing 40 mg ml^{-1} of fibrinogen and 125 IU ml^{-1} of thrombin – final concentrations in the gels) could result in successful bone formation, whereas β-TCP with fibrin glue only did not induce any bone formation in subcutaneous space on the dorsum of rats. Similarly, Bensaid *et al.*[65] reported that, when implanted in nude mice, MSC-fibrin scaffold-coral implants were invaded by numerous fibroblastic-like cells and a high number of blood vessels, in a larger extent than in the fibrin scaffold-coral implants (with no cells) and coral implant groups. Finally, a recent study by Kang *et al.*[153] showed osteogenic properties of a combination made of SDMSC, demineralized bone, and fibrin glue both *in vitro* and *in vivo*.

Overall, these studies show the potential synergistic effects between fibrin and other biomaterials as well as growth factors and seeded cells for bone tissue engineering applications.

2.217.4.3. Cartilage Tissue Engineering

Fibrin has been successfully used as a scaffold and adhesive to improve healing and regeneration of fibrocartilage, elastic cartilage, craniofacial cartilage, and articular cartilage.[167]

For example, the implantation of fibrin glue containing MSC into rat meniscal defects showed that the cells could survive and proliferate, as well as produce abundant extracellular matrix contributing to meniscal repair.[168] When implanting fibrin seeded with human pediatric auricular chondrocytes into nude mice, Ruszymah *et al.*[169] showed that the engineered cartilage resembled native elastic cartilage. While investigating the use of fibrin for craniofacial applications, Silverman *et al.*[170] showed that the implantation of fibrin (80 mg ml^{-1} of fibrinogen and 50 IU ml^{-1} thrombin) mixed with swine articular chondrocytes into a subcutaneous pocket on the back of nude mice led to the formation of a neocartilage layer between the two native cartilage discs after 6 weeks. The neocartilage also adhered to the normal cartilage matrix. With regard to articular cartilage, multiple studies reported on the use of fibrin with articular chondrocytes. For example, Hendrickson *et al.*[171] reported improved cartilage surface, a significantly greater aggrecan level, and a significantly higher proportion of type II collagen when using fibrin for articular chondrocyte transplantation in trochlea of horse distal femur compared to controls (empty defects). While implanting constructs made of fibrin with articulating chondrocytes into defects in swine knees, Peretti *et al.*[172] showed new cartilage formation and filling of the defects. Finally, while evaluating the use of a fibrin-based scaffold as a delivery vehicle for C5.18 cells for hyaline cartilage regeneration, Dare *et al.*[51] showed that when cultured in chondrogenic medium, fibrin-encapsulated C5.18 cells elaborated an extracellular matrix containing type II collagen as well as aggrecan, two components of hyaline cartilage. These results indicated a more articular-like chondrogenic differentiation of C5.18 cells encapsulated in fibrin, demonstrating that the C5.18 cell line could possibly be used as a tool to evaluate potential scaffolds for articular cartilage tissue engineering.

Biodegradable polymers have been one of the key components in cartilage tissue engineering, and synthetic and naturally derived biodegradable polymers have been widely used for the scaffolds. In order to incorporate the advantages of multiple biomaterials, fibrin has often been investigated in combination with other biodegradable polymers for cartilage tissue engineering applications. For example, Ameer *et al.*[49] evaluated the use of a biodegradable composite system made of pig chondrocytes entrapped in a fibrin gel phase and dispersed throughout the void volume of a PGA nonwoven mesh. After 28 days in culture, results showed an increase in GAG content up to 88% that of native pig cartilage. Total collagen content per cell represented 40% of the value determined for native cartilage. When implanting subcutaneously a fibrin–hyaluronan composite gel seeded with rabbit knee chondrocytes in the back of nude mice, Park *et al.*[173] detected the formation of cartilage-like tissue earlier than when using fibrin alone. Recently, the same group reported on the capacity of such composite to promote chondrogenic differentiation of rabbit MSC *in vitro*.[174] Sha'ban *et al.*[175] also used fibrin to immobilize rabbit articular chondrocytes and provide homogenous cell distribution in PLGA *in vitro*. Results showed that fibrin–PLGA constructs promoted early *in vitro* chondrogenesis and could therefore potentially be used for *in vitro* tissue-engineered articular cartilage. In a recent study, Jung *et al.*[176] showed that constructs made of poly(L-lactide-co-ε-caprolactone) scaffolds and fibrin gels promoted the secretion of cartilaginous extracellular matrix and the formation of mature cartilage tissue by seeded rabbit chondrocytes after implantation into the subcutaneous dorsum of mice.

Finally, other studies also investigated the combination of fibrin with cells, other biomaterials, and growth factors such as TGF-β1 to induce stem cell differentiation into the chondrogenic lineage in order to enhance repair strategies for damaged cartilage. For example, Jung *et al.*[177] showed that hybridization of fibrin and poly(lactide-*co*-caprolactone) scaffolds for 3D spatial organization of the cells as well as effective delivery of TGF-β1 using heparin-functionalized nanoparticles could induce the differentiation of human adipose tissue-derived stem cells. Dickhut *et al.*[178] analyzed whether the combination of collagen-type I/III carrier with fibrin glue into a biphasic construct could support *in vitro* chondrogenesis of MSC and allow for local release of bioactive TGF-β1. The authors reported that the biphasic carrier constructs showed a high biofunctionality with improved chondrogenesis and long-term local supply of bioactive TGF-β1. Very recently, Park *et al.*[179] showed increased chondrogenesis in human MSC seeded in fibrin hydrogels both *in vitro* and in nude mouse and rabbit defect models when the gels contained TGF-β3-loaded nanoparticles. Other studies have shown that, in addition to TGF-β, other factors could alternatively be used with fibrin for cartilage repair.[167] For example, using a model of extensive cartilage loss

in horses, Fortier *et al.*[180] showed that the addition of IGF-1 to composites made of chondrocytes and fibrin enhanced chondrogenesis in the defects as well as graft incorporation into the surrounding cartilage.

2.217.4.4. Nervous Tissue Engineering

Tissue-engineered neural structures may present an alternative strategy to treat serious clinical conditions of the nervous system, such as brain and spinal cord injuries as well as neurodegenerative diseases.[167]

As explained in **Section 2.217.3** of this chapter illustrating the use of fibrin matrices containing the heparin-based delivery system developed by Sakiyama-Elbert and Hubbell[107] for the delivery of growth factors, studies using such system and incorporating NGF showed an enhancement of neurite extension.[111,115] More recently, a study by Gao *et al.*[181] using a combination of fibrin and NGF without the heparin-based delivery system technology also showed more regenerated nerve fibers with the development of axons compared to fibrin alone or NGF alone. In addition, when combining NGF and GDNF with fibrin matrices containing the heparin-based delivery system, Wood *et al.* reported peripheral nerve regeneration[112,113] as well as motor neuron regeneration and functional recovery in a rat sciatic nerve model.[114]

Similarly, some studies illustrating the use of fibrin for the delivery of NT-3 showed an increase in neural fiber density in spinal cord lesions.[108,109] For example, as previously described in **Section 2.217.3**, a study by Taylor *et al.*[108] using the heparin-based delivery system to immobilize NT-3 within fibrin gels showed stimulated neural outgrowth from chick dorsal root ganglia by up to 54% *in vitro* and an increased neural density at 9 days in a rat accurate spinal cord injury model. Another study by the same authors using the accurate spinal cord injury model in rats showed an enhanced initial regenerative response when delivering NT-3 in a controlled manner using the same heparin-based delivery system in fibrin gels, as depicted by an increase in neuronal fiber sprouting and cell migration into spinal cord lesions.[109] Interesting, a more recent study from the same group showed that the controlled release of NT-3 could enhance neural fiber sprouting even when the treatment was delayed 2 weeks following injury.[182] Finally, when combining the controlled delivery of NT-3 and PDGF using, once again, the heparin-based delivery system in fibrin gels, the same authors showed promising results for enhancing functional recovery following spinal cord injury in a subacute rat model.[110]

In a recent study, Kalbermatten *et al.*[183] compared the use of fibrin versus poly-3-hydroxybutyrate as a conduit to guide nerve regeneration and bridge nerve defects using a rodent sciatic nerve injury model. Results showed a potential advantage of using fibrin as a conduit for the initial phase of peripheral nerve regeneration, demonstrated by a superior nerve regeneration distance after 1 month and an enhanced Schwann cell intrusion from the proximal and distal ends. A study by Isaacs *et al.*[184] investigating different commercially available fibrin sealants to suture nerve repairs and decrease the gapping at the repaired site, showed that fibrin sealants helped preventing the initial gapping in cadaveric nerve specimens. Johnson *et al.*[185] showed that the use of fibrin induced significantly higher levels of neural fibers in a rat spinal cord injury site at 2 and 4 weeks after treatment. In addition, the accumulation of glial fibrillary acidic protein (GFAP)-positive reactive astrocytes surrounding the lesion was delayed. Finally, Itosaka *et al.*[186] showed that the bone marrow stromal cell transplantation in rats using a fibrin construct led to a more pronounced recovery of neurologic function than fibrin alone or cells alone, concluding that fibrin matrix may be a promising scaffold candidate for spinal cord injury.

2.217.4.5. Other Tissue Engineering Applications

Fibrin has been evaluated for and used in many more tissue engineering applications, including those in skin, liver, muscles, tendons, and ligaments.

2.217.4.5.1. Skin

The use of fibrin for skin repair will be further discussed when reviewing fibrin use in plastic and reconstructive surgery in the next section of this review (**Section 2.217.5**). The present section will only summarize a few studies on the use of fibrin in *in vitro* models to induce wound reepithelialization and give some examples of the use of fibrin in skin substitutes in preclinical studies.

Geer *et al.*[187] developed a wound reepithelialization model based on engineered composite skin equivalents and human keratinocytes. Using this model, the authors evaluated fibrin as a substrate for keratinocyte growth and migration after incisional wounding, showing that the use of fibrin decreased the length of the lag phase of keratinocyte activation and increased the consistency of the healing response. Such models are also used to investigate regulatory mechanisms of cell growth and differentiation under conditions mimicking those *in vivo*. Using a combination of keratinocytes, fibrin suspension, and acellular dermis (AlloDerm®), Bannasch *et al.*[188] reported closure of full-thickness wounds in a porcine model, with reduced wound contraction. Finally, when using fibrin as a delivery vehicle for human umbilical cord perivascular cells, Zebardast *et al.*[189] showed accelerated early wound healing in full thickness skin defects created on the dorsum of Balb/c nude mice, with thicker and more organized dermal repair tissue compared to contralateral controls that had received fibrin only.

Because of the limited availability of autografts (especially in some patients with extended burns), the development of skin substitutes for wound coverage is very important for the care of burn wounds. Cultured skin substitutes, composed of keratinocytes and fibroblasts in fibrin matrix have been developed as an adjunctive burn wound therapy. For example, a study from Ronfard *et al.*[190] showed that human keratinocytes cultured on a fibrin matrix had the same growth capacity and transplantability as those cultured on plastic surfaces, but the presence of fibrin greatly facilitated the preparation, handling and surgical transplantation of the grafts. Recently, a study by Tanikawa *et al.*[191] evaluated the long-term growth and differentiation characteristics of keratinocytes cultured onto a fibrin gel under immerse and air-liquid interface culture conditions. Results showed that the resulting composite had promising ultrastructural, morphological and functional characteristics, suggesting that such composite may have some potential for clinical use. However, vascularization of such cultured skin substitutes is slower than that of split-thickness skin autografts,

and therefore grafted cells are exposed to ischemia and nutriment deprivation early on after implantation. In order to improve the vascularization of the substitutes, growth factors such as VEGF and bFGF have been added to these substitutes. Some studies showed increased angiogenesis when using such enhanced skin substitutes in athymic mice.[192,193]

2.217.4.5.2. Liver

Hepatocyte transplantation are under investigation as an alternative to liver transplantation (limited by donor organ shortage and immunosuppression), and therefore, 3D scaffolds have been investigated as carrier systems.[194] Fibrin matrices have been considered for such scaffolds. For example, a study by Bruns *et al.*[195] evaluated the use of fibrin as a carrier for hepatocytes in culture and developed an intrahepatic injection technique to transplant the fibrin gel-immobilized hepatocytes in rats. Culture of hepatocytes in the fibrin matrix allowed stable cell numbers and 3D neotissue formation, and *in vivo* results showed integration of hepatocytes and hepatic stellate cells into the host liver. A study by Gwak *et al.*[59] also showed that one week after transplantation of hepatocytes using fibrin matrix in an athymic mouse model, the cells retained their hepatocyte-specific functions whereas no transplanted cells were visible in the control groups (transplantation of hepatocytes suspended in culture medium).

2.217.4.5.3. Skeletal muscles

Tissue engineering of skeletal muscle tissue still remains a major challenge. Skeletal muscle tissue engineering aims to create autologous neomuscle, involving the differentiation of myoblasts to myofibers either *in vitro* or *in vivo* after implantation.[196] In a recent review of the current state of the art in tissue engineering of skeletal muscle, Koning *et al.*[197] reported that optimal scaffolding for structural support and regulation of proliferation and differentiation of muscle progenitor cells could comprise a fibrin gel and cultured monolayers of muscle satellite cells obtained through the cell sheet technique. A study by Beier *et al.*[198] showed that expanded primary rat myoblasts cultured for 1 week in a fibrin matrix were integrated into the host's skeletal muscle fibers after transplantation. Another study by the same authors also evaluated the possibility of filling the muscle defect with fibrin containing myoblasts using an injection system instead of implanting precultivated 3D myoblast cultures.[196] Results showed that injected myoblasts with fibrin increased integration into the host muscle fibers in a time-dependent manner, with a conservation of the transplanted cell phenotype. *In vitro*, Khodabukus and Baar[199] were able to rapidly (about 10 days) engineer a functional tissue using the C2C12 mouse myoblast cell line in fibrin supplemented with aprotinin and natural cross-linker genipin. Finally, Bian and Bursac[200] reported on combining cell-mediated fibrin gel compaction with precise microfabrication of polydimethylsiloxane molds to guide cell alignment along the microfabricated tissue pores and control the overall tissue porosity, size, and thickness. The interconnected muscle bundles within the porous tissue networks were composed of densely packed, aligned, and highly differentiated myofibers.

2.217.4.5.4. Tendons and ligaments

Injuries of tendons and ligaments are among the most common orthopedic injuries, and unfortunately, incomplete regeneration of the tissue often occurs during healing.[167] The properties of anterior cruciate ligament (ACL) and medial collateral ligament (MCL) fibroblasts were analyzed in a 3D fibrin matrix gel, with or without TGF-β1, to investigate the possible differences in ACL and MCL fibroblast ability to perform the key events of wound repair, including wound matrix contraction mimicked by fibrin matrix gel contraction.[201] Results showed that MCL fibroblasts synthesized a significantly higher amount of collagen per cell than ACL fibroblasts between days 2 and 6 of culture. The addition of 5 ng ml^{-1} of TGF-β1 caused a significantly faster rate of the 3D construct contraction than control (0.5% fetal bovine serum), without having to increase the initial cell number. By injecting a mixture of human bone marrow stem cells with fibrin glue into patellar tendon defects of immunodeficient rats, Hankemeier *et al.*[202] showed more mature tissue formation with more regular patterns of cell distribution compared to untreated defects or defects filled with fibrin glue only. Interestingly, using the same model, the authors more recently compared the effects of fibrin glue seeded with human bone marrow stem cells versus fibroblasts on the ultrastructural morphology, mRNA expression of essential extracellular matrix proteins, and material properties of the healing tissue.[203] Results showed that only the mean collagen fibril diameter was significantly higher compared to the defect group but the group with human bone marrow stem cells showed also more collagen I mRNA expression, collagen I/collagen III mRNA ratio, and an increase in the Young's modulus at 20 days postoperatively. Finally, Thomopoulos *et al.*[204] recently reported that the delivery of bFGF and PDGF-BB using the heparin-binding delivery system in fibrin gels initially developed by Sakiyama-Elbert and Hubbell[107] stimulated tendon fibroblast proliferation and promoted some changes in the expression of matrix genes related to tendon gliding, strength and remodeling *in vitro*. The authors concluded that the controlled delivery of these factors *in vivo* may allow for sustained biological stimulation in the early period after repair. However, such *in vivo* studies remain to be conducted to verify that the observed improvements *in vitro* translate to improvements *in vivo*. Previous studies from the same authors using PDGF-BB in a canine flexor tendon model had shown improved gliding but not improved strength.[205] Similarly, in a recent study, the authors showed that bFGF administration alone led to increased tendon cellularity and matrix synthesis but no improvement of the functional and mechanical properties of the repair.[206]

Mechanical properties still remain a challenge for the functionality of fibrin for tendon and ligament applications. Indeed, by injecting bone-marrow-derived MSC mixed with fibrin sealant in rabbit Achilles tendons, Chong *et al.*[207] showed improved modulus compared to control, but only at the early stages of healing. Similarly, a study by Thomopoulos *et al.*[208] analyzed both the functional and structural properties of the healing tissue in an intrasynovial flexor tendon repair model using fibrin/heparin-based delivery system of PDGF-BB. Results showed that cell activity was accelerated as a result of PDGF-BB at 14 days and tendon gliding properties were significantly higher for the PDGF-BB-treated tendons than for the repair-alone tendons at 42 days. However, there was no improvement in the tensile properties.

2.217.5. Fibrin in Clinical Practice

2.217.5.1. Commercially Available Fibrin Sealants

Commercial fibrin sealants are currently composed of plasma-derived complexes of purified, pathogen-inactivated human fibrinogen and thrombin.[209] Other components, such as factor XIII, tranexamic acid, or aprotinin (bovine origin or synthetic), are added in some fibrin sealants. Factor XIII, activated by thrombin in the presence of calcium ions, serves as the cross-linking reagent.[15] Either tranexamic acid or aprotinin, which acts as a fibrinolytic inhibitor (or plasmin inhibitor), is added in some fibrin sealants to prolong the life of the fibrin clot. For some formulations, however, a manufacturing step is added to remove the plasminogen from the fibrinogen component, so that no plasmin inhibitor is needed.

There are currently several commercially available fibrin sealant products, including ARTISS™ (Baxter Healthcare Corp., Westlake Village, CA), Beriplast® P Combi-Set (CSL Behring, King of Prussia, PA), Cryoseal® (Thermogenesis, Rancho Condova, CA), Evicel™ (replacement of Crosseal™/Quixil® (Omrix biopharmaceuticals Ltd. and Ethicon Inc. J&J, Somerville, NJ), and TISSEEL™/TISSUCOL™ (Baxter AG, Vienna, Austria; also available through Baxter Healthcare Corp., Westlake Village, CA). To ensure that clotting occurs quickly and effectively, commercial fibrin sealants need to be prepared with very high amounts of fibrinogen and thrombin, up to 60 mg ml^{-1} of fibrinogen and 300–500 IU ml^{-1} of thrombin after mixing.[209–211] The two component solutions are usually applied through a double-barreled syringe system, which allows simultaneous application of the fibrinogen and thrombin through a blunt-ended needle or spray tip.[5] The two components passively mix at the ends of the delivery needles or spray tip. The method of application can have a significant effect on the clinical outcome and should therefore be chosen carefully depending on the clinical need. Some concerns have indeed raised clinically with regard to the learning curve of the clinical staff for techniques of applications as well as for reconstitution of the fibrin sealants that can affect their usability.[212]

Production method generally includes several precipitation steps to enhance the purity of fibrinogen by decreasing the relative proportion of fibronectin, albumin, or immunoglobulins. Viral inactivation methods include two-step vapor heating, solvent–detergent step, and pasteurization. Therefore, in addition to the factor XIII and/or a plasmin inhibitor supplements in some fibrin sealants as explained above, the precipitation mode and purification, as well as the viral inactivation treatment influence the composition and behavior of the final product, including the stability after reconstitution or thawing, the speed of hemostasis, the preparation time, and the ease of use. The direct comparison between properties of different fibrin sealants remains difficult because of variable testing conditions between studies (such as differences in rheological devices, different animal models, etc.). However, because of the variations between formulations, outcomes for a particular clinical application can vary depending on the fibrin sealant used.[213–215] Choice of the sealant should therefore be carefully considered. **Tables 1 and 2** illustrate the differences in composition (**Table 1**) as well as handling and storage requirements (**Table 2**) of some commercially available fibrin sealants in Europe.

Although fibrin sealants have been approved by the FDA for hemostasis in various surgical applications, as adhesives (e.g., burn wound skin graft attachment) and sealants (e.g., colon sealing),[216] they have also been used off-label in many other applications. Some of the clinical applications in which they have been applied include cardiovascular and thoracic surgeries, plastic and reconstructive surgeries, gastrointestinal surgeries, neurosurgeries, ophtalmology, urology, and others (some examples of these uses are provided below). They have been also used clinically as an adjunct therapy to replace sutures or staples because of their enhancement of healing, minimizing scarring, and ease of application.[211]

2.217.5.2. Examples of Fibrin Uses in Clinical Practice

2.217.5.2.1. Cardiovascular and thoracic surgeries

Cardiovascular applications for fibrin sealants are numerous, including bypass surgery, vascular graft attachment, cardiovascular patches, heart valve implantation, and synthetic vascular grafts or preclotting of porous vascular grafts. This is probably the surgical area where fibrin sealants have been the most applied, with a primary use as an adjunct to hemostasis during vascular and cardiac procedures. Study examples of some of these clinical applications are given below.

2.217.5.2.1.1. Applications as a hemostatic agent in cardiac surgeries

A randomized clinical trial of fibrin sealant in 333 patients undergoing resternotomy or reoperative cardiac surgery was

Table 1 Comparison of the composition of some commercial fibrin sealants

Product	*Plasma protein fraction (mg ml^{-1})*	*Human fibrinogen (mg ml^{-1})*	*Human factor XIII (U ml^{-1})*	*Human thrombin (IU ml^{-1})*	*Fibrinolytic inhibitor*
Quixil	60–80	40–60	Not available	1000 (800–1200)	Tranexamic acid, 100 mg ml^{-1}
Tisseel/Tissucol Duo	75–115	70–110	~1 (USA, UK); 10–50 (mainland Europe)	500	Bovine aprotinin, 3000 KIU ml^{-1}
Tisseel/Tissucol Kit	75–115	70–110	~1 (USA, UK); 10–50 (mainland Europe)	4 or 500	Bovine aprotinin, 3000 KIU ml^{-1}
Beriplast P	90 (65–115)	90	60 (40–80)	500	Bovine aprotinin, 1000 KIU ml^{-1}

Adapted from Tredree, R.; Beierlein, W.; Debrix, I.; *et al*. *EJHPScience* **2006**, *12*, 3–9.

Table 2 Comparison of the handling and storage requirements of some commercial fibrin sealants

Product	*Presentation*	*Applicator*	*Storage*	*Preparation*	*Time of preparation*	*Shelf-life after thawing/reconstitution*
Quixil	Frozen components in vials	Triple lumen, drip and spray	Below −18 °C	Thaw, draw into applicator	5–7 min thawing in the hand; <1 min after thawing	30 days at 2–8 °C
Tisseel/ Tissucol Duo	Frozen components in syringes	Single lumen blunt needle (by default). Spray also available for purchase	Below −18 °C	Thaw, warm to 37 °C, attach tip to syringe	20–30 min if thawed at room temperature; warming to 37 °C recommended	36 h
Tisseel/ Tissucol kit	Lyophilized components for reconstitution	Single lumen blunt needle (by default). Spray also available for purchase	2–8 °C	Reconstitute, warm to 37 °C, assemble applicator	About 40 min warming/stirring	4 h
Beriplast P	Lyophilized components for reconstitution	Single lumen blunt needle (by default). Spray also available for purchase	2–8 °C	Reconstitute, warm to 37 °C, assemble applicator	10–15 min waiting time for components to mix	8–24 h

Table from Tredree, R.; Beierlein, W.; Debrix, I.; *et al*. *EJHPScience* **2006**, *12*, 3–9, reproduced with permission.

published by Rousou *et al.*[217] The study was conducted to test the efficacy and safety of fibrin sealant as a topical hemostatic agent. Results showed a 92.6% success rate for fibrin sealant in controlling bleeding within 5 min of application, compared to only a 12.4% success rate with conventional topical agents. By using fibrin sealant, 82.0% of those bleeding episodes not initially controlled by conventional agents were also more rapidly controlled, and postoperative blood loss was significantly less in the fibrin sealant group than in the matched controls. Additionally, resternotomy rates after re-operations were significantly lower in the fibrin sealant group (5.6%) than in the control group (10%). A more recent randomized, double-blind clinical study (phase 3) evaluated the topical hemostatic efficacy and safety of a fibrin sealant (TISSEEL VH S/D™) compared to a previous formulation (TISSEEL VH™) during cardiac surgery.[218] Results showed that 88.2% of the patients treated with TISSEEL VH S/D and 89.6% of the ones treated with TISSEEL VH achieved hemostasis within 5 min and maintained it until surgical closure. These results suggested that both fibrin sealants were safe and effective for use as an adjunct to hemostasis in patients undergoing cardiac surgery. In a recent prospective randomized controlled trial, Chalmers *et al.*[219] showed that the use of another fibrin sealant (EVICEL™) compared to manual compression in PTFE arterial anastomoses shortened the time to haemostasis and reduced the incidence of treatment failure.

2.217.5.2.1.2. Applications in synthetic vascular grafts

A prospective randomized multicenter trial evaluating the safety and efficacy of a fibrin sealant (Beriplast® P) in stopping bleeding from needle or suture holes in polytetrafluoroethylene (PTFE) grafts after anastomosis to the femoral artery of 201 patients was published by Taylor *et al.*[220] The fibrin sealant was compared to a thrombin-soaked gelatin sponge. The authors reported that time to hemostasis was shorter in the fibrin sealant group, blood loss was less, and time to wound closure was shorter. There was no difference in recurrent bleeding or any other adverse events. The authors concluded that the fibrin sealant was more effective than the thrombin-soaked gelatin sponge for achieving hemostasis after needle or suture hole bleeding in PTFE femoral artery grafts.

2.217.5.2.1.3. Applications in cardio patches

A prospective randomized trial including 20 patients investigated whether the application of Quixil® sealant to the suture line of an expended PTFE (ePTFE) patch could improve the time to achieve hemostasis and reduce local blood loss compared to standard topical hemostat Kaltostat® (a soft, white, sterile nonwoven dressing of calcium sodium alginate containing 80% calcium and 20% sodium).[221] Results showed that the blood loss and the time to achieve hemostasis after clamp release were significantly lower in the Quixil® group compared to controls. A study by Aigner *et al.*[222] reported on the use of a double pericardial patch with a layer of human fibrin glue in between (sandwich technique) to cover the defect caused by intraoperative coronary sinus rupture, a rare event but potentially mortal. The study included four patients. The authors reported that all patients could be treated successfully, with excellent bleeding control. Finally, in a case study report by Toda *et al.*,[223] a patient with penetrating cardiac injuries to both ventricles was treated by two different methods: buttressed sutures on one side, and a collagen mesh dressing covered by a fibrin glue (TachoComb® patch) on the other side. The study reported that the patient recovered without a ventricular pseudoaneurysm.

2.217.5.2.2. Plastic and reconstructive surgeries

Fibrin has been widely used as an adhesive in plastic and reconstructive surgeries, including burn surgeries, craniofacial surgeries, and microvascular surgeries,[224] mainly because of its graft adherence and hemostasis properties. As mentioned at the beginning of this chapter, fibrin has been used as an adhesive for skin grafts as early as in the 1940s. Grafting of skin has been successful regardless of the fibrin sealant production method in areas such as hands in burn patients, face lifts, and rhynophyma repair.[3]

2.217.5.2.2.1. Graft adherence

Fibrin has been shown to improve the percentage of skin graft take, especially in difficult grafting sites or sites with unavoidable movement.[48] By facilitating graft adherence, fibrin sealants can improve the graft survival and cosmetic results.[225] In 1983, Vibe and Pless[226] reported an improvement in skin graft area take from 83 to 92% with the use of a fibrin glue (TISSEEL™) in 20 patients. The authors reported that, in difficult areas such as over mobile muscle or close to skin folds, 88% of cases were successful when using fibrin to glue the tissue and only 44% without using fibrin. A study by Stuart *et al.*[227] a few years later also achieved 99% graft take in 16 patients when using a single-donor fibrin glue as an adjunct in early excision and grafting hand-burned patients.

A recent multicentered, prospective, randomized, and evaluator-blinded phase 3 clinical study evaluated ARTISS™ for skin graft adherence compared to staples in burn wounds.[228] The study reported that, by day 14, complete wound closure occurred in 48.8% when using the sealant compared to 42.6% when using staples. These numbers reached 70.3% versus 65.8%, respectively, at day 28. The sealant also scored better by the investigators in terms of graft adherence, preference for method of fixation, satisfaction with the graft fixation, and overall quality of healing. This study was carried out after a multicenter, randomized, and controlled phase 1/2 clinical study comparing the fibrin sealant and staples for the same purpose, that is, attaching split-thickness autologous sheet grafts in patients with deep, partial, or full-thickness burn wounds.[229] In the latter study, the authors had showed that the percentage of completely closed sites was generally greater with the sealant than with the staples, with the maximum difference at day 28 (79.5% vs. 59%, $p = 0.0215$).

2.217.5.2.2.2. Hemostasis

Several studies have been reported on the effects of fibrin sealants on wound hemostasis. A phase III multicenter, randomized, comparative clinical trial was performed by Nervi *et al.*[230] to evaluate the topical hemostatic efficacy of a fibrin sealant in burn patients undergoing skin graft procedures. The sealant evaluated in that study consisted of a human topical fibrinogen complex and a solution of human α-thrombin at 250–350 IU ml^{-1} once reconstituted. Each patient served as his or her own control. A contiguous donor skin harvest site was bisected into two equal halves, and one of them was treated with the fibrin sealant. The time of hemostasis in each of the donor site halves was identified by the operating surgeon. The study reported a significant difference in the mean time to hemostasis between the fibrin sealant-treated donor sites compared to the control sites. In a previous study in 95 burn patients and investigating the hemostatic effect of a human fibrin sealant (which appears to be similar to the one used later by Nervi *et al.*[230]), McGill *et al.*[231] (same group of researchers as Nervi *et al.*) had previously reported an estimated blood loss/graft ratio of 0.50 ± 0.30 ml cm^{-2} (median = 0.46) for the study group versus 0.98 ± 2.4 ml cm^{-2} (median = 0.56) for the control group. The difference was not statistically significant unless considering only patients more than 16 years old. Although the use of the fibrin sealant did not show a major improvement in the clinical outcome in terms of hemostasis, the authors had reported a reduced need for blood transfusion, as well as a reduced alloantigen exposure and a reduced blood-borne viral infection risk when using fibrin compared to controls. A former study by Achauer *et al.*[232] including ten patients with burns had also not reported any significant difference in the bleeding between the donor site sprayed with fibrinogen and thrombin (i.e., fibrin glue) compared to the site sprayed with thrombin and plasma placebo. Likewise, when evaluating the safety and potential efficacy of a solvent/detergent-treated commercial fibrin sealant (same as the one previously described by McGill *et al.*[231]) for topical hemostasis in skin grafting, Greenhalgh *et al.*[233] did not report any differences between the fibrin sealant-treated site and the control site (no treatment) with regard to acceleration of donor site healing, graft take, or scar maturation. A subjective observation by the investigators revealed that graft sites treated with the fibrin sealant may, however, progress through the maturation phase of healing more rapidly than other burn wounds that were not treated with the fibrin sealant, but such observation would need to be investigated further.

2.217.5.2.2.3. Face-lift surgeries and seroma prevention

Although some studies did not show clear advantages of fibrin for face-lift surgery, others have shown benefits. For example, a prospective, randomized, nonblinded controlled trial published by Marchac and Greensmith[234] showed only minimal differences when comparing scores among grades of haematomas, ecchymosis, and edema between sprayed fibrin sealant (TISSEEL™) and drainage versus drainage treatment only in 30 face-lift patients. On the other hand, another prospective, randomized, double-blind trial in 20 consecutive patients undergoing bilateral face lifts showed a significant difference in drainage between the two sides at 24 h.[235] The side treated with the fibrin sealant had a median drainage of 10 ml compared to 30 ml for the control side. In a recent review of ten different papers on the topic, Por *et al.*[236] concluded that there was no statistically significant benefit from the use of tissue sealants in face-lift surgery. The parameters analyzed were postoperative drainage at 24 h and ecchymosis, as well as postoperative edema measurement.

On the basis of the tissue-adhesive qualities of fibrin glue, seroma prevention is a natural avenue of exploration for clinical use.[224] Few studies have been published on the use of fibrin sealants to prevent seroma formation after breast cancer surgery, abdominoplasty, and body-contouring surgery.[237,238] However, these reports seem to be too few to draw conclusions on the use of fibrin for these applications, and more randomized clinical trials should be performed to determine the efficacy of fibrin for such applications.

2.217.5.2.3. Other clinical applications

2.217.5.2.3.1. Gastrointestinal

Bleeding in the upper gastrointestinal tract is often managed by local endoscopic injection of hemostatic agents.[5] The injection of a fibrin sealant provides an effective therapy that can be administered repeatedly as required. For example, fibrin sealant can help control the diffuse oozing associated with liver surgery.[239] In a large randomized multicenter study, 854 patients with ulcers or active gastroduodenal bleeding (spurting, oozing) received either a single application of polidocanol 1%, a single application of a fibrin sealant (Beriplast®P), or repeated applications of the fibrin sealant.[240] Results showed that patients treated with repeated applications of the fibrin sealant were significantly less likely to have recurrent bleeding compared to those treated with polidocanol. In a retrospective analysis of bleeding upper gastrointestinal ulcers, 452 patients with benign gastric or duodenal ulcers were examined.[241] Eighty-five patients exhibiting stigmata or fresh bleeding were treated endoscopically by injection of a fibrin sealant. Results showed that initial endoscopic hemostasis was achieved in all patients, and permanent hemostasis was reached in 85.9%. In another prospective and randomized study, 121 patients undergoing liver resection were treated either with Crosseal™ fibrin sealant (58 patients) or using standard commercially available topical hemostatic agents (44 patients).[242] Results showed that hemostasis was achieved within 10 min in 91.4% of the patients treated with the fibrin sealant versus 69.8% of the patients treated with standard topical hemostatic agents. In addition, the time to hemostasis was 282s with the fibrin sealant compared with 468s with the standard topical hemostatic agents. Finally, postoperative complication rate was also lower with the fibrin sealant.

Another potential organ for fibrin use in gastrointestinal applications is the pancreas. For example, Jang *et al.*[243] reported on the efficacy of a fibrin sealant (TISSEEL™) injected endoscopically for closure of pancreatocutaneous fistula and abdominal wall defects following transgastric endoscopic necrosectomy. A systematic literature search was actually recently performed by Fingerhut *et al.*[244] to determine the use of fibrin sealants in pancreatic surgery. The authors reported on 24 studies that included six controlled randomized trials. However, because of the heterogeneity and lack of high-level evidence, they concluded that, as of today, it is hard to say if fibrin sealants are of any real utility in pancreatic surgery. Further large-scale controlled trials may be necessary before concluding on the use of fibrin sealants in this surgery field.

2.217.5.2.3.2. Neurosurgery

Fibrin sealants have been used in various neurosurgery applications, including the prevention and treatment of cerebrospinal fluid leakage after neurosurgery,[245,246] as well as peripheral nerve repair.[247,248] Kamada *et al.*[245] reported a successful treatment of a spontaneous intracranial hypotension due to a cerebrospinal fluid leak at the C2 level by epidural fibrin glue patching (Beriplast® P). A prospective randomized study evaluating the efficacy of autologous and commercial (Beriplast®) fibrin sealants to decrease postoperative cerebrospinal fluid leak in spinal cord surgery reported that the volume of drainage fluid was significantly lower in the groups with fibrin sealants (both autologous and commercial) than in the group without fibrin sealant.[246] On the other hand, a study by Jankowitz *et al.*[249] did not report any difference in dural repair when using a fibrin glue (TISSEEL VH™) in patients who experienced a durotomy during lumbar spine surgery. However, Narakas[247] had previously reported earlier that using a fibrin glue in repair of peripheral nerves offered an advantage on suturing alone and allowed a considerable gain of operative time. A significant advantage of fibrin glue over microsuturing is based on the fact that the expected nerve appositioning can be fixed into place with no significant migration, making the procedure easier and faster, and reducing or avoiding the use of sutures.[3,4]

2.217.5.2.3.3. Ophthalmology

Fibrin-based matrices have been used extensively for the treatments of many corneal diseases, including total limbal cell deficiency and corneal perforation.[167] For example, in their attempt to restore corneal integrity in patients with total limbal stem cell deficiency, Rama *et al.*[250] evaluated the efficacy of the transplantation of fibrin-cultured limbal stem cell constructs (using TISSUCOL™) and showed successful results in 14 out of 18 patients, with reepithelialization within the first week. A study by Siatiri *et al.*[251] evaluated the use of a fibrin sealant (TISSEEL VH™) for the repair of corneal perforations up to 3 mm in diameter and showed successful healing in 15 out of 18 patients after 3 months.

Amniotic membrane has been commonly used as a substrate for limbal stem cell transplantation.[252] A study by Kim and Park[253] evaluated the use of a fibrin glue (Green Plast) to create a multilayered amniotic membrane (five to seven ply of amniotic membrane with fibrin applied to each sheet) for transplantation into large corneal perforations, which eliminates the requirement for sutures. The authors reported that 90% of the patients showed complete epithelialization over the amniotic membrane with a mean reepithelialization time of 14.9 ± 4.9 days.

2.217.5.2.3.4. Urology

Fibrin sealants have been used in a large number of applications in urology, including hemostasis during partial nephrectomy, renal reconstruction after trauma, bladder surgery, ureteral anastomosis, microsurgical vasal anastomosis (vasovasostomy and vasoepididymostomy), and fistula repair. For example, the use of a commercial fibrin sealant (TISSEEL™) was successful in obtaining strict hemostasis during laparoscopic partial nephrectomy in 15 patients following conventional hemostatic measures of electrocauterization and argon-beam coagulation.[254] There was also no evidence of urinary leak during or after surgery, a common complication after laparoscopic partial nephrectomy, suggesting that the fibrin sealant may have helped to prevent such complication by helping to seal or close small defects in the urinary collecting system. Similarly, percutaneous fibrin glue (TISSUCOL™) injection allowed controlling urine leakage in a 71-year-old man with a single kidney and renal cell carcinoma who subsequently underwent laparoscopic partial nephrectomy.[255]

Reviews have been reported on the use of fibrin sealants in urology.[256,257] For example, Shekarriz and Stoller[257] reported on a number of case series and case reports showing the

efficacy of fibrin sealant for ureteral anastomosis, microsurgical vasal anastomosis, fistula repair, and other reconstruction applications, and concluded that fibrin sealant was an effective and safe topical agent for controlling surface bleeding during elective and trauma-related urological procedures. Evans and Morey[256] detailed diverse urological applications of fibrin sealant in the management of genitourinary injuries, surgeries, and complications. The authors concluded that fibrin sealant offered an effective adjunct for hemostasis, tissue adhesion, and reinforcement of urinary tract sealing.

2.217.6. Conclusion

The literature on fibrin is extremely large and continues to expand. This chapter provided a summary of the main characteristics and properties of fibrin and presented a wide range of fibrin uses in tissue engineering approaches as well as in clinical practice. It was shown that fibrin can serve as a cell and/or bioactive substance delivery system and be used as a bioactive matrix on its own or combined with other biomaterials. This versatility, in addition to unique intrinsic biological properties, make fibrin a very attractive candidate for the development of the next generation of biomaterials designed to achieve site-directed stimulation of tissue regeneration processes. Because fibrin mechanical and fibrinolytic properties greatly vary depending on the fibrin components and their concentrations, it will be important to keep in mind the matrix parameters necessary for a specific application. For example, whereas a fast degradation and a more open matrix structure may be beneficial for applications requiring a rapid cell or bioactive substance delivery, a more stable matrix may be necessary for tissue growth applications where cells need time to differentiate and produce their own matrix. By varying fibrin composition, many different structures of fibrin gels with different overall properties can be developed, which will make fibrin suitable for multiple new applications in tissue engineering and clinical practice.

2.218.1. Recombinant Human Tropoelastin-Based Constructs

2.218.1.1. Introduction

Research into elastin-containing biomaterials has for many years been hampered by elastin's extreme insolubility and the short *in vivo* lifetime of its precursor tropoelastin, making the formulation of constructs from intact elastic fibers exceedingly difficult.[1] The increased availability of soluble animal-derived elastin, obtained through alkaline (κ-elastin), acid (α-elastin), and enzymatic hydrolysis, and of elastin-based peptides, and in particular the development of the recombinant full-length elastin precursor tropoelastin (rhTE) now allow for enhanced and improved use of this class of protein in the development of advanced biomaterials.

Tropoelastin is a 60–70 kDa protein (whose size is dependent on the splice variant) encoded by a single copy gene located in the 7q12.2 region in humans.[2,3] It is characterized by alternating hydrophobic and hydrophilic domains, encoded by separate exons.[4] The hydrophobic domains are implicated in the association of the monomer in solution and the elastic function of the polymer, while the lysine- and alanine-rich hydrophilic domains are involved in polymerization of the monomer through cross-linking.[5] The lysyl oxidase (LO)-mediated formation of lysine-derived cross-links is preceded by coacervation, the self-association of tropoelastin monomers at physiological temperature and salt concentration.[6,7]

rhTE was first expressed in a bacterial expression system following the construction of the vector containing the human cDNA sequence.[8] This expression and purification system was further optimized to reproducibly generate multigram quantities of the most common splice variant of human tropoelastin.[9] The extensive study of this 60 kDa protein has since contributed vastly to our understanding of the tropoelastin structure, assembly, and function. rhTE has also been developed into a range of promising biomaterials for vascular and skin tissue engineering purposes and has been used to functionalize a number of polymer and metallic surfaces for improved biocompatibility.

As a recombinant human protein, rhTE carries little risk of immunorejection and pathogen transfer. It is isolated from bacterial cells through a tightly controlled and highly reproducible process that gives rise to little batch-to-batch inconsistency often observed in preparations isolated from animal sources.

2.218.1.2. Synthetic Human Elastin Hydrogels

Hydrogels are highly hydrated hydrophilic polymer networks.[10] Because of their tissue-like water content, their ability to transport nutrients and waste, and the versatile range of materials that can be used in their construction, hydrogels have proved to be particularly effective tissue engineered scaffolds.[11] Hydrogels can be cast into a variety of different macromolecular structures and physical forms. Their tissue-engineering applications are wide ranging and include soft contact lenses,[12] pills and capsules,[13] implants and catheters,[14] and wound dressings.[15]

The potential of elastin-based hydrogels in soft tissue bioengineering has long been recognized. Elastin-based hydrogels have been engineered from α-elastin,[16–18] recombinant elastin-like polypeptides (ELPs),[19–21] and rhTE.[22–26] Polymerization of rhTE into synthetic human elastin (SHE) hydrogels has been achieved by (i) introducing chemical cross-linkers to coacervating rhTE,[22,25] (ii) enzymatic cross-linking of rhTE by yeast LO,[24] or (iii) exposure of rhTE solutions to alkaline conditions in the absence of a cross-linker.[23]

2.218.1.2.1. Chemically cross-linked SHE hydrogels

In the presence of sixfold molar excess of chemical cross-linker bis-sulfosuccinimidyl suberate (BS3), over 80% of rhTE monomers are incorporated into the elastic array to form SHE hydrogels. BS3 is an amine-reactive homobifunctional cross-linker that inserts an 11.4 Å spacer arm between closely placed lysine residues of rhTE.[22] SHE hydrogels self-assemble in distinct stages, involving the association of rhTE monomers in spheres that coalesce into open-linked networks, which finally consolidate to form the porous SHE scaffold (**Figure 1**).[27] These constructs are highly elastic, displaying a Young's modulus of 220–280 kPa, similar to that of native elastin, which has a Young's modulus of 300–600 kPa. SHE hydrogels display a purely elastic region to above 150% strain and elongation at break ranging from 200% to 370%.[22] They show stimuli-responsive characteristics to salt concentration, where they absorb 33 times their weight in water and only 3.8 times their weight in PBS at 37 °C.[22]

SHE hydrogels have been shown to possess favorable biological properties *in vitro* and *in vivo*. They support cellular interactions with a range of adherent epithelial cell lines and with dermal fibroblasts.[22] Dermal fibroblasts also interact favourably with SHE hydrogels[25] coblended with α-elastin,[18] heparin, and dermatan sulfate.[26] Interestingly, when rhTE is coblended with glycosaminoglycans (GAGs) such as heparin and dermatan sulfate, the resultant hydrogels displayed increased porosity, pore size, and therefore cell penetration into the scaffold.[26] Fibroblasts grown on SHE hydrogels express ECM proteins including fibronectin and type I collagen.[25] These scaffolds are well tolerated *in vivo*, generating at most a bland immunological response when implanted subcutaneously in guinea pigs. Unlike collagen which is largely dispersed by week 4 postimplantation, SHE hydrogels remain intact up to 13 weeks postimplantation, showing only minor breakdown of the material.[22]

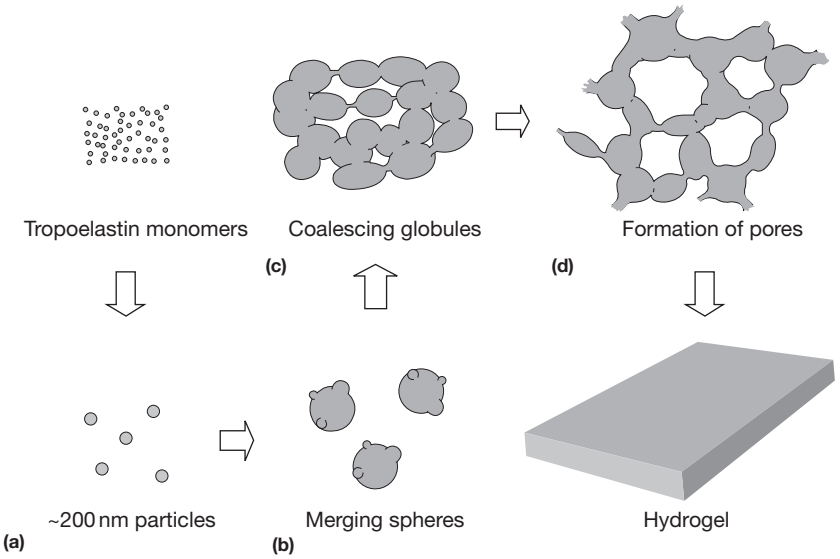

Figure 1 Stages of SHE hydrogel formation. Reproduced from Tu, Y.; Wise, S. G.; *et al*. *Micron* **2010**, *41*(3), 268–272.

2.218.1.2.2. Enzymatically cross-linked SHE hydrogels

rhTE can be cross-linked by LO isolated from a yeast strain *Pichia pastoris* in a process that mimics the cross-links formed in mammalian elastin.[24] Yeast LO oxidizes the lysine residues of rhTE *in vitro* to form cross-links found in natural elastin polymers, including lysinonorleucine, allysine aldol, and desmosine. However, the cross-linking efficiency in this system is reduced compared to that in natural elastin, resulting in 25-fold reduction in desmosine cross-links and ten times higher number of residual lysines compared to elastin isolated from horse *ligamentum nuchae*. A lower Young's modulus and greater swelling in water in these artificially cross-linked constructs also point to a lower number of cross-links formed. While resulting in less efficiently cross-linked materials compared to natural and chemically cross-linked elastin, these scaffolds are the first successful demonstration of LO cross-linking of rhTE *in vitro* and are therefore a valuable model in gaining a better understanding of the elastin cross-linking process, including mapping of regions involved in the intra- and intermolecular cross-links formed between tropoelastin molecules *in vivo*.[24]

2.218.1.2.3. SHE hydrogels formed under alkaline conditions in the absence of a cross-linker

Exposing rhTE to an alkaline environment at physiological temperature results in a sol–gel transition that enables the formation of stable, highly elastic hydrogels without the need for chemical or enzymatic cross-linking.[23] These materials consist of coacervated rhTE spherules that have self-assembled through association of the exposed hydrophobic rhTE side chains.[28] The resulting hydrogel is a stable, porous material that can be cast into a variety of shapes *in vitro* or injected *in vivo*. The material is highly flexible and elastic, with a Young's modulus of 1.69 ± 0.04 MPa. It displays favorable biological properties, supporting dermal fibroblast attachment and proliferation *in vitro* and persisting for up to 2 weeks subcutaneously *in vivo*, while eliciting only a mild foreign body response.[23] This material shows promise as a bulking agent or a biomaterial for the treatment of soft tissue injuries or defects, especially where the use of chemical cross-linkers raises biocompatibility concerns and impacts on the material approval process.

2.218.1.3. Electrospun rhTE Fibers

Electrospinning is a novel way of producing nano- to microscale fibers from a variety of natural and synthetic polymers.[29] It utilizes a strong electric field to process a polymer solution into a fibrous construct.[30] It has generated much interest in the tissue-engineering field in the past two decades as a simple, inexpensive means of mimicking native ECM fiber morphology.[30] Electrospinning results in thin, continuous fibers with a high surface area-to-volume ratio that promotes cellular adhesion.[29–32] The high porosity and pore interconnectivity of electrospun scaffolds allow for nutrient and metabolic waste transport necessary for cell survival and proliferation.[33,34] Compositional, structural, and functional properties of electrospun scaffolds can be easily controlled and adapted to a range of tissue-engineering applications.[32] Electrospun scaffolds are currently being investigated as a means of replacing and regenerating a range of tissues including skin, tendon, bone, cartilage, and blood vessels (for reviews see Liao *et al.*,[35] Kumbar *et al.*,[33] Ramachandran and Gouma,[36] Sell *et al.*[37]). They also present a potential for drug and gene delivery and coating of medical and dental implants.[33,38]

A number of elastin derivatives including solubilized bovine elastin,[39–48] elastin-mimetic peptide polymers,[49,50] cell culture-produced ECM sheets containing tropoelastin,[51] and rhTE[25,44,52,53] have been successfully electrospun. The majority of electrospun elastin-containing constructs have been generated by co-electrospinning α-elastin with other natural or synthetic polymers to mimic the components of the native tissue or increase the mechanical and structural stability of the electrospun construct.

Elastin-based scaffolds are generally electrospun from hexafluoropropanol (HFP),[41–48,51] but electrospinning from

trifluoroethanol (TFE)[49,50] and hydrochloric acid[40] has also been achieved. During the electrospinning process, α-elastin and rhTE adopt flat, ribbon-like fiber morphologies that are independent of the electrospinning parameters. Interestingly, when rhTE and α-elastin are electrospun alone, rhTE fibers are always two to three times wider than α-elastin fibers under identical electrospinning conditions. Electrospun rhTE fibers are also more elastic and possess higher tensile strength than electrospun α-elastin fibers.[44]

Elastin-based scaffolds require chemical cross-linking following electrospinning to retain the structural and mechanical integrity of the scaffold. Electrospun elastin scaffolds have been successfully cross-linked with glutaraldehyde (GA) vapors,[42,43,46,52,53] 1,6-diisocyanatohexane (HMDI),[44,52] and *N*-(3-dimethylaminopropyl)-*N*′-ethylcarbodiimide hydrochloride and *N*-hydroxysuccinimide (EDC/NHS).[40]

Solubilized bovine elastin[39–48] is the most commonly electrospun elastin derivative, but electrospun rhTE-based scaffolds are proving to be promising constructs in vascular and skin tissue engineering. rhTE was first electrospun in 2005[44] and its electrospinning and cross-linking parameters have since been optimized to generate a range of constructs with different physical and biological properties. rhTE can be electrospun into flat scaffolds of different shapes and sizes and into hollow tubular constructs. rhTE can be electrospun into randomly oriented or aligned fibers of different widths, and the scaffold pore size and porosity can be altered by changing the electrospinning parameters. Altered electrospinning parameters as well as introduction of other natural and synthetic polymers have also been shown to allow fine tuning of the mechanical and biological properties of electrospun rhTE-based scaffolds, including modulation of the scaffolds elasticity, tensile strength, and cellular interactions.

rhTE retains its functional activity following electrospinning. The electrospinning process does not negatively impact on the molecular weight, secondary structure, coacervation properties, or cell binding on rhTE.[52] Cross-linked electrospun rhTE scaffolds interact favorably with a number of cell types, including embryonic palatal mesenchymal cells,[44] human umbilical vein endothelial cells (HUVECs),[52,53] and primary dermal fibroblasts.[25]

2.218.1.3.1. Electrospun rhTE and vascular tissue engineering

Elastin is a promising candidate for vascular tissue engineering because of its prevalence in vessel walls, favorable cellular interactions, and blood compatibility. Elastin comprises up to 50% of the dry weight of major arteries, where it provides elastic recoil, resilience, and durability.[4] Additionally, it offers important cell signaling cues that promote attachment and proliferation of endothelial[54,55] but not smooth muscle cells[56] and results in reduced platelet adhesion and activation.[53,57,58] Its particular promise lies in the design of small diameter (<6 mm) vascular conduits where compliance mismatch between stiff commercially available conduits and native vessels results in graft failure.[59]

An rhTE-based small-diameter vascular conduit was constructed by electrospinning a multilayer construct comprising a GA cross-linked rhTE luminal layer and rhTE-polycaprolactone (PCL) hybrid outer layers. Cross-linked rhTE supported HUVEC attachment and proliferation *in vitro* allowing the establishment of a fully confluent cell layer on the scaffold surface by day 3 post seeding. Platelet attachment to these constructs was significantly lower than on commercially available ePTFE or on PCL-based constructs. Mechanical properties of the rhTE-based conduit were optimized to mimic the permeability, compliance, elastic modulus, and burst pressure of the human internal mammary artery. Importantly, these conduits were well tolerated and retained their superior mechanical properties for at least 1 month in a rabbit carotid interposition model.[53]

2.218.1.3.2. Electrospun rhTE and skin tissue engineering

Electrospun scaffolds hold immense potential as both dermal substitutes and wound dressings. The porous nature of electrospun scaffolds promotes the drainage of wound exudates, while retaining wound moisture and promoting the exchange of gases.[60] While much effort has been invested into the design of electrospun elastin-containing vascular grafts,[39,42,43,45–48,51] the addition of elastin to electrospun dermal substitutes has been largely overlooked. Dermal elastic network is a strong determinant of skin resilience, texture, and quality, but is not sufficiently regenerated following burn injury.[61–64] Elastin-based dermal substitutes have the potential to decrease wound contraction, improve scar appearance and functionality, and contribute to wound-healing outcomes through a combination of elastin's mechanical and cell signaling properties.[65]

A dermal substitute scaffold electrospun entirely from rhTE and cross-linked with GA vapors was found to support the attachment, spreading, and proliferation of primary dermal fibroblasts. This scaffold consists of flat, ribbon-like fibers that resemble the size and morphology of native elastin fibers, showing an average fiber width of $2.3 \pm 0.5\,\mu m$. Its elasticity is similar to that of native elastin, with a Young's modulus of $265 \pm 17\,kPa$. Altering the electrospinning conditions allows for easy modification of the scaffold properties to generate highly porous and open-weave scaffolds that promote fibroblast infiltration.[25] Dermal fibroblasts actively migrate into the scaffold and secrete ECM proteins, including type I collagen and fibronectin. These scaffolds are well tolerated *in vivo* in a rat full-thickness excision model, where they support fibroblast infiltration and collagen deposition.[65] Electrospinning also allows for addition of other ECM proteins, such as collagen to rhTE-based scaffolds, to further improve their handling and cell interactive properties without negatively impacting on the scaffold elasticity.[65]

2.218.1.4. Functionalized Surfaces

Synthetic polymers and metal alloys are vastly employed in the development of medical devices. Many commercially available vascular grafts, heart valves, bone and joint implants, and wound dressings are manufactured from synthetic polymers, while many cardiovascular devices such as heart valves, pacemaker components, and stents are composed of metal alloys, including stainless steel, titanium, and cobalt chromium. These materials are mostly biologically inert and therefore do not promote cellular interactions necessary for the long-term success of the device *in vivo*.[66] Many of the metallic surfaces are also not sufficiently blood compatible and therefore cause thrombosis and device failure.[67,68]

Coating of polymer and metal devices with rhTE has the potential to overcome these problems, as elastin modulates the behavior of a number of cell types and is known to be nonthrombogenic. Multiple peptides from the alternating hydrophobic domains of tropoelastin modify cell behavior. These include the hexapeptide VGVAPG and peptides containing a GXXPG motif, as well as the recently identified C-terminal GRKRK motif. Cells interact with elastin and its derivatives via several different cell surface receptors, including the elastin-binding protein (EBP), αvβ3 integrin and through GAGs on the cell surface (for review see Almine *et al.*[69] and references therein).

Covalent immobilization of rhTE onto a polymer surface was demonstrated on plasma immersion ion implantation (PIII) treated polystyrene. Covalent binding of proteins to polymer surfaces ensures presentation of proteins in a conformationally relevant state and reduces protein resorption following implantation. This treatment can be used to selectively guide fibroblast spreading on rhTE-coated surfaces, as was demonstrated by patterning the surface to achieve cell spreading on rhTE treated areas only.[70]

Covalent immobilization of rhTE onto stainless steel was achieved by creating a plasma deposited interface on the metal surface.[55] This new, rhTE-coated surface significantly enhances HUVEC attachment, spreading, and proliferation compared to untreated stainless steel and to plasma treated steel alone.[54,55] The plasma-treated surface in the presence and absence of rhTE reduced the thrombus weight by more than tenfold after 30 min under flow in a modified Chadler loop and delayed the time to thrombus formation by threefold.[54] The plasma-modified rhTE-coated surface therefore has the potential to enhance endothelialization and reduce thrombosis of endovascular stents. Importantly, this technique was not only demonstrated on flat pieces of stainless steel, but the coating technology was also translated to modification of coronary stents.[54]

The use of stem cells is of extreme importance in tissue engineering and the ability to propagate these cells while maintaining them in undifferentiated state is challenging. rhTE-coated surfaces have recently been demonstrated to enhance the propagation of human and murine hemopoietic stem and progenitor cells. This phenomenon is attributed to the elastic nature of rhTE rather than specific signaling roles of the protein, as truncated and cross-linked forms of rhTE do not display the same effect. Furthermore, inhibition of mechanotransduction abolishes the positive effects of rhTE.[71]

2.218.2. The Elastin-Like Recombinamers

2.218.2.1. Introduction

In the last few decades polymer science has developed rapidly and has had a profound impact on society showing that macromolecules can be excellent candidates to create highly functional materials. Within macromolecules, we can find proteins as indispensable part of biological structures and systems, especially as regards control of tissue formation, biological functions, or physical performance.[72]

Natural proteins are usually large and very complex linear polymers, which contain diverse specific functional groups that generate and promote self-assembly and function. Nature has designed proteins with specific practical functionality, such as ability to self-assemble, specific recognition, energy interconversion, or monodispersity, and enhances these attributes in protein-based biomaterials. All of this amazing functionality displayed by natural proteins seems to be based on a simple fact: a complex and completely defined primary structure. In living cells, protein biosynthesis is carried out with an absolute control of the amino acid sequence, from the first amino acid to the last with a complete absence of randomness.[73] For this reason, a basic understanding of amino acid-based peptides and proteins forms the foundation for the current development of peptide-based biomaterials. As such, peptides and high molecular weight polypeptides are emerging as a new class of biomaterials because of their unique chemical, physical, and biological properties.

This explosion of new peptide-based materials is founded on parallel developments in both our understanding of protein function and the maturation of recombinant DNA technologies to obtain recombinant protein-based polymers, also known as 'recombinamers.'[74] These macromolecules, with total lack of randomness in their sequence, permit the required functionalities to be designed in the final material in a highly precise manner with an exponential increase of complexity and low costs.

The genetic engineering of recombinamers enables the easy and highly effective design and synthesis of complex and highly functional molecules with selected and sophisticated properties, such as the incorporation of selected exogenous bioactivities in order to develop materials for cutting-edge applications in biomedicine and nano(bio)technology.[75] Furthermore, genetic engineering can recreate simple or complex properties that are present in natural proteins in these recombinamers. Additionally, as it is possible to construct any coding gene required, base by base, on the basis of original designs without being restricted to the gene fragments present in living organisms, materials and systems exhibiting functions of particular technological interest that are not displayed in living organisms can also be designed and produced.[76] As an example of these approaches (**Figure 2**), we show here how elastin-like recombinamers (ELRs), which combine sequential and architectural molecular complexity with diverse bioactivities, play an important role in the synthesis of advanced materials for biomedical and nano(bio)technological applications.

2.218.2.2. The Extraordinary Properties of ELRs

ELRs are a promising model of biocompatible protein-based polymers. The basic structure of ELRs involves a repeating sequence based on the recurring sequences found in the mammalian elastic protein elastin.[77] As far as their properties are concerned, some of their main characteristics are derived from those of the natural protein. Elastin is an extracellular matrix protein that is present in all vertebrate connective tissues. Its functions include the provision of elasticity and resilience to tissues, such as large elastic blood vessels (aorta), elastic ligaments, lung, and skin, which are subjected to repetitive and reversible deformation.[4,78]

The importance of ELRs resides in the fact that these polymers show a versatile and broad range of interesting properties

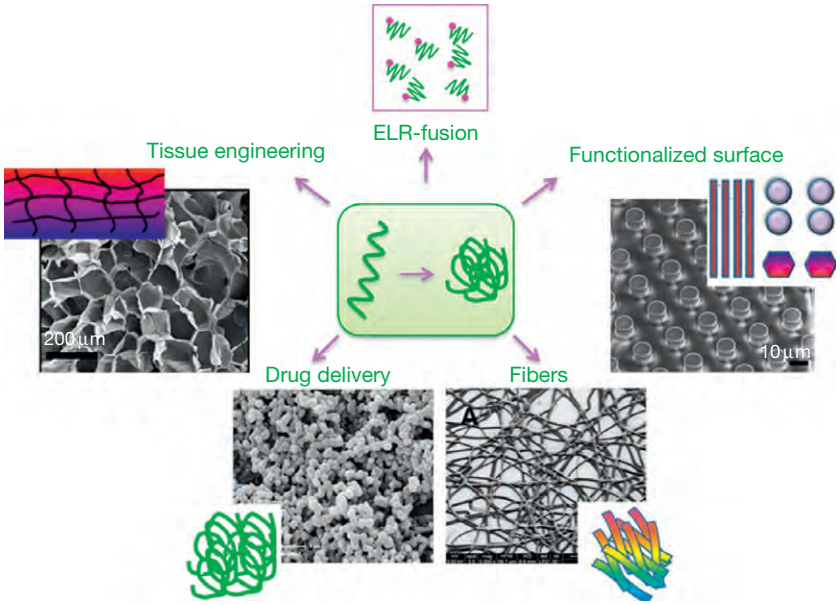

Figure 2 Different applications of elastin-like recombinamers, including tissue engineering, drug delivery, fibers, functionalized surface, and ELRs-fusion constructions.

above and beyond their simple mechanical performance that are not easily found together in other materials, including stimuli-responsive behavior or the ability to self-assemble. These properties arise because of a molecular transition of the polymer chain in the presence of water at temperatures above a certain level. This transition, known as the 'inverse temperature transition' (ITT),[79–81] has become the key issue in the development of peptide-based polymers for use as molecular machines and materials.

ELRs show an additional property – an outstanding high biocompatibility – which is highly relevant for the use of these polymers in advanced biomedical applications such as tissue engineering and controlled drug delivery. Indeed, the complete series of ASTM generic biological tests for materials and devices in contact with tissues and tissue fluids and blood demonstrate their unmatched biocompatibility.[82] Perhaps somewhat surprisingly, it appears that the immune system simply ignores these polymers as it cannot distinguish them from natural elastin because the β-spiral, the common structural feature of all ELRs, strongly contributes to preventing their identification.[83] In addition, their degradation products – natural amino acids – are nontoxic.[84–87]

The polymer poly(VPGVG) (V=L-valine; P=L-proline; G=glycine) is considered to be a model for all ELRs.[81] Indeed, most ELRs are based on the pentapeptide VPGVG (or its permutations), with amino acid side chains, other than glycine, comprising simple aliphatic and mainly hydrophobic chains, without further functionalization. A wide variety of ELRs based on the ELP model, with the general formula VPGXG, where X is any natural or modified amino acid other than L-proline, have been (bio)synthesized.

Initially, the monomers, oligomers, and higher polymers of this repeat, and modifications thereof, were chemically synthesized. More recently, however, with the increased development of molecular biology, these and more complex ELRs have been produced using genetic-engineering techniques.[88,89]

2.218.2.3. Genetic Engineering of ELRs

The use of genetic-engineering techniques to produce these polymers as recombinant proteins has several advantages over their synthetic counterparts. These techniques permit precise control over ELR sequence and chain length, as well as construction of new polymers with physical, mechanical, and/or biological features, such as variations of folding, chain interactions within protein structure, temperature or pH responsiveness, etc.[84,90]

The design of an appropriate strategy at the nucleotide level is critical for the efficient synthesis of the protein encoding sequence and to produce a uniform protein product with an optimal quality and yield. The biosynthesis of any artificial protein generally includes (1) the construction of a synthetic gene that encodes the protein of interest in a plasmid with close transcription control; (2) the cloning of a recombinant gene with the necessary transcriptional regulatory elements into competent cells; (3) the screening of plasmids containing the desired clones and verification of their DNA sequence; (4) transformation of the chosen plasmids into expression-competent host cells; (5) the growth of appropriate volumes of host cells and induction of protein expression; and (6) purification of the protein of interest from cell lysates.[91]

Molecular biology techniques are typically employed to self-ligate monomer DNA fragments in an oligomerization process that relies on restriction enzyme-based approaches when designing genes that encode repetitive recombinamers. In this case, the monomer fragments must be oligomerized in a 'head-to-tail' orientation and can either be seamless in sequence or can contain intervening linkers between the desired repeats. Approaches to oligomerization can be classified as (1) iterative, where a DNA segment is oligomerized in a series of single, uniform steps, each of which extends the oligomer by one unit length of the monomer gene; (2) random method or 'concatemerization,' where an uncontrolled

number of monomer DNA segments are oligomerized in a single step to create a population of oligomerized clones with different lengths; and finally, (3) recursive directional ligation (RDL), an alternative method in which DNA segments with two different restriction sites flanking the insert are joined in sequential steps, with the length of the ligated segments growing geometrically in each step. This approach is suitable for the synthesis of repetitive polypeptides with a specific and predetermined chain length as it seamlessly joins the two monomeric inserts and also eliminates the restriction sites placed at either end of the dimerized gene.[79,80,92]

2.218.2.4. The Stimuli-Responsive Behavior and Self-Assembly Properties of ELRs

The responsive behavior of ELRs has been defined as their ability to respond to external stimuli. This property is based on the molecular transition of the polymer chain in the presence of water at a temperature above a certain level, known as the ITT. Below a specific transition temperature (T_t), the free polymer chains remain as disordered, random coils that are fully hydrated in aqueous solution, mainly by hydrophobic hydration.[93] This hydration is characterized by ordered, clathrate-like water structures somewhat similar to those described for crystalline gas hydrates,[94,95] although somewhat more heterogeneous and of varying perfection and stability surrounding the apolar moieties of the polymer.[96] However, above T_t, the chains fold hydrophobically and assemble to form a phase-separated state containing 63% water and 37% polymer by weight.[97] In this folded state, the polymer chains adopt a dynamic, regular, nonrandom structure, known as a β-spiral, which contains type II β-turns as the main secondary feature and is stabilized by intraspiral, interturn, and interspiral hydrophobic contacts.[93] The ITT process is completely reversible, and the polymer returns to its initial state when the temperature drops below T_t.[98] During the initial stages of polymer dehydration, hydrophobic association of the β-spirals results in their taking on a fibrillar form. According to Urry's model, this process begins with the formation of filaments composed of three-stranded, dynamic polypeptide β-spirals that grow to lengths of several hundred nanometers before settling into a visible phase-separated state.[93,97]

The specific T_t can be measured by different techniques (see **Figure 3**), such as turbidity analysis or calorimetric methods. The T_t values obtained by these methods usually differ because of the influence of several factors.[99]

The magnitude of T_t also depends on several factors. For example, any intrinsic modification to the composition of the polymer chain as a result of changing the sequence or distribution of the different domains, or extrinsic factors such as salt additions, that modifies the tendency of water molecules to take part in hydrophilic versus hydrophobic hydration will alter the clathrate structure and modify the T_t. This effect is a result of both the mean polarity of the polymer chain and the molecular architecture and distribution of the different amino acid domains in the ELRs.[100] T_t can also be affected by the polymer concentration and by other factors, such as changes in pH or the oxidation state of a side chain or functional group, the addition of extrinsic factors such as salts and organic solutes, the presence of other ions and molecules, or pressure changes.[101–103]

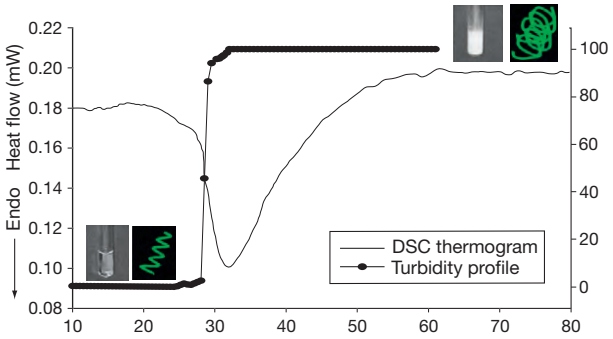

Figure 3 Turbidity profile as a function of temperature for poly(VPGVG) (5 mg l^{-1}) in water. The two photographs are below (5 °C) and above (40 °C) its T_t. Also, a DSC thermogram of a 50 mg l^{-1} aqueous solution of the same polymer is shown (heating rate 5 °C min^{-1}). Reproduced from Rodriguez-Cabello, J. C.; Prieto, S.; *et al. J. Biomater. Sci. Polym. Ed.* **2007**, *18*(3), 269–286, with permission from Brill.

As far as self-assembly is concerned, many synthetic strategies have been developed to obtain advanced devices in an attempt to mimic the efficiency of biology in nature. These techniques are usually developed on the basis of the concepts of self-organization and self-assembly, both of which are widely found in nature, to arrange hierarchically ordered systems in such a way that they can be exploited in synthetic devices. Proteins are useful building blocks for the formation of ordered nanostructures via self-assembly because of their well-understood folding, stability, and protein–protein interactions.[104] Natural elastin undergoes a self-aggregation process in its natural environment that leads to the formation of nanofibers.[83] However, genetic engineering and the tailored molecular design of ELRs allow this possibility to be extended to other topologies and nanostructures that involve the directed self-assembly of ELRs[105,106] such as nanopores.[107]

2.218.2.5. Biomedical and Biotechnological Applications

2.218.2.5.1. Tissue engineering

ELRs are useful for tissue engineering because they are soluble in aqueous solutions, have good *in vivo* biocompatibility, a controllable degradation rate *in vivo*, and break down into natural amino acids that can be metabolized by the body to produce nontoxic degradation products.[84] Besides this proven compatibility, their smart and self-assembling characteristics and their ability to be easily genetically functionalized to enhance their interactions with cells provide an optimal platform for cellular activities and tissue functions. Thus, they are excellent candidates for use in regenerative and reparative medicine.[108] They are also highly versatile as these properties can be tuned and extended in many different ways simply by changing their amino acid sequence, thereby opening up new possibilities for the formation of biomimetic advanced bio- and nanomaterials that can actively participate in the formation of functional tissue.

The first candidates for tissue-engineering applications were simple polymers of the type poly(VPGVG) and their

cross-linked matrices that promote unspecific cell adhesion because of lack of specific bioactivities. But, immediately these simple molecules were subsequently enriched with short peptides having specific bioactivities, such as cell-adhesion peptides RGD (R, L-arginine; D, L-aspartic acid) and REDV (E, L-glutamic acid). The complexity of these still relatively simple ELRs was subsequently increased by adding different functionalities such as cross-linking domains.[109–113] Numerous examples based on more complex designs, including various bioactivities[114,115] and other functionalities,[116–119] have since been synthesized in an effort to mimic the complex composition and function of the natural ECM. Thus, the addition of different functionalities such as cross-linking domains results in more uniform substrates, which are usually based on lysine residues, incorporated in the elastin-based repeat unit (VPGXG).[109,113,120]

ELRs are able to form stable viscoelastic hydrogels that mimic many of the characteristics of the ECM. These ELR hydrogels can be produced by photoinitiation,[121] irradiation,[122,123] amine reactivity,[124,125] or enzymatic cross-linking by tissue transglutaminase[114] to maintain their interesting properties as stimuli-responsive substrates. Furthermore, they are a new class of soft materials, which, in response to a small change in temperature, light, or other environmental stimulus, swell to several times their original volume or shrink to the same degree.[126,127] These materials have proved very useful in biomedical and pharmaceutical applications because of their high water content and rubbery nature, which are similar to that of natural tissue.

The physical properties of chemically cross-linked hydrogels can be modulated by varying the ELR's concentration, molecular mass, and lysine content. This ability to prepare 'tunable' hydrogels allows these ELRs to be used in a wide range of applications. Although there are many examples of ELRs hydrogels cross-linked in organic solvents, the application of *in situ* cross-linking in aqueous solution is limited by factors such as the toxicity of the reagents and by products, and slow gelation kinetics. Lim *et al.*[19] have reported that the chemical gelation of ELRs under physiological conditions results in a biocompatible and injectable biomaterial for support tissue regeneration. Similarly, Tirrell's group has developed this idea further and has demonstrated that chemically cross-linked hydrogels from ELRs-containing fibronectin cell-binding domains can successfully be used to support the growth and spreading of endothelial cells.[109,128] The tunable, elastin-like mechanical properties of ELR hydrogels and their ability to mediate cellular adhesion and proliferation make them suitable candidates for use in small diameter vascular grafts.[108] In addition, ELR hydrogels have also demonstrated the ability to induce the differentiation of adult human adipose stem cells into the chondrocytic phenotype and the accumulation of cartilage-specific extracellular matrix in the absence of exogenous chondrogenic supplements *in vitro*, thereby potentially simplifying and reducing the cost of the differentiation process.[129] Likewise, we have reported the production of 3D-ELR structured hydrogels with controlled microtopography and different size and depths by replica molding (see **Figure 4**).[130] These hydrogels may find a use in the study and control of cell behavior by controlling their topography and their smart nature enables changing the dimension of the microstructures during cell culture.[124,125]

One of the ELRs bioproduced by a group associated with some of the authors is an 877 amino acid complex polymer (REDV-ELR biopolymer) (see **Figure 5**) whose monomer unit contains four different functional domains in order

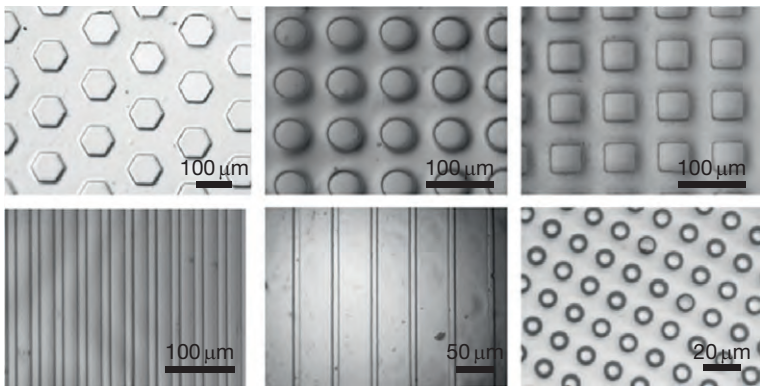

Figure 4 Micropatterned gels with different features obtained by replica molding. Optical micrographs of swollen gels in PBS by DIC microscopy. Reproduced from Martin, L.; Arias, F. J.; *et al. Soft Matter* **2010**, *6*(6), 1121–1124, with permission.

Figure 5 Schematic composition of monomer used in ELP design described in the text. The scheme shows the different functional domains of the monomer that can be identified with their corresponding peptide sequences. Reproduced from Rodriguez-Cabello, J. C.; Prieto, S.; *et al. J. Biomater. Sci. Polym. Ed.* **2007**, *18*(3), 269–286, with permission from Brill.

to achieve a suitable balance between mechanical and bioactive responses.[102,103] The polymer framework contains two elastomeric pentapeptides (VPGIG and VPGKG), which provide the desired mechanical properties, stimuli-responsive nature, biocompatibility, and cross-linking domains, namely, the CS5 domain from fibronectin, which contains the cell-selective adhesion REDV motif,[131] and the human elastin hexapeptide VGVAPG, which is targeted by the elastases that rearrange and renew the ECM. Three-dimensional matrices with controlled pore sizes formed from chemically cross-linked REDV-ELR have been obtained for use in cell culture, and salt-leaching and gas-foaming techniques have been used to improve the homogeneity of the pore size, the mechanical properties, and their interconnectivity. The 3D culture of HUVEC endothelial cells has shown the suitability of these scaffolds, with infiltration of these cells inside the porous network being essentially complete.[124,125] A study of the physical changes which occurred as a result of their temperature responsiveness showed that the collapse due to the phase transition above T_t decreased the mean pore size by about 30% (see **Figure 6**). This technique should provide a simple method for the fabrication of advanced scaffolds with tunable biological and physical applications.

This ELR-containing REDV cell-adhesion sequence has also been used to prepare hybrid scaffolds. Thus, the ELR was introduced as an elastic element in collagen-based scaffolds with a view to providing increased proteolytic sensitivity and increased functionality to the scaffolds by carrying a specific sequence for microbial transglutaminase cross-linking, endothelial cell adhesion, and drug delivery. These scaffolds showed that cross-linking ELR–collagen affects the physicochemical properties of the scaffolds such as their porosity, presence of cross-linking, thermal behavior, and mechanical strength. These enzymatic cross-linked ELR–collagen scaffolds were tested *in vitro* as substrates to study cell viability with different cell lines. An increasing ELR fraction in the scaffold was found to have an antifouling effect in fibroblasts, whereas endothelial cells displayed normal behavior and proliferation in the hybrid scaffolds. This differential colonization of the scaffolds with a specific cell type makes these scaffolds an attractive platform for biomedical applications, as varying the proportion of both materials should allow us to design the optimal requirements for future applications, such as vascular tissue or skin wound healing.[114] Other complex hybrid scaffolds containing ELR and collagen have been produced with the aim of creating an innovative acellular arterial substitute. For instance, Caves *et al.*[132] described the creation of artificial multilamellar vessel-like scaffolds consisting of several layers of an ELR matrix reinforced with synthetic collagen microfibers.

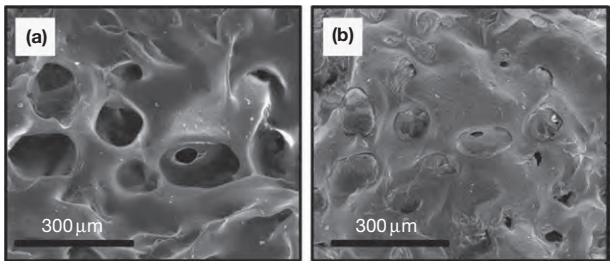

Figure 6 ESEM micrograph showing the change in pore size with temperature in swollen hydrogels: (a) 4 °C and (b) 37 °C. Reproduced from Martin, L.; Alonso, M.; *et al*. *Biomacromolecules* **2009**, *10*(11), 3015–3122, with permission from American Chemical Society.

Another type of hybrid scaffold has been synthesized for use as a provisional bone tissue. Thus, ELRs were amalgamated with chitosan to develop hydrogels with applications in bone tissue engineering, which requires temporary scaffolds to regenerate bone and improve its healing rate. These hydrogels can be injected into the body, as a liquid that gels *in situ*, thus allowing the material and cells to be implanted using a minimally invasive procedure. In this work, the ELR was incorporated into two different hydrogel formulations. First, physically cross-linked chitosan/β-glycerophosphate (Cht-β/GP) thermosensitive hydrogels were prepared where incorporation of the ELR into the (Cht-β/GP) formulation seemed to drastically improve the mechanical properties of this gel under physiological conditions. Second, chemically cross-linked chitosan hydrogels were prepared with the ELR acting as a coating. An ELR containing an osteoconductive sequence was found to improve the bioactive properties of chitosan-based systems and besides this, the mechanical properties of this gel under physiological conditions induced precipitation of calcium phosphate when the materials were soaked in simulated body fluids for 7 days.[117]

The REDV-containing polymer described above has also been used as a substrate to culture cells from the ocular surface. Epithelial cell adhesion and proliferation were investigated on this ELR, which mimics the functional characteristics of extracellular matrices. Corneal wound healing requires cell adhesion and proliferation, both of which are mediated by binding of epithelial membrane-bound integrins to substrate ligands such as fibronectin. A significant improvement in the adhesion and proliferation of the conjunctival epithelial cell line on the ELR-coated surface containing REDV peptides was observed. ELR-coated surfaces containing REDV peptides supported the normal phenotype and functions of epithelial cells *in vitro*, thus confirming that this recombinant polymer resembling the ocular surface extracellular matrix is a suitable substrate for sustaining epithelial cell attachment and growth. One of the potential applications we envision for this kind of protein-based polymer is the preparation of scaffolds to be used for ocular surface tissue engineering.[115]

Other examples of ELRs demonstrate the complexity attainable for this class of biomaterials. Thus, a sophisticated ELR has been biosynthesized to generate temporary scaffolds that support neural regeneration, thereby helping to repair injuries to the central nervous system (CNS). This engineered protein includes cell-adhesion sequences to enable neural attachment as well as sequences sensitive to cleavage by urokinase plasminogen activator (uPA), a protease secreted locally at the tips of growing neurites, to enable highly localized and tunable degradation. These ELRs were chemically cross-linked into highly swollen hydrogels with controllable mechanical properties. In addition, it was found that increasing the density of RGD peptides present in the protein substrates led to increased cell adhesion and more extensive neurite growth.[133]

It is also possible to make use of the thermosensitive behavior of ELRs to form hydrogels. Thus, raising the temperature of

a concentrated solution of an ELR above its T_t results in aggregation of the ELR's chains and the formation of an insoluble coacervate phase. Reverse thermosensitive polymers are very promising base materials for '*in situ* generated implants' because of their ability to form low viscosity physiological solutions at room temperature which gel at higher temperature. This property opens up numerous possibilities, although the two principal areas of research involve hydrophobic materials, which acquire desired mechanical properties, or water-based systems for the controlled release of hydrophilic macromolecules. The structural complexity of ELRs with specific mechanical, chemical, and biological properties allows us to design specific features that make it possible to acquire some or all of these properties. The self-assembly behavior of ELRs, for example, has been triggered by the addition of different main peptide blocks in the structure, with the hydrophilic block providing conformationally elastic properties[134] and the hydrophobic blocks forming physical cross-links through hydrophobic aggregation.[74]

In a recent example, ELR triblock copolymers with different hydrophobic architectures were found to form gels with a complex shear modulus, which can be varied by changing the hydrophobicity of the inner block.[49] Although the modification of ELRs allows some control of their mechanical properties, the physically cross-linked ELR hydrogels lack the strength required for some tissue-engineering applications. When greater mechanical integrity is desired, the elastic modulus can be enhanced by including additional chemical cross-linking sites between the ELR chains,[134,135] thus making them excellent candidates for biomedical applications. Sallach *et al.* have also developed a recombinant elastin-mimetic triblock copolymer in the absence of either chemical or ionic cross-linking that shows minimal inflammatory response and robust *in vivo* stability for periods exceeding 1 year. This example demonstrates the high and extraordinary biocompatibility of ELRs. These triblock copolymers could also be used as structural components of artificial organs and engineered living tissues, as carriers for controlled drug release, or as biocompatible surface coatings.[136]

2.218.2.5.2. Functionalized surfaces

One of the most active research areas in the field of materials science concerns the control and modification of surfaces and interfaces, also known as surface engineering.[102,103,137] The surface can be functionalized with fouling/antifouling properties, specific groups to promote cell material interactions, smart behavior (stimuli responsive or environmentally sensitive), or with micro- or nanopatterns.

Surfaces modified with stimuli-responsive biopolymers change their physical and chemical properties in response to changes in the environment or under external stimuli. This advantage has been exploited in some smart surfaces covered with a chemically synthesized polymer that exhibits a lower critical solution temperature, especially poly(*N*-isopropylacrylamide) (pNIPAM) and its derivatives. A change in the environment causes such a surface to undergo a significant change in its bioactive properties, for instance, protein adsorption/desorption or cell or bacterial attachment/detachment.[138–141] For instance, Ozturk *et al.* have demonstrated recently that RGD-ELR adsorbed on micropatterned pNIPAM films is crucial to maintain the cell attachment in dynamic cell culturing. Thus, cell behavior was studied upon application of mechanical stress generated by changing the temperature to shrink and stretch pNIPAM films under *in vitro* conditions. This is a promising strategy to obtain smart cell carriers for bone formation.[142] The major disadvantage of this system is the nondegradability of pNIPAM, although it should be possible to resolve this problem by replacing it with an ELR-containing biodegradable sequences, such as that described by Girotti *et al.*[102,103]

ELRs have some additional advantages that make them excellent candidates for the development of smart surfaces, especially the fact that they can be obtained by recombinant technologies, thus enabling a close control of their sequence, length, and stereochemistry. This allows, among others, a nanometer level of control of the position where functionality is located along the polypeptide chain and leads to a tremendous potential for the self-assembling and other advanced functionalities displayed by these systems.

Chilkoti's group has also created what they refer to as the 'thermodynamically reversible addressing of proteins' (TRAP),[137,143] where an ELR is covalently micropatterned onto a glass surface against an inert background. This TRAP technology enables the reversible, spatial–temporal modulation of protein binding at the solid–liquid interface and can be applied in different systems for bioanalytical applications, such as protein-based microsensors for detecting single biomolecules. The adhesion of other binding proteins coupled to designed polypeptides on solid surface has also been reported.[144] Along similar lines, a novel protein for controlling cellular functions has been constructed by combining the RGD sequence, epidermal growth factor (EGF), and a hydrophobic sequence into a single molecule. This protein was found to have both cell-adhesive and growth factor activity, while its hydrophobic sequence contributed to assembly of the RGD and retention of its activity on a solid-phase surface. This fusion protein could therefore prove to be of use for wound healing and tissue regeneration.[145]

A novel temperature-responsive culture surface, consisting of a cell sheet harvested from a culture dish, that exploits the stimuli-responsive characteristics of ELRs has been developed. This technique involves changing the temperature once the cells have become confluent in order to reverse the coaggregation. The cells are then detached from the culture dish as a single sheet and subsequently transferred to new surfaces, thereby suggesting the potential of this approach for the fabrication of multilayer cell sheets.[87] Na *et al.* have also taken advantage of the rapid response of a smart material surface created by adsorption of ELRs to external stimuli for use in cell-based biochips. The smart transition of ELR micropatterns between a hydrophobic and hydrophilic surface glass at T_t enabled these authors to control the reversible cell adhesion by way of the incubation temperature.[146]

Another simple technique commonly used in the field of ELRs is the layer-by-layer deposition of alternating ELR–polyelectrolytes, which is a simple technique for generating bioactive surfaces.[147] In this way, cells were cultured on multilayer substrates formed by depositing alternating layers of ELR and a polyelectrolyte to show that the thickness and the mechanical integrity of the multilayer substratum are important to regulating cell proliferation and formation of focal

adhesions.[147] Costa *et al.*[118] have also developed thermoresponsive thin coatings by electrostatic self-assembly (ESA), which involves simple deposition of an ELR containing the cell-attachment sequence RGD from an aqueous solution onto chitosan surfaces. The thermoresponsive behavior of these coatings can be exploited for tunable cell adhesion and controlled protein adsorption by nanoscale surface tailoring.[118]

The chemical functionalization of ELRs has also been used in biomimetic surface modification strategies to obtain metallic (commercial pure titanium, Cp Ti) dental implants with osteostimulative capabilities. A simple process using silane chemistry has been shown to be specific, rapid, and reliable for the covalent immobilization of biomolecules on the Cp Ti surface to obtain mechanically and thermochemically stable ELR-containing coatings.[148]

2.218.2.5.3. Fibers

The ability to generate micro/nanoscale fibers from synthetic and natural polymers has been improved by electrospinning.[149,150] This technique generates an electrically charged jet of the polymer solution, which dries to leave a polymer nanofiber network containing fibers with diameters ranging from a few micrometers to less than a hundred nanometers, depending on processing parameters such as polymer concentration and viscosity, flow rate, and applied voltage, among others.[151] The ability to vary the fiber size in the nanometer range opens up the possibility of mimicking the size scale of fibrous proteins found in the natural extracellular matrix. Thus, electrospinning techniques were employed to produce fibers with different morphologies (beaded fibers, thin filaments, and broad ribbon-like structures) in a form that mimics the diameter of native elastin utilizing a genetically engineered ELR,[152] and as in other ELR constructions, the inclusion of specific biofunctionalities may provide a wide range of possibilities.

Recently, and continuing with the theme of nanofiber architecture formation, core–shell nanostructures of CdSe nanoparticles with a shell of ELRs have been used as building blocks to fabricate functional 1D nanostructures. The ELR stabilizes the CdSe nanoparticles in an aqueous medium and controls their nucleation, growth, and spatial distribution, thus leading to the self-assembly of core–shell building blocks into fibril architectures. Moreover, in presence of ELR the material is potentially noncytotoxic; thus, these types of nanofibers could find future applications in fields such as medical nanotechnology and the diagnosis and treatment of various diseases.[153]

2.218.2.5.4. Drug delivery

When traditional oral or injectable drug formulations cannot be used, controlled drug delivery can be an important factor. A wide range of materials have been employed to control the release of drugs and other active agents, although polymeric systems are the most common because of their desirable physical properties.[154] Here, ELRs display several properties that can be useful for drug-delivery purposes, including precise control over size and sequence, smart behavior, self-assembly, biocompatibility, biodegradability, and monodisperse character, parameters that are critical to tune the pharmacokinetics of polymers. The genetic engineering of ELRs permits the incorporation of targeting peptides, such as cell-penetrating domains[155–157] or receptor ligands, and the introduction of reactive sites for chemical conjugation of drugs[158] or fluorescent probes[159] into the ELR sequences. ELRs can also be designed to self-assemble in response to an extrinsic temperature stimulus for applications such as soluble macromolecular carriers that can be used for the systemic delivery of antitumor agents or the local delivery of therapeutics directly to the tumor.[84]

The first ELR-based drug-delivery systems were reported by Urry. These systems were quite simple devices in which γ-radiated cross-linked poly(VPGVG) hydrogels were loaded with the model water-soluble drug (Biebrich Scarlet), which was then released by diffusion. Additionally, the introduction of various chemical functions along the polymer chain led to enhanced performance and release efficiency.[160]

In a different example, the ability of some ELRs, to form stable, drug-loaded, nano- and microparticles has facilitated the development of injectable systems for controlled release.[161] The drug is entrapped in these nano- and microparticles when the particles self-assemble as the temperature is raised above T_t and then it is released. Thus, the production of self-assembled nanoparticles for the combined release of bone morphogenetic protein-2 (BMP-2) and bone morphogenetic protein-14 (BMP-14) by exploiting the ITT of the poly(VPAVG) in a period of 14 days has been reported to show significant potential for future bone tissue-engineering applications.[162] More recent studies showed a hysteresis behavior in this polymer, with thermal absorption/release of components depending on the salt concentration of the polymer solution.[162]

The ability to control the ELR aggregation both *in vivo* and *in vitro* opens the way to a series of advanced medical applications, such as hyperthermia-induced localized extravascular drug accumulation, drug depot formation, and the design of novel materials suitable for tissue repair or engineering. For example, ELRs specially designed for targeted intracellular drug delivery have been produced by taking advantage of the soluble–insoluble transition of ELRs to target a solid tumor by local hyperthermia.[79,80,163] This mild hyperthermia-assisted approach to enhancing the accumulation of thermally responsive polymer carriers in tumors following systemic delivery has been demonstrated by Dreher *et al.*[159] Besides, this drug-delivery system could serve as an alternative to fusogenic peptides in gene-therapy formulations and to enhance the intracellular delivery of protein therapeutics that function in the cytoplasm.[79,80,135,164]

Continuing with this idea, but following a different strategy that involves enhancing the complexity of ELRs, a simple ELR-fusion form of the cell-penetrating Tat peptide (derived from the HIV-1 Tat protein) has been developed with an antimetastatic potential in an experimental ovarian cancer metastasis model *in vivo*.[165] By adding the L12 peptide (lactoferrin-derived peptide) to the previous construction, it was able to overcome several obstacles that commonly thwart drug development, including poor pharmacokinetics and systemic toxicity. These conjugates are therefore promising candidates for future *in vivo* studies because of their degree of selectivity in inducing cancer cell inhibition under hyperthermal conditions.[166] Other ELR fusions have been developed such as Bac-ELR1-p21, being promising macromolecular carriers for the delivery of cell cycle inhibitory peptides to solid tumors.[165]

Electrospraying, which is a versatile, efficient, and flexible technique, has also been used to generate nanoscale

bioresponsive peptide-based particles of defined morphology that can encapsulate drugs, such as in the preparation of ELR particles that contain the chemotherapy agent doxorubicin.[163,167]

Polymer vesicles and micelles have recently received an increasing amount of attention as potential carriers for hydrophobic drugs or genes. ELR-based block copolymers can be tailor-made to form smart, self-assembling, protein-like micellar systems with controlled structure and function. Chilkoti *et al.*, for instance, have focused on the potential therapeutic application of heat-triggered, reversible ELR-containing micelles.[168] Similarly, Dreher *et al.* have utilized ELRs in a linear diblock architecture with an N-terminal peptide ligand to form multivalent spherical micelles when heated slightly above body temperature. The critical micelle temperature is controlled by the length of the hydrophobic block, and the size of the micelle is controlled by both the total ELR length and hydrophilic-to-hydrophobic ratio. This study also identified a subset of elastin-like block co-recombinamers that could be useful for drug targeting by thermally triggered multivalency.[169] Recently, Kim *et al.*[170] have developed stabilized nanoparticles through the use of disulfide cross-linking between two amphiphilic diblock polypeptides modified with cysteine residues incorporated at the core–shell interface that could be stable under complex, physiological conditions. Most of these studies involve diblocks, although there are also some examples based on triblocks, including one where a reversible change in micelle compacticity is triggered by a helix-to-sheet protein folding transition upon raising the temperature above T_t.[171] Moreover, it has been shown that these triblocks, which can be produced in the absence of either chemical or ionic cross-linking, show minimal inflammatory response and robust *in vivo* stability for periods exceeding 1 year.[136]

As a further example, the 'one-pot' synthesis of pH- and temperature-sensitive gold clusters mediated by an ELR has been reported recently by some of the authors. This ELR promoted the formation of 2D linear arrangements of gold clusters with interparticle distances ranging from 10 to 40 nm. Furthermore, the gold–biopolymer hybrid displayed spectroscopic properties (UV–vis absorption) that could be modulated by varying the pH and temperature of the environment as a result of reversible aggregation and expansion of gold particles.[172]

In a subsequent step, Álvarez-Rodríguez *et al.*[173] have explored the use of cyclodextrins and the formation of alkanethiol mixed monolayers over the previously described hybrid ELR in order to decouple the photoisomerization of azobenzene from the bulk phase absorption. If they can be tuned to work under physiological conditions, these smart gold–ELR hybrids could be interesting for the development of multistimuli biosensors and drug-delivery applications.

2.218.2.5.5. ELR-fusion constructions

A great amount of ELR-fusion construction has been demonstrated during the writing of this manuscript in different applications. The emergence of the genetic engineering of ELRs has permitted the incorporation of targeting peptides, such as cell-penetrating domains,[155–157] growth factors,[145] proteases sequences[133] or receptor ligands, and the introduction of reactive sites for chemical conjugation of drugs[158] or fluorescent probes[159] into the ELR sequences.

However, in the last few years, the most acclaimed applications of the ELR-fusion constructions have resulted in an improvement in the recovery and purification efficiency of fusion proteins, an alternative to conventional chromatography methods approaching the thermal phase transitions of this type of polymer. Although chromatography-based protein purification methods yield proteins of high purity, they also have several drawbacks that limit their industrial scale-up, including their high cost, and specialized equipment.[108]

The temperature-dependent, reversible aggregation of ELRs provides a novel means to avoid this cost-intensive affinity chromatography by one of several strategies, including direct ELR tagging by simple ELR-based protein purification or ELR coaggregation and purification by ELR-mediated affinity capture. In the first case, cleavage of the ELR moiety from the fusion protein by treatment with specific proteases could raise cost issues for large-scale protein production and could also result in some of the problems inherent to protein recovery using conventional chromatographic procedures mentioned above. However, a combination of ELR and intein technology, which is designed to induce self-cleavage, eliminates the need for postpurification enzymatic or chemical cleavage of the ELRs. In the second case, namely, ELR-mediated affinity capture, the ELR can bind the fusion protein specifically and reversibly, thereby eliminating the need for postpurification enzymatic or chemical cleavage and possibly allowing reuse of the ELR-capture molecule.[174] In this regard, Araújo *et al.*[175] have reported the microbial production of a functionalized high molecular weight subtilisin for controlled enzymatic hydrolysis of wool surface whose activity was successfully restricted to the cuticle of wool, thereby allowing a significant reduction in pilling, weight loss, and loss of tensile strength of the wool fibers.

Another novel approach is a new platform known as ELR-mediated affinity capture, EMAC, which has been proposed to improve antibody purification. The main advantage of this new platform is its universality as it does not require the construction of a fusion protein for each individual antibody of interest, and involves the construction of a fusion protein in which the ELR is joined to an antibody-binding domain. Selective affinity interaction between the antibody and the antibody-binding domain allows recovery of the antibody after triggering the transition of the ELR.[176]

2.218.2.6. Outlook

The wide spectrum of biomedical and biotechnological applications in tissue engineering, surface engineering, drug delivery, and protein purification are some examples of the enormous potential of these versatile materials due to their numerous advantages, superior properties, and unconventional features with respect to any other polymer family. Here, we have attempted to highlight the enormous potential of genetic engineering for producing highly complex functional polymers characterized by extreme biocompatibility, smart and self-assembling characteristics, and programmed biodegradation providing them a huge potential for this wide range of applications in many different fields. Moreover,

these recombinamers have a monodisperse character and are obtained with a precise sequence and molecular weight, which makes them highly valuable as biomaterials.

However, these polymers are still far from reaching their full potential. It is therefore reasonable to expect that the near future will bring new recombinamers with widely diverse functionalities, which will establish a new standard in polymer function and, perhaps, a clear quantitative and qualitative leap that will contrast with the current slow but nevertheless continual development of polymer-based innovation, along with encouraging applications.

2.218.3. Animal-Derived Solubilized Elastin

2.218.3.1. Introduction

Solubilized elastin is equivalent to partly hydrolyzed elastin, and can also be referred to as elastin peptides, although the latter term is not confined to solubilized elastin alone. Peptide bonds of the insoluble elastin are hydrolyzed, thereby fragmenting the insoluble elastin and reducing its molecular weight.

Solubilized elastin can – as does tropoelastin – signal through the elastin–laminin receptor.[177] Elastin synthesis,[178] chemotaxis,[179] and proliferation of fibroblasts,[180] keratinocytes,[181] and smooth muscle cells[182] are examples of effects of (solubilized) elastin mediated by this receptor. These are important effects that may guide cells in a biomaterial construct in a certain direction. More elastin–laminin receptor-related effects can be found in other reviews.[183,184]

2.218.3.2. Types of Solubilized Elastin

2.218.3.2.1. α- and β-elastin

The most commonly used method to hydrolyze insoluble elastin is treatment with 0.25 M oxalic acid at 100 °C. The produced solubilized elastin preparation can be coacervated in 10 mM sodium acetate with 10 mM NaCl (set to pH 5.5 with acetic acid) at 37 °C. After centrifugation, two fractions will appear: α-elastin as the viscous coacervate with an average molecular weight of 60 kDa, and β-elastin in the supernatant with an average molecular weight of 3–10 kDa.[185,186]

2.218.3.2.2. κ-elastin

Another widely applied solubilized elastin is prepared by treatment with 1 M potassium hydroxide in 80% (w/v) ethanol at 37 °C. The elastin solubilized with KOH is called κ-elastin and is a heterogeneous mixture of elastin peptides with a mean molecular mass of approximately 70 kDa, soluble in aqueous solutions.[187]

2.218.3.2.3. Enzymatically solubilized elastin

Insoluble elastin can also be enzymatically digested with proteolytic enzymes that are able to degrade the elastin, mostly the elastases like serine-type elastases from neutrophils and pancreas and metalloelastases, for example, matrix metalloproteinase 12 (MMP12) of monocyte/macrophage origin.[183]

In one of these solubilization methods, human neutrophil elastase was used to digest elastin in PBS (pH 8.0) at 37 °C for 24 h, followed by centrifugation to remove remaining insoluble aortic elastin. The enzyme was subsequently removed by affinity chromatography for over 99%.[179] In another method, elastin was solubilized with porcine pancreatic elastase in 0.1% (w/v) ammonium bicarbonate, pH 7.8. After a 24 h incubation at 37 °C, over 90% of the elastase activity in the starting reaction mixture was removed by multiple affinity absorptions with coarse-mesh elastin and separation of the digested elastin from the insoluble elastin by centrifugation.[188] When using MMP12 on a larger scale, usually (the catalytic domain of) recombinant human MMP12 is used.[189]

2.218.3.3. Biomaterials Containing Animal-Derived Solubilized Elastin

Solubilized elastin has been employed in biomaterials as a component of porous scaffolds, as hydrogels, as (electrospun) tubes, and as coatings to materials. We will further introduce the various biomaterials by their stage of research, that is, *in vitro* experimentation including biomaterial preparation and cell culture experiments (see 2.218.3.4), *in vivo* experimentation using animal models (see 2.218.3.5), and clinical application (see 2.218.3.6).

2.218.3.4. *In Vitro* Experiments

Early biomaterials containing solubilized elastin were made by Rabaud and coworkers and included a matrix with collagen and κ-elastin,[190,191] a collagen matrix with κ-elastin and heparan sulfate or hyaluronic acid,[192] and a collagen matrix with κ-elastin and calcium phosphate.[193] Some of these biomaterials, including type I + III collagen containing κ-elastin, were tested in animal models, for example, for its use as a tympanic membrane.[194]

In 2005, solid disks from α-elastin were prepared by polymerizing coacervated elastin with a diepoxy cross-linker. By influencing the degree of cross-linking, the elastic modulus could be modified to some extent. Although vascular smooth muscle cells could adhere to the disks, proliferation capacity was decreased.[195] However, succeeding publications on these elastin disks are sparse.

Elastin hydrogels were prepared from α-elastin by mixing with GA, directly followed by pipetting the mixture into a Teflon mold (without and with high pressure CO_2) and leaving the material at 37 °C for 15 min to 24 h. Cross-linked hydrogels were washed with water and quenched with a Tris-based buffer. Increased pressure resulted in an increased swelling rate of the hydrogel and substantially increased pore interconnectivity together with a reduction in wall thickness and pore size.[16,17] In a preceding study, high pressure CO_2 was seen to impede the coacervation of an α-elastin solution.[196] Elastin-based hybrid gels were made using 50% tropoelastin and 50% α-elastin blends by the same procedure to introduce more lysine residues for cross-linking and to increase mechanical integrity. It indeed enhanced the mechanical properties, that is, compressive modulus 6-fold, elastic modulus 2.5-fold, and stress at break 2-fold, as compared to hydrogels without tropoelastin.[18] In a similar setup, but using another cross-linker (hexamethylene diisocyanate, HMDI), high pressure CO_2 also increased pore size and swelling ratio, which

stimulated the penetration and proliferation of fibroblasts through the hydrogels.[16,17]

2.218.3.4.1. Blends with natural materials

Next to biomaterials which are made solely out of elastin, blends with natural materials are often used to create an artificial extracellular matrix. A set of 48 fully characterized biomaterials based on collagen, insoluble elastin, α-elastin, and GAGs was screened by Lammers *et al.*[197] for stimulating proliferation of human primary keratinocytes. Scaffolds consisting of 80% collagen and 20% α-elastin induced proliferation, but further analysis revealed that proliferating cells were mainly of fibroblast morphology. Especially, scaffolds containing insoluble elastin fibers (80% collagen and 20% elastin fibers, and to less extent 50% collagen and 50% elastin fibers) increased keratinocyte proliferation, but not fibroblast proliferation.

Rat tail tendon collagen with κ-elastin (90–10%) was used to prepare biomaterial films. The κ-elastin component mainly functioned as an inductor of thermal cross-linking for collagen after treatment at 60 °C.[198]

Other elastic biomaterials were made from oxalic acid-solubilized elastin and combined with silk fibroin and/or hyaluronan with chemically introduced amine groups.[199] Starting from a 25% (w/v) solubilized elastin solution, 0–2.3% (w/v) hyaluronan, and 0–5.8% (w/v) silk fibroin were introduced followed by BS3 cross-linking. Using different contents, Young's moduli could be varied from 100 to 230 kPa and strain to failure from 15 to 40%, whereas ultimate tensile strengths were generally 30 kPa (higher for elastin only, 50 kPa). These materials sustained proliferation of human primary smooth muscle cells, but cell morphology differed on various materials, that is, isolated cells on elastin only, stretched cells that formed a network on elastin/hyaluronan, and cluster-forming cells on elastin/silk fibroin.

Miyamoto used specific fractions of oxalic acid-solubilized elastin for electrospinning in the presence of the new cross-linker 4-hydroxyphenyldimethylsulfoniummethylsulfate (DSP)-activated ester, and the oxalic acid-solubilized elastin isotype that formed fibers promoted by differentiation of vascular smooth muscle cells while suppressing the proliferative capacity.[200]

Matriderm is a clinically applied collagen scaffold containing 3% α-elastin (also see **Section 2.218.3.6**). In 2006, Matriderm was used as a scaffold for the cultivation of porcine primary chondrocytes, and cells not only maintained their proliferative capacity, but also showed improved differentiation as type II collagen synthesis was increased, even in the absence of a differentiation medium.[201] Specific follow-ups on this work are sparse in the literature.

Matriderm has also been used as a transport carrier system to transfer proliferating epidermal cells to human dermis *in vitro*,[202] for simultaneous culture of human keratinocytes and human preadipocytes,[203] and as a substrate to culture pancreatic stem cells *in vitro*.[204]

2.218.3.4.2. Blends with polymers

Electrospinning is often applied in combination with polymers, especially in the preparation of vascular tubes. Examples of these are described here. An electrospun bilayer scaffold composed of gelatine, elastin, PCL, and poliglecaprone (a copolymer of glycolide and ε-caprolactone) was used to construct a Ø 4-mm porous tubular graft,[205,206] which promoted human aortic endothelial cell proliferation and was functional as cells were able to form tight junctions and secrete prostacyclin.[205,206]

A no further specified soluble elastin from the Elastin Products Company was used to prepare polydioxanon–elastin Ø 6-mm tubes with different blending ratios in order to meet the mechanics of the native vessel.[45] Suture reinforced electrospun polydioxanon–elastin Ø 1.5-mm tubes were cross-linked with 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC), GA vapor (at both 100 and 25 °C for 30 min and 1 h, respectively), or ethylene–diglycidyl ether (EGDE), but only EDC (45% cross-linking) and heated GA (17% cross-linking) tubes did not dissolve upon wetting.[207] The EDC-cross-linked tubes had burst pressures ten times higher than normal systolic pressures with a range of compliances, including those matching the native artery.

A three-layered PCL-soluble elastin-collagen electrospun matrix was made to further mimic the structure of the native artery, with an intimal layer (98-2-0 blend), medial layer (45-45-10; 55-35-10; 65-25-10 blends), and adventitial layer (70-0-30 blend).[208]

The copolymer of glycolide with trimethylene carbonate (TMC), known as Maxon, was used in combination with gelatin and elastin to prepare tubes for vascular grafts. A triple-layered tubular scaffold was prepared by sequential electrospinning of the blend.[47]

Combinations with polymers also include the coatings for vascular grafts. Dutoya *et al.*[209] also coated a layer of κ-elastin without (0.4–2 μm) and with (3 μm) insoluble elastin onto polyethylene terephthalate (PET).[209] The elastin–κ-elastin–PET biomaterial promoted endothelial cells growth while maintaining their phenotype. Such a biomaterial could eventually function as a small-caliber vascular prosthesis, but reports of an announced implantation at the abdominal femoral junction in a dog model were not found in the literature. In another study, coacervated α-elastin was coated onto Dacron vascular grafts, which resulted in an inhibition of smooth muscle cell migration without an effect on endothelial cell motility. Such a coating may therefore prevent intimal hyperplasia.[210]

2.218.3.5. *In Vivo* Experiments

Matriderm (collagen-solubilized elastin scaffold) was directly compared to Integra (collagen–chondroitin sulfate scaffold) in immune-incompetent rats.[211] A two-stage setup was used and the time between scaffold implantation and epidermal transplantation was either 1 or 2 weeks. No differences were found in epidermal graft take, vascularization, and neodermal regeneration. In order to make a good comparison, both scaffolds were used as 2-mm thick constructs, which means that the thickness of Matriderm was double that of those used in other studies, making it difficult to compare with other Matriderm studies.

Ring *et al.* used Matriderm to which a glow discharge technique was applied, a method more generally applied to

polymer surfaces. When applied to full-thickness grafts in balb/c mice, accelerated neovascularization was observed.[212]

Carbodiimide cross-linked scaffolds composed of 50% insoluble collagen and 50% oxalic acid-solubilized elastin induced angiogenesis and showed synthesis of small elastic fibers, as shown with antibodies against rat elastin and rat fibrillin-1. Rat fibrillin-2, however, mainly colocalized with elastin blood vessels.[213] Please note that the solubilized elastin was prepared by oxalic acid solubilization and was not coacervated but filtrated in centrifugal filter tubes. The resulting solubilized elastin had an isoelectric point of 6 and a mean molecular weight of 1100 kDa, much larger than the expected 60 kDa for α-elastin.[214] Nillesen *et al.*[215] used the same solubilized elastin preparation to create an acellular full-thickness skin graft. The dual-layered skin graft was composed of a dermal porous part composed of 80% collagen and 20% solubilized elastin, which was then chemically cross-linked by a carbodiimide in the presence of the GAGs dermatan sulfate and heparin (3:1) and the growth factors vascular endothelial growth factor (VEGF) and fibroblast growth factor 2 (FGF2); the epidermal layer was composed of a dense structure of collagen cross-linked with heparin and containing fibroblast growth factor 7 (FGF7 or keratinocyte growth factor). Both layers were attached to each other using a collagen suspension, frozen and lyophilized. The construct was both biochemically and structurally characterized and used as an acellular full-thickness skin graft in a rat wound model where it was compared to the commercially available Integra dermal regeneration template and untreated wounds. At early time points, the double-layered skin construct showed more cell influx, significantly less contraction, and increased blood vessel formation. At the latest time point (day 112), it showed more elastic fibers than both other groups. Strikingly, structures resembling hair follicles and sebaceous glands were found in the double-layered skin construct and the untreated wound, but these were scarce in the Integra-treated wound. Lammers *et al.*[216] used the explants from the double-layered skin construct and the untreated wounds to run high-density gene expression microarrays and studied the biological processes in an unbiased manner using gene ontology (GO) analysis with the freely available program DAVID. They showed that microarray analysis is a promising tool that can be used complementarily to other methods like histology. However, the method is still in its infancy as for this rat study not all genes were annotated, GO terms were not well defined, and not all genes that belonged to a certain biological process were incorporated. This may explain why not all processes that were observed by histology, for example, elastic fiber development, were picked up in the GO analysis.

2.218.3.6. Clinical Applications

To our knowledge, Matriderm is the only clinically applied biomaterial that contains solubilized elastin. Matriderm is a 1-mm thick matrix made of porous insoluble collagen scaffold obtained by washing bovine skin (containing type I, III, and IV collagen) which is then coated with 3% oxalic acid-solubilized elastin obtained by hydrolysis of bovine nuchal ligament. The scaffold is cryogenically cross-linked and sterilized by gamma irradiation.[217–219]

Matriderm has been used as a dermal graft in clinical trials, and can be used either in a one or two-stage grafting procedure. This means that an epidermal (split skin) graft can be applied at the same time as applying the collagen–elastin matrix (one-stage) or some time (usually 2–3 weeks) after introducing the collagen–elastin matrix (two-stage). One-stage grafting is of course favored when it does not negatively influence the outcome of grafting. For Integra, only two-stage grafting is indicated, and time is needed to let the collagen–chondroitin sulfate (nonelastin) matrix be vascularized to allow a good epidermal graft take.[220]

In an early clinical trial concerning an intraindividual comparison study, the number of regrafting procedures was similar when using Matriderm with split skin in a one-stage procedure compared to split skin alone. When followed up on the short term, skin elasticity was considerably improved by Matriderm as analyzed by cutometer measurements,[221] but after 1 year, this difference was no longer statistically significant.[222] In a 12-year follow-up of this study, an objective scar assessment was performed and patients treated with Matriderm generally showed more improved scar parameters than patients treated with the epidermal graft alone. Examples of this are that scars treated with Matriderm and a largely expanded meshed skin graft were significantly more elastic and that a specific surface roughness parameter was significantly improved in Matriderm-treated reconstructed scars. In addition, pliability, relief, and the general observer score were better in acute and reconstructive burn scars which were initially treated with the collagen–elastin matrix.[223]

Ryssel *et al.* also intraindividually compared Matriderm with a split-thickness skin graft (one-stage procedure) to split-thickness skin graft alone in burn patients. In one study, results from ten burn patients showed a similar take and number of regrafting procedures, with improved elasticity for the Matriderm group.[224] In another study from 18 patients with hand burns, after 6 months a significantly improved range of motion was observed as well as a significantly better skin quality.[225] Ryssel *et al.*[219] also used Matriderm with split-thickness skin graft in one step after high voltage injuries (nine patients) and necrotizing fasciitis defects (five patients),[226] complex cases that often need to cover exposed bone and tendon, and saw promising results. Clinical comparative studies for treatment in these cases still need to be performed.

Generally, most studies have not used (in-patient) comparative studies. In one clinical study, Matriderm was applied after severe burn injuries of the hand in a one-stage procedure in ten patients which resulted in good take of the split-thickness skin graft. After 3 months, excellent pliability and full range of motion were observed.[217] After 12 months, scars showed good pliability and height and a well-established hand and wrist motion function. Also critical care patients, for example, patients with burns that covered a large percentage of the total body surface area, showed good results.[227] Improved cosmetics, facial contour, texture, and expression were found 4 months after treatment of a patient with a full-thickness chemical burn to almost all of the face with Matriderm and a homogenous graft.[228] Other case studies include the use of Matriderm in a breast reconstruction,[229] in the covering of exposed Achilles tendon secondary to burn injury,[230] and the surgical treatment of diabetic ulcers,[231] all with satisfying results.

The use of the collagen–elastin matrix looks highly auspicious, but so far few studies have made a direct comparison between Matriderm treatment and current treatments. Only such direct comparisons can persuade clinicians to explicitly choose a dermal matrix in specific one-stage grafting procedures.

2.218.3.7. Future Directions

Biomaterials containing solubilized elastin have been mainly used in skin (dermal substitute) and cardiovascular applications (small diameter blood vessel or coating of stents). Because of the wide range of cells that are capable of responding to solubilized elastin, because they carry the elastin–laminin receptor, its biological function can be exploited much more in biomaterials. Examples of effects of solubilized elastin that may be utilized are its function as a protector from ischemia by binding to S-Gal,[232] its capacity as a cell-surviving factor antagonizing apoptosis,[233] and its role as an inhibitor of platelet aggregation.[234]

Glossary

Amphipathic Containing polar and nonpolar regions.
Amyloidosis Disease resulting from abnormal deposition of amyloid.
CMC Critical micelle concentration, minimum phospholipid concentration that forms micelles in water.
Cross-β conformation β-sheet secondary protein structure with parallel β-strands oriented perpendicular to the assembly axis.
Curli Extracellular bacterial amyloid used for surface adhesion and colony formation.
Lewy body Amyloid-containing inclusions found in neurons in the brain of Parkinson's patients.
Melanosome Mammalian cellular organelle containing melanin residing in skin and eye cells.
Micelle Around 5-nm-diameter spherical aggregate, formed from phospholipids in water above a characteristic concentration, the critical micelle concentration.
Neurodegenerative disease Disease characterized by progressive loss of functional neurons in the brain, like Parkinson's and Alzheimer's disease.
Oligomer Assembly of a limited number of identical monomers.
Pme117 A transmembrane protein that mediates the early steps in the formation of melanosomes.
Polymorphism The variety of morphologies exhibited by assemblies of identical subunits.
Protofibril Intermediate amyloid aggregation state between protofilament and mature fibril.
Protofilament Intermediate amyloid aggregation state between monomer and protofibril.
Raman spectroscopy Vibrational spectroscopy that yields insight into the secondary structure and chemical composition of a sample by measuring the intensity and spectral distribution of light emitted by a sample after excitation with high-intensity laser light.

2.219.1. Introduction

Insoluble amyloid fibrils self-assemble from a wide variety of proteins that are soluble under physiological conditions. In general, fibrillar amyloid nanostructures have typical diameters of around 10 nm, can grow to several micrometers in length, are extremely stable, and consist mainly of β-sheet folded protein in a typical hydrogen-bonded cross-β conformation (**Chapter 2.204, Peptoids: Synthesis, Characterization, and Nanostructures**). Amyloid formation has long been associated with disease. Besides neurodegenerative disorders, such as Alzheimer's, Parkinson's, Huntington's, and Creutzfeld–Jacob disease, other diseases such as type II diabetes and cardiovascular amyloidosis are also accompanied by the development of amyloid fibrils.[1] Amyloids have also gained more positive recognition since several functional amyloid-containing materials have been identified in nature, from bacteria to humans.[2] Examples are spider silk, biofilms formed from bacterial curli, fibrillar chorion proteins in insect egg shells,[3] and Pme117 fibers in human melanosomes.[4] Amyloid formation also plays an important role in the food industry, where food processing induces fibrillar aggregation of globular proteins, for instance, during heating.[5] In particular, there is a specific interest in the use of amyloid structures for optimization of food texture.

The extreme stability of amyloid fibrils, with a reported mechanical strength similar to polystyrene and nylon, has instigated the interest for use in novel bionanotechnological applications.[6,7] The fibrillar character is particularly interesting for fabrication of nanostructured scaffolds. The spontaneous self-assembly of specific proteins enables the formation of biomaterials with extraordinary characteristics. The proteinaceous nature offers the possibility of using the toolbox of molecular biology to specifically functionalize the fibrils with a variety of chemical or biological conjugation partners resulting in a biomaterial with unique biophysical and physicochemical properties. Compared to chemically synthesized materials, amyloid-based materials have advantageous qualities with respect to biocompatibility and biodegradability. Their versatility offers great potential for creative applications in bionanotechnology. An obvious possibility is the fabrication of nanophotonic or nanoelectronic devices from amyloid-based nanowires.[8,9]

Although protein aggregation in general has been studied extensively for many years, the mechanism of amyloid fibril formation has not been resolved. Full understanding of the assembly mechanism is however essential, not only for development of therapeutic means to fight hitherto incurable diseases but also for optimal utilization of amyloid as nanobiomaterials. To achieve these aims, a range of available biophysical approaches can be deployed that provide molecular level information on the structure of amyloid fibrils.

This chapter gives an overview of biophysical methods that we have applied to the amyloid-forming Parkinson disease (PD) related *α-synuclein* protein,[10,11] but may be considered as relevant for amyloids in general. We describe the revealed information with a focus on those aspects of amyloid formation that are most relevant for a better understanding of the aggregation mechanism, concurrently enhancing insights into the material properties of amyloids. The molecular level assembly process (in this case of α-synuclein) is reflected in characteristics of the monomeric protein and oligomeric folding intermediates, kinetics of fibril formation, fibrillar ultrastructure, and mechanical fibril properties (**Figure 1**).

We describe recent progress in the application of advanced biophysical methods such as (single-molecule) fluorescence spectroscopy, electron paramagnetic resonance (EPR) spectroscopy, circular dichroism (CD) spectroscopy, and atomic force

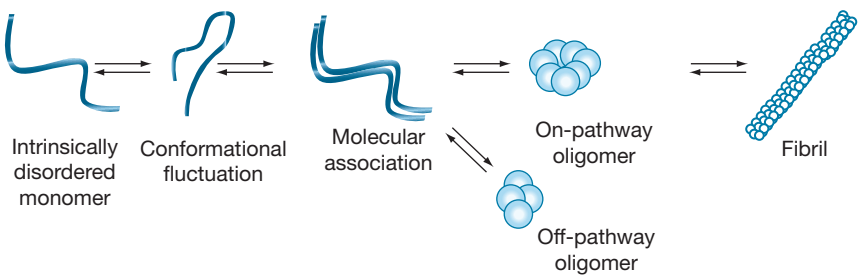

Figure 1 Schematic representation of the proposed amyloid formation mechanism for human α-synuclein.

microscopy (AFM) to study α-synuclein aggregation. This broad ensemble of approaches provides a deeper perspective into the fascinating research field of amyloids, both from a mechanistic and a materials perspective.

2.219.2. Monomer Folding

2.219.2.1. α-Synuclein Structural Heterogeneity

It has long been believed that protein stability and function are inevitably associated with proper folding into a characteristic three-dimensional conformation. In recent years, it has become apparent that there exist a large number of intrinsically disordered proteins, such as human α-synuclein, that are functional without having a structured conformation.[12] Both classes of proteins, structured and unstructured, are able to aggregate into amyloid fibrils, requiring partial unfolding of globular proteins or partial acquisition of structure by intrinsically disordered proteins, respectively.[13] The assembly of amyloid fibrils from protein monomers is believed to take place by a nucleation-dependent polymerization process. Partially folded/unfolded monomers may assemble to form oligomers of still unidentified size and conformation, possibly functioning as nuclei, followed by transformation into elongated protofibrillar structures and finally into mature fibrils.[1,14–16]

Human α-synuclein protein (**Figure 2**), a 140 residue intrinsically disordered protein, plays a central role in the etiology of PD,[10] and forms fibrillar aggregates that are found in Lewy bodies in the brain, structures which are the hallmark of the disease.[11,17,18] Three point mutations (A30P, A53T, and E46K) are associated with early onset PD.[19–21] Modifications such as phosphorylation of the serine residue at position 129, and truncations of the protein, are reported to play an important role in the toxicity of α-synuclein.[22–26]

The conformation of the intrinsically disordered protein α-synuclein is known to depend on the environment, binding to targets, and the aggregation state. Although its exact function remains obscure, α-synuclein has been associated with dopamine neurotransmission and regulation of the synaptic vesicular pool.[27] Furthermore, it has been suggested to act at the presynaptic membrane interface.[28] Free in solution, α-synuclein has random-coil-like conformations,[29] but on binding to negatively charged membranes α-helical structures dominate.[30,31] In the fibrillar state, a rigid cross-β structure is prominent,[32] likely lining up the fibril core. Obviously, the protein is structurally highly flexible, which may be fundamental to its putative biological function and implications for disease. The structural transition of the unstructured protein into β-sheet-rich fibrils may be initiated and driven by the occurrence of local structure in α-synuclein molecules. The transient nature, inherent heterogeneity, and low frequencies of occurrence of intramolecular fluctuations and intermolecular associations at physiological concentrations can be addressed only by advanced single-molecule spectroscopy approaches that can detect distributions of structures in ensembles.

Therefore, we and others have used *single-molecule confocal fluorescence microscopy* to study the flexibility and to map the 'structure' of individual α-synuclein monomers, both free in solution and upon binding to SDS (sodium dodecyl sulfate) molecules of monomeric or micellar nature.[33,34] The interaction with SDS is particularly interesting because of its resemblance to membrane components. Single-molecule techniques are specifically required to resolve the occurrence and characteristics of substructures within a population of protein monomers, information that is impossible to obtain from ensemble methods. We have used *single-molecule Förster resonance energy transfer* (SM-FRET) to investigate the structural architecture of α-synuclein.[34] FRET is a nonradiative transfer of the excitation energy from a donor to an acceptor chromophore that involves a distance-dependent interaction between the emission and the absorption transition dipole moments of the donor and acceptor, respectively.[35–37] The rate of energy transfer depends on the spectral overlap of the donor emission and acceptor absorbance, the donor fluorescence quantum yield, the relative orientation of their transition dipole moments, and the distance between donor and acceptor molecules. FRET efficiencies depend on the donor–acceptor separation distance with an inverse sixth power law. The Förster radius, the characteristic distance for a given donor–acceptor pair at which the energy transfer efficiency is 50%, is comparable to the size of biological macromolecules. Therefore, FRET is very useful for measuring distances between different sites on proteins.[38–40]

The N-terminal domain of the α-synuclein protein is known to be involved in membrane binding.[30] Using recombinant techniques, we have engineered a variant of α-synuclein with two cysteines in the putative membrane-binding domain (amino acids 9 and 69). These engineered cysteines act as molecular 'hooks,' and were specifically labeled with donor and acceptor dyes suitable for SM-FRET. FRET efficiency (E_{obs}) histograms of 100 pM Alexa Fluor 488 and Alexa Fluor 568 labeled α-synuclein-9C/69C at increasing concentrations of SDS are presented in **Figure 3**. Initially, without SDS, α-synuclein adopts conformations resulting in an E_{obs} centered at 0.54 (first panel, 0 mM, **Figure 3**).

At low SDS concentrations (up to ~0.5 mM), no apparent changes in the histograms were observed. However, upon

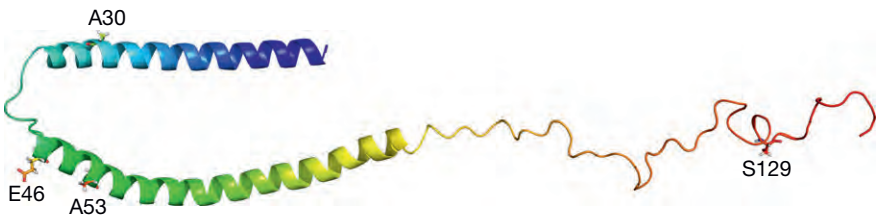

Figure 2 Representation of the α-synuclein protein indicating the Parkinson's disease-related mutation sites (A30P, E46K, and A53T) and the S129 phosphorylation site.

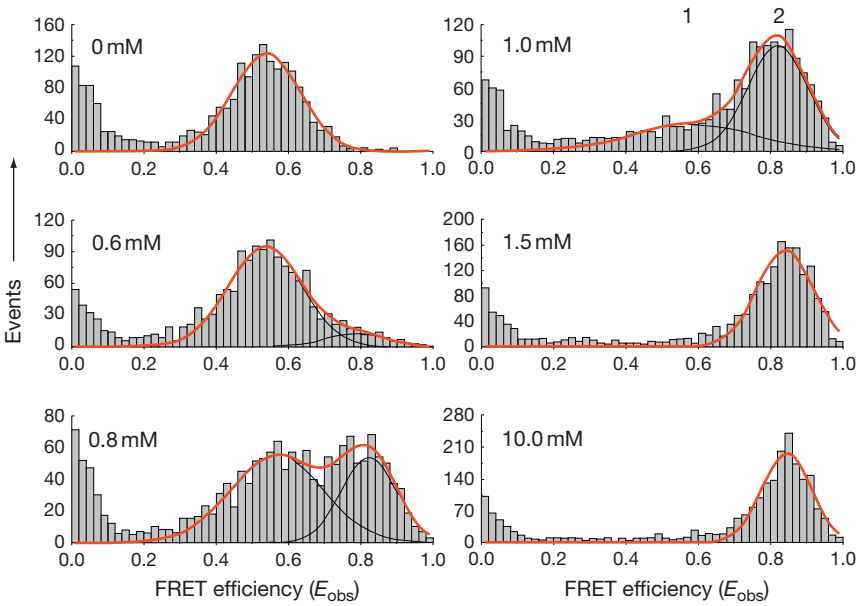

Figure 3 FRET efficiency histograms of α-synuclein-9C/69C as a function of SDS concentration. Solid lines indicate Gaussian fits to one or two populations (marked 1 and 2). Where applicable, individual Gaussians are shown.

increasing the SDS concentration from 0.5 to 1.0 mM, a clear second distribution centered at E_{obs} ~0.82 and of smaller width appeared (peak 2). The higher E_{obs}-value is indicative of a population of proteins where positions 9 and 69 are closer together, leading to increased FRET. The area of the first peak decreased concomitantly with the increase in area of the second peak, suggesting that SDS-induced structural changes in α-synuclein result in one or the other of the conformers, at least within the 1 ms time frame of the experiment. At even higher SDS concentrations (1.5–10.0 mM), the first distribution completely disappeared. Remarkably, above 1.5 mM SDS, although the mean value of the peak did not alter significantly, the width decreased further by ~15% (with an error in the full width half maximum (FWHM) below 5%). We attribute this narrowing of the distribution width to a further stabilization of the horseshoe structure as has been structurally resolved with NMR (nuclear magnetic resonance)[41] (see Figure 4).

We also used *CD spectroscopy* to assess the α-synuclein secondary structure content over the applied SDS concentration range. CD spectroscopy measures directly, without a need for additional labeling, the presence and abundance of specific secondary structures.[42] In CD spectroscopy, the differential absorbance of left- and right-circularly polarized light that is alternately radiated into a sample is detected. A CD spectrum is recorded by measuring this differential absorption as a function of wavelength. CD spectroscopy is mostly performed in the far-UV spectral region, where peptide bonds generate CD signals dependent on the environment. Thus, the CD signals are determined by the secondary structure of the protein and can even be used to semiquantitatively estimate the α-helix, β-sheet, and random-coil content.

CD measurements, with a five orders of magnitude higher protein concentration than that used in the SM-FRET experiments, revealed an increase in α-helix content that corresponded very well with the peak positions and relative areas

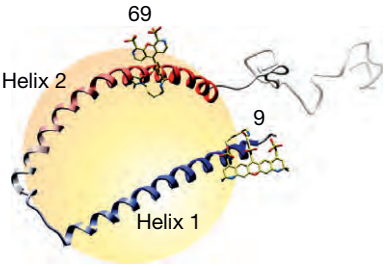

Figure 4 Representation of the horseshoe conformation of SDS micelle bound AF488 and AF568-labeled α-synuclein-9C/69C. Helix 1 and helix 2 indicate the two putative membrane-binding helices. The unstructured C-terminal tail is also shown.

determined from the FRET efficiency histograms (Figure 5). These data confirm previously reported SDS-induced structural alterations in wild-type α-synuclein.[43]

Taking into account the reported value of 62 Å for the Förster radius of the dye pair used and the mean E_{obs}-value at SDS concentrations >1.5 mM, the most frequently found distance between the two dyes in the SDS-bound state can be estimated at 45 Å. This value is higher than the 32 Å distance between amino acid positions 9 and 69 obtained from either NMR[41] or EPR.[44] One should keep in mind, however, that the labels have ~10 Å linkers between the maleimide and fluorophore moiety (Figure 4) and that the observed distance is the distance between the centers of the two fluorophores. As the exact orientation of the dyes with respect to α-synuclein bound to the SDS micelle is not known, it is in this case not possible to translate the observed distance to exact topological distance information within the α-synuclein molecule.

It has been shown that α-synuclein in solution does not behave as a fully random-coil protein; apparently it contains

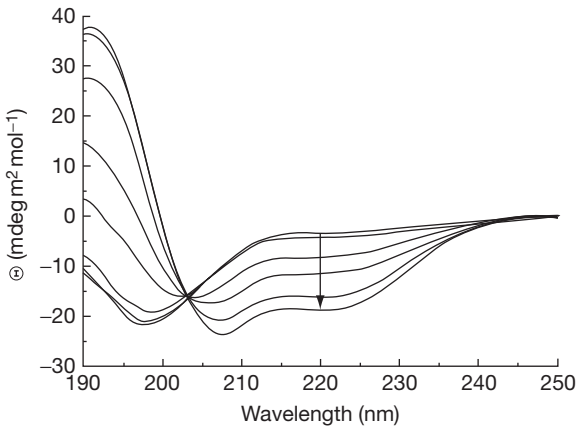

Figure 5 Structural changes in α-synuclein-9C/69C (unlabeled) induced by increasing concentrations of SDS measured with far-UV circular dichroism. The arrow indicates increasing concentrations of SDS and an increase of α-helix content.

some residual structure in the polypeptide chain.[30,45] The rather wide distributions of the histograms found for free α-synuclein in solution could point to the presence of residual structure within α-synuclein. However, care should be taken in interpreting the distribution widths as they are highly dependent on the timescale of chain motions relative to the observation time of each molecule.[46–50] The apparent broadening (an increase in the FWHM of 35%) of the low FRET peak in the histograms at SDS concentrations up to at least 0.8 mM could point to an increased heterogeneity and/or altered flexibility within this population caused by binding of SDS monomers to the polypeptide chain. However, the broadening could also arise from slower conformer interconversion or chain stiffening caused by SDS binding, especially as the average E_{obs}-value did not shift. Although techniques resolving faster timescales will be necessary to elucidate the detailed mechanism, the observed broadening does indicate dynamic structural alterations within α-synuclein, potentially induced by selective SDS binding.

The α-synuclein protein, with its amphipathic motif in the N-terminal region,[29] has been shown to adopt a horseshoe-like structure upon binding to SDS micelles[41] (see **Section 2.219.2.2**) and large unilamellar vesicles (LUVs).[44] Upon closer inspection of our data, we observe that the appearance of peak 2 in SM-FRET occurs just at the onset of α-helix formation measured with CD. This observation is a strong indication that peak 2 contains the conformers with high α-helical content, while peak 1 represents largely unstructured conformers. Furthermore, peak 2 very likely represents the horseshoe conformation,[41] as judged from the high mean E_{obs} and the width corresponding to the state bound to fully formed micelles at much higher SDS concentrations.

The existence of two peaks within the narrow SDS concentration regime (~0.5–1.0 mM) suggests that α-synuclein is able to adopt metastable structures via some sort of all-or-none mechanism for structural rearrangement (on the timescale of the experiment). Even more surprising is that these transitions occur below the CMC (critical micelle concentration) of SDS (6.5 mM at our experimental conditions), as has been reported before.[43] We hypothesize that α-synuclein may locally induce micelle formation at such low amounts that it is not detectable. Interestingly, tryptophan (Trp) residues engineered at positions 9 and 69, probing local polarity, also displayed a dependence on the SDS concentration. However, the blue shifts of the Trp fluorescence approached their maxima already at ~0.6 mM SDS, just at the onset of α-helix formation measured with CD and the appearance of peak 2 in SM-FRET. Thus, below the apparent CMC of SDS, Trps report apolar environments very likely arising from the apolar hydrocarbon tails of SDS, suggesting either micelle formation or at least some sort of SDS encapsulation or binding around the Trp. It is interesting to speculate whether this putative micelle formation is induced by α-synuclein. Once SDS monomers were bound (blue shift) and α-helical structure formation was induced (increase in ellipticity), the second distribution became prominent (SM-FRET). Although analysis of more double-cysteine and single-Trp mutants will be necessary to probe if these transitions occur along the whole peptide, it will also be interesting to resolve whether these apparent sharp transitions also occur *in vivo* and what their role may be.

In conclusion, the SM-FRET approach in combination with ensemble CD and Trp fluorescence spectroscopy has enabled us to discriminate two apparent conformational states of α-synuclein and to analyze these conformers in terms of distribution and heterogeneity, information that is otherwise impossible to extract from ensemble measurements.

2.219.2.2. Antiparallel Arrangement of α-Synuclein Helices

The mode of binding of α-synuclein to membranes has generated significant discussion in the literature. It was proposed that α-synuclein binds to membranes either as an extended, continuous helix (residues 1–100)[51–53] or in a horseshoe-like conformation, consisting of helix 1 (residues 3–37), a bend around residue 42, and helix 2 (residues 45–92),[41] with the two helices in an antiparallel arrangement but not touching (see **Figure 4**).[54,55] Supporting evidence for the latter proposal was given by the single-molecule fluorescence study described in the previous paragraph, revealing structural information from interaction of α-synuclein with monomeric and micellar SDS. Micelles have typical diameters[56] of 5 nm and may thus be too small to accommodate α-synuclein in the extended conformation (around 15 nm for an extended helix of 100 residues).[57] Therefore, micelles could enforce an antiparallel configuration of the helices even if that is not the preferred state of α-synuclein on a larger surface such as that of a biological membrane. In contrast, even small unilamellar vesicles (SUVs) have diameters on the order of 20–30 nm,[30] providing a surface area that is large compared to the dimensions of α-synuclein[57] and a larger radius of curvature than that of micelles. Therefore, SUVs are more suitable models for biological membranes than micelles.

In collaboration with the group of Martina Huber at the University of Leiden, we have investigated the structure of α-synuclein on SUVs using pulsed EPR techniques[44] that enable the acquisition of long-range information on the conformation of α-synuclein bound to the vesicle surface. In short, the distances between pairs of spin labels introduced by site-selective cysteine mutagenesis were measured for four double-cysteine mutants, α-synuclein-9/90, α-synuclein-18/90, α-synuclein-18/69, and α-synuclein-9/69, each containing one

label in the proposed helix 1, and a second label in helix 2 (see Figure 4). These cysteine residues were labeled with MTSL (1-oxy-2,2,5,5 tetramethylpyrroline-3-methyl-methanethiosulfonate). EPR measurements on labeled α-synuclein in the presence of SUVs of POPG [1-palmitoyl-2-oleoyl-*sn*-glycero-3-(phosphorac-(1-glycerol))] lipids yielded distance distributions that provided a redundant set of distances that proves that the arrangement of the two helices must be antiparallel, as shown in Figure 4. This result has implications for the conformation of α-synuclein *in vivo*, where α-synuclein interacts with synaptic vesicles with diameters of around 40 nm.

2.219.3. Aggregation Intermediates

2.219.3.1. Aggregation Kinetics

The development of cross-β conformation during amyloid formation is commonly detected by the interaction with specific *fluorescent dyes*, such as Congo red and thioflavin T. The most frequently used dye, thioflavin T, shows significantly enhanced fluorescence emission upon binding to cross-β conformations,[58–60] and is therefore a very useful dye to follow the kinetics of amyloid formation. In general, *in vitro* kinetics studies utilize purified, often recombinantly produced, proteins that spontaneously form amyloid fibrils when incubated at specific conditions of protein concentration, temperature, pH, ion concentration, and agitation.

The formation of amyloid fibrils usually involves a lag phase, during which a sufficient concentration of nucleating species is formed to initiate the subsequent rapid development of protofilaments, protofibrils, and mature fibrils. Elimination of the lag phase can be accomplished by seeding; the addition of a small amount of preassembled fibrils to monomers induces the start of amyloid formation almost instantaneously. Considering disease-related amyloid formation, it is important to note that during the lag phase, oligomers are formed that have been hypothesized to be the potentially toxic species.[61–63] Figure 6 illustrates the difference in aggregation kinetics for an unseeded and a seeded aggregation reaction of recombinantly produced α-synuclein performed with constant shaking. For the unseeded aggregation, the thioflavin T fluorescence intensity curve clearly displays a lag phase, followed by a phase of rapid growth and the saturated final stage. Upon seeding, the thioflavin T emission intensity increases right from the beginning.

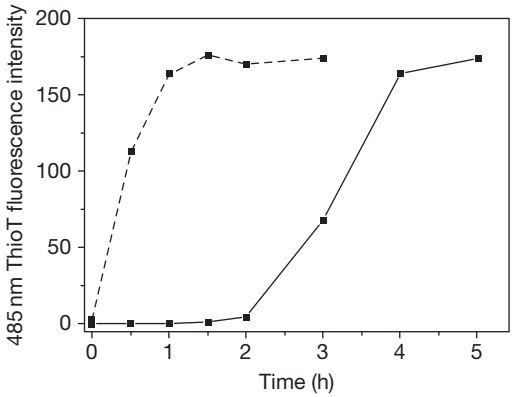

Figure 6 Aggregation of α-synuclein followed in time by thioflavin T fluorescence. Solid line: without seeding; dashed line: with seeding.

Thioflavin T is a popular and useful dye to follow the kinetics of amyloid fibril formation, although the binding is rather unspecific and the sensitivity quite poor. Especially in the lag phase, where processes from dimerization to oligomerization take place, thioflavin T is not sufficiently sensitive to resolve these important stages. Therefore, in search for better alternatives, novel dyes have been developed and synthesized that are promising specifically for detection of early stage aggregates.[64–68]

2.219.3.2. Morphology of Aggregation Intermediates

Aggregation intermediates of amyloidogenic proteins have characteristic dimensions in the nanometer range, which makes them ideally suited for study by *AFM*. AFM[69] is a scanning probe microscopy technique derived from scanning tunneling microscopy (STM) (**Chapter 3.302, Atomic Force Microscopy**). In AFM, a cantilever with a sharp (typically 10 nm) tip scans across a surface and records topography and material properties of the sample surface through the variation in tip–sample interaction forces experienced by the cantilever. Specifically for imaging of relatively soft biological samples such as DNA, proteins, and cells, and also for amyloid fibrils, the AFM technique has several advantages over scanning electron microscopy (SEM): no special sample treatment is required; measurements can be performed in ambient air and in physiologically relevant aqueous milieus without a need for a vacuum environment;[70,71] and measurement of true heights in the nanometer range is possible. The application of AFM to biological and supramolecular systems has been reviewed in recent publications.[70–74] In amyloid fibril research, AFM can be used as an imaging modality, mapping the topography and material properties of the protein aggregates, and also for force spectroscopy measurements, where the tip is used to push and pull individual protein molecules, dimers, or (proto-) fibrils in a controlled fashion.

The high-resolution AFM technique can be effectively employed to study the aggregation kinetics by imaging the intermediate structures formed after different incubation times[75] or by time-lapse imaging of *in situ* growing fibrils[76] on a surface. Figure 7 gives representative AFM images taken during the α-synuclein aggregation presented in Figure 6 by thioflavin T fluorescence. The early phase images from the unseeded aggregation are dominated by small dot-like aggregates that represent oligomeric structures.

The oligomeric species form a focal point of attention in the field of amyloid fibril formation, because of their proposed toxic function. In the course of the aggregation, the oligomeric species is replaced by an increasing number of fibrils. The AFM images demonstrate that thioflavin T is indeed not suitable as an early indicator of amyloid formation; after 90 min, the thioflavin T emission intensity of the unseeded aggregation reaction is still at background level, while the AFM images already show some fibrils.

Because of its exceptionally high spatial resolution, the AFM technique is applicable not only for kinetic studies but also for

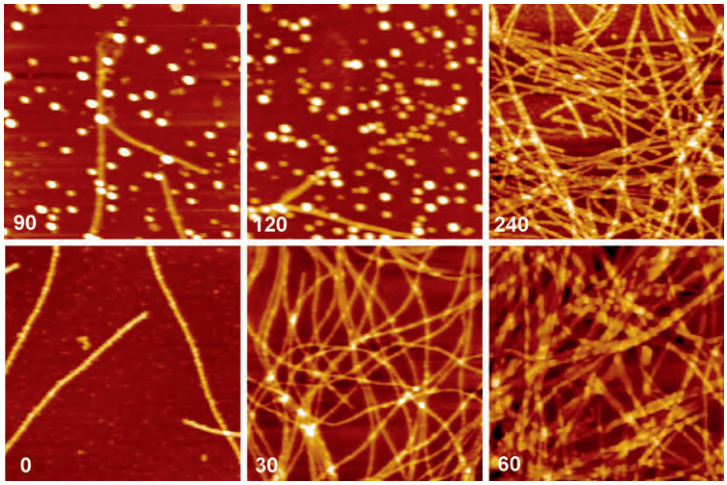

Figure 7 AFM images taken at different time points, indicated in hours, during aggregation of α-synuclein. Top row unseeded aggregation; bottom row seeded aggregation. Image size: 2.5 × 2.5 μm. Height scale: 10 nm.

quantitative morphological analysis of the fibrillar aggregation products formed (see Section 2.219.4.1).

2.219.3.3. Secondary Structure of Aggregation Intermediates

CD spectroscopy is an attractive method to monitor conformational changes and transitions in the course of the amyloid formation process[77] (see also Section 2.219.2.1). Figure 8 shows far-UV CD spectra measured from monomeric and oligomeric (lag phase) α-synuclein indicating random-coil and β-sheet structure, respectively. The CD spectrum of monomeric α-synuclein shows a minimum at 198 nm and close to zero CD signals in the 210–220 nm region, which is characteristic for an unfolded protein. The spectrum of the oligomers is completely different, and with a minimum at 220 nm typical for β-sheet structure. Specifically, in the early aggregation phase, where thioflavin T is not sufficiently sensitive, CD spectroscopy is able to demonstrate changes in protein conformation.

Alternatively, *Raman spectroscopy*[78–80] is another method that may be applied to obtain information on the secondary structure content of aggregation intermediates (Chapter 3.322, Infrared and Raman Microscopy and Imaging of Biomaterials).

2.219.3.4. Protein Interactions

In a natural *in vivo* environment, amyloid formation takes place in the presence of many other components. Interactions with various chemical and biological components such as metal ions, proteins, and enzymes, are therefore likely. In this context, we have studied the interaction of the enzyme tissue transglutaminase (tTG) with α-synuclein protein variants at physiologically relevant concentrations. The tTG enzyme catalyzes cross-link formation between protein-bound glutamine residues and primary amines and plays a role in various neurodegenerative diseases.[81] tTG enzyme activity has been shown to be upregulated in PD affected brain.[82] tTG-catalyzed cross-links have been found colocalized with Lewy bodies, the cytoplasmic inclusions composed of fibrillar α-synuclein that are characteristic of PD,[11] suggesting a role for tTG in the

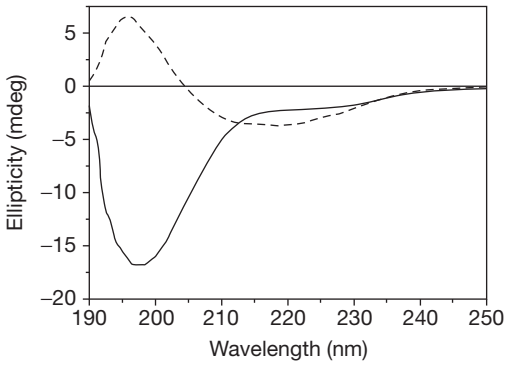

Figure 8 CD spectra of monomeric (solid line) and oligomeric (dashed line) α-synuclein.

pathophysiology of PD.[83] Cross-linked α-synuclein appeared to correlate with disease progression, indicating that tTG cross-linking may change the structure of monomeric α-synuclein resulting in altered functionality. Intramolecular cross-linking by tTG was hypothesized to be protective in PD, by inhibiting the assembly of monomeric α-synuclein into amyloid fibrils and its potentially toxic oligomeric precursors.[84]

To shed light on the pathological relevance of tTG cross-linking, we have systematically investigated tTG cross-linking of wild-type and disease-related mutant A30P, E46K, and A53T α-synuclein.[85] We evaluated the effect of physiologically relevant[86,87] nanomolar tTG concentrations on cross-linking kinetics, on affected α-synuclein fraction, and on inhibition of aggregation.

Figure 9(a) shows that nanomolar tTG concentrations are sufficient for complete inhibition of fibrillization by effective α-synuclein cross-linking, resulting predominantly in intramolecularly cross-linked monomers accompanied by an oligomeric fraction. AFM indicated the formation of very distinct, uniform, oligomeric species (Figure 9(b)). As oligomeric α-synuclein structures are most likely implicated in the pathophysiology of PD,[84] we determined the secondary structure, foldability, and vesicle permeabilization properties of

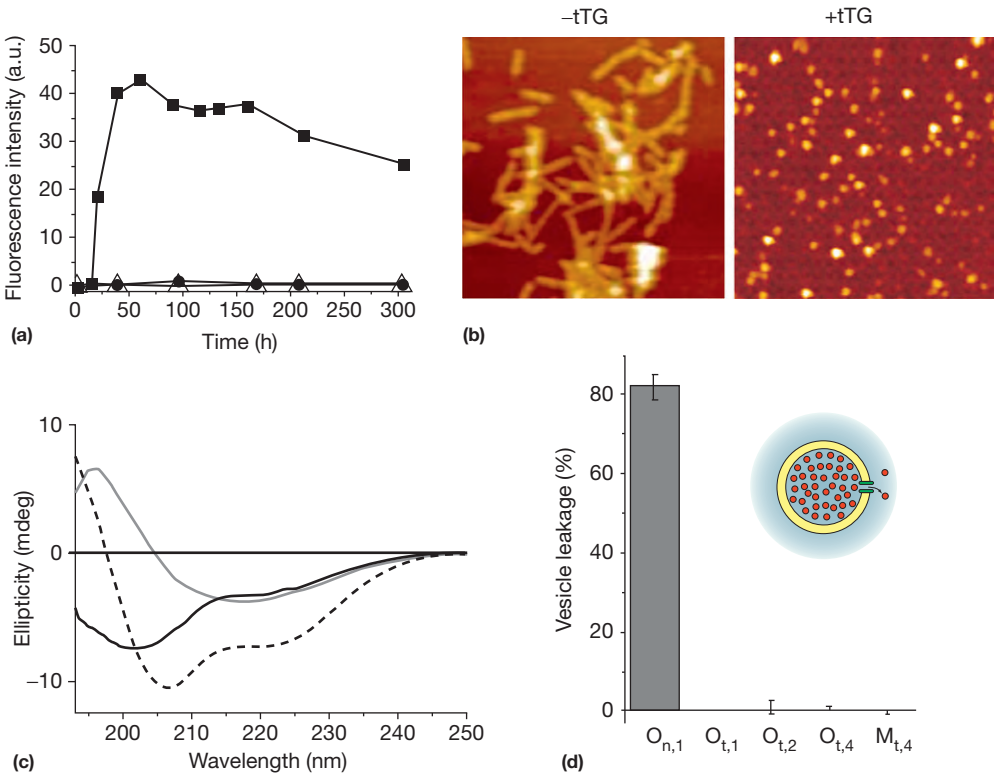

Figure 9 Aggregation of 100 μM E46K α-synuclein in the presence and absence of tTG. (a) Thioflavin T fluorescence assay: without (squares), and with 50 nM (circles) and 1.3 μM tTG (triangles). (b) AFM images: after 214 h without tTG (left) and after 310 h with 1.3 μM tTG. Images are $1.25 \times 1.25\ \mu m^2$. (c) CD spectra of tTG/α-synuclein oligomers and normal α-synuclein oligomers. Black spectra: oligomeric tTG/α-synuclein, before (solid line) and after (dashed line) addition of 0.1% (w/v) SDS. Gray spectrum: normal α-synuclein oligomers. (d) Vesicle permeabilization assay. $O_{n,1}$: normal α-synuclein oligomers used at 1 μM; $O_{t,1}$, $O_{t,2}$, and $O_{t,4}$: tTG/α-synuclein oligomers used at 1, 2, and 4 μM, respectively. $M_{t,4}$: tTG/α-synuclein monomers used at 4 μM.

purified tTG/α-synuclein oligomers compared to normal oligomers. Our results demonstrate that although tTG/α-synuclein oligomers contain no secondary structure (Figure 9(c)), they are nevertheless able to fold into α-helix conformation on binding SDS. To investigate the membrane permeabilization capability of the tTG/α-synuclein oligomers, we performed a dye efflux assay.[88] POPG LUVs were prepared by drying an aliquot of a solution in chloroform. After rehydration in a buffer solution containing the fluorescent dye calcein, the solution was extruded through a 100 nm pore size polycarbonate membrane filter. Free dye was removed by gel filtration and the phospholipid concentration of the calcein-filled LUVs was determined.[89] In the permeabilization assay, 40 μM phospholipid-containing vesicle solution was mixed 1:1 (v/v) with α-synuclein solution and incubated for 30 min at room temperature. Fluorescence (emission: 505–550 nm, excitation: 494 nm) was measured using a spectrofluorimeter. From the background-corrected fluorescence, the vesicle leakage was calculated relative to maximum vesicle disruption induced by 0.5% (w/v) Triton X-100. Figure 9(d) indicates that the tTG/α-synuclein oligomers, unlike normal oligomers, are not capable of permeabilizing phospholipid vesicles.

The comprehensive data that we have acquired suggest that tTG binds to all α-synuclein variants effectively and prevents formation of toxic oligomers and successive progression into fibrils by forming intramolecular cross-links, imposing structural constraints on α-synuclein. The formation of small, harmless, tTG cross-linked, α-synuclein assemblies suitable for removal by intracellular degradation systems may be a mechanism to prevent formation of pathogenic aggregates. We speculate that intramolecular cross-linking may be the predominant process early in PD, while at later stages, with higher tTG and α-synuclein concentrations[81,90] the probability of intermolecular cross-linking and formation of large, insoluble protein clusters may increase.

2.219.4. Mature Amyloid Fibrils

2.219.4.1. Structural Polymorphism of Amyloid Fibrils

The structural polymorphism of amyloid fibrils, resulting in a multitude of distinct morphologies, is a particularly important element in scientific understanding of amyloid fibrillogenesis[91] because polymorphism suggests that it is likely that there are multiple pathways of amyloid fibril formation and potential neurodamage. Particularly in this area, nanoscale imaging methods such as AFM can contribute to the understanding of amyloid fibril formation. From high-resolution AFM images, the multitude of aggregate morphologies that occur both *in vivo* and *in vitro* may be classified. In general, amyloid fibrils are unbranched, linear fibrils with a diameter of around 10 nm and lengths that run into the micrometer range.

The discovery by AFM imaging of several types of filaments differing in their diameter, and the observation of periodicity or even twist in the thicker fibrils, has led to the development of the hierarchical assembly model (HAM).[59] This model describes that mature fibrils consist of a twisted pair of protofibrils, each of which is composed of two thinner intertwined protofilaments. However, polymorphism observed by AFM and scanning transmission electron microscopy in amyloid-β (Aβ) fibrils suggests that other mechanisms, not involving protofilaments, may also play a role in the assembly of amyloid fibrils.[92] Possibly mature fibrils are also formed by assembly of discrete independent entities, morphologically resembling twisted fibrils.

Mature fibrils formed by various proteins differ in the number of constituent filaments. For example, β_2-microglobulin fibrils, involved in dialysis-related amyloidosis, form three types of mature fibrils: consisting of two or four intertwined filaments, or consisting of four filaments and forming a twisted-ribbon structure.[93] These authors also found fibrils exhibiting supercoiling: the superhelical twist period was twice the twist period, which gives the fibrils a zig-zag appearance. Whether the various species form sequentially or in parallel is as yet unclear.

Polymorphism is evident not only when comparing different fibrils. Fibrils formed by full-length prion protein display polymorphism even within individual fibrils, differing in number of constituent filaments and twisting at different points along their length.[22,23] One assembly mechanism that may contribute to this behavior is 'lateral seeding': monomers and oligomers from solution may attach to an existing fibril surface and initiate a new filament alongside an existing filament. This mechanism has been proposed for insulin,[94] when fibrils were formed at an unusual condition of high pressure. However, an argument against the generality of lateral seeding is that the mechanism implies that fibrils would grow in width indefinitely, whereas it has been shown on fibrils formed by many different proteins and peptides that only a small range of fibril diameters is formed.

We have used different contrast modes of high-resolution AFM to study in detail the morphology of α-synuclein fibrils prepared *in vitro* from recombinantly produced wild-type human α-synuclein and the familial disease-related A30P, E46K, and A53T mutant proteins.[95] Aggregation half-times measured using thioflavin T fluorescence spectroscopy at low salt reaction conditions indicated different aggregation kinetics for the variants: 150 h for wild-type and 75, 100, and 250 h for A53T, E46K, and A30P, respectively. These results are consistent with the literature.[96] AFM images in air (**Figure 10(a)–10(d)**) were recorded to verify if the different aggregation kinetics influence the fibril morphologies. Visual inspection of the images suggests that the morphology is not identical for all variants.

Quantitative analysis was performed of heights, modulation depths, and periodicities of a large number of fibrils for each variant (**Figure 10(e)** and **10(f)** and **Table 1**).[97] Wild-type fibrils exhibit the lowest height; A30P and E46K have intermediate values, while A53T fibrils are highest. The modulation depth is not significantly different among the mutant proteins, although wild-type protein has a smaller modulation depth commensurate with the lower measured fibril height. Together with the fibril height, the periodicity of the fibrils is the most characteristic parameter for each α-synuclein variant. The E46K mutant displays a very distinct average periodicity of about 60 nm, A53T an intermediate value of 110 nm, and wild-type and A30P display the largest periodicities of ~140 nm. The distribution of period lengths is narrowest for E46K (main mode at 40–50 nm), whereas A30P and A53T display wider distributions. Wild-type protein displays a main

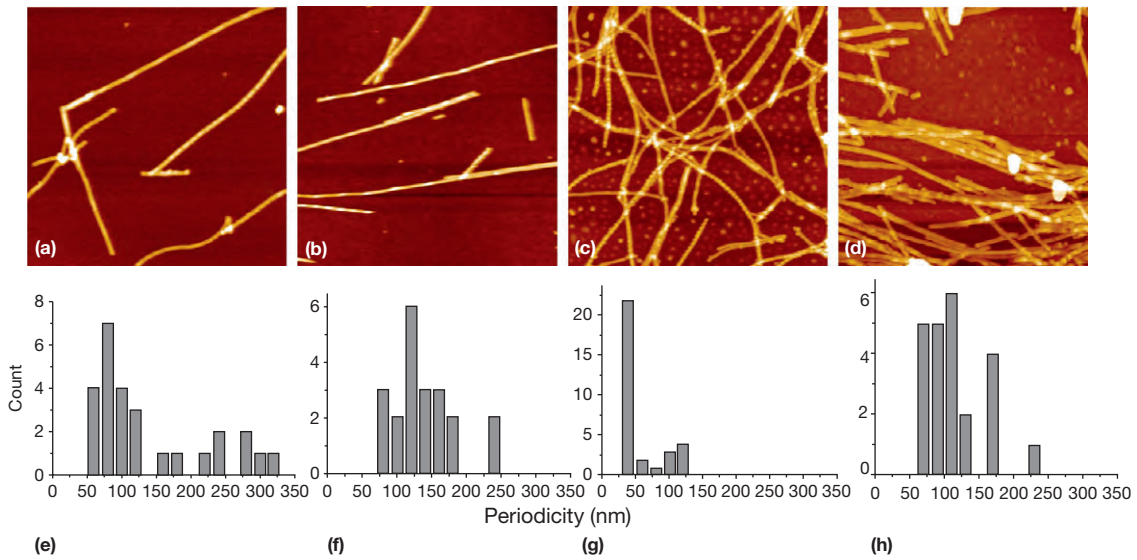

Figure 10 Representative tapping mode AFM images of wild-type (a), A30P (b), E46K (c), and A53T (d) variants of α-synuclein in air. The color scale represents 15.6 nm in height for wild-type, 20.2 nm for A30P, 22.4 nm for E46K, and 31.3 nm for A53T α-synuclein. Image size is 2500 × 2500 nm. Distributions of fibril periodicities are given for wild-type (e), A30P (f), E46K (g), and A53T (h) variants of α-synuclein. The number of fibrils analyzed is indicated in **Table 1**. Histogram bin size is 20 nm.

periodicity of around 80 nm, but larger periodicities were also observed. The fibril heights and modulation depths measured in air for A30P and E46K variants are consistent, within the accuracy of the data, with earlier AFM results in liquid.[97] The measured heights and modulation depths of wild-type protein are somewhat smaller in air than in liquid. Periodicities measured for A30P and E46K are similar in air and in liquid, and also for wild-type protein considering the main mode in the broad distribution.

Table 1 summarizes the quantitative data obtained and indicates that a single-point mutation in the α-synuclein protein has significant consequences for the ultrastructure of the fibrils formed.

High-resolution phase images were recorded to examine the nanoscale structure of individual α-synuclein fibrils in detail. Phase imaging is sensitive to differences in material properties like sample viscoelasticity or hydrophobicity, and is a complementary contrast mode yielding more details than can be observed in height images.[98] Fibrils shown in Figure 11(a) clearly display twisted fibril morphology, providing evidence for the presence of a skewed pitch. In contrast, Figure 11(b) shows a high-resolution image of a small area scan revealing assembly of fibril segments of 100–150 nm in length. Figure 11(c) and 11(d) demonstrate that both assembly modes can be found within one sample, an observation made for all α-synuclein variants.

Our results indicate that the aggregation of genetic variants of α-synuclein not only follows different kinetics but is also accompanied by the formation of morphologically different fibrils. Individual mutant forms of α-synuclein fibrils may be distinguished on the basis of their characteristic heights and periodicities. Specific point mutations appear to affect fibril assembly and may drive fibril formation into energetically more favorable structures with characteristic periodicity. The measured modulation depths in relation to the fibril heights are compatible with a twisted HAM within the accuracy of the data. For this model, we expect the modulation depth not to exceed 25% of the maximum height of the fibril, an expectation supported by the data shown in Table 1. However, we also observe morphologies that do not resemble the expected twisted structure, but appear like a series of associated segments. This type of morphology has also been observed for insulin fibrils.[94] We thus have evidence for both hierarchical and segmented α-synuclein fibril formation, potentially on the basis of a multipathway mechanism. We speculate that segmented assembly may precede the twist formation, because we mainly observe segmented morphologies in lower height fibrils (protofibrils). Higher resolution imaging and further analysis are required for definitive conclusions.

Tapping mode AFM (TM-AFM) *phase imaging* provides another unique source of information on the mechanical properties of amyloid fibrils.[99] The contrast mechanism in TM-AFM phase contrast imaging is the time lag between the oscillation of the cantilever and the driving oscillation. This lag is due to the interaction between the tip and the sample/substrate, which may depend on any number of material properties and the electrical charge of tip and sample. For good phase contrast imaging, the correct choice of tapping frequency, tapping amplitude, set-point ratio, humidity, the thickness of a potential thin water layer on the dry sample, and surface charges on the tip and/or the sample are important. We have recently obtained high-resolution AFM phase contrast images (Figure 12) that demonstrate that the ends of the α-synuclein fibrils and certain specific points in the bulk of the fibrils have a decidedly different phase lag than the rest of the fibril, possibly representing local differences in material properties. The resolution of these patches of alternate tip–sample interaction is higher than the resolution of the height image, presumably because only just the 'tip of the tip' participates in the interactions that cause the phase difference. Possibly for the same reason, tip–sample convolution does not reduce the phase resolution in the same way as it reduces the lateral resolution

Table 1 Quantitative characteristics of fibrils of α-synuclein variants

α-synuclein variant	*N fibrils*	*Fibril top height (nm)*	*Modulation depth (nm)*	*Periodicity (nm)*
Wild-type	33 (27)	7.5 ± 0.9	1.5 ± 0.4	141 ± 82
A30P	41 (21)	8.7 ± 1.4	2.3 ± 0.7	139 ± 46
E46K	37 (29)	9.8 ± 1.2	2.1 ± 0.6	59 ± 28
A53T	33 (20)	10.4 ± 1.3	2.2 ± 0.8	115 ± 41

N fibrils is the total number of fibrils analyzed per mutant; the number of periodic fibrils is in brackets. The fibrils classified as nonperiodic were irregular in height. Height values are averages over all *N* fibrils; the modulation depth and periodicity are calculated over only the periodic fibrils. The standard deviation is used as the measurement error.

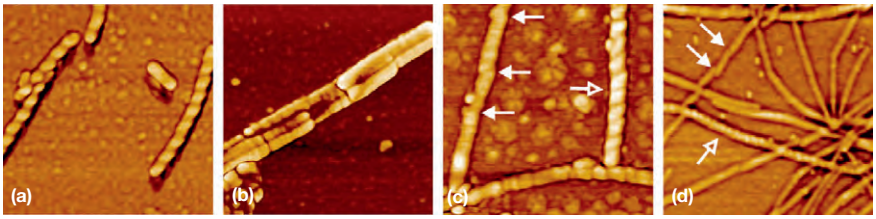

Figure 11 Tapping mode AFM phase images in air. (a) E46K fibrils displaying twisted morphology. (b) Wild-type fibril with appearance of associated segments. (c) and (d) Contain both twisted and segmented E46K fibrils. Image sizes are for (a), (b), and (c): 620×620 nm, for (d) 1250×1250 nm. Closed arrows point out segmented fibrils, open arrows twisted fibrils.

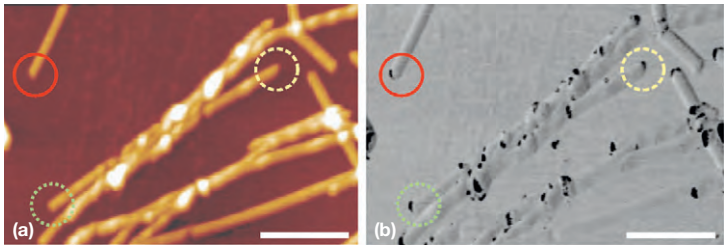

Figure 12 AFM phase contrast shows high-resolution fibril features TM-AFM height image of α-synuclein fibrils (a) with the corresponding simultaneously recorded AFM phase contrast image (b). The phase image (b) shows that fibril ends (*circles*) and certain specific parts of the fibril bulk have material properties different from those of the bulk fibril. Scale bar 500 nm, resolution 256 pixels/line.

of height images. The exact origin of the oscillation lag and thus of the phase contrast is unclear, but probably involves the higher harmonic mode of the cantilever oscillation as the tapping cantilever touches the sample surface.

The examples given here indicate that phase contrast imaging holds great promise as a method for characterization of material properties of amyloid fibrils. Phase imaging may play an important role in providing the necessary differential contrast and sensitivity that are lacking in height images to reveal differences in material properties at fibril segment interfaces.

2.219.4.2. Mechanical Deformation of Fibrils

The application of AFM imaging is not limited to characterization of fibril morphology properties under various conditions by imaging; also the mechanical properties of the fibrils may be deduced from the images. In contact mode AFM (CM-AFM), the tip is in constant contact with the surface. The tip is effectively 'dragged along' the sample while the feedback loop keeps the interaction force constant by maintaining the deflection at a set-point value. This mode allows for very high lateral resolution on periodic samples with low corrugation, but is typically too damaging for fibrillar protein aggregates, especially in liquid. The damaging nature of CM-AFM can be used as a tool to study the effect of controlled damage applied to fibrillar aggregates. **Figure 13(a)** depicts an image of A30P mutant fibrils obtained by scanning in tapping mode. Then the same area was rescanned in contact mode, followed by another larger scan in tapping mode. The combined images taken before and after contact mode scanning clearly show deformed fibrils in the area scanned in contact mode; outside this area the fibrils are not affected. The regular pattern of nanoscale deformations is the result of the force imposed on the fibrils during contact mode scanning (**Figure 13(b)**). A closer look at a single fibril reveals that the spacing between the deformations corresponds to the 140 nm periodicity of the original intact fibrils (**Figure 13(c)** and **13(d)**). **Figure 13** shows that α-synuclein fibrils have 'weak spots' at intervals corresponding to their periodicity.[95,97] This same effect was found for Aβ: N-terminal 1–42 residues ($A\beta_{1\text{-}42}$) fibrils.[100] Fibrils may be damaged by indentation forces ranging from 40 to 100 nN.[101,102]

Lateral forces in contact mode are much higher than in tapping mode because the tip is continuously in contact with the sample. The contact force is mainly dominated by the adhesion force between the Si_3N_4 tip and the sample. The periodicity of the deformations may arise from the

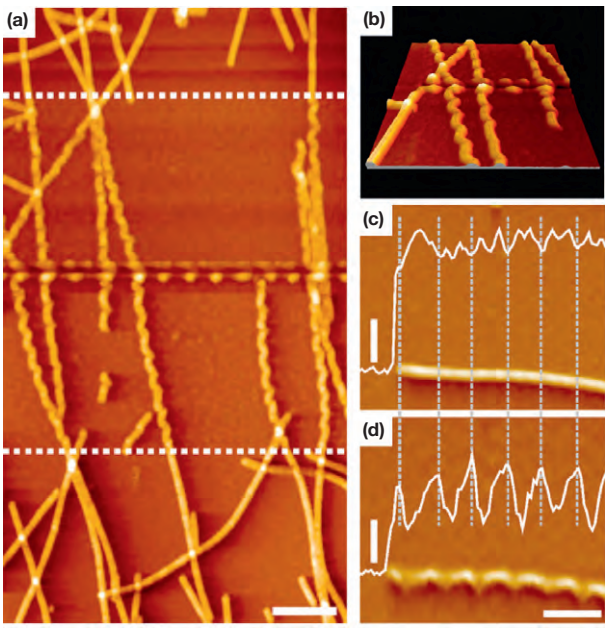

Figure 13 Contact mode AFM imaging reveals mechanical weak spots in α-synuclein fibrils. (a) Composite tapping mode AFM height image of A30P α-synuclein fibrils. The section between the *dotted lines* has been subjected to contact mode imaging before this image was made. The horizontal track in the middle results from repeated line scanning for optimization of imaging parameters. Scale bar 500 nm. (b) 3D rendering of affected area. Comparison of morphology of one fibril before (c) and after (d) contact mode imaging. The height profiles show that least damage was done on those sections that were lowest before scanning (*gray dashed lines*, scan direction was vertical). Horizontal scale bar 200 nm, vertical scale bars 2 nm.

characteristic fibril structure, assembled in such a way that it is locally more sensitive to deformation by lateral force. Another reason may be the intrinsic variation in adhesion force. Hydrophilic parts of the sample will display higher adhesion forces.[103] Possibly, these fibril parts are more prone to damage by high local lateral forces. The fibril deformation results may support both hierarchical and segmented α-synuclein fibril assembly. This AFM-based fibril deformation method may be applied more generally to study the mechanical properties of various fibrillar structures. The extent of the deformations may be even converted into quantitative mechanical data.

2.219.5. Conclusion

Amyloids experience a growing scientific interest, from both a fundamental biomedical and a materials science perspective. Initially amyloid formation was observed as a pathological hallmark of several neurodegenerative diseases. More recently functional amyloids have been discovered in many species, and these structures also play a role in industrial processes, such as in the optimization of food texture. Nevertheless, the process of amyloid formation is still not well understood. More knowledge about the mechanism and about factors that may affect fibril formation will improve our understanding of the molecular origin of amyloid diseases and about the role of functional amyloid. In the case of pathogenic amyloid, this information is indispensable in the search for effective medication, when targeting of a specific aggregation stage may be considered. Widespread application and exploitation of amyloid nanobiomaterials require further information about not only the details of the aggregation process, but also the final material properties.

This chapter describes the application of a variety of biophysical approaches to understand important aspects of amyloid fibril formation. Although we have mainly focused on a single model system, the human α-synuclein protein, the approaches are generally applicable to the broader genre of amyloid-forming proteins.

Acknowledgments

The authors thank Kees van der Werf for assistance and advice on atomic force microscopy; Kirsten van Leijenhorst-Groener, Yvonne Kraan, and Marloes ten Haaff-Kolkman are acknowledged for production and purification of α-synuclein protein. We acknowledge a fruitful collaboration with Martina Huber at Leiden University, and Malte Drescher at the University of Konstanz for the EPR work. Biological vascularized scaffold (BioVaSc) XXX
Biomechanical stimuli XXX
Biomimicry XXX
Extracellular matrix XXX
Indirect revascularization XXX
Matrix XXX
Revascularization XXX
Scaffold XXX
Tissue differentiation XXX

Abbreviations

BioVaSc	Biological vascularized scaffold
ECM	Extracellular matrix
PERV	Porcine endogenous retrovirus
RGD	Arginine-glycine-aspartate sequence on integrins, which mediates adhesion between cells and the extracellular matrix
SFF	Solid free-form fabrication
SIS	Small intestinal submucosa
TE	Tissue engineering

Tissue engineering (TE) is an interdisciplinary field that applies the principles of engineering and the life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function.[1] It offers the potential to fabricate new, physiologic, functioning tissues from biodegradable scaffolds and autologous cells[2] by

1. Guided tissue regeneration with engineered matrices,
2. Use of cells seeded on or within matrices (cell matrix construct), or
3. Injection of autologous or allogenic or xenogenic cells (cell therapy).

with the latter two approaches being the most common. This chapter, however, will not address cell therapies, but focus on the use of cell-free or seeded matrices as scaffolds to generate bioartificial tissues.

Scaffolds give bioartificial tissues their macroscopic three-dimensional shape and their matrix functions as carrier structure for cells, establishing a three-dimensional framework for cell seeding. Besides its role in providing mechanical support it participates in cellular communication pathways. Porosity, surface chemistry, topography, three-dimensional architecture, immunogenecity, and mechanic parameters are matrix properties.[3]

Without going into great detail it has to be acknowledged that cells and the extracellular components of the surrounding matrix (extracellular matrix (ECM)) interact with each other, resulting in a complex interplay composed of cell–cell and

cell–matrix interactions (Figure 1). Additionally, biomechanical stimuli and soluble factors within the physiological tissue environment influence tissue differentiation and growth (microenvironment). Unfortunately, this complex interplay is currently only beginning to be understood.

Therefore, one of the most difficult obstacles facing tissue engineers is defining the conditions that direct cell behavior, and recapitulating these conditions in a suitable *in vitro* growth environment.[4] Additionally, the arrangement of assorted cells into correct spatial organization is of fundamental importance.

Initial success has been achieved primarily in tissues of relatively simple architecture, including skin and cartilage. In comparison, engineering tissues with greater complexity has been rather unsuccessful. These tissues comprise multiple cell types within a highly structured and defined organization. Reproducing this organization in an engineered tissue constrains the juxtaposition of specific cells with various gradients of soluble factors, specific ECM scaffolds, physical forces, and other cell types, and therefore is likely to be required to recapitulate the signals that drive cell and tissue function.[4]

Depending on the intended application, matrices have to meet numerous requirements for tissue suitability (Table 1). Therefore, the composition of the tissue-specific ECM composition is analyzed to develop biomimetic materials.

2.220.1. Extracellular Matrix

In vivo, cells are embedded in a complex ECM and exposed to a wide range of stimuli. Depending on the tissue type, cells communicate by cell–cell contacts with neighboring cells or secrete soluble factors. Examples for the biomolecules released into the intercellular environment are hormones, growth factors, and neurotransmitters. One of the most important stimuli for cellular behavior is the cell's interaction with its surrounding ECM.[5] The ECM is generated from biological molecules synthesized by these cells and maintained in a dynamic milieu. It provides the substrate for anchorage-dependent cells to firmly adhere and organize.

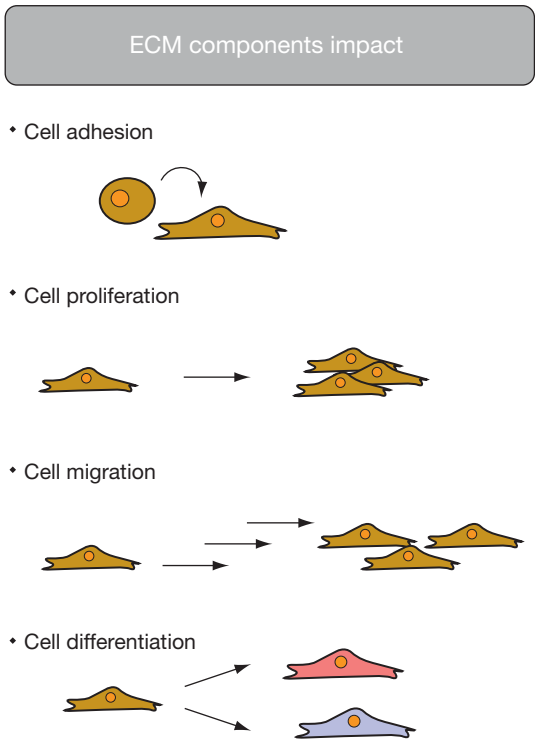

Figure 1 The matrix interacts with the fundamental cell functions.

The extracellular microenvironment, which surrounds cells and comprises the molecular signals, is a highly hydrated network hosting three main effectors: (1) insoluble hydrated macromolecules (fibrillar proteins such as collagens, noncollagenous glycoproteins such as elastin, laminin or fibronectin, and hydrophilic proteoglycans with large glycosaminoglycan side chains), (2) soluble macromolecules (growth factors, chemokines and cytokines), and (3) proteins on the surfaces of neighboring cells. Thus, the ultimate decision of a cell to differentiate, proliferate, migrate, apoptose, or perform other specific functions is a coordinated response to the molecular interactions with these ECM effectors. It is noteworthy that the flow of information between cells and their ECM is highly bidirectional, as, for example, observed in processes involving ECM degradation and remodeling.[6]

Considering the multitude of different tissues, a wide variety of ECM compositions becomes apparent: While bone ECM is characterized by its durability and porosity, brain ECM resembles a flexible hydrogel. According to this, the ECM-associated stimuli like topography of globular, porous, crystalline or febrile structures, stability, elasticity, roughness, wettability and water storage capacity, chemical composition, and ligands vary. These various material properties and compositions define the tissue-specific properties.[7]

Basically, the ECM is composed of febrile and globular proteins.[8] In higher vertebrates, collagen is the most abundant protein found. Twenty-nine types have been identified with type I being the most abundant. Over 90% of the collagen in the body, however, is of type I, II, III, and IV, as indicated by Table 2. Elastic fibers are composed of fibrillin and elastin.[9] Additionally, the ECM contains globular proteins (i.e., laminin or fibronectin), which frequently present specific amino acid sequences for the specific adhesion of cells – with the

V	Cell surfaces

arginine-glycine-aspartate (RGD) sequence being the most common.[10,11] Glycosaminoglycans represent another large group of ECM macromolecules. They are long-chained polysaccharides that form proteoglycans by association with proteins. The diversity and interaction of proteins, glycosaminoglycans, and proteoglycans set the basis for the various ECM properties.[12]

To initiate signaling cascades that lead to changes in cell growth, proliferation, migration, differentiation, and survival soluble factors were applied in cell culture media and incorporated into TE scaffolds. For example, hepatocytes dedifferentiate *in vitro* in the absence of collagen I, dynamic culture maintain endothelial cells (EC) in a quiescent, whereas cells cultured in static conditions resemble cells in an inflammatory state. Simply combining cells with matrix proteins in culture is not sufficient to generate bioartificial tissues with specific and long-term function. A specified spatial arrangement, the application of physical factors, surrounding proteins, and neighboring cells control the degree to which cells are in contact with matrix versus neighboring cells. This balance is important to direct cell and tissue behavior *in vitro*[4] (**Figure 2**).

2.220.2. Materials Applied in TE

2.220.2.1. Synthetic Materials

Ample experience exists regarding the use and biocompatibility of synthetic materials as implants in reconstructive surgery. For decades they have been applied mainly in dentistry and orthopedic- and cardiovascular surgery. Synthetic materials currently used for biomedical applications include metals and alloys, polymers, and ceramics (see **Chapter 1.102, Metals for Use in Medicine**; **Chapter 1.104, Shape Memory Alloys for Use in Medicine**; and **Chapter 1.109, Bioactive Ceramics**, Inert ceramics, Polymers).

2.220.2.2. Biological Materials

Biological materials can be (1) composed artificially from single or few ECM components, such as collagen and fibronectin or (2) generated from three-dimensional biologic auto-, allo-, or xenogenic tissues.

2.220.2.2.1. Synthetic biological materials

Biological materials can be fabricated from single or multiple ECM proteins. The material properties can be tailored to the specific needs by adding various additives such as, growth factors or RGD-peptides to optimize cellular microenvironment and graft stability. However, these synthesized biological materials lack the physiological three-dimensional structure and various ECM components, changing the microenvironment for seeded and in growing cells (**Table 3**). Especially, the speed of material degradation has been shown to depend on the material's elastin content.[14]

Various fabrication techniques have been applied for material generation:

1. solid freeform fabrication (SSF),[15]
2. electrospinning,[16] and
3. bioprinting.[17]

As a result of these new technologies, tissue-engineered constructs that contain a controlled spatial distribution of cells and growth factors, as well as engineered gradients of scaffold materials with a predicted microstructure can be generated.[15]

2.220.2.2.2. Decellularized biological materials

In contrast to fabricated synthetic biological materials, biological tissues that are decellularized adequately provide a naive ECM composition, a biomimetic environment, and physiological three-dimensional scaffold composition that may serve as structural landmark for reseeding and tissue differentiation. Auto-, allo-, and xenogenic tissues may serve as starter materials to generate cell-free biological scaffolds for TE applications (**Table 4**).

The specific properties of every scaffold preparation, however, largely depend on the applied fabrication methods. Decellularized biological materials may be (1) implanted as

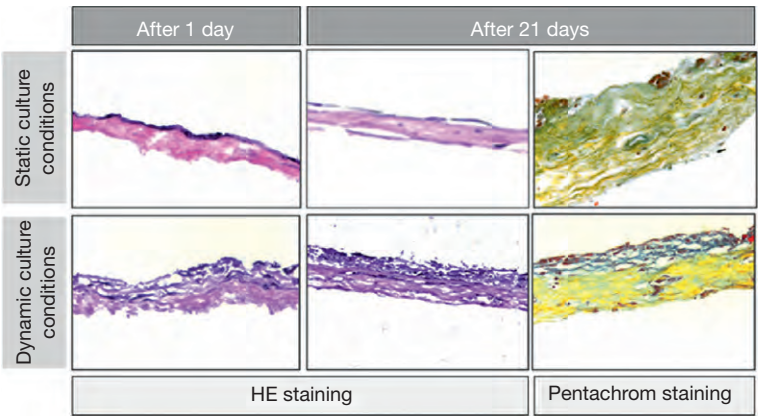

Figure 2 Biomechanical stimulation supporting tissue differentiation. Porcine jejunal segments were decellularized chemically, reseeded with allogenic fibroblasts and cultured for 3 weeks under static culture conditions (upper row) and dynamic culture conditions (lower row). In the static culture, cell proliferation and migration are detectable (HE staining), but only scarce collagen synthesis (PC staining). In the dynamic culture, there is evidence of additional matrix synthesis (HE staining). The entire extracellular matrix shows a higher degree of organization (PC staining). (HE staining: nuclei are stained blue, collagen is stained pink; PC staining: nuclei are stained brown, collagen is stained yellow, proteoglycans are stained green, elastic fibers are stained red, calcifications are stained black).

cell-free scaffolds (guided tissue regeneration), (2) lyophilized and injected as hydrogel or (3) recellularized *in vitro* and implanted as cell–matrix construct (TE). As a matter of fact, a good portion of the potential interdependencies, however, has not been understood so far and is currently the subject of ongoing research. For example, ECM isolated from heart tissue supports myocardial regeneration far better than the ECM of a different origin.[30]

Regarding the potential threats of decellularized porcine tissues, concerns regarding the possibility of porcine endogenous retrovirus (PERV) transmission[37] onto human recipients have been disproved by experimental and clinical findings.[38]

2.220.3. Induction of Graft Vascularization

The advances in cell and tissue culture techniques and the progress in materials research led to the development of uncounted bioartificial tissues for experimental and clinical applications, as was already indicated in Table 4.

Table 3 Important noncollagenous ECM components

Component	*Function*
Fibrin	Controls stiffness, resists tension, easily degraded, and remodeled
Elastin	Provides elastic recoil, hinders degradation processes
Proteoglycan	Resists compression, hinders water transport, hinders macromolecular transport, binds growth factors and chemokines

Source: Retrieved from Griffith and Swartz[13].

The multitudinous transplantation studies of the past displayed the elementary importance of tissue vascularization for graft function: When *in vitro* engineered cellular constructs are transplanted *in vivo* they have to rely on processes like interstitial fluid diffusion and blood perfusion. Here resides a core limitation for transfer of TE models from the *in vitro* to the *in vivo* environment.[4] With one exception, the (clinically) realized TE applications represent simple tissues that are supplied by diffusion, but not by vascularization. Therefore, one of the major obstacles in TE of thick, complex tissues is to keep the construct viable *in vitro* (during cultivation and formation of the tissue) as well as *in vivo* (on implantation).[39] *In vivo*, the construct must be vascularized immediately to allow for its survival and later integration as the host's vascularization is not sufficient to feed the implant.[40] The importance of this issue led to the development of various strategies and experimental approaches to vascularize bioengineered grafts directly or indirectly.[41]

2.220.3.1. Indirect Revascularization

Diffusion is the initial process involved following tissue transplantation, but it can only provide for cell support within a maximum range of 200 μm[42] into the matrix. Therefore, prompt formation of new blood vessels by budding or sprouting of preexisting vessels is necessary to sustain the newly formed tissue. Animal experiments investigating the capillary ingrowth in a rodent transplant model showed that avascular tissues with a diameter of less than 1 mm are supplied by diffusion over a time period of 2 weeks.[40] Tissue revascularization was detectable about 2 weeks following transplantation and continued up to the 8th postoperative week.[14]

Table 4 Various tissue types applied as biological scaffolds for tissue engineering applications[a]

Target tissue	*Decellularized donor tissue*	*Applied*			*Reference*

Indirect revascularization, the concept of wrapping the TE graft with viable tissue (i.e., greater omentum, peritoneum, muscle, subcutaneous tissue) and stimulating ingrowth of microvessels, has been intensively investigated in the experimental literature.[43] In this approach, the new capillaries emerge from neighboring vessels induced by an inflammatory wound-healing response as a reaction to the surgical implantation.[44] This, combined with the hypoxia within the implant evokes local expression of angiogenic growth factors. Recently, it was shown clinically that this approach may result in vascularized tissue transplants.[45] However, this process took 4 months.

2.220.3.2. Induction of Angiogenesis *In Vitro*

The vascular network branches in a hierarchical fashion and is organized spatially to provide adequate nutrients to the cells of all organs and supporting structures by diffusion and convection. The maturation of nascent vasculature requires recruitment of mural cells, generation of an ECM and specialization of the vessel wall for structural support, and regulation of vessel function. In addition, the vascular network must be organized so that the parenchymal cells receive adequate nutrients. All of the processes are orchestrated by physical forces as well as by a constellation of ligands and receptors whose spatiotemporal patterns of expression and concentration are tightly regulated.[46]

Physicists, chemists, engineers, material scientists, biologists, and physicians try to mimic the only partially understood biological processes of vasculogenesis, angiogenesis, and vessel maturation. Three approaches have been used for vascularization of bioengineered tissues[41]:

1. incorporation of angiogenic factors in the bioengineered tissue,
2. seeding EC with other cell types, and
3. prevascularization of matrices prior to cell seeding.

Optimized surgical implantation techniques are one more essential step toward clinical application of engineered bioartificial tissues.[47]

2.220.4. Biological Vascularized Scaffold

As the angiogenic capabilities of most engineered tissues are not sufficient, complex bioartificial tissues that are viable and functional can currently be generated only by implementation of a fully developed capillary network. Recently, a biological vascularized matrix (BioVaSc) was introduced that supplies a capillary bed for the nutrition of complex man-made biological tissues[48] including clinical transplants[35,49] (Figure 3).

2.220.4.1. Generation

The BioVaSc represents an acellular collagenous network generated from a porcine jejunal segment by removal of all cellular components. Its histologic composition is similar to the small intestinal submucosa (SIS) matrix, which has been shown to

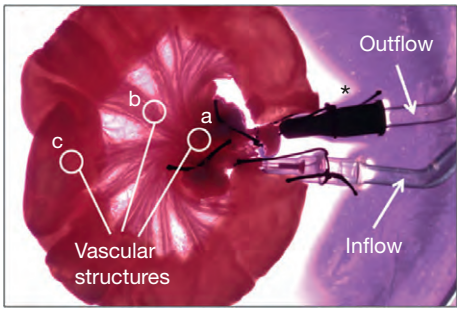

Figure 3 The biological vascularized scaffold represents an acellular biological matrix that is endued with a capillary network and feeding vascular structures. It is obtained from a porcine jejunal segment that is explanted with its feeding artery and draining vein and decellularized chemically by flushing the vascular structures. For reseeding, the acellular matrix is perfused in a bioreactor. The asterisk symbol indicates the canula in the draining vein, (a), (b), and (c) indicate different sections of the vascular network within the BioVaSc.

- represent a complete absorbable biocompatible framework,[50]
- enable cellular migration and differentiation,[51]
- show early capillary ingrowth and endothelialization,[51]
- provide high infection resistance,[52] and
- be nonimmunogenic.[50]

The SIS has been successfully applied as a biological matrix for numerous body tissues in animal studies and human clinical trials including

- musculoskeletal,[53]
- cardiovascular,[54]
- urogenital,[55] and
- laryngeal applications.[56]

Although the SIS shows excellent biomimetic and therefore favorable remodeling properties,[57] its applicability is limited by the lack of graft vascularization.[41] The BioVaSc may surmount this difficulty.

2.220.4.2. Application as *In Vitro* Test System

Given the documented favorable biomimetic properties of the SIS, complex bioengineered human tissues built on the BioVaSc represent sustainable alternatives to animal models for pharmaceutical, chemical, cosmetic, and nutritional investigations. Additionally, they can be applied as model systems for basic research to study cell–cell and cell–matrix interactions as well as angiogenesis processes[58] (Figure 4). Moreover, they afford antiangiogenesis studies and the *in vitro* growth of human tumor tissues.[59]

2.220.4.3. Application as Transplant

If nothing else, clinical applications have confirmed the assumable outstanding healing properties of the BioVaSc including its nonimmunogenicity (see Section 2.220.4.1).[35,49,57] Short-term implantations confirmed the functionality of the generated vascular structures affording transplant survival.[35] Applied for tracheal reconstruction, the BioVaSc showed a substantial tissue maturation process within the first 3 months following

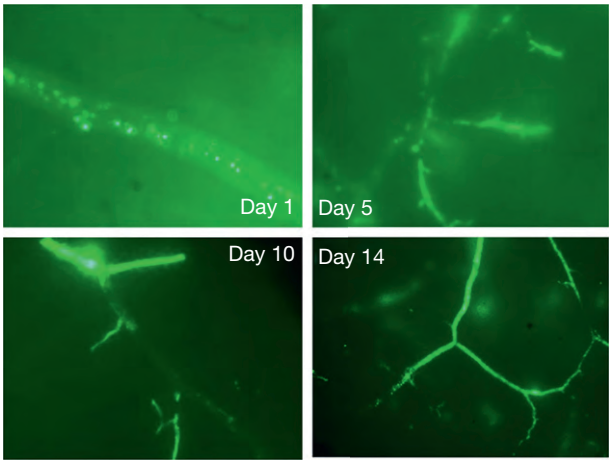

Figure 4 Angiogenetic *in vitro* studies afforded by the biological vascularized scaffold (BioVaSc). Human microvascular endothelial cells were cultivated on the BioVaSc for 2 weeks. Endothelial cells were labeled green with carboxyfluorescein diacetate succinimidyl ester.

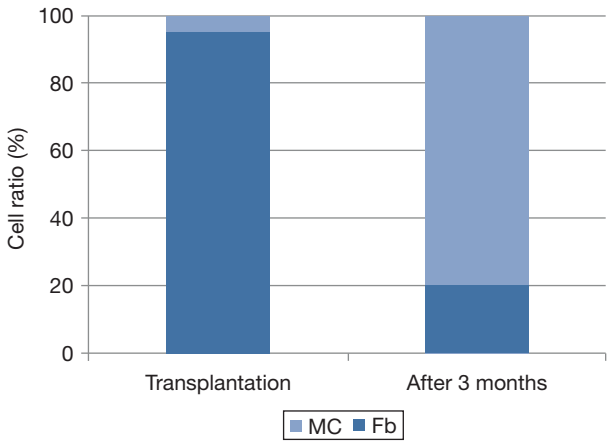

Figure 5 The bioartificial tissue undergoes a significant remodeling process within the first 3 months following transplantation (MC = muscle cells, Fb = fibroblasts).

transplantation, mirrored by shifted cell-populations, epithelial repopulation of the surfaces and vascularization[49] (Figure 5).

2.220.5. Summary and Future Directions

Many applications in the TE field currently depend on the identification of biological materials that support and stimulate the self-assembly and organization of cells, tissues and organs. Today, TE provides numerous promising medical applications and may expand the spectrum of methods in basic and applied research. In the light of a growing understanding of biomimetic signals, vasculogenesis, and angiogenesis, it is foreseeable that the complexity and applicability of the artificial tissues will increase.

Despite apparent successes using synthetic materials, at present the biological materials set the basis for studying the underlying mechanisms and interactions to develop easier available and manageable artificial materials for future applications. Looking into the future, a further diversification of the field is foreseeable. For example, the potential impact of nanomedicine will radically change the composition of materials applied for TE.

Besides the importance of material-specific interactions, clinical applications have taught the paramount importance of the physiological microenvironment for the artificial tissues. These have to be studied and understood to be calculable in future applications.

Triton® X-100	Octyl phenol ethoxylate	**VEGF**	Vascular endothelial growth factor

2.221.1. Introduction

Organ demand is a major healthcare issue that is growing in magnitude, globally. Although organ donations are increasing, the number of patients waiting for a transplant is increasing more rapidly. In 2006, the world market for organ replacement therapy was estimated to be in excess of $350 billion and expected to surpass $500 billion within 20 years.[1] An area of study that holds great potential to combat this ever-increasing crisis is tissue engineering. Tissue engineering applies the principles of cell transplantation, material science, and engineering to develop biological substitutes that can restore and maintain normal function.[2] The pioneering work of Robert Langer, Joseph Vacanti, and colleagues introduced the concept of using a degradable three-dimensional (3D) scaffold as a temporary substitute for the extracellular matrix (ECM).[3–6] The ECM is, by definition, nature's ideal biologic scaffold material.[7] The composition and ultrastructure of the ECM consists of a complex combination of structural and functional proteins, glycosaminoglycans (GAGs), glycoproteins, and small molecules all arranged in a unique, tissue-specific 3D architecture.[8] In addition to providing structural support, the ECM modulates cellular behavior by regulating the activity of growth factors, cytokines, matrix-degrading enzymes, and their inhibitors. More importantly, the ECM is in a state of dynamic equilibrium with its surrounding microenvironment.[8] Consequently, the ECM facilitates the bidirectional flow of information between adjacent cells and the external environment, which is crucial in a number of biological processes such as embryonic development, wound repair, and hemostasis.

Briefly, native ECM is composed primarily of collagen (collagen type I being the predominant type), providing the necessary mechanical strength to the scaffold. Elastin is another dominant structural protein found in the ECM that provides elasticity and resilience to connective tissues. Fibronectin, a glycoprotein, is also found in abundance within the ECM, in particular in the basement membrane, submucosal structures, and in interstitial tissues. Fibronectin is important in mediating cell–matrix communication, due to its rich content of Arg-Gly-Asp (RGD) subunits that are important for cell adhesion.[8] Laminin, another adhesion protein found abundantly in the basement membrane of the ECM, plays an important role in early embryonic development as well as a critical role in the process of cell and tissue differentiation.[8] In addition, the ECM contains various mixtures of GAGs such as chondroitin sulfate A (CS-A) and B (CS-B), heparin, heparan sulfate (HS), and hyaluronan (HA). The GAGs bind various growth factors and cytokines in the ECM, as well as promote water retention and contribute to the gel properties of the ECM.[8,9] Moreover, although native ECM contains very small quantities of growth factors and cytokines, they are vital in modulating a variety of cellular activities (i.e., cell migration, proliferation, differentiation, and maturation).[8,9]

An important characteristic of native ECM that distinguishes it from the variety of other scaffolds used in tissue engineering applications is its diversity of structural and functional proteins. In general, the scaffold approach in tissue engineering falls under two categories: (1) the use of synthetic matrices; and (2) the use of natural matrices, which include decellularized matrices. The objective of this chapter is to provide an overview of the current knowledge surrounding decellularized matrices including the various methods used to decellularize tissues, the manufacturing effects of decellularization, and lastly the origin and applicability of decellularized matrices in a therapeutic tissue engineering context.

2.221.1.1. What is Decellularization

Decellularization is the process of removing the allogeneic or xenogeneic cellular antigens from a tissue that would initiate an immune response while leaving behind an intact ECM comprising a mixture of structural and functional molecules. Decellularization results in a decellularized matrix also referred to as acellular or devitalized matrix in the literature. The particular terminology used to denote a decellularized matrix in this chapter has been kept consistent as that referred to the referenced publication. Decellularization strategies vary depending on the tissue being processed. In general, the manufacturing process involves a series or combination of physical, chemical, and enzymatic treatments that ideally removes all cellular and nuclear materials without adversely affecting the composition, organization, biological activity, and mechanical integrity of the native ECM tissue. The efficiency of decellularization is a factor of both the processing methodology and the nature of the tissue.[10,11]

2.221.1.2. Benefits and Challenges of Decellularization

Decellularization of tissue has been widely shown to be an attractive method of obtaining scaffolds for tissue engineering. An alternative to decellularization is the use of synthetic scaffold materials. These materials are typically characterized by uniform and reproducible mechanical and material properties. However, synthetic materials can lack the bioinductive and constructive remodeling properties inherently characteristic of ECM-derived scaffolds.[10,12–14]

The use of decellularized scaffolds for a tissue engineering approach provides a number of benefits, as listed in **Table 1**. First, removal of allogeneic or xenogeneic cellular antigens not only minimizes the source of immunogenicity on implantation, but also preserves the ECM components, which are highly conserved among species allowing the use of xenogeneic materials.[15] Moreover, decellularized scaffolds can retain a

Table 1 Comparison of the benefits and challenges of decellularization

Benefits
Minimizes immunological response upon implantation
Allows for the use of xenogeneic materials
Ability to conserve the mechanical integrity of native tissue
Ability to retain the biochemical composition of native tissue
Ability to retain the three-dimensional microarchitecture of native tissue
Retains the bioinductive properties (cryptic peptides) to facilitate tissue remodeling
Widely applicable and economical
Long-term storage capability
Potential for an off-the-shelf product
Challenges
Requires optimization of decellularization process for each tissue source
Immunological response from incomplete cellular removal
Decellularization efficiency dependent on tissue source, thickness, and architecture
Bioactivity and structural integrity of tissue may be impaired during manufacturing process
Difficulty in characterizing efficiency of decellularization
Scaffold properties constrained by the tissue source characteristics
Reliance on host cell availability and infiltration
Rapid *in vivo* degradation before recellularization

more physiologically relevant composition and microenvironment to the native ECM tissue. For instance, the ultrastructure and 3D architecture of the tissue can be preserved throughout the decellularizing process, retaining defining structures such as laminin and collagen type IV of the basement membrane in urinary bladder matrix (UBM)[16] and placental decellular matrix (PDM),[17] which are crucial in modulating cellular behavior. Moreover, decellularization may preserve the alignment and organization of collagen fibers,[10,18] as well as elastic fibers,[14,19] that aid in retaining not only elasticity to the scaffold but also biological activity.[20,21] Consequently, the functionality and mechanical stability of decellularized scaffolds can provide the closest match to that of native tissues.[22] Decellularized scaffold may also function as resorbable, provisional matrices whose degradation products release cryptic peptides such as endostatin, angiostatin, and canstatin, which actively participate in long-term tissue remodeling.[7,23] Lastly, decellularized scaffolds present a widely applicable yet economical option with the potential for an off-the-shelf product with long-term storage capabilities for clinical applications.[8,24–29]

Despite the numerous benefits decellularized scaffolds provide, some challenges still exist. First, the decellularization process needs to be optimized for each tissue source, as the ECM harvested from the tissue contains a unique arrangement and composition of structural and functional components specific to that particular tissue or organ.[11] As a result, incomplete cellular removal may elicit immune reactions on implantation. In addition, tissue variability may exist in terms of tissue thickness or the age of the tissue, which further complicates the efficacy of decellularization.[7,11,12,15,30] Likewise, depending on the methods and/or reagents used in the manufacturing process, the bioactivity and structural integrity of the scaffold may be impaired. Therefore, a systematic and perhaps lengthy approach may be needed to fine tune the decellularization strategy. Challenges in characterizing the decellularized scaffold also exist in terms of accurately identifying and quantifying both the bioactive components and residual decellularizing agents in the matrix.[11,15] Moreover, the material properties of the decellularized scaffold are inherently constrained by the characteristics of the tissue source including shape, and mechanical behavior.[10] Thus, additional processing such as cross-linking may need to be introduced to improve the versatility of the scaffold. Decellularized scaffolds, by definition, also rely on cellular infiltration by host cells whose availability *in vivo* may be limited or whose infiltration may be inhomogeneous.[29,31] Lastly, decellularized scaffold can degrade quickly *in vivo*, however, before complete recellularization[23,25,32]

2.221.2. Decellularization Methodology

In 1975, Meezan *et al.* described the first decellularization strategy for extracting cells from the ECM through a multistep chemical and enzymatic process in preparation of basement membranes from several tissues.[33] In recent years, there have been a number of methods developed to manufacture biologic scaffolds derived from decellularized tissues and organs, as summarized in **Table 2**. The resulting decellularized ECM-derived scaffolds have been broadly applied to a multitude of applications including adipose,[17] bladder,[53,77,85–88] nerve,[83,89–92] and cardiovascular[27,57,69,73,93–100] tissues. The most robust and effective decellularization protocols include a combination of physical, chemical, and enzymatic treatments.[11] In general, a typical decellularization protocol contains the following series of steps: (1) lysis of cell membranes by physical treatments or ionic solutions, (2) separation of cellular component from the ECM using enzymatic treatments, (3) solubilization of cytoplasmic and nuclear cellular components by detergent treatment, and finally (4) rinsing and removal of cellular remnants from the ECM. Each of these steps may be coupled with mechanical agitation, and repeated a number of times to increase the effectiveness. The effectiveness of decellularization and preservation of the native ECM can be evaluated at each of the steps by a variety of methods, as will be discussed. Nonetheless, it is important to acknowledge that tissues depending on their origin, composition, structure, and thickness may respond variably to a decellularization process. Decellularization strategies must therefore be optimized for each tissue by controlling the concentration and duration of each treatment, and subsequently analyzing their effects on the composition, architecture, as well as function of the remaining decellularized ECM.[68,101]

2.221.2.1. Physical Methods

To facilitate the decellularization of tissue, physical methods such as lyophilization, repeated freeze-thawing, sonication, direct pressure, and agitation may be used. The premise for each method employed is to disrupt the cell's plasma membrane resulting in cell lysis and removal from the tissue. These methods provide a direct and rapid means of decellularization. However, these methods typically need to be used in conjugation with chemical extraction treatments to increase their effectiveness.[40]

Table 2 Common decellularization methods and reagents

Method	*Mode of action*	*Effects on ECM*	*Examples of tissue/organ*	*References*
Physical				
Snap freezing & lyophilization	Intracellular ice crystal formation resulting in permeabilization of cell membrane	ECM is disrupted or fractured during rapid freezing	Ligament; cardiac valves; pericardium; bone matrix; amniotic membrane; embryoid bodies; liver	34–41
Repeated freeze–thaw			Heart valves leaflets; meniscus; ligament; nerve; embryonic chick knee; dermis; embryoid bodies	40,42–48
Mechanical force (delamination and pressure)	Pressure can burst cells and tissue layer removal eliminates cells	Mechanical force can damage ECM components	SIS; UBM; UBS; aorta; tendon; meniscus	16,49–52
Mechanical flow (agitation and perfusion)	Facilitates chemical exposure and removal of cellular debris; may lyse cells	Aggressive conditions may harm ECM components	Heart valves; bladder; heart; placenta; umbilical veins	17,19,53–59
Chemical				
Solvent extraction (ethanol, xylene, butanol, acetone)	Facilitates membrane lipid removal, specifically triglycerides and cholesterol	Prolonged exposure may induce collagen structural changes in the ECM	Blood vessels; heart valves; umbilical veins	12,56,60,61
Tri(*n*-butyl)phosphate	Organic solvent that disrupts protein–protein interactions	Variable outcome with cell removal and disruption to ECM	Articular cartilage; tendon; ligament	62–65
Alkaline and acidic treatments	Solubilizes cytoplasmic components of cells; disrupts nucleic acids	Potential oxidative damage to GAGs such as HA, as well as microscopic structural changes to collagen	SIS; UBM; UBS; blood vessels; gallbladder; embryoid bodies	50,60,66–68
Detergent extraction				
Nonionic detergents (Triton® X-100, Tween® 20, Tween® 80)	Disrupts lipid–lipid and lipid–protein interactions but leaves protein–protein interactions intact	Variable outcome dependent on tissue type	Ligaments; tendons; cartilage; aortic valves; embryoid bodies	62,63,65,68–70
Ionic detergents (SDS, sodium deoxycholate, Triton® X-200, lauroyl sarcosinate)	Solubilizes cytoplasmic and nuclear cellular membranes; tends to denature proteins	Variable outcome dependent on tissue type, detergent concentration, and treatment duration; potential loss of GAG content, collagen structural change, and change to mechanical integrity	Cartilage; ligament; tendon; pericardium; meniscus; heart valves; blood vessels; bladder; skin; placenta	17,33,53,62,63,71–82
Cationic detergents (CTAB)	Disrupts cellular membrane and solubilizes cellular content	Structural damage to ECM proteins	Nerve	83
Zwitterionic detergents (CHAPS, Empigen BB, SB-10, SB-16)	Exhibits properties of both nonionic and ionic detergents	Sufficient cell removal and minimal ECM disruption	Umbilical arteries; nerve	27,83,84
Hypotonic and hypertonic solutions	Cell lysis by osmotic shock	Effective at cell lysis but requires additional processing for removal of cellular debris	Bladder; blood vessels; aortic valves; meniscus; ligament	22,53,58,74,77,79,81
Enzymatic				
Trypsin	Serine protease, cleaves proteins at the C-side of Arg and Lys residues; chelating agents (EDTA) typically used with trypsin	Longer incubations may disrupt ECM structure and composition	Heart valves; blood vessels; pericardium	12–14,19,70,76,82
Endonucleases	Cleaves the interior phosphodiester bond of ribonucleotide and deoxyribonucleotide chains	Difficult to remove from the tissue and could invoke an immune response	Heart valves; pericardium; bladder; placenta; embryoid bodies	17,53,58,68,69,73,74,77,80,82
Exonucleases	Cleaves the terminal phosphodiester bond of ribonucleotide and deoxyribonucleotide chains

Snap freezing followed by lyophilization has been utilized to decellularize a variety of tissues prior to therapeutic application, including ligaments,[36,37,41] cardiac valves,[34] pericardium,[38,102] bone matrix,[35] amniotic membrane,[103] and more recently embryoid bodies.[40] Rapid freezing of the tissue or matrices results in intracellular ice crystal formation, disrupting the cellular membrane and thereby cell lysis. Subsequent removal of water molecules by freeze-drying may also facilitate removal of cellular debris. Freeze–thaw cycling is another physical technique consisting of submerging the tissue in liquid nitrogen (snap freezing) followed by room temperature thawing in a buffered aqueous solution. Multiple tissues have been decellularized by freeze–thaw cycling including peripheral nerve grafts,[43,92] meniscal tissue,[46,47,79] embryonic chick knees,[48] and human dermis.[42] In both techniques, the rate of temperature change needs to be optimized for each tissue or matrix in order to prevent damage to ECM components.[11]

Application of direct pressure is another physical technique,[11,16,49,51,52,104] but this technique is only effective for tissues that are not characterized by densely organized ECM (e.g., liver, lung); otherwise, the treatment may leave cellular debris behind thereby inducing potential immunogenic reactions.[11,78] Recently, supercritical carbon dioxide containing a small amount of ethanol has been used as an extraction medium to decellularize porcine aortas.[52] Physical separation or delamination of tissue layers is a common technique reported by the Badylak group[16,50,105,106] in creation of the small intestinal submucosa (SIS)-ECM as well as the urinary bladder submucosa (UBS) and urinary bladder matrix (UBM)-ECM. Delamination has proven to be an effective physical technique in decellularization of the tissue without disruption to the native ECM structure and architecture.[11,16,50,107,108] Mechanical agitation using a magnetic stir plate or an orbital shaker and the introduction of sonication are among other common physical techniques used in decellularization procedures.[11]

In many decellularization protocols, physical techniques are employed in conjugation with chemical treatments to assist in decellularizing the tissue. The latter strategies are largely based on passive diffusion, which require extensive washing steps to not only remove the cellular debris from the ECM, but also remove any residual chemical compounds. In addition, the optimal speed, volume of reagent, and length of agitation all affect the efficiency of decellularization, which in turn is dependent on the composition, architecture, and thickness of the tissue.[11,56] More recently in the literature,[17,54,56,57,59] the application of convective flow or perfusion has been commonly reported as an effective decellularization strategy, especially in thick tissues. For instance, Flynn *et al.* used a perfusion system to aid decellularization of human placenta,[17] while Ott *et al.* decellularized whole rat hearts using a modified Langendorff apparatus.[57]

2.221.2.2. Chemical Methods

A variety of chemical treatments can be used independently or in a multistep extraction process to decellularize tissues. As summarized in **Table 2**, the reagents used to decellularize different tissues can be generally categorized into solvents for extraction, alkaline or acidic detergents, hypotonic and hypertonic solutions, and enzymes.[11] The choice of reagent(s) is largely dependent on the suitability to effectively treat the tissue source, in terms of conserving the native ECM's biochemical and structural properties and also simultaneously removing the undesirable cellular elements.[68] It is important to recognize, however, that the extraction process may result in cell damage and death, which can consequently produce divergent secondary signals on implantation. For instance, capase found on the cell surface of apoptotic cells can degrade elastin, where the resulting peptides can signal through the elastin–laminin receptor in the presence of transforming growth factor β 1 (TGF-β1) to ultimately produce bone.[109] Therefore, as with each decellularization treatment, care must be taken to optimize the extraction process best suited for the tissue of interest.

2.221.2.2.1. Solvent extraction

Solvent extraction through the use of reagents such as ethanol,[12,56,60,61] xylene, and butanol[12] as well as acetone[56] has been reported to facilitate decellularization of blood vessels,[12,60] heart valves,[110] and umbilical veins.[56] Predominantly used in combination with other chemical treatments, this pretreatment has been reported to extract membrane-bound lipids such as phospholipids, triglycerides, and cholesterol while minimizing tissue calcification.[12,61] In comparison to proteins, the chemistry of the phospholipid molecules, for example, allows for greater solubilization by organic solvents. However, disruptions to the ECM structural components and biomechanical behavior have been observed post solvent extraction treatment.[12,61]

Tri(*n*-butyl)phosphate (TnBP) is another commonly used organic solvent, reported to aid in the extraction of cells from blood derivatives as well as lipid-enveloped viruses,[111,112] articular cartilage,[63] tendon,[62] and anterior cruciate ligament (ACL).[64,65] Unlike other solvents, TnBP disrupts protein–protein interactions.[11] To date, mixed outcomes on the effectiveness of cellular removal and disruption to the ECM with TnBP treatment have been reported. Decellularization of rat tail tendon with 1% TnBP for 48 h yielded complete removal of nuclear remnants and preserved the natural structure and mechanical properties of the tissue.[62] On the other hand, treatment of articular cartilage with 2% TnBP had a minimal effect on tissue decellularization but exhibited a decrease in GAG content and change in mechanical integrity in comparison to native tissue.[63] Similarly, decellularization of an ACL graft with a Triton–TnBP treatment showed equivalent levels of cellular extraction to that with Triton–sodium dodecyl sulfate (SDS) in the midsubstance of the graft; however, incomplete decellularization was observed at the femoral insertion.[65] Moreover, ACL treatment with TnBP preserved both the ECM structure and mechanical behavior of the tissue better than other extraction techniques, although disruption to the GAG content and collagen structure was reported.[64,65]

2.221.2.2.2. Alkaline and acid treatments

Alkaline and acidic treatments have been used to decellularize tissues such as SIS, UBM, UBS,[50,66] blood vessels,[60] the cholecyst wall (gallbladder),[67] and, more recently, mineralized human primary osteoblast-derived matrices.[113] Alkaline extraction procedures use alkaline salts such as those of sodium or

potassium as well as alkaline earth metals such as calcium.[60] Acidic treatments may involve the use of acetic acid, peracetic acid (PAA), hydrochloric acid, and sulfuric acid.[11] These treatments not only disrupt the cellular membrane but can also solubilize major cytoplasmic components of the cells (i.e., organelles), which aids in the removal of nucleic acids from the matrices.[11] Goissis and colleagues[60] devitalized small and large blood vessels from beagle dogs using a multistep process centered on an alkaline extraction process, and showed that the efficiency of cell removal is dependent on the segment and the type of blood vessel. Moreover, despite the harsh alkaline conditions used, no denaturation of the collagen matrix was found and the collagen and elastic fibers were preserved. On the other hand, Badylak *et al.*[50,66] have decellularized a variety of porcine tissues including SIS, UBM, and UBS using PAA at concentrations of ~0.10–0.15% (w/v).[11] The PAA treatment has been reported to effectively decellularize thin intact ECM matrices[11] while simultaneously disinfecting the matrices by penetrating into microorganisms and oxidizing microbial enzymes.[114,115] Despite the oxidative nature of PAA, the treatment has been found to retain both structural and functional molecules of the native ECM such as collagen,[16] sulfated GAGs (HA, heparin, HS, CS-A, and dermatan sulfate),[9,116] and various growth factors (vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), TGF-β1).[9,116–118] However, oxidative damage to HA in SIS after PAA treatment[117] and microscopic changes to the structural integrity of collagen fibers are issues that have been raised in the literature.[50,116,117]

2.221.2.2.3. Detergent extraction

Detergents are water-soluble molecules that have the ability to incorporate themselves into the lipid bilayer of the cellular membrane. Consequently, they solubilize the lipid membrane by disrupting the lipid–lipid and lipid–protein interactions and encapsulate proteins within detergent micelles at certain concentrations.[11,119] A variety of detergent extraction techniques have been utilized to decellularize tissues, which can range from the use of nonionic, ionic, cationic, or zwitterionic detergents.[11,119] Differences in the size, charge, denaturing ability, and critical micelle concentration may determine the tissue penetration, membrane disruption, and pattern of protein–detergent interaction, all of which may ultimately influence the effect on the ECM.[119] Regardless of the type of detergent used in the decellularization protocol, steps must be taken to efficiently remove residual detergent from the matrices to avoid pronounced immune responses.[75,120]

2.221.2.2.3.1. Nonionic detergents

Nonionic detergents, such as octyl phenol ethoxylate (Triton® X-100), Tween® 20, and Tween® 80, are mild or nondenaturants capable of breaking lipid–lipid and protein–lipid interactions but leaving protein–protein interactions intact.[11,119] Triton® X-100 is the most widely studied nonionic detergent used to decellularize a variety of tissues such as ligaments,[65] tendons,[62] cartilage,[63] bladder,[24,53] nerve,[83] liver,[39] aortic valves,[69,70] blood vessels[121] and embryoid bodies.[122] However, the effectiveness of Triton® X-100 in terms of complete cellular and nuclear removal as well as preservation of ECM components is variable, depending on the nature of the tissue. For instance, similar cellularity and nuclear content to controls were observed after 1% Triton® X-100 treatment of carotid arteries[121] and tendons[62] while complete removal of cellular remnants from aortic valve leaflets has been observed with the same treatment.[70,74] Mixed results on collagen density and structure, GAG content, and mechanical integrity of tissues after Triton® X-100 treatment have also been reported. For example, Triton® X-100 treatment of aortic valves showed a reduction in the collagen density,[69,70] as well as loss of GAG content (especially CS) and loss of adhesion molecules, laminin, and fibronectin.[70] Conversely, treatment of ACL with Triton® X-100 showed no effect on the collagen and GAG content, as well as on mechanical properties. As such, the effectiveness of using a mild, nonionic detergent to decellularize largely depends on both the type of tissue as well as the subsequent decellularization treatments used.

2.221.2.2.3.2. Ionic detergents

Ionic detergents such as sodium dodecyl sulfate (SDS), sodium deoxycholate (SD), Triton® X-200, and more recently lauroyl sarcosinate (LS) are commonly used in decellularization protocols as they are effective in solubilizing both cytoplasmic and nuclear cellular membranes.[11] In general, ionic detergents are denaturants. They disrupt the noncovalent bonds within proteins, causing them to lose their native conformation,[119] and in terms of the ECM, potentially disrupt the integrity of collagen.[56]

In a number of extraction protocols, sufficient levels of cell removal from tissues such as cartilage,[63] tendon,[62] ligament,[22] skin,[72] and heart valves[74,76] have been achieved through the use of the surfactant SDS. As an amphipathic molecule, SDS effectively binds to proteins via its hydrophobic domain, resulting in an increased negative charge that can lead to both swelling of the tissue and destabilization of the collagen triple helical domain.[73,76] In the literature, there have been concerns about the use of SDS in extraction protocols because of its effects on collagen stability, potential toxicity, and retention within the matrix.[62,64,76,123] However, recent reports suggest SDS to be an effective decellularization agent with minimal ECM disruption but favorable cellular repopulation that can, in part, be linked to detergent concentration, treatment duration, and the nature of the tissue.[22,63,78,79,120,124] Gratzer *et al.*[22] found that residual SDS in decellularized porcine ACL tissue did not influence the viability and repopulation of autologous ACL fibroblasts. However, treatment with 1% SDS for 48 h significantly reduced GAGs levels and caused structural changes to collagen while no significant change in mechanical behavior was noted in the decellularized ACL tissue. On the other hand, Lichtenberg *et al.*[124] re-endothelialized decellularized ovine pulmonary valves post 0.5% SDS treatment, and not only maintained a confluent layer of endothelial cells under physiological pulmonary flow conditions, but also found preservation of the ECM structure and mechanical integrity of the decellularized scaffold to be comparable to that of the native tissue. Lastly, Elder *et al.*[63] found that the duration of SDS treatment in decellularizing articular cartilage determined the level of biochemical and ultrastructural change in the tissue. For instance, treatment with 2% SDS for 1 or 2 h resulted in a 33% reduction in DNA content but maintained the biochemical (i.e., GAG and collagen content) and biomechanical

properties of the tissues. In contrast, 2% SDS treatment for 6 or 8 h resulted in a greater reduction in DNA content, and significantly decreased both the GAG content and compressive properties of the tissue.

SD is another ionic detergent that is very effective in removing cellular remnant, but tends to have even more significant impact on the ECM structure than SDS.[11] The specific effect of SD on decellularized ECM is unclear to date[11] as it is typically used in conjunction with other decellularizing agents.[76,82]

2.221.2.2.3.3. Cationic detergents

In general, for decellularization, the class of cationic detergents is typically deemed to be that of the most cytotoxic as well as too strong detergents that cause structural proteins in the native ECM to denature.[83] Cetyltriethylammonium bromide (CTAB) is a cationic detergent used as part of a detergent-based decellularization method for nerve tissue. Although CTAB was found to be effective at removing cellular components from the nerve tissue, it was unable to preserve the ECM structure.[83]

2.221.2.2.3.4. Zwitterionic detergents

A variety of zwitterionic or amphoteric detergents have also been incorporated in decellularization methodologies, such as 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS), as well as sulfobetaine-10 (SB-10) and -16 (SB-16). Zwitterionic detergents exhibit properties of both nonionic and ionic detergents, but have a greater tendency to denature proteins than nonionic detergents.[11] In the literature, zwitterionic detergents are typically used in combination with an ionic detergent that allows for tighter packing of the detergent micelles.[83] More specifically, the use of both a zwitterionic and an ionic detergent allows the neutrally charged zwitterionic molecules to intersperse between the ionic molecules, lowering the repulsion between head groups and thus, increasing the packing density of the micelles. A tighter packing density is presumed to result in smaller, more robust micelles that are able to better penetrate into the tissue and mediate the removal of more hydrophobic materials (i.e., cell membranes).[83] Zwitterionic detergents have been used in decellularization strategies for nerves[83] and umbilical arteries.[27,84] In general, zwitterionic detergents are considered to be mild detergents as they yield sufficient cell removal and preserve the ECM to some extent.[11,83]

2.221.2.2.4. Hypotonic and hypertonic treatment

To enhance the action of detergents or as a measure on its own, osmotic shock may be incorporated into the decellularization strategy as a means to effectively lyse cells. Osmotic shock has been used in decellularization strategies for a number of tissues including bladder,[53,58,77] blood vessels,[81] placenta,[17] aortic valves,[74] meniscus,[79] and ligament.[22] Its introduction generally involves treatment with a hypotonic solution followed by treatment with a hypertonic solution. Osmotic lysis with a hypotonic solution causes the cells to swell and burst. Swelling of the cell, caused by the inward movement of water, may also enhance the uptake of detergents into the cellular membrane. The opposite effect occurs in a hypertonic solution where water moves outward from the cell causing cellular dehydration and shrinkage, which aids in cellular death and detachment from the matrix.[119] Although this strategy is highly effective at lysing cells, additional processing is required to remove the resultant cellular debris from the tissue, especially residual nucleic acids. Therefore, an additional nuclease enzyme digestion step typically follows the osmotic shock treatment.[11,119]

2.221.2.2.5. Enzymatic treatment

Enzymatic treatments, involving proteases and nucleases, are incorporated into the decellularization strategy to aid in the removal of cellular proteins and nucleic remnants. Trypsin is one of the most commonly used proteolytic enzymes in decellularization methodologies, and is typically used in combination with the calcium chelating agent, ethylenediaminetetraacetic acid (EDTA).[11,119] EDTA is used to inactivate intracellular proteases that are released by the trypsinized cells and are capable of degrading the ECM constituents. Trypsin is a serine protease that cleaves proteins at the carboxyl side of lysine and arginine residues except when followed by proline, as is the case with collagen. It is predominantly used in decellularization protocols to aid in the detachment of cells from the surrounding ECM proteins by disrupting protein interactions, resulting in a more open matrix that can facilitate the removal of cellular debris.[11,119] Trypsin has been part of enzymatic treatments for decellularization of a number of tissues including heart valves,[13,19,70,76] vascular grafts,[12,14] and pericardium.[82] Nonetheless, variable cell loss has been reported in the literature following trypsin treatment.[13,19,76] Schenke-Layland and colleagues reported insufficient cell removal from pulmonary valves but preservation of ECM components (GAG, collagen, and elastin) following shorter trypsin-EDTA incubation times (5 and 8 h). At a longer incubation period (24 h), complete cellular removal was reported. However, the ECM biochemical composition (especially in terms of *o*-sulfated GAGs as well as acid and salt soluble collagens) and ECM integrity were negatively impacted in a time-dependent manner.[19] On the other hand, complete cellular removal and well-conserved and arranged collagen and elastin fibers were found by Teebken *et al.* who used a multistep enzymatic extraction method with trypsin-EDTA, deoxyribonuclease (DNase), and ribonuclease (RNase) to decellularize thoracic aortas.[14] Therefore, the nature of the tissue as well as the duration of enzymatic digestion must be taken into consideration when incorporating trypsin-EDTA into a decellularization strategy.[11,12,76]

Nucleases such as endonucleases and exonucleases may also be incorporated in enzymatic treatments.[11] DNases and RNases have been commonly used in decellularization methodologies in combination with detergent extraction treatments to aid in the removal of nuclear debris. Many of the nucleases used in decellularization protocols are extracted from bovine tissues running the risk for prion disease transmission.[11] An alternative may be to use recombinant nucleases. As with protease treatment, the duration of nuclease treatment must also be optimized in order to effectively remove cellular antigens without harming the ECM composition and structure.[68,122] As such, decellularization protocols using either proteases or nucleases must incorporate effective steps for the removal of residual enzymes in the tissue prior to *in vivo* implantation.

2.221.2.3. Additional Reagents

Lysing of cellular membranes during decellularization may also release a number of cellular proteases into the environment, causing additional, yet unintentional damage to the ECM. Moreover, maintaining the tissue above 4 °C for any length of time after removal can result in tissue breakdown.[109] In order to account for these disruptions, a number of lengthy decellularization processes are run in cooler conditions and include protease inhibitors such as phenylmethylsulfonylfluoride (PMSF), aprotonin, and leupeptin.[11] In addition, decellularization may be conducted in buffered solutions of pH 7–8, as proteases function optimally in acidic conditions.

Lastly, many decellularization protocols include antibiotic solutions such as those of penicillin, streptomycin, or amphotericin to prevent bacterial contamination.[11] However, special attention must be taken to ensure that residual antibiotic does not remain in the decellular matrix prior to *in vivo* implantation; otherwise regulatory approval for clinical use will be difficult.[11]

2.221.2.4. Additional Processing

Following physical, chemical, and/or enzymatic treatments, decellularized ECM scaffolds are typically disinfected and/or terminally sterilized before being used or stored. Decellularized scaffolds are commonly disinfected using oxidizing agents such as hydrogen peroxide, sodium peroxide, PAA, or an ethanol–peracetic acid solution (PES).[25,50,114,116,125] However, long exposure periods of these disinfectants may cause oxidative damage to collagen fibers and GAGs, ultimately reducing the structural integrity of the matrix.[26,50,116] Prior to *in vivo* implantation, decellularized scaffolds are also subjected to terminal sterilization usually by ethylene oxide (ETO) treatment, gamma irradiation, or electron beam irradiation.[25,50,117,126] Several studies have shown that these sterilants can have detrimental effects on the mechanical behavior of the scaffolds. However, certain sterilants can cause more significant damage to the matrix than others. For instance, Freytes and colleagues found that in comparison to the ionizing radiation treatments, ETO treatment had the least detrimental effect on the mechanical properties of a lyophilized form of the UBM.[25] Moreover, they also suggested that the overall effect of sterilization depends on the relative amounts, density, and distribution of the ECM constituents, as well as dosage of the sterilant.[25]

Decellularized ECM scaffolds may also take on a variety of different forms upon additional processing steps to not only improve their shelf life but also expand their clinical applicability, as recently reviewed elsewhere.[10] For instance, decellularized scaffolds can be hydrated or dehydrated,[127] comminuted into a powdered ECM form,[128,129] or solubilized into a liquid or gel form.[130,131] **Table 3** summarizes some of the commercially available decellularized scaffolds that have been packaged and stored under various conditions, including hydrated (Pelvicol™, Bard), laminated and vacuum dried (Restore™, Depuy Orthopedics), and freeze-dried (Bard® Dermal Allografts, Bard).[7,10,127] Storage of processed ECM scaffolds in a hydrated state helps to maintain the native tissue architecture. However, continuous leaching and/or hydrolysis of structural (i.e., collagen) and nonstructural (i.e., growth factors) components may disrupt the functionality and shelf life of the scaffold.[10,127] Dehydration of processed ECM scaffolds, by lyophilization or by vacuum pressing, may minimize hydrolytic degradation during storage. However, dehydration may also result in scaffold ultrastructural changes that can consequently affect cellular attachment, infiltration, and remodeling.[10,127] Powdered or gelated forms of decellularized scaffolds can potentially conform to any 3D shape as well as have the capability of being delivered to a site of interest by minimally invasive techniques.[129,130] Regardless of the manufacturing process, the effect of storage duration and temperature on the scaffold's structural and functional properties must also be taken into consideration in order to have a therapeutically relevant material.[26]

2.221.2.5. Important Considerations

2.221.2.5.1. Characterization of decellularization

Decellularization strategies aim to remove all cellular debris while preserving the composition, mechanical integrity, and biological activity of the remaining ECM. Therefore, decellularization efficiency and reproducibility are characterized not only by the cellular constituents that are removed, but also by the desired components of the ECM that are retained. In this chapter, there is very little information comparing the effectiveness of different decellularization methods in treating a tissue of interest.[82] Nonetheless, it is important to recognize that the decellularization process needs to be optimized for each harvested tissue to account for tissue variability. A number of different techniques can be used to characterize a decellularized scaffold that in general fall under the following categories: (a) histological, immunohistochemical, and biochemical assessment; (b) scaffold architecture assessment; (c) biomechanical assessment; (d) biofunctionality assessment; and (e) microbiological assessment, as summarized in **Table 4**.

A simple yet effective initial test that is commonly performed to detect any residual nucleated cells or cell fragments throughout the decellularization process is the histological stain Hematoxylin and Eosin (H&E). A variety of other histological stains such as Masson's Trichrome, Movat's Pentachrome, and methyl green-pyronine (MGP) can be used to evaluate the intracellular components of the decellularized tissue, as depicted in **Figure 1** for a PDM.[17] Immunohistochemical assessment for collagen, laminin, actin, and fibronectin can be used to gain a qualitative understanding of the biological composition, while a combination of biochemical assays such as for DNA content, GAG content, and/or collagen content can be used to quantify the biological composition of the decellularized tissue in comparison to its native form. Assessment of both scaffold ultrastructure and biomechanical behavior provides insight into the structural integrity of the decellularized scaffold. Assessment of collagen denaturation temperature and tissue shrinkage temperature has also been routinely performed to determine the structural stability of collagen.[60,73,74,82] The biofunctionality of the decellularized scaffold can be evaluated through *in vivo* and/or *in vitro* biocompatibility markers such as cytotoxicity and cellular infiltration.[17,53,80,120,133] Lastly, prior to their use, decellularized scaffolds are commonly disinfected and/or terminally sterilized; therefore, the effectiveness of the sterilization procedure should be evaluated against microbial viability and growth.[77,120]

Table 3 Commercially available devices composed of naturally derived extracellular matrix

Product	*Company*	*Material*	*Chemical modification*	*Form*	*Use*
Acell Vet®	Acell, Inc.	Porcine urinary bladder	Natural	Powder	Treatment of canine arthritic hips
AlloDerm®/Cymetra®	LifeCell Corp.	Human dermis	Natural	Dry sheet/ gel	Hernia, abdominal wall repair and breast reconstruction, soft tissue defects
AlloPatch HD™	MTF Sports Medicine	Human fascia lata	Natural	Dry sheet	Tendon augmentation
Axis™ dermis	Mentor	Human dermis	Natural	Dry sheet	Pelvis organ prolapse
Bard® Dermal Allograft	Bard	Cadaveric human dermis	Natural	Dry sheet	Pelvic floor reconstruction
CardioGRAFT®	LifeNet Health	Human cardiac tissue	Natural		Cardiovascular repair
CuffPatch™	Arthrotek	Porcine SIS	Cross-linked	Hydrated	Soft tissue reinforcement
CryoValve® SG	CryoLife, Inc.	Human pulmonary valve	Natural	Hydrated	Cardiac valve repair
DurADAPT™	Synovis Life Technologies, Inc.	Equine pericardium	Cross-linked	Dry sheet	Repair dura matter
Dura-Guard®	Synovis Life Technologies, Inc.	Bovine pericardium	Cross-linked	Hydrated	Spinal and cranial repair
Durasis®	Cook SIS	Porcine SIS	Natural	Dry sheet	Repair dura matter
Durepair®	TEI Biosciences	Fetal bovine skin	Natural	Dry sheet	Repair of cranial or spinal dura
FasLata®	Bard	Cadaveric fascia lata	Natural	Dry sheet	Urological repair
FlexHD®	Ethicon 360, Inc.	Human dermis		Hydrated	Connective and soft tissue reinforcement
Graft Jacket®	Wright Medical Tech	Human dermis	Natural	Dry sheet	Foot ulcers
MatrixP/ MatrixP plus™	AutoTissue^{GmbH}	Porcine pulmonary valve	Natural		Pulmonary valve reconstruction
MatriStem®	ACell, Inc.	Urinary bladder matrix	Natural	Dry sheet or powder	Soft tissue reconstruction
Oasis®	Healthpoint	Porcine SIS	Natural	Dry sheet	Partial and full thickness wounds & superficial and second degree burns
OrthADAPT™	Synovis Life Technologies, Inc.	Equine pericardium	Cross-linked	Dry sheet	Rotator cuff and Achilles tendon repair
Pelvicol®	Bard	Porcine dermis	Cross-linked	Hydrated	Pelvic floor reconstruction
Peri-Guard®	Synovis Life Technologies, Inc.	Bovine pericardium	Cross-linked	Dry sheet	Pericardial and soft tissue repair
Permacol™	Tissue Science Laboratories	Porcine dermis	Cross-linked	Hydrated	Soft connective tissue repair
PriMatrix™	TEI Biosciences	Fetal bovine skin	Cross-linked	Hydrated	Wound management
Prima™	Edwards Lifesciences	Porcine heart valve	Cross-linked	Dry sheet	Valve reconstruction
ProPatch®	CryoLife, Inc.	Bovine pericardium	Natural	Hydrated	Soft tissue reconstruction
Restore® Orthobiologic	DePuy Ortho Tech	Porcine SIS	Natural	Dry sheet	Soft tissue treatment
Stratasis®	Cook SIS	Porcine SIS	Natural	Dry sheet	Urinary incontinence treatment
Strattice™ (formerly XenoDerm)	LifeCell Corp.	Porcine dermis	Natural	Dry sheet	Soft tissue reinforcement
SurgiMend™	TEI Biosciences	Fetal bovine skin	Natural	Dry sheet	Soft tissue membrane repair
Surgisis®	Cook SIS	Porcine SIS	Natural	Dry sheet	Soft tissue repair and reinforcement
Suspend™	Mentor	Human fascia lata	Natural	Dry sheet	Urethral sling
TissueMend®	TEI Biosciences	Fetal bovine skin	Natural	Dry sheet	Rotator cuff reconstruction
Vascu-Guard®	Synovis Life Technologies, Inc.	Bovine pericardium	Cross-linked	Dry sheet	Vascular reconstruction
Veritas®	Synovis Life Technologies, Inc.	Bovine pericardium	Cross-linked	Hydrated	Soft tissue repair
Xelma™	Molnlycke	Amelogenins in propylene glycol alginate and water		Gel	Venous leg ulcer repair
Xenform™	TEI Biosciences	Fetal bovine skin	Natural	Dry sheet	Soft tissue reenforcement
Zimmer Collagen Patch®	Tissue Science Laboratories	Porcine dermis	Cross-linked	Hydrated	Rotator cuff repair

2.221.2.5.2. Host response to decellularized scaffolds

Decellularization aims to remove cellular antigens that are recognized as foreign by the host in response to the ECM-derived scaffold, which if unsuccessfully decellularized can ultimately result in an adverse inflammatory response or immune-mediated rejection on implantation.[7,10,136] With decellularized scaffolds, the host is presented with a different scenario from what is normally encountered with autogenous, allogenous, or xenogeneic whole organ grafts. In a typical tissue graft, immune recognition of cellular antigens occurs

Table 4 Summary of decellularization characterization techniques

A. Histological, Immunohistochemical, Biochemical Assessment	
Histological evaluation:	17,58,59,75,80,82
Hematoxylin and Eosin (H&E) – detects residual nucleated cells or cell fragments	
Masson's Trichrome – characterizes collagen structure	
Van Gieson – differentiates between collagen and elastin	
Miller's Elastin stain – detects elastin	
Picrosirius Red stain – detects collagen	
Hoechst – detects DNA	
Methyl Green-Pyronine (MGP) – detects DNA and RNA	
Movat's Pentachrome – detects collagen, elastin, nuclei, GAGs	
Alizarin stain – detects calcification	
Gomori Trichrome stain – detects connective tissue	
Herovici stain – discriminates between collagen type I and III	
Immunohistochemical evaluation:	17,58,65,70,79
Various markers – collagen type I, III, and IV; laminin; chondroitin sulfate; peripherin; van Willebrand factor; fibronectin; α-Gal; major histocompatibility complex (MHC) molecules	
Biochemical evaluation:	11,12,19,22,27,40,59,63,68,73–75,77,80,124
DNA quantification – Hoechst; DAPI; propidium iodide; PicoGreen	
Total protein content – Bradford method; Bicinchoninic acid	
Collagen content – Hydroxyproline assessment; Sircol Assay	
Denatured collagen content – Hydroxyproline assessement post digestion	
GAG content – Dimethylene blue; Blyscan Assay	
Elastin content – Fastin Elastin Assay, Hydroxyproline assessment post digestion	
Triglyceride content: Triglyceride SL Assay	
B. Scaffold Ultrastructure Assessment	
SEM, TEM, Near-infrared multiphoton laser scanning microscopy	60,73,82,132
DSC – collagen denaturation temperature, tissue shrinkage temperature	
C. Biomechanical Assessment	
Uniaxial tensile properties	25,50,59,73,77,80,130
Biaxial tensile properties	
Viscoelastic behavior	
D. Biofunctionality Assessment	
In vivo/in vitro biocompatibility – cytotoxicity, cellular infiltration	17,53,80,120,133–135
E. Microbiological Assessment

followed by the production of proinflammatory mediators and cytotoxicity, ultimately resulting in organ rejection.[8,137] However, in the case of the decellular scaffold, only the constituent proteins of the ECM and their degradation products are present, eliciting a different inflammatory and immunologic response. Unlike whole organ transplantation, the mechanisms of the host immune response to allogeneic or xenogeneic decellular scaffolds are neither well studied nor well understood.[137] In the literature, decellularized scaffolds have been noted to be immunologically tolerated as allografts for dural or dermis,[138] heart valve,[13,139] and nerve[28,91] replacement. However, concerns over the use of decellular xenogeneic grafts have been raised.[139–143] A comprehensive analysis of the immune response to biologic materials has been recently reviewed by Badylak and Gilbert; therefore, the reader is directed to this literature for a more thorough discussion.[136]

In brief, one of the major obstacles facing transplantation of living animal tissue to humans (i.e., xenotransplantation) is the interaction between the human natural galactose-α-1,3-galactose antibody (anti-α-Gal) and the α-Gal epitope (Galα1-3Galβ1-4GlcNAc-R), the latter being found in high density as a cell-surface molecule in nonprimate mammals and New World monkeys.[144,145] In humans, apes, and Old World monkeys, the α-Gal epitope is not expressed because of two frameshift mutations in the α1-3-galactosyltransferase gene. Instead, they produce large amounts of anti-Gal antibodies (Ab) constituting approximately 1% of circulating immunoglobulins (Ig) such as IgG, IgM, and IgA, which consequently mediate hyperacute or delayed rejection of xenotransplants.[140,145,146] A number of studies have attempted to identify and/or quantify the presence of the α-Gal epitope post decellularization including in porcine medial meniscus,[79] porcine heart valves,[143] porcine pericardium,[141] and porcine SIS.[147] In the decellularized scaffold of porcine pericardium, the decellularization process was able to completely remove the α-Gal epitope, some of which incorporated the use of α-galactosidase to aid in xenogeneic antigen removal.[141] In contrast, porcine SIS has been found to contain small amounts of the α-Gal epitope,[147] but its presence was unable to either activate the complement pathway in human plasma or influence its ability to serve as a bioscaffold for tissue remodeling following implantation.[148] More specifically, implantation of SIS was found to elicit an immune response but the response was restricted to the Th-2 pathway and not to the Th-1 pathway, which allowed acceptance and remodeling of the xenogeneic graft.[149]

Another area of concern with decellular xenogeneic grafts, in particular porcine grafts, is the presence of porcine DNA

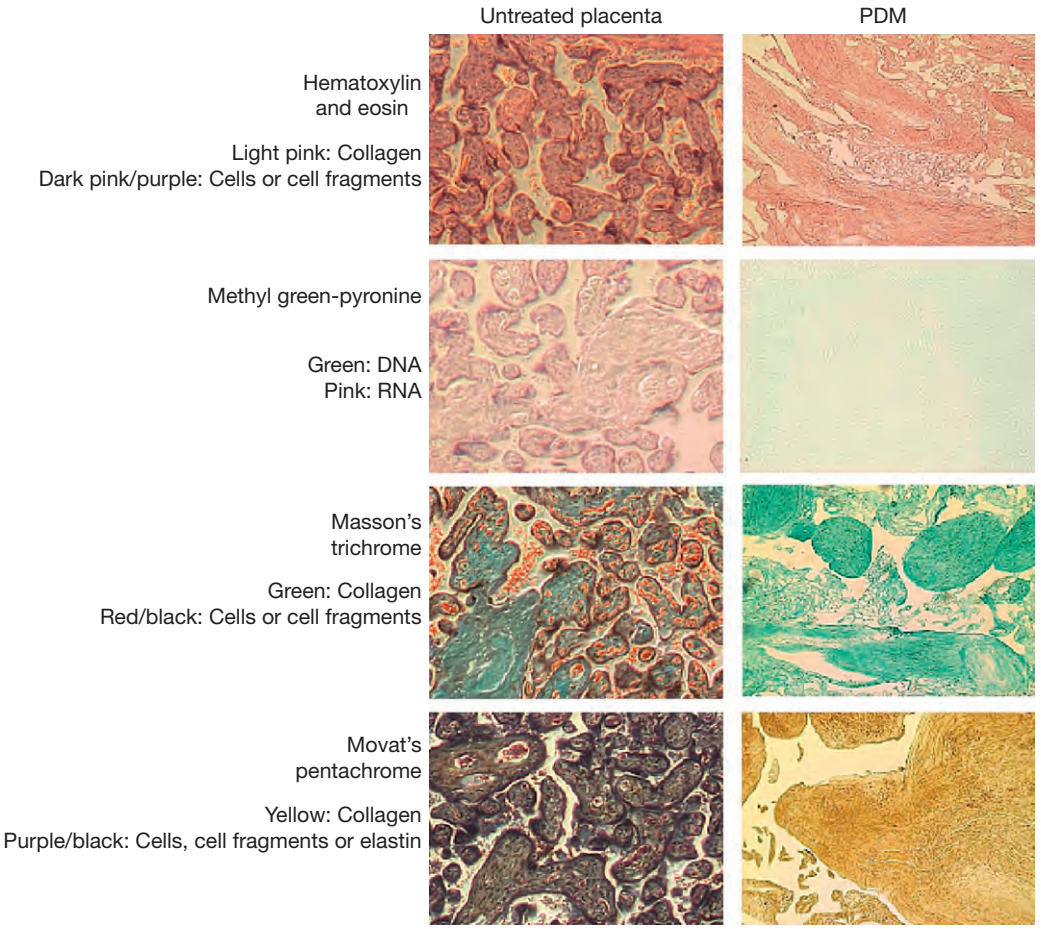

Figure 1 Histological assessment of placental decellular matrix (PDM) following the completion of decellularization, and untreated placenta. Hematoxylin and Eosin, Masson's trichrome, and Movat's pentachrome stainings indicate that there are no cells or cellular debris in the PDM following processing. The MGP staining shows that the PDM is free of residual RNA and DNA. Original magnification × 50. Adapted and reprinted with permission from Flynn, L.; Semple, J. L.; Woodhouse, K. A. *J. Biomed. Mater. Res. A* **2006**, *79*, 359–369. © Wiley InterScience.

remnants. It has been suggested that these remnants may be the cause of 'inflammatory reactions' following implantation in orthopedic applications.[150] However, a number of commercially available decellularized scaffolds such as Restore® (porcine SIS), GraftJacket™ (human dermis), and TissueMend™ (bovine dermis) contain trace amounts of DNA remnants.[150–152] In a recent study by Gilbert and colleagues, it was found that in all of the decellularized products investigated, small amounts of remnant DNA were present. However, the remaining DNA was present as small fragments (<300 bps) in most of the scaffolds with the exception of GraftJacket™ that contained full DNA strands.[152] Even with the most rigorous decellularization protocol, complete cellular removal is very unlikely.[152] Nonetheless, despite the presence of DNA remnants, the investigated commercially available decellularized scaffolds have been clinically effective for their intended applications.[136,152]

2.221.3. Origin of Decellularized Scaffolds and their Applications

Decellularization of tissues has yielded a variety of naturally derived decellular matrices, many of which are commercially available to treat an assortment of conditions such as rotator cuff repair, bladder repair, and spinal and cranial repair, as listed in Table 3. Decellularized scaffolds have a rich history and this section will highlight the origin of some tissues used to produce decellularized matrices and their applicability to tissue engineering.

2.221.3.1. Small Intestine

SIS is a resorbable xenogeneic bioscaffold derived from porcine small intestine, as shown in Figure 2.[105] SIS is prepared by mechanically removing the tunica mucosa, serosa, and tunica muscularis from the inner and outer surfaces of the intestine. The material is thoroughly rinsed in water, treated with peracetic acid, and then rinsed with buffered saline or water to yield a neutral pH. The resultant thin, translucent matrix (0.1 mm wall thickness) is composed primarily of 90% collagen (mostly collagen type I), fibronectin, laminin, proteoglycans (decorin), glycoproteins (biglycan and entactin), GAGs (HA, heparin, HS, CS-A, CS-C, dermatan sulfate), and growth factors (bFGF, VEGF, TGF-β).[10,105] This milieu of structural and functional molecules establishes a unique 3D scaffold that may assist in cell migration, cell-to-cell interactions, as well as cell

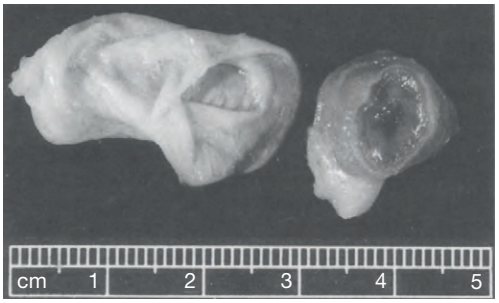

Figure 2 A cross section of intact small intestine with an attached piece of mesenteric adipose tissue (about 7 O'clock position) is shown on the right side of this figure. The tissue on the left is a longitudinal view of the SIS graft material after the superficial mucosa, the serosa and mesenteric connective tissue, and the muscularis externa have been removed. This material is very flexible and strong and is partially transparent when viewed against the light. Reprinted with permission from Badylak, S. F.; Lantz, G. C.; Coffey, A.; Geddes, L. A. *J. Surg. Res.* **1989**, *47*, 74–80. © Elsevier Ltd.

growth and differentiation during the regenerative process. The exact cellular mechanisms involved in remodeling following SIS implantation are not completely understood. However, the remodeling process has been strongly associated with angiogenesis, cell migration, and differentiation, and deposition of extensive ECM.[9] SIS grafts also have the ability to rapidly and completely degrade within a short term following implantation.[32,153,154]

The capacity of SIS to induce site-specific *in vivo* cellular repopulation and regeneration without *in vitro* cell seeding in a variety of applications has been well documented throughout the literature, as summarized in **Table 5**. Despite its xenogeneic nature, implanted SIS grafts are capable of surviving without signs of rejection in a number of animal systems including rat, mice, dog, and rabbit as well as in human patients.[7,136,140,147]

Early studies found SIS to function well as arterial and venous grafts with rapid replacement by native tissue.[105,156,157] Despite SIS's significant potential as vascular grafts, challenges of endothelialization and long-term vascular patency rates (>18 months) have been raised.[105,156,183] SIS has also been extensively used in the genitourinary system. Kropp *et al.*[108,171] found successful histological and functional regeneration of both rodent and canine bladders using SIS in a partial (40%) cystectomy model. For instance, at 15 months postoperative, histological analysis of the SIS augmented bladders showed significant regeneration of all three major layers of the bladder wall (urothelium, smooth muscle, and serosa) with no evidence of scar formation. *In vitro* contractility studies on SIS regenerated bladder strips demonstrated that the contractile activity of the augmented bladder tissue matched that of the native tissue. Similarly, *in vitro* tensile testing demonstrated no significant differences in the stress–strain properties of the graft tissue versus native bladder. The regenerated bladders also showed functional nerve regeneration and innervation comparable to native bladder.[171,172] Nonetheless, recent SIS studies have been inconsistent with regard to bladder regeneration.[184,185] For instance, significant morphological and histological differences between distal and proximal segments of SIS in bladder regeneration and calcification within the regeneration bladder have been observed.[184,185] Larger SIS grafts in a subtotal cystectomy (90%) model were unable to induce the same quality and quantity of bladder regeneration as previously observed with a partial (40%) cystectomy model.[186] Lastly, long-term bladder reconstitution with SIS augmented bladders has shown variable outcomes with regard to fibrosis, capacity, and compliance.[187–189]

Table 5 Applications of SIS in tissue engineering

Application	*Model*	*References*
Vascular	Canine, porcine	105,155–161
Cardiac	Canine, porcine	162–164
Dura mater	Rodent, canine	165,166
Abdominal wall	Canine, rodent	167,168
Bladder	Rabbit, canine, rodent	108,169–173
Bowel	Canine	174
Esophagus	Canine	175
Tendon	Canine, rabbit	107,176
Ligament	Canine	177
Cartilage (Meniscus)	Rabbit, canine	178–180
Dermal	Rodent	168
Bone	Rodent	181,182

Despite mixed results with certain applications of SIS grafts between various studies, a multitude of positive clinical outcomes have been reported. In addition, as of 2007, more than one million human patients have received an SIS graft to reconstruct a variety of tissues.[7] To date, the reasons for the disparate results are unknown but may be related to patient selection, surgical technique, and/or lack of our understanding regarding optimal use of an inductive scaffold for reconstruction of certain tissues.[7]

2.221.3.2. Dermis

Decellularized dermal tissue or acellular dermal matrix (ADM) can be derived from full or split-thickness skin from which the cellular components (keratinocytes, sweat glands, sebaceous glands, fibroblasts, vascular endothelium, and smooth muscle) are removed or extracted.[135] Studies with an ADM, AlloDerm® (LifeCell Corp.), processed from banked human cadaver skin have shown the material to be safe and efficacious in a variety of surgical procedures.[190] These procedures include treatment of full-thickness burns,[135,191] use as a substrate for oral resurfacing and periodontics,[192] a substrate for dural replacement,[190] a small-caliber vessel substitute,[193] as well as a soft tissue filler in plastic surgery.[194,195] A porcine equivalent of AlloDerm®, XenoDerm (LifeCell Corp.), has also shown efficacy as a viable dura substitute in a mini-pig model.[138] In both cases, porcine and human dermis are decellularized by first removing the epidermis by incubating the skin in 1 M sodium chloride (NaCl) at 37 °C for 8 h. Dermal fibroblast and epithelial cells are then removed by incubating the material in 2% SD containing 10 mM EDTA at room temperature overnight. The dermis is then cryoprotected with a combination of 35% maltodextrin and 10 mM disodium-EDTA and packaged as a freeze-dried sheet until it is rehydrated at the time of surgery.[138,190] This decellularization process has shown to reduce major histocompatability complex (MHC) Class I and Class II molecules, as well as preserve the normal architecture of the dermis.[138,190,196] Decellularized dermis has been noted to be

rich in collagen type I, type IV, and type VII as well as in elastin content, providing the graft with favorable elastic properties.[183] Grafted acellular dermal matrix has also been shown to support fibroblast infiltration, neovasculation, and epithelialization in the absence of an inflammatory response.[135]

A number of other methods have been attempted to decellularize dermal tissue using a combination of extraction (i.e., Triton® X-100, SDS) and enzymatic (i.e., trypsin, dispase, DNase/RNase) treatments resulting in varying degrees of decellularization efficiency.[72,197–200] For instance, Walter *et al.* prepared an ADM by two different methods using either dispase followed by Triton® X-100 treatment (dispase–Triton) or hypertonic NaCl solution followed by SDS (NaCl–SDS) treatment. Both methods completely removed the epidermis and most cellular components from the dermis while preserving the basic dermal architecture. However, the NaCl–SDS method retained a greater amount of cell-surface antigens as well as ECM components in comparison to the dispase–Triton method.[200] Moreover, despite the clinical effectiveness of allogeneic decellularized dermis, challenges such as limited availability of cadaver skin, high cost of commercially available human ADM, and the risk of disease transmission (i.e., Cruetzfeldt–Jakob disease) exist.[197,198] Lastly, variable outcomes have been reported in the literature regarding the histological and biocompatible differences between ADM xenografts and allografts,[197,198,201] warranting further investigation into the underlying mechanisms.

2.221.3.3. Urinary Bladder

The bladder is a soft tissue organ and despite its relative structural simplicity, it is one of the most distensible and strongest muscles in the body.[202] Early work by Badylak *et al.* showed promising results for esophageal repair using UBS produced by mechanical delamination, resulting in only the tunica submucosa.[175] More recently, decellularized bladder tissue, in the form of UBM, has been used for esophageal repair[203,204] as well as for treatment as a cardiac patch,[162,164,205,206] and thoracic wall repair,[207] displaying great potential for tissue restoration. UBM is prepared by first trimming the residual external connective tissue and soaking the urothelial layer in saline before the remaining bladder tissue is mechanically delaminated to remove the epithelium, serosa, muscularis externa, and the tunica submucosa. The remaining basement membrane of the tunica mucosa and the subjacent tunica propria, collectively termed UBM, is disinfected in a PES solution followed by a saline solution rinse.

Pioneering work by Tanagho[208–211] and Atala,[24,212,213] has driven the use of decellularized bladder tissue to a number of urological applications such as urethral, ureteral, bladder wall, and vaginal replacement, as shown in **Figure 3**.[214] Tanagho and colleagues[208,215–219] decellularized bladder tissue, termed bladder acellular matrix graft (BAMG), according to an adapted methodology described by Meezan *et al.*[33] The decellularization process consisted of a combination of hypotonic cell lysis, DNase digestion, and lipid membrane solubilization by an anionic detergent. This process has been applied to a variety of species' bladder tissue such as hamster, rabbit, dog, rat, pig, and human bladder tissue, and subsequently evaluated for bladder regeneration in homologous or heterogenous bladder augmentation. Early studies showed promising results of morphologic and functional rat bladder regeneration following homologous BAMG augmentation cystoplasty.[208,209,218] Findings by Sutherland *et al.* confirmed these results with a similar rat BAMG homologous *in vivo* model.[220] However, concerns of bladder stone formation and clinical relevancy were raised over the rat model. Subsequently, homologous BAMG augmentation in a canine model was performed and showed that the augmented bladders were functionally compliant and closely resembled native bladder with only minimal scar formation.[219]

Work in our own and collaborator's laboratory[53,55,58] decellularized porcine bladder tissue, termed bladder acellular matrix (BAM), using a multistep detergent-enzymatic extraction process originally established by Wilson *et al.*[99]

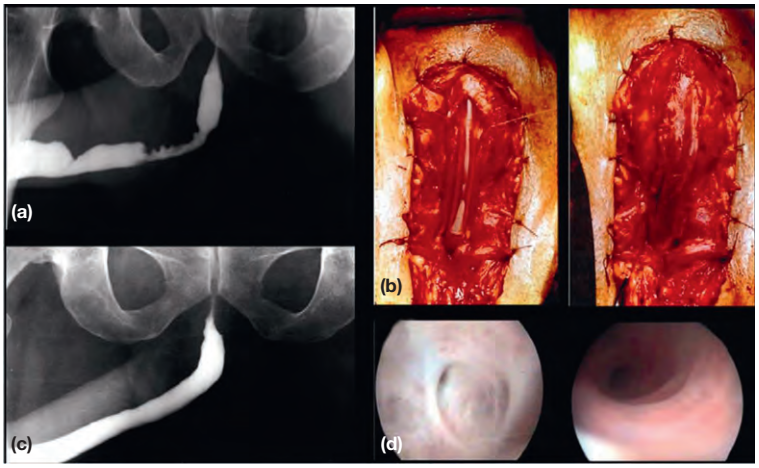

Figure 3 Tissue engineering of the urethra using an acellular collagen matrix obtained and processed from porcine bladder submucosa. (a) Representative case of a patient with a bulbar stricture. (b) During the urethral repair surgery, strictured tissue is excised, preserving the urethral plate on the left side, and matrix is anastamosed to the urethral plate in an onlay fashion on the right. Opin. Biotechnol.* **2009**, *20*, 575–592. © Elsevier Ltd.

to decellularize small-diameter blood vessels. Initial work demonstrated that BAM, used in an *in vivo* short-term (12 week) homologous model of bladder augmentation, promoted the ingrowth of urothelium, smooth muscle, and blood vessels. By 12 weeks postoperatively, the augmented bladders also exhibited capacity and compliance comparable to normal bladders.[58] However, in a follow-up study evaluating BAM at a longer time frame (22 weeks), histological results were less encouraging indicating a fibroproliferative response resulting in gross graft contracture and decrease in elasticity. As with many decellularized scaffolds, the mechanisms promoting regeneration with restoration of bladder tissue function have not been fully elucidated. A desire to understand the dynamic and reciprocal dialogue between the cells and their extracellular microenvironment has prompted studies to incorporate cell-based models and bioactive molecules as a means to potentially improve *in vivo* organ restoration following implantation.[133,221–223]

2.221.3.4. Vascular and Cardiac Tissue

Decellularization of vascular tissue is an encouraging approach for treatment of cardiovascular disease, including coronary artery and peripheral vascular disease. A number of vascular tissues have been decellularized including umbilical arteries,[27,56] carotid arteries,[12,14,224] pulmonary arteries,[75] and iliac arteries[60,71] for the intended application as either small or large caliber vascular grafts. Although decellularized vascular grafts provide the ease of procurement and availability, concerns of incomplete cellular repopulation[75] as well as susceptibility of the elastin-based scaffolds to vascular calcification[225–227] have been raised.

A number of studies report decellularization of cardiac valves including pulmonary valves[13,76,81,124,132,228] and aortic valves.[69,70,74,81,96,229–232] Cardiac valves from a wide variety of species have also been used, such as canine, porcine, ovine, and rodent, all for their intended organ-specific application. Challenges with these particular decellularized scaffolds include maintenance of hemodynamic function,[233] control of early calcification,[228] cellular repopulation, and matrix generation.[132,234] Moreover, the importance of ensuring complete decellularization has been exemplified with the Synergraft™ (CryoLife, Inc.) decellularized porcine aortic valves. Although *in vitro* and *in vivo* experimental results with Synergraft™ were encouraging, early clinical performance in young children was not successful. Macroscopically and histologically, the explanted grafts showed fibrous overgrowth and a strong inflammatory response, initially attributed to a foreign-body-type reaction.[235] In this follow-up study, not only was incomplete decellularization confirmed using the Synergraft™ method, but also detection of the α-Gal epitope suggested that it might have triggered hyperacute rejection.[235] However, to what extent and quantity the presence of α-Gal epitope in heart valve bioprostheses triggers a host inflammatory response needs to be further investigated.

Recently, as a means to meet the growing demand for a bioartificial heart for end-stage heart failure, Ott and colleagues decellularized whole rat hearts by retrograde coronary perfusion (Langendorff) using a SDS-Triton® X-100 extraction method to generate a biocompatible whole-heart scaffold with a perfusable vascular tree, patent valves, and a four-chamber geometry.[57] Subsequently, the whole-heart scaffolds were recellularized with cardiac and endothelial cells and allowed to mature under physiologically relevant conditions in a bioreactor. By 28 days in perfused organ culture, whole heart constructs showed electric and contractile response as well as pump function equivalent to 2% of adult or 25% of 16-week fetal heart function. On a larger scale, Badylak and colleagues have recently decellularized in a reproducible and time-effective manner (<10 h) porcine whole hearts by pulsatile retrograde aortic perfusion to generate cardiac-ECM (C-ECM).[59] The perfused decellularization process consists of an enzymatic (trypsin), nonionic detergent (Triton® X-100), ionic detergent (deoxycholic acid), and acid solution (PES) treatment with systematic hypotonic and hypertonic rinses to remove cellular debris, as depicted in Figure 4. The resultant C-ECM preserved the composition and complex 3D

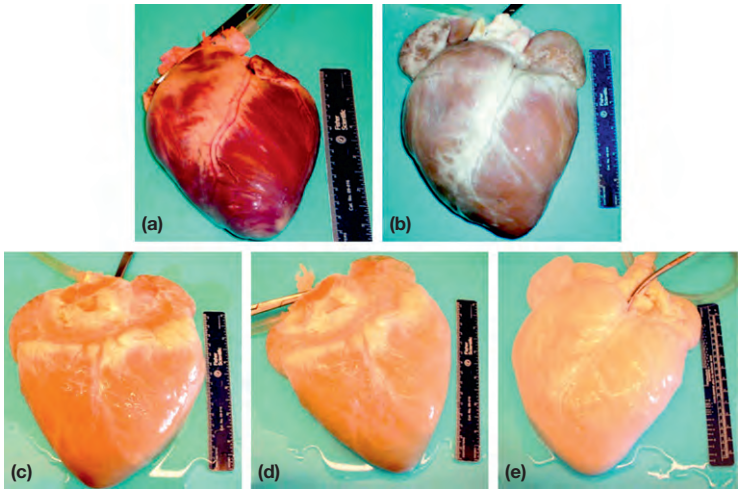

Figure 4 Representative images of the gross appearance of intact porcine hearts subjected to decellularization by retrograde perfusion. (a) Before decellularization, (b) after 0.02% trypsin, (c) after 3% Triton® X-100, (d) after 4% sodium deoxycholate, and (e) after 0.1% peracetic acid/4% ethanol. architecture of the native heart. Moreover, C-ECM was found to be a suitable substrate for chicken embryonic cardiomyocyte attachment and maintenance of phenotype. Collectively, both investigations identify the significant potential this novel whole organ decellularization approach may bring to the field for tissue engineering. Not only is this technique potentially scalable to hearts of human size and complexity, but also adaptable to a wide range of other organs such as lung, liver, and kidney.

2.221.3.5. Embryoid Body Matrix

New to the area of decellularization, ECM has recently been isolated from differentiating mouse embryonic stem cells (ESCs), termed embryoid bodies (EBs), as a means to recapitulate the dynamic stem cell niche.[40,68,122] Recent evidence suggests that the spatiotemporal composition of biomolecular factors synthesized and released by ESCs *in vivo* plays an indispensible role of regulating stem cell behavior and thus, regenerative events.[236–240] Studies by the McDevitt group have decellularized EBs in a scalable manner at different time-points along their differentiation pathway by two different strategies: (1) chemical treatment consisting of Triton® X-100 in combination with DNase[68,122], and (2) physical disruption by either lyophilization or freeze–thaw cycling in combination with DNase treatment.[40] For both strategies, decellularization efficiency was assessed on the basis of cell viability, DNA removal, ultrastructure assessment, and protein retention. Not only were the EBs successfully decellularized, but retention and distribution of adhesive ECM proteins (i.e., collagen type IV, laminin, fibronectin) and the sulfated GAG hyaluronan were found to vary as a function of differentiation time in the acellular EB matrices in a similar fashion as native EBs. Moreover, the acellular EB matrices permitted exogenous repopulation and attachment of fibroblast *in vitro*.[40]

Many of the existing decellularized scaffolds originate from adult tissue sources that have limited regenerative capacity. The concept of using decellular matrices from stem cells actively undergoing morphogenic differentiation provides a unique and inherently flexible route to deliver morphogenic factors, in particular morphogens and mitogens, to an injured or diseased adult tissue that can potentially mimic early stages of embryogenesis and promote functional regeneration.

2.221.4. Concluding Remarks

The area of decellularization has contributed significantly to the progression of where tissue engineering is today and perhaps more importantly, toward its future direction. In comparison to other tissue engineering approaches that use synthetic matrices or single purified ECM matrices (e.g., collagen, elastin, or fibrin-based matrices), decellularized scaffolds offer the advantage of a more physiologically relevant composition of ECM components that is organ and tissue specific. With an optimized decellularization process, decellularized scaffolds can preserve the intricate complexities of the spatial and temporal ECM microenvironment that plays an integral role in modulating cellular behavior such as migration, proliferation, and differentiation. Moreover, decellularization offers the possibility of using xenogeneic tissues under the condition that all cellular antigens have been effectively removed to minimize an adverse immunologic response. Despite the significant advancements made in the area of decellularization to date, questions remain unanswered.[241] These include the following: Is there an optimal decellularization strategy for each tissue in the body? Is there an optimal method of storage/preservation so that an 'off-the-shelf' product is achievable? Is it necessary for recellularization of the bioscaffold prior to implantation? Although these questions exist, it is encouraging to realize from the results observed both experimentally and clinically from the vast number of different decellularized tissues and more recently embryonic stems cells and whole organs that our ultimate goal of functional tissue restoration is achievable.

Glossary

Allograft A tissue graft that is harvested from one individual and transplanted in a genetically nonidentical individual of the same species.

Autograft A tissue graft that is harvested from and implanted in the same individual.

Extracellular matrix Cell-secreted molecules that form highly ordered insoluble aggregates around a given tissue or organ.

Xenograft A tissue graft that is harvested from one individual and implanted in another individual of different species.

Abbreviations

ADSCs	Adipose tissue-derived stem cells
BMP	Bone morphogenetic protein
bMSCs	Bone marrow-derived mesenchymal stem cells
DDD	Disc degeneration disease
ECM	Extracellular matrix
FGF	Fibroblast growth factor
GAGs	Glycosaminoglycans
HA	Hyaluronic acid
IVD	Intervertebral disk
NP	Nucleus pulposus
NSAIDs	Nonsteroidal anti-inflammatory drugs
PDGF	Platelet-derived growth factor
PGA	Polyglycolide
PLLA	Poly(L-lactide)
rhBMP	Human recombinant bone morphogenetic protein
SAARDs	Slow acting antirheumatic drugs
TGF-β	Transforming growth factor beta
VEGF	Vascular endothelial cell growth factor

2.222.1. Introduction

Autografts, allografts, and xenografts are currently being considered as the gold standard in many clinical applications, including those for bone, skin, tendon and ligament, nerve, and heart valves, because their structure is identical to the tissue being replaced. Properties such as rapid fixation, fast healing, imitation of native tissue architecture, and the ability to promote functional regeneration have led to several, commercially available, tissue grafts, which have demonstrated normal tissue ingrowth and have be shown to facilitate functional regeneration of injured or degenerated tissues, both in preclinical animal models and in human clinical studies.[1–14]

However, allografts are associated with the potential risk of transmitting infectious diseases and autografts have the disadvantage of creating a secondary morbid site during harvesting.[15–18] For this reason, tissue-engineering strategies that provide a valuable solution to shortfalls in the availability of tissue grafts have been developed. Tissue engineering started with the use of materials that were designed to interact with the body, encourage tissue regeneration, and restore its function.[19–21] The ideal tissue substitute should enable its easy processing to end-products of different textures that are similar in structural conformation and mechanical integrity to the tissue being replaced. To this end, advancements in micro- and nanofabrication technologies have enabled topographical and spatial control over cellular behavior and have facilitated the creation of more functional tissue facsimiles.[22–32] It is also important that the engineered device be composed of materials that will elicit neither an immunological response nor a

clinically detectable foreign body reaction. It is also desirable that the scaffold material offers opportunities for functionalization, such as facilitating delivery of bioactive or therapeutic molecules to the site of injury.[26,33–36] Currently, there are several types of material, such as (a) synthetic biodegradable and bioresorbable polymers (e.g., polyglycolide (PGA), racemic polylactides, polydioxanone, polyvinyl alcohol, polycaprolactone, polyethylene glycol); (b) nonabsorbable polymers (e.g., polyetherketone, polytetrafluoroethylene, polypropylene, silicone); and (c) responsive to stimuli 'smart' polymers (e.g., *N*-ethyl morpholine metacrylate, *N*-ethyl morpholine methacrylamide, *N*-ethyl pyrrolidine methacrylamide, *N*-isopropylacrylamide), that are commercially available. These have been shown to stimulate repair and regeneration of tissues *in vivo*.[26,37–40]

Nondegradable synthetic materials, however, may be harmful due to mechanical impingement or infection and may require a second operation for their removal,[41] while the degradation products of biodegradable synthetic materials could be deleterious to the surrounding cells and tissue.[42–44] Moreover, synthetic materials are associated with a foreign body reaction[45–48] because they lack cell-recognition signals and also because their hydrophobic property hinders cell adhesion.[49–51] For these reasons, biological scaffolds, composed of natural polymers (e.g., collagen, elastin, fibrin, hyaluronan), have been evaluated for biomedical applications.[38,52–56] Such materials possess several inherent advantages such as the ability to present receptor-binding ligands to cells, susceptibility to cell initiated proteolytic degradation, and enhancement of natural remodeling.[13,38,52,57,58] The following section will provide an overview of the most abundant extracellular matrix (ECM) components that are used in tissue-engineering applications.

2.222.2. ECM Composition

ECM can be defined as the cell-secreted molecules that form highly ordered insoluble aggregates, which combine to form various tissues and organs. The cell-ECM has been characterized as a 'dynamic equilibrium' between the cells and the matrix; the composition, conformation, and architecture of the matrix depend upon the phenotype of the resident cells and the biochemical/biomechanical milieu, while the matrix influences the behavior and phenotype of the surrounding cells.[11] The primary function of the matrix is to provide structural support. Collagen and elastin are typical examples of structural proteins. However, the ECM has manifold effects, apart from providing structural integrity.[59] For example, ECM proteins, including laminin and fibronectin, contain and bind to adhesion receptors (e.g., integrins) that mediate cell–matrix adhesion, cell migration, proliferation and apoptosis, transduce signals into cells, and are involved in developmental and inflammatory processes.[60–62] Growth factors constitute another functional unit of the matrix; the matrix is responsible for their distribution, activation, and presentation to cells.[63,64] Proteoglycans and their constituent glycosaminoglycans, despite their minor proportion in the ECM, influence many physiological processes, including collagen fibrillogenesis, cell–cell interactions, growth factor binding and cell regulation.[65–68] For these reasons, all the above molecules, either alone or combined, are used as constructive scaffolds that can induce functional regeneration.

2.222.2.1. Collagen and Elastin

The term collagen is often used to describe a family of protein molecules. Forty vertebrate collagen genes have been described to date, the products of which combine to form 29 distinct homo- and/or heterotrimeric molecules,[69–74] each having, as a common feature, at least one tripeptide helical sequence of repeated $(Gly–X–Y)_{100\text{-}400}$, where X is often proline and Y is sometimes hydroxyproline.[71,72,75–77] These distinct collagens differ by minor alterations in the properties of the collagen molecule such as changes in the length of the triple helix, the Mw, the charge profile along the helix, interruptions in the integrity of the triple helix, the size and shape of the terminal globular domains, the cleavage or retention of the latter in the supramolecular aggregate, and by variations in posttranslational modifications.[76,77] The most acceptable approach to categorizing these forms of collagens is based upon the structure of the aggregate. As such, four main groups have been identified, named fibrous, nonfibrous, filamentous, and fibril-associated collagens with interrupted triple helices.[69–72,76–84] Most of the research into the assembly and molecular organization of collagen is based on type I collagen, which is abundant in the skin, bone, cornea, dentin, ligament, and tendon.[85–90] Although type I collagen accounts for up to 70–90% of the collagen found in the body and is normally encountered in biomaterial applications, when it comes to evaluating the performance of biomaterials *in vivo*, however, the distribution and roles of the other less abundant collagen types is also important.[72,80] For example, type II collagen is important while evaluating the properties of a scaffold designed to replace cartilaginous tissues;[91–94] type III[95–102] and type V[100,103] collagens are important modulators of fiber diameter. The pathway of collagen synthesis, from gene transcription to secretion and assembly into functional fibrils in tissues, is a complex multistep process that requires the coordination of temporal and spatial biochemical events. Briefly, fibril-forming collagens are synthesized in their precursor form, termed procollagens, with N- and C-terminal propeptide extensions. Following or during secretion into the ECM, the propeptides are cleaved by specific procollagen proteinases[71,78,80,85,97,99,104–108] that leave short, non-triple-helical domains, termed telopeptides, at each end of the collagen molecule.[80,104,106,109–112] Individual collagen molecules then aggregate spontaneously in a quarter-staggered arrangement to form elongated fibers (termed fibrils). After fibril formation, the lysyl-oxidase pathway forms cross links in a head-to-tail fashion, which gives exceptional strength to collagen fibers.[76,77,79,105,113–120]

Collagen is extensively used in tissue-engineering applications due to its inherent properties, such as high tensile strength; being inexpensive and easy to prepare in large reproducible quantities; biodegradability; hemostatic properties; low antigenicity; high degree of resistance to proteolysis; biostability; low inflammatory and cytotoxic properties; and the ability to interact with cells and other ECM molecules, which promotes cellular attachment and growth, and consequently, tissue healing and regeneration.[71,72,121–139] Collagen type I is primarily extracted

from skin and tendons, while cartilaginous tissues are used for extracting type II collagen. Dilute acidic solutions are used to break intermolecular crosslinks of the aldimine type, while proteolytic enzymes, such as pepsin, are used to cleave the more stable crosslinks of the ketoimine type. Limited pepsin digestion will cleave only the non-triple-helical C- and N-telopeptides, leaving the triple-helical molecule intact,[98,132,140–142] unless it has been partially unfolded, molten or broken.[143] Extracted collagen, under appropriate conditions of temperature, pH, ionic strength, collagen concentration and composition, and in the presence of other connective tissue macromolecules, will spontaneously self-assemble to form microscopic fibrils, fibril bundles and macroscopic fibers with structural characteristics that are virtually indistinguishable from their native counterparts.[88,98,144–161] The lysyl-oxidase-mediated crosslinking does not occur *in vitro*, and consequently, reconstituted collagen constructs lack sufficient strength and may disintegrate upon handling or collapse under the pressure from surrounding tissue upon implantation. To this end, a number of crosslinking methods (chemical, physical, and biological) have been introduced that offer control over mechanical and thermal properties, biological stability, residence time in the body, and to some extent, the immunogenicity and antigenicity of the device.[127,132,134,162–171]

Elastin is an ECM protein that is responsible for the elasticity and resilience of tissues and organs such as skin, blood vessels, lung, and elastic ligaments.[172,173] The amount of elastin in a tissue depends on the tissue function; elastin comprises 1–2% of tendons, 2–4% of skin, 30% of lung, 50% of large arteries, and 70% of elastic ligaments by dry weight mass.[174–179] Under physiological conditions, smooth muscle cells, endothelial cells, fibroblasts, and chondrocytes synthesize elastin as a 72-kDa soluble precursor (termed tropoelastin).[180–187] Elastin has also been reported to be produced by neoplastic cells.[188] Tropoelastin undergoes a number of post-translational modifications before it is assembled into the elastic fibers. Each elastin molecule is composed of alternating hydrophobic and lysine-rich crosslinking domains that are critical for extracellular assembly and elastic function. Lysine side chain oxidation (by lysyl-oxidase) allows the formation of covalent crosslinks with neighboring molecules.[180,189–193] A transglutaminase crosslink between tropoelastin and fibrillin-1 has also been identified.[194] Crosslinking results in mature elastin, which is insoluble and extremely stable. Overextension of tissues is prevented by these crosslinks; these enable almost complete recovery of the wavy configuration of the collagen fibers after muscle contraction.[191,195–197] These elastic fibers are composed of an abundant amorphous core, of which elastin is the major constituent, and a highly ordered microfibrillar structure of about 10–12 nm in diameter, which is located around the amorphous core and is composed of fibrillin 1 and/or 2.[150,173,198–203] Fibrillins, together with the elastin microfibril interface located proteins (EMILINS), act as a template for the organization of the elastic tissue and are distributed in tissues where resilience and elastic recoil are prominent.[198,202–207] Elastin, its degradation products, and synthetic elastin-like peptides interact with the elastin–laminin receptor, and mediate elastin synthesis, chemotaxis, inhibit vascular calcification, proliferation, migration and differentiation of numerous cells, and other biological processes.[208–211] It is for these reasons that elastin-based biomaterials of different physical forms are used for skin regeneration and as vascular constructs.[33,212–218]

2.222.2.2. Proteoglycans and Glycosaminoglycans

Proteoglycans are a family of glycoproteins that consist of a protein core with a variable number of covalently attached carbohydrate moieties.[219] These ECM molecules form a gel-like structure in which collagen fibrils are embedded.[220] There are two major classes of proteoglycans present in connective tissues; the first is represented by large molecules (>1000 kDa), having the capacity to form aggregates with hyaluronan,[221–223] while the second class is characterized by low-molecular weight aggregates (<100 kDa) that are not capable of interacting with hyaluronate.[224] Although proteoglycans and their constituent glycosaminoglycans are found in very low quantities in connective tissues, they influence many physiological processes, including collagen fibrillogenesis, cell–cell interactions, growth factor binding, and cell regulation.[65–68] Small, leucine-rich proteoglycans (e.g., decorin, biglycan, fibromodulin, and lumican)[225–231] regulate collagen fibril assembly and growth by preventing aberrant, lateral fusion of collagen fibrils in connective tissues such as the tendon.[232–234] Chondroitin sulfate and hyaluronate are primarily encountered in fetal tendon tissue, while dermatan sulfate is the main glycosaminoglycan in the mature tendon,[235] and have been shown to facilitate structural integrity of collagen fibrils.[116,236] Due to the important biological functions of proteoglycans and glycosaminoglycans in native tissues, these molecules are frequently used to enhance the properties of implantable devices for several tissue-engineering applications,[237] including those for cartilage,[238] nucleus pulposus (NP),[239] tendon,[240] bone,[241] and skin[242,243] regeneration.

2.222.2.3. Fibronectin and Laminin

Fibronectin is the major product of diploid fibroblasts[244] organized in discrete ECM fibrils that also contain procollagen types I and III.[245,246] Fibronectin is a dimmer with a molecular weight of 250 kDa and is found in the ECM at an early stage of embryonic development. During this period, a dynamic relationship between fibronectin, laminin, and collagen type IV has been documented.[247] Fibronectin is an abundant component of the ECM of the submucosa, basement membranes, and the interstitial tissues.[248,249] It possesses ligand binding sites, such as Arg-Gly-Asp (RGD sequence), for adhesion and migration of many cell types. Specifically, fibronectin induces receptor clustering by binding to two integrins, which, subsequently, creates a relatively high local concentration of fibronectin. This promotes self-association and also facilitates attachment to the actin cytoskeleton through interactions with the cytoplasmic domain of the receptor.[250–252] Fibronectin has also been shown to modulate the deposition of several ECM molecules, including type I and type III collagens,[253–256] and is involved in wound healing.[257] For these reasons, fibronectin is extensively used to enhance the biological properties of biomaterials for bone,[258] tendon,[259] and other tissue-engineering applications.[260]

Laminins are extracellular, cross-shaped molecules with one long and two or three short arms, heterotrimeric

glycoproteins of molecular weight between 400 and 900 kDa. Laminins consist of noncovalently associated α, β, and γ chains that facilitate the assembly and structural integrity of basement membranes.[248,261–264] Laminin molecules bind to each other in the extracellular space and form laminin networks that are located close to the cell surface.[265,266] Extracellular assembly of a laminin network has been postulated to be important in epithelial morphogenesis.[267] Laminins are adhesion molecules that contain specific domains that are capable of interacting with cellular receptors or ECM ligands, thereby influencing cell proliferation, differentiation, adhesion, and migration under normal and pathological conditions.[262,268–271] Laminin is crucial in early embryonic development and tissue morphogenesis[272] and deletion of any of its subunits results in periimplantation lethality.[273,274] Laminin 2 and 4 are present in the basement membrane of skeletal muscle.[275,276] It has also been shown that laminin is essential for myo-differentiation, muscle cell survival *in vitro* and *in vivo*, and muscle integrity.[277] Absence of laminin leads to different types of muscular dystrophy and myopathies that are manifested by discontinuities in or breakdown of the myofiber basement membrane under constant stress of contractions.[278–283] Laminin has also been shown to influence nerve regeneration by facilitating the extension of neurites.[252,284–286] Laminin also plays an important role in wound healing, and keratinocytes activated at the leading edges of wounds have been shown to express high levels of laminin.[287–289] Mutations in the isoforms of laminin 5 are associated with epidermolysis bullosa, a group of inherited disorders of the dermoepidermal region in the skin, where blistering occurs as a result of even slight mechanical trauma.[290–292] Given the importance of laminins in physiological and pathophysiological conditions, therapeutic approaches based on laminin are under investigation. For example, gene therapy studies have been used to successfully treat epidermolysis bullosa,[293,294] while biomaterials coated with laminin have been used for nerve regeneration.[295–298]

2.222.2.4. Growth Factors

Growth factors are ECM molecules with specific biological activity. Although they are present in very small quantities, growth factors act as potent modulators of cell behavior, including differentiation, migration, adhesion, and gene expression.[299] Growth factors initially interact with receptors on the plasma membrane to deliver mitogenic signals that are required for cell proliferation.[300,301] The association of microtubules and microfilaments with proteins of the plasma membrane also plays a regulatory role in conveying the signals delivered by the growth factors to specific intracellular targets,[302–305] even when the cytoskeleton is not intact.[306] Several growth factors, including the vascular endothelial cell growth factor (VEGF), fibroblast growth factor (FGF), transforming growth factor beta (TGF-β), platelet-derived growth factor (PDGF), and the bone morphogenetic protein (BMP), are used to enhance the biological functions of biomaterials and modulate cell functions.[171,307–314] For example, incorporation of growth factors in scaffolds has been shown to be crucial at the early stages of the repair and it is likely to result in superior repair, and therefore, a functional tissue. VEGF, insulin-like growth factor, PDGF, basic FGF, and TGF-β have all been shown to increase the mechanical properties of the tissue, to enhance intrinsic reparative processes after tendon injury, to enhance tendon healing and, in general, to modulate cell proliferation and to stimulate matrix synthesis.[312,315–327] However, growth factors are typically labile; when intravenously administered, the biological half-lives of PDGF, basic FGF, and VEGF are 2, 3, and 50 min, respectively.[64] As a result, the use of polymeric drug-delivery vehicles, to encapsulate the active molecules and maintain a sustained localized delivery to the target site, has been adopted.[328–331] Gradients in the concentration of growth factors have also been investigated as a means to enable directional cell migration, create patterns of cellular differentiation and direct tissue organization into complex structures, such as the branching networks of vascular or nervous systems.[332–335]

2.222.3. Xenogenic Tissues, ECM Biopolymers, or Cells in Tissue Engineering

More than 33 million musculoskeletal injuries occur annually in the United States alone.[336–341] As the human population ages and life expectancy increases, injuries and degenerative conditions of the skeletal system will continue to rise, adding to the physical and financial strain of healthcare systems. It is therefore of paramount importance to develop strategies that enable functional regeneration of tissue. This section provides an overview of the current tissue-engineering solutions aimed at musculoskeletal regeneration.

2.222.3.1. Bone Reconstruction

Early attempts at xenogenic bone grafting used fresh, fresh frozen, or freeze-dried calf bone. Boplant® is an example of an early, commercialized xenograft. Unfortunately, these xenografts were poorly tolerated by the body and were ineffective at bone regeneration.[342] Currently, two types of xenografts are available: those in which the inorganic matrix has been removed and those in which the organic matrix has been removed. The former are known as demineralized bone matrix (DBM), while the latter are biologically produced hydroxyapatite. The most common sources of a xenograft are bovine bone or natural coral. Unlike autografts, xenografts must undergo substantial processing before they can be implanted into a human recipient. Such processing involves the removal of host cells, the organic or inorganic matrix, and sterilization. Freeze/thaw cycles are used to kill the host cells; alternatively, the xenograft is treated with gamma radiation, which simultaneously kills the cells and sterilizes the implant. The xenograft can also be immersed in alcohol, detergents, or in a glycosidase solution to remove fatty components and antigens, or soaked in demineralization solution to remove the inorganic structure, leaving a porous collagenous xenograft. It has been hypothesized that the removal of the inorganic phase allows greater access to proteins within the collagenous structure, which may aid in osteoinduction. For removal of the organic phase, the xenograft is either subjected to high temperature treatment or to deproteinization using chemicals such as hydrogen peroxidase. The reason for removing the organic phase is

to reduce the risk of cross-species reactivity and the transmission of any disease, for example, the Creutzfeldt–Jakob disease. A number of deproteinized bovine-derived bone substitutes are commercially available, such as Bio-Oss®, Cerabone®, Endobon®, and Osteograf®.[343,344] All of these products provide an osteoconductive surface for bone growth and a structure that mimicks the natural environment.

Bone xenografts are commonly mixed with bone marrow aspirate to enhance the regenerative process. The first clinical attempt to use bone xenografts combined with bone marrow was reported in 1978 by Salama *et al*. This study used partially deproteinized bovine bone (Kiel Bone) mixed with bone marrow from the iliac crest and implanted them in 28 patients. The results were promising and infection occurred only in one case.[345] Horowitz *et al*. used the same xenografts, mixed with bone marrow aspirate, to treat cystic defects in the jaws of 20 patients. On a 4-year follow up, the success rate was 80%; however, none of the failures were attributed to host rejection.[346] The Kiel bone has been used in almost every bone-grafting situation but with mixed results. Salama and Horowitz, as mentioned above, have found excellent success rates, while McMurray *et al*. have found it unsuitable in orthopedic practice.[347] The Kiel bone, when used by McMurray, was infiltrated with fibrous tissue by as early as 6 weeks, and was still present at 17 months after the operation. It was concluded from this study that the Kiel bone only provides a temporary structural support for the invasion of fibrous tissue and eventually leads to tissue necrosis due to the absence of a vascular network. As the popularity of the Kiel bone decreased, the market was gradually taken over by the fully deproteinized bone. Bio-Oss®, which is a biologically produced hydroxyapatite, is the current world leader in xenograft materials. There have been reports of varying and unpredictable degradation rates;[348] however, a review of 20 patients, who in 1999 received Bio-Oss® for maxillary sinus reconstruction, over a period of 6 months to 4 years showed that the material was surrounded by host bone *in vivo* and that osteoclasts were present, suggesting a slow degradation profile.[349] Bio-Oss® is now available in combination with porcine collagen, that is, Bio-Oss Collagen®, to improve the regenerative process.

Xenograft materials for bone tissue engineering can also be derived from marine animals as their ECM mainly comprises hydroxyapatite. Ewers performed a 15-year study in 118 patients who were implanted with marine-derived xenografts for maxillary sinus grafting.[350] The biomaterials used were AlgiPore®, C Graft™, and AlgOss™, and were implanted along with 10% autogenous bone mixed with either venous blood or platelet-rich plasma (PRP). The dental implants were placed six months after maxilla grafting. The survival rate of the resulting dental implants was 95.6%, indicating that sufficient bone regeneration had occurred in the 6-month interim period. Schopper *et al*. have examined biopsies from 26 patients who had received Algipore® implants in the maxilla.[351] They found that new bone had formed around the xenograft after 7 months. Multinucleated giant cells were observed within the implanted material and resorption was evident. Algipore® and C Graft™ have also been successfully used along with autologous bone in maxilla graft operations.[352]

Xenografts that have been processed for implantation purposes, however, are not without limitations. Despite xenografts being osteoconductive, they offer little toward osteoinduction. It is hypothesized that the absence of the protein component leads to the loss of osteoinduction properties. It is for this reason that xenografts are commonly combined with autologous bone, bone marrow, or growth factors. Despite the advances in processing techniques and sterilization, there still exists a fear of cross-species contamination, thus limiting their use as grafting material.

Before the introduction of biomaterials, the obvious high strength and structural stability of bone left surgeons with no choice but to replace irreversibly damaged bone tissue with more bone tissue, hence the use of xenografts. Gallie published a paper in 1914 entitled 'The history of a bone graft,'[353] which investigated the fate of autologous bone grafts, boiled bone grafts, and xenogenic bone grafts. This paper also highlighted the early, practical search for new materials to replace bone. The use of metal plates to stabilize long bone fractures has also been discussed by Lane in 1895;[354] however, the development of the first generation of modern biomaterials did not begin until the mid-twentieth century. The first biomaterials were permanent structures designed to support the bone and prevent fracture reoccurrence, however, the tissue engineering had one further goal, namely regeneration. If tissue regeneration was to be achieved then degradable biomaterials were a necessity. Such degradable biomaterials can be divided into two distinct groups: natural and synthetic.

Synthetic polymers are the most versatile of all materials used in tissue engineering. Mechanical and degradation properties can be tailored by blending a series of polymers with few limitations on the scaffold architecture. A discussion of the commonly used polymers has been provided by Hutmacher.[355] Polyester is a type of polymer defined by ester linkages in its main chain. Poly(L-lactide) (PLLA) and PGA are the types of polyesters that have been extensively used in tissue engineering. These polymers are a promising scaffolding material; however, the by-products created during *in vivo* degradation are a major disadvantage. A clinical trial in patients receiving PLLA bone plates or screws has been reported to result in swelling at the site of implantation.[356] Remnants of the implant were surrounded by a fibrous capsule, and on closer examination, highly crystalline particles were found both intra- and extracellularly at 5.7 years postimplantation. Bostman *et al*. have also frequently observed clinical foreign body reaction to PLLA and PGA materials.[357–360] It should also be noted that there have been many successful clinical outcomes using these materials,[361,362] however, given the frequent incidence of foreign body reaction, this is not an ideal implant material.

It is for this reason that xenogenic biopolymers (polymers derived from natural origins) are processed before use as biomaterials. The most commonly used natural material is collagen type I. Other examples include chitosan, glycosaminoglycan, hyaluronan, fibrin, and silk; however, collagen or composites of collagen are the only xenogenic biomaterials that are being widely used in bone tissue engineering today. As these materials are derived from natural materials, they have the advantages of biological recognition, availability of receptor-binding ligands, a natural hierarchical structure and susceptibility to cell- triggered proteolytic degradation.[363] Natural polymers such as collagen are composed of polypeptides which contain chains of amino

acids. Most natural polymers contain a higher level of complexity compared to synthetic polymers. There is a hierarchy in structure, for example, in collagen, amino acid chains form peptides, peptides combine to form polypeptides, polypeptides form helical chains which are referred to as tropocollagens, tropocollagen chains combine to form fibrils which eventually unite to make fibers of collagen.[132,364] Due to this structure, these materials also revert to their lower hierarchical forms upon degradation,which can be easily cleared by the body.[364] Many natural polymers are commercially available either individually or as composites, such as, Collagraft® (collagen plus biphasic calcium phosphate), Healos® (collagen plus hydroxyapatite), DuraGen™ (collagen), Veritas® (collagen), and Integra™ (collagen). Most scaffolds that are based on naturally occurring materials, however, are suitable only for nonload bearing applications or when in combination with a metallic implant, for example, collagen has been used as a carrier for rhBMP-2 in spinal interbody fusion when used in combination with a titanium cage.[365,366] Collagen is ideal for such applications as it is pliable, absorbent, and highly biocompatible. Collagen sponges loaded with rhBMP-2 have also been used for maxillary sinus reconstruction followed by successful dental implant placement[367] and also in the repair of open tibial fractures.[368] Although collagen has been used for bone tissue engineering, it is more suitable when combined with either ceramic or a polymer. Collagen and calcium phosphate have often been combined to form composites as their composition is similar to that of the bone, for example, Collagraft® and Healos®.

In a clinical trial in 213 patients, autologous bone grafts were compared with a collagen/biphasic calcium phosphate ceramic (Collagraft®) mixed with autologous marrow.[369] At 24-month postoperation, 98% of the autografts resulted in fracture healing, while 97% of the Collagraft® treated fractures had also healed. In a separate study by Cornell *et al.*, which monitored 267 patients over a 12-month period, Collagraft® appeared to function as well as an autograft.[370] Neen *et al.* have performed a study using Healos® along with bone marrow aspirate to treat posterolateral lumbar fusions and lumbar interbody fusions. They found that Healos® was effective in the posterolateral lumbar spine fusion model but was radiographically ineffective in lumbar interbody fusions.[371] Carter *et al.* have used Healos® for transforaminal lumbar interbody fusion in combination with interbody cages and posterior pedicle screws; however, patient numbers are low ($n = 20$) and no controls were applied.[372] Despite these inadequacies Healos® was shown to be effective in achieving a successful fusion. DePuy, manufactures of Healos®, have released an injectable version of this product, Healos® Fx., in 2009. An injectable product is always desirable as it can be used during minimally invasive surgery and has the added benefit of complete defect filling.

Despite these advances in tissue-engineering scaffolds, they have failed to become the primary choice of surgeons, which suggests inadequate healing. The majority of tissue-engineering scaffolds described above are empty templates, and depend on a compromised healing site to upregulate the genes necessary for osteogenesis. It is therefore not surprising that a scaffold alone is inadequate in regenerating the defective site. As collagen is a hydrophilic material and well tolerated in the body, it has received a lot of attention for use as a drug carrier. Some of the studies described above have used BMPs to aid the regenerative process. This combination of xenogenic biopolymers and growth factor delivery has been shown to be an effective for the treatment for critical-sized bone defects. Chung *et al.* have developed a nanoparticles–hydrogel complex consisting of fibrin, heparin functionalized nanoparticles, and BMP-2. **Figure 1** shows the regeneration of six critical-sized defects over a 4-week period.[373] Such technologies have resulted in the commercialization of the OP-1® putty available from Stryker® and the INFUSE® bone graft available from Medtronic; however, more recent developments have also used collagen as a carrier for plasmid DNA for bone regeneration.[374–376] The collagen scaffolding material acts as a reservoir for controlled release, and hence, prolonged delivery of the therapeutic agent can be achieved.[377] **Figure 2** shows an osteosarcoma cell transfected with plasmid DNA that was released from a collagen/calcium phosphate scaffold developed for bone tissue engineering.[378] The same material was then used to correct femoral defects in mice.[379] The collagen/calcium phosphate scaffold was loaded with plasmid DNA encoding $VEGF_{165}$. **Figure 3** shows remnants of the scaffold material and evidence of bone regeneration at the defect site. There was a statistically significant increase in bone formation when scaffolds loaded with the $VEGF_{165}$ plasmid were used compared to plain scaffolds. This study heralds an exciting, new age for xenogenic biopolymers.[379]

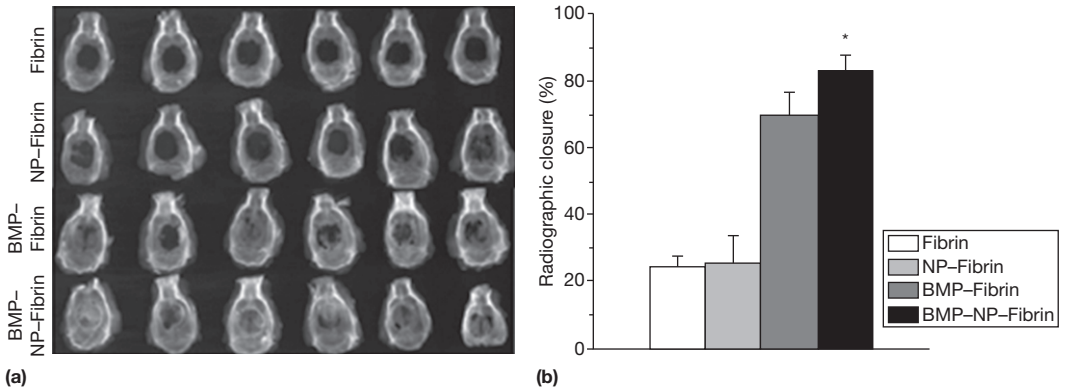

Figure 1 Regeneration of critical-sized defects over a 4-week period using functionalized with heparin and BMP-2 fibrin systems. Reproduced from Chung, Y. I.; Ahn, K. M.; Jeon, S. H.; Lee, S. Y.; Lee, J. H.; Tae, G. *J. Control. Release* **2007**, *121*, 91–99.

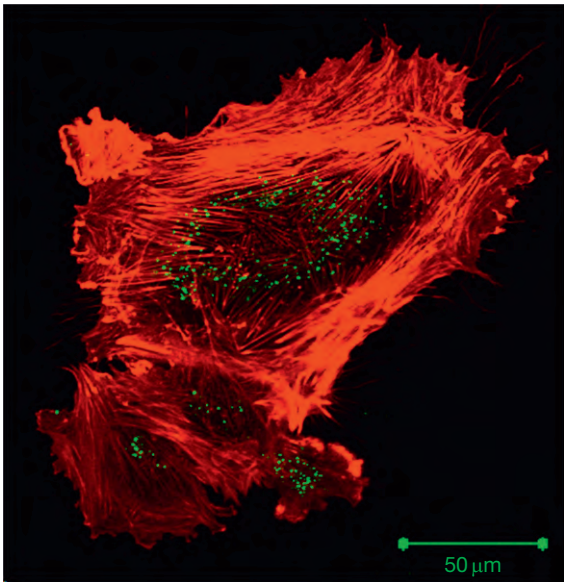

Figure 2 Uptake of plasmid DNA by a marrow stromal cell following delivery from a collagen/calcium phosphate scaffold. Plasmid DNA has been labeled with a cyanine 3 (green) marker, while the phalloidin filaments have been stained with rhodamine (red). Plasmid DNA was complexed with a commercially available transfection agent for efficient delivery.

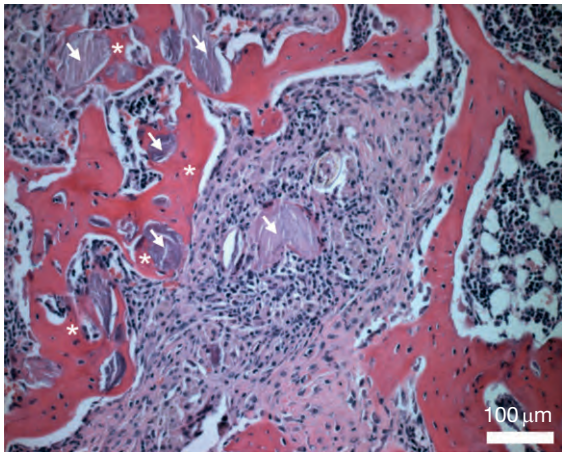

Figure 3 Resorption of a collagen/calcium phosphate scaffold and replacement with bone in a mouse femur after 4 weeks of implantation. The scaffold was loaded with plasmid DNA encoding vascular endothelial growth factor 165. Arrows indicate remenants of scaffold, while asterisks indicate bone formation with the defect site. Decalcified histological section stained with hematoxylin and eosin. Image captured at 200×.

2.222.3.2. Intervertebral Disc Reconstruction

Neck and low back pain are the two highest causes of job-related disability, with significant associated social and economic costs,[380] accounting for a total annual direct healthcare cost estimated between $50 and $90 billion each year in the United States alone.[381] These pathologies are strongly associated with degeneration of the intervertebral disc (IVD).[382] Disc degeneration disease (DDD) is defined as 'an aberrant cell mediated response to progressive failure.'[383] The onset of the degeneration process results in the IVD being inherently incapable of adequate self-repair.[382] Currently, the most prevalent treatment modalities associated with DDD involve conservative methods, including physical therapy, drugs, and interbody fusion surgery.[380,381] Tissue-engineering strategies offer many advantages in the treatment of DDD. This will potentially have a significant impact on medical practices and will facilitate a reduction in the social and economic costs associated with DDD.[384]

Current technologies for disc replacement are designed to preserve flexion, extension, and lateral bending motions, and ultimately, to restore disc space height.[385] The use of the poly(vinyl)alcohol hydrogels has been advocated, although a significant delay in the regeneration process has been observed after implantation into baboon and rabbits.[386,387] It is also worth pointing out that their long-term behavior is still unknown[388] and that ejection of the implant (out of the disc) due to mechanical movements and the absence of adherence of this material to the native tissue limit its use in clinical practice.[387] Furthermore, the inability of such materials to biointegrate, and subsequently, remodel the tissue, imposes the need for developing new strategies. To respond to these problems, other types of hydrogels are under investigation. A promising preclinical trial of an injectable hydrogel 'NuCore™' (Spine Wave, USA) has been carried out recently. This commercial hydrogel is composed of an *in situ* crosslinked copolymer of elastin and silk which mimics the biomechanical properties of the native nucleus. The disc maintained 93% of its original height at the central region and 92% at the posterior disc region after 24 weeks during this preclinical trial.[389] However, this material can only replace, but not regenerate, a damaged disc.

New tissue-engineering approaches are based on either the regeneration or replacement of the IVD using biomaterials that are enriched with cells and/or bioactive macromolecules. Cell implantation, generally associated with scaffolds, has received great attention in recent years. Cells-based tissue engineering can be envisaged in two ways: either injection of cells alone[390] or injection of cells with a carrier system (often a biodegradable scaffold).[391] These carriers provide physical support for cell placement into the disc. Furthermore, with these, a specific cellular environment can be created[392] to direct a desired cellular activity, such as cell proliferation or production of ECM. These scaffolds can be functionalized by gene or drug carriers, which can influence signaling pathways[393] and/or enable the production of new functional ECM[394] (**Figure 4**).

The major challenge in cell-based therapies is the identification and development of a material, which resembles native tissue, and is capable of promoting phenotype maintenance, proliferation and differentiation of NP cells, and/or stem cells. Cell carriers such as alginate,[395] bioactive composite scaffolds including chitosan–glycerophosphate,[396] type II collagen–aggrecan–hyaluronan,[384] fibrin–hyaluronan scaffolds,[397] and gene carriers such as nanoscaffolds including nanoshells, dendrimers, and polymers[398] have the following advantages when used as therapeutic solutions: (a) biodegradability; (b) injectability (less invasive than the use of surgical techniques); (c) preservation of the native tissue; and (d) nonpreclusion of future spinal surgery and multilevel disc

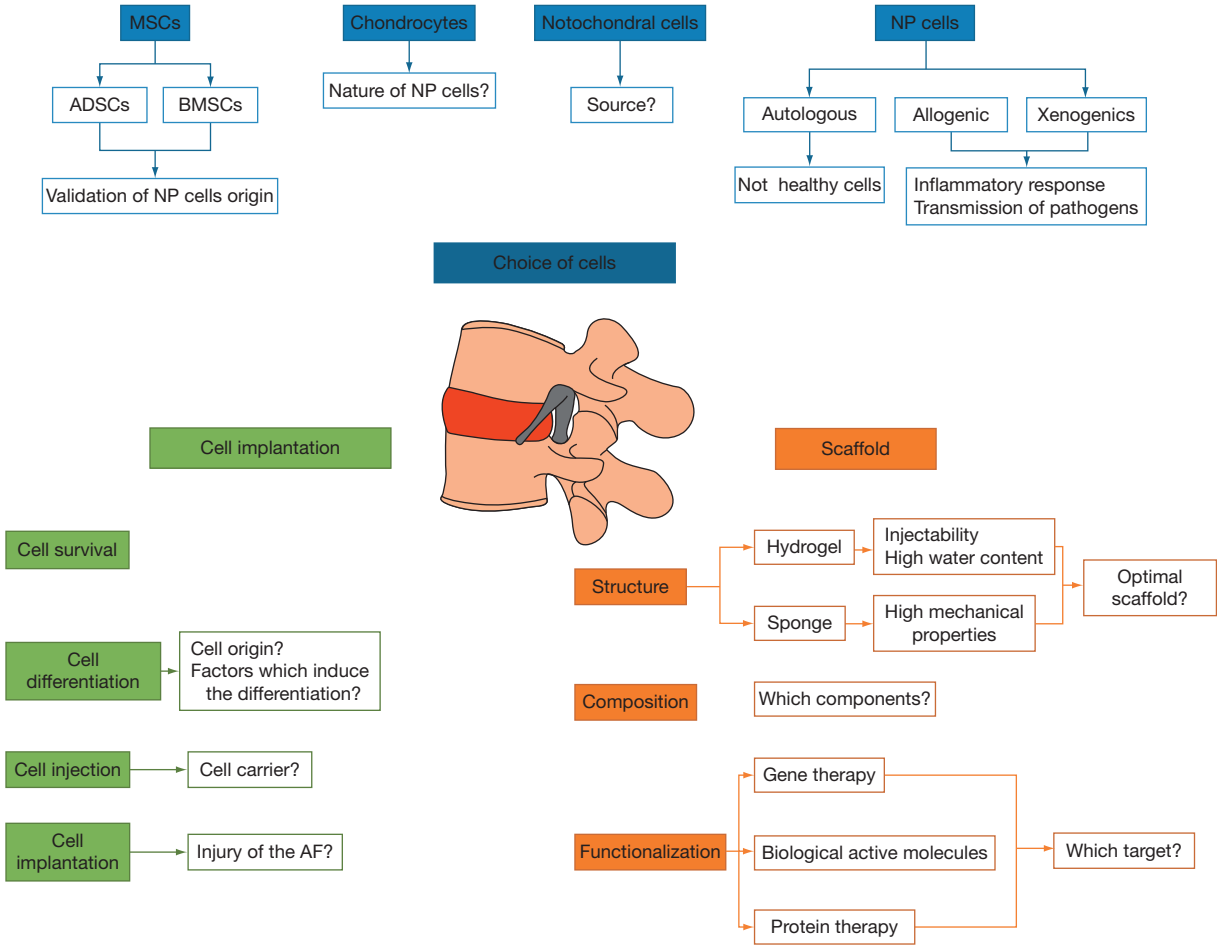

Figure 4 Potential strategies for the treatment of the intervertebral disc.

treatments.[399] Ideally, this three-dimensional matrix should closely mimic the environment of the native tissue at the site of interest.[400] An ideal scaffold should be biodegradable at a rate that matches ECM deposition without any toxic or inhibitory products. In addition to being highly biocompatible, the scaffold should have a chemical/structural make-up that permits the transport of nutrients, metabolites, and regulatory molecules to and from the cells[401] and should not affect cell phenotype and differentiation.[402]

The composition of the hydrogels used for cell delivery is important for NP regeneration. It has been shown that the low antigenic character of type II collagen, its mechanical properties and its dominance in the composition of the native tissue make it a candidate of choice for IVD tissue engineering.[54,403] Copolymers of type II collagen have been reported to be promising scaffolds for cartilage and disc regeneration,[239,404,405] inducing, notably, the regeneration of the disc after bone marrow-derived mesenchymal stem cell (bMSCs) implantation (**Figure 5**).[406] Type II collagen hydrogels have also been shown to enhance chondrogenesis of adipose tissue-derived stem cells (ADSCs) at a greater rate than hydrogels of collagen type I.[402] Furthermore, microenvironments of chondroitin sulfate and hyaluronic acid (HA) have been shown to promote cell aggregation and chondrogenic differentiation. These molecules also help maintain the NP cell phenotype.[397,407]

HA is an abundant glycosaminoglycan in NP tissue. Tissue-engineering strategies are based on molecules derived from HA. Studies have shown that acellular hydrogels (HYAFF-R 120) and cell-loaded hydrogels (HYADD-R 3) are capable of inducing repair of an IVD following nucleotomy. Although the biological effect of hyaluronan-derived materials has not been studied,[408] it has been reported that HA has a positive effect in stimulating ECM biosynthesis, cell proliferation, cell migration, and phenotype maintenance in chondrocytes and NP cells.[397,409–411] Furthermore, an anti-inflammatory effect of this molecule has also been shown that prevent arthritis formation in joints and discs.[412] Soluble HA, blended within collagen gels, can provide the biological benefits of HA without the associated mechanical limitations.[413]

Different cell sources have been envisaged for cell therapy of IVD, such as autologous and xenogenic cells from the NP and mesenchymal stem cells. The use of autologous and xenogenic cells is limited by the low number of cells available in the disc. For this reason, mesenchymal stem cells have been investigated extensively with regard to their availability, proliferation, and differentiation properties.[400] Two types of mesenchymal stem cells are used for IVD therapy: bMSCs and ADSCs.

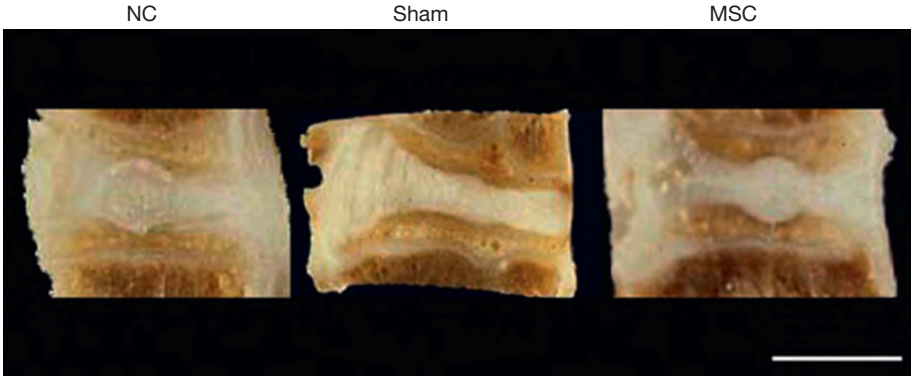

Figure 5 Macroscopic view of normal control (NC), sham-operated (Sham), and mesenchymal adult stem cell (MSC)-transplanted discs (MSC) after MSC transplantation using a type II collagen hydrogel as cell carrier. Reproduced from Sakai, D.; Mochida, J.; Iwashina, T.; *et al*. *Biomaterials* **2006**, *27*, 335–345.

In vitro, cocultures of bMSCs and ADSCs with NP cells have been shown to induce the production of type II collagen, GAGs, and a decrease in type I collagen production and markers of differentiation into a NP cell-like lineage.[414–416] The environment of culture of stem cells affects their properties and differentiation. Micro-mass cultures have shown a significant improvement in the production of type II collagen and aggrecans.[92] ADSCs have been the subjected to extensive research in orthopedic tissue engineering in recent years. They have been described in literature as having the same properties as bone marrow stem cells. However, ADSCs present distinct advantages compared to bone marrow stem cells, that is, widely available sources and larger numbers. ADSCs have shown properties of differentiation into IVD cell-like and chondrogenic lineages.[417] Mesenchymal stem cells could be a good alternative to cell therapy for IVD. However, the origin of NP cells is still unknown and the use of mesenchymal stem cells is under debate.[418,419]

A combination of the datasets suggests that the association of different types of ECM molecules would help guide the differentiation of stem cells into a NP cell-like phenotype. O'Halloran *et al.* have shown that a composite hydrogel of HA and type II collagen was most suitable for maintaining a NP cell phenotype.[384] Consequently, a cell carrier with a composition that closely mimics the native environment could be envisaged as ideal for IVD regeneration. Therapies that use direct injection of growth factors or cytokine inhibitors have been shown to be unsuccessful because of their short half-life *in vivo*.[382] Furthermore, a degenerated disc in a more advanced stage of degeneration may require prolonged exposure to growth factors to restore biochemical composition and disc function. It appears that the use of gene therapy can prolong the exposure period of IVD cells to these therapeutic molecules (e.g., growth factors,[393] transcription factors,[420] RNA interferent[394]). In order to keep the composition of the biodegradable carriers closer to the native tissue, carriers based on ECM proteins are currently being developed. The advantages of these carriers are their biocompatibility due to their similarity to the ECM and their biodegradability. Nagae *et al.* have shown that the delivery of PRP-impregnated gelatin microspheres slowes down the process of degeneration.[421] The biodegradability of the microsphere, controlled by the degree of crosslinking, induces a time-dependent release of the molecule of interest. However, repeated injections are essential for continuous inhibition of the degeneration factors.[420,421]

The treatment of the IVD seems to be a complex association of cells and biologically active molecules, all embedded within a biodegradable polymeric carrier. It is anticipated that an association of the macroscale (carrier of cells) and the microscale (carrier of gene or/and proteins) components will provide a solution that not only will slow down the process of IVD degeneration but also promote its regeneration (**Figure 4**).

2.222.3.3. Tendon Reconstruction

There are over 15 million tendon- and ligament-related injuries in the United States alone with approximately 95 000 new cases per year.[336–341] As the life expectancy increases, it is anticipated that tendon injuries will remain the most common cause of morbidity throughout the world. Therefore, it is essential to develop therapeutic strategies for functional tendon regeneration. Noninvasive pharmacological strategies for the prevention of ligament and tendon injuries, based on slow acting antirheumatic drugs (SAARDs) or nonsteroidal anti-inflammatory drugs (NSAIDs), have been introduced.[422–425] However, SAARDs and NSAIDs are effective only during the early stages of disease, are associated with severe side effects[426–428] and have an inhibitory effect on proteoglycan synthesis and cell proliferation.[429] For these reasons, their use has been limited.

The use of tissue grafts has been advocated repeatedly due to superior functional results in a clinical set up for anterior cruciate ligament and extensor tendon.[430–433] Palmaris longus and plantaris longus tendon autografts are commonly employed for tendon reconstruction in the digit, hand, and wrist, as they are similar in size and have been proven to be reliable.[433–435] Allografts have also been used extensively for tendon regeneration with variable results that range from limited success[436–439] to properties similar or even superior to autografts.[5,440–442] Xenogenic tissues have also been used for tendon and ligament repair. Xenogenic tissues have a structure that is identical to the host tissue and do not compromise patient's tissues. Early drawbacks[3,443–445] have now been addressed[446,447] and recent data demonstrate normal tissue ingrowth in several animal models.[2,448–450] Despite the very

promising results with the use of tissue grafts, allografts still face the risk of potential transmission of infectious diseases[15–18] and autografts have the disadvantage of creating a secondary morbid site during harvesting. Development of tissue-engineering strategies is therefore essential to address shortfalls of tissue grafts.

Synthetic and natural scaffolds have the potential to significantly improve the treatment of tendon and ligament injuries, especially those associated with degenerative and congenital conditions, where autografts or allografts may not be available in sufficient quantity.[433,435,451–454] Numerous synthetic materials have been evaluated for tendon regeneration including polylactic acid,[455] carbon–polylactic acid polymer composite,[456,457] polytetrafluoroethylene,[458,459] polyethylene terephthalate,[460,461] poly(glycolic acid) and Dacron® composite,[462–464] nylon,[323,465] polypropylene,[466,467] PGA/polyglyconate/polydioxanone,[457,468] and polyglactin.[469] Since synthetic materials are associated with foreign body reaction[45–48] and a lack of cell-recognition signals and also because their hydrophobic properties hinder smooth cell seeding,[49–51] biological molecules (collagen, gelatin, HA, growth factors, and RGD peptides sequences) have been used to modulate cell attachment, decrease adhesions, accelerate tendon healing and improve the quality of repair tissue.[259,323,470–485] Despite the early promising results, several drawbacks in the use of synthetic devices have been identified. For example, Dacron® does not allow the functional orientation of neotissue[486] and fails to protect the patellar tendon graft during neovascularization.[487] Polyglycolic acid fibers induced a thinner and significantly weaker neotissue compared to natural tendon.[488] Nylon-based repair approaches have failed to successfully produce a new functional substitute.[489] Polypropylene devices were characterized by a disordered fibrous capsule.[490] The use of carbon fibers has also been limited due to the association of carbon with skin diseases.[491–493] Potential toxic degradation products of synthetic materials have also been shown to be deleterious to the surrounding tissue and have suppressed cell growth.[43,494,495] For these reasons, no artificial materials have been able to meet the requirements of functional tissue remodeling.[496]

Given that natural polymers (e.g., fibrin, silk, chitosan, and collagen) possess several inherent advantages such as ability to present receptor-binding ligands to cells, susceptibility to cell initiated proteolytic degradation, and natural remodeling,[13,38,52,57,58] they are preferred for scaffold fabrication for tendon repair. Although it has been shown that fibrin glue demonstrates significantly better functional and cosmetic results compared to treatment with sutures[497,498] and that it also promotes a smooth gliding surface and restricts adhesion after repair of the flexor tendon,[499–501] the properties of the regenerated tissue did not match those of the original tissue.[502] Silk has been used extensively for tendon reconstruction due to its exceptional mechanical and biological properties.[503–506] Moreover, silk-based biomaterials support cell attachment, expansion and differentiation of adult human progenitor bone marrow stromal cells and promote the expression of collagen types I and III and tenascin-C, all of which are characteristics of ligament.[507] However, early unsuccessful results[489] and potential allergic reactions have restricted its use in tissue engineering.[508] Chitosan has also been used successfully for tendon and ligament regeneration; in fact neotissue formation following implantation of chitosan-based scaffolds was characterized by very good mechanical properties.[509–513] Collagen-based devices have also been used very successfully for tendon and ligament regeneration. Self-assembled collagen fibers (**Figure 6**) have been shown to closely imitate native ECM supramolecular assemblies with regard to structural and mechanical properties,[88,156,162,168,514–529] while their unique nanotexture topography has been shown to facilitate directional cell migration, which is essential for neotissue formation.[527] Cross-linking approaches (chemical, physical, and biological) that have been investigated over the years have offered control over mechanical and thermal properties, biological stability, residence time in the body and, to some extent, the immunogenicity and antigenicity of the device.[127,132,134,162–171] Moreover, using transglutaminase, an enzyme that catalyze several posttranslational modifications of proteins in the ECM in a Ca^{2+}-dependent manner,[530–534] we have been able to functionalize collagen scaffolds.[93,168,535–539] Collagen fibers also avoid the problems that are associated with long-term foreign body implantation or a granuloma that could interfere with the smooth gliding of tendon repairs.[240,514,515,518,522,529] Indeed, it has been shown in animal studies that an aligned neotissue, similar to the one obtained from an autograft and almost identical to a normal tendon, is formed.[516,540] For ligament repair, self assembled collagen fibers have been shown to remodel host tissue within 12 weeks,[529] and an organized and crimped neoligament tissue was observed at 20 weeks postimplantation.[521] A combination of mesenchymal adult stem cells (MSCs), biological cues, and scaffolds have also been investigated for tendon injuries.[541] The hypothesis in this case was that MSCs could replace the limited number of host cells that reside in the endotendon tissue between the collagen fascicles and adjacent to the vasculature, and therefore, can potentially regenerate or repair the tendon and ligaments.[542,543] To this end, it has been shown that MSCs have proliferation rates and function that are comparable to tenocytes, while adipose-derived MSCs have been shown to proliferate fast *in vitro* and have been used to successfully repopulate acellularized tendon *in vivo*.[544,545] Animal models and human clinical trials have demonstrated significantly improved mechanical, structural, biological, and biochemical properties in the repaired tendon.[341,546–554]

2.222.4. Limitations

Allogeneic and xenogenic biological scaffolds based on ECM are being customarily used for numerous tissue-engineering applications because of their superior inherent properties, although the effects of such scaffolds on the host immune response are yet to be fully investigated.[141,555,556] Despite the advancements in extraction and purification procedures and the minimal regulatory requirements already in place, ECM components could potentially be responsible for disease transmission.[557–562] For example, the transmission of Bovine Spongiform Encephalopathy across species barriers has proven to be a significant drawback in manufacturing bovine-derived biomaterials despite reports that state that the transmission of this disease to humans, if at all it occurs, requires an effective dose for a sufficiently prolonged period of time.[563]

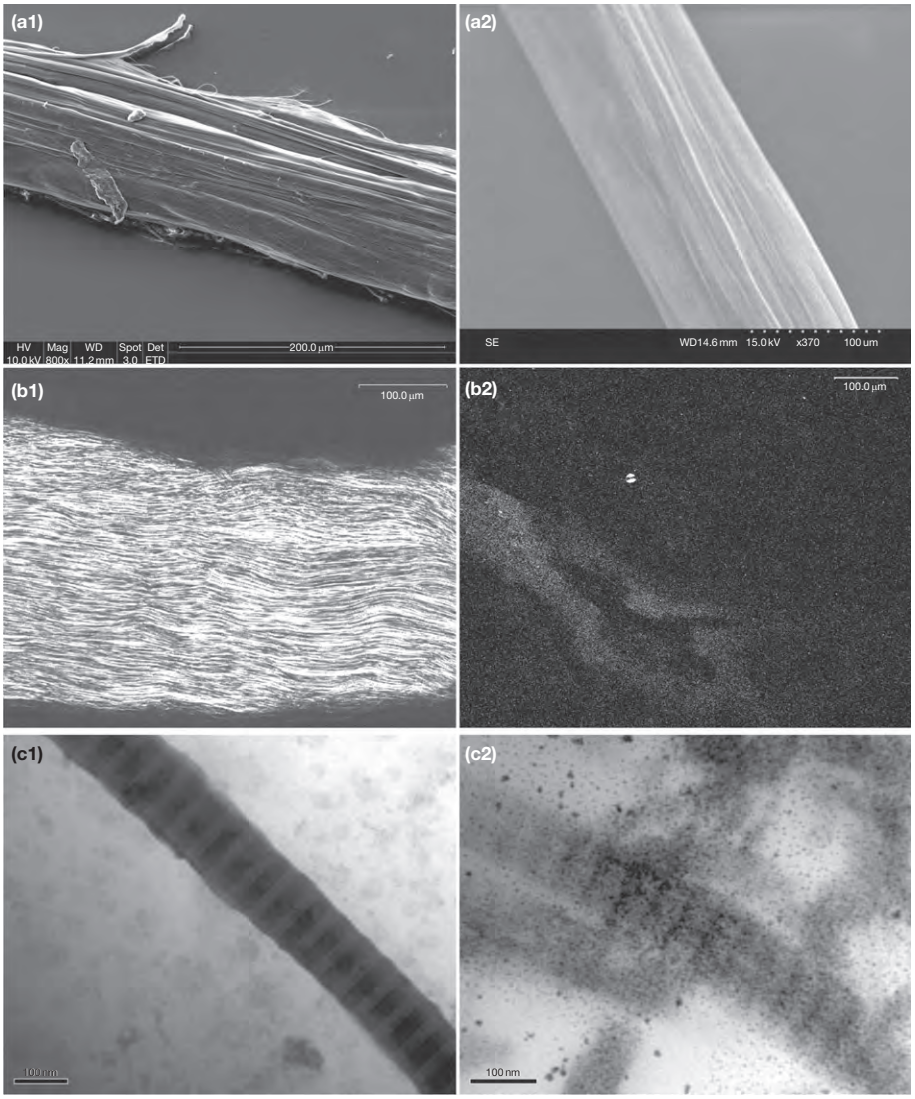

Figure 6 Extruded collagen fibers (a2) exhibit similar surface topography to native tendon (a1) as revealed by scanning electron microscopy. Second harmonic generation analysis demonstrates that extruded collagen fibers (b2) possess high level of crystallinity and structural alignment proportional to native tendons (b1). Transmission electron microscopy reveals that extruded collagen fibers (c2) are quarter-staggered arranged as native tendons (c1).

Recombinant and peptide synthesis technologies, have in the recent years, introduced a means of producing ECM-like components[564] such as collagen[565–569] and elastin.[570–573] Invaluable insights into physiological[574,575] and pathophysiological[576] collagen folding pathways, as well as information about triple-helix stability[577–579] and biological functions, including cell-adhesion and crosslinking sites,[580–583] have been obtained using collagen-like peptides. Similarly, several expression systems including transfected mammalian cells,[584,585] insect cells,[586,587] yeast,[588,589] bacteria,[590–592] transgenic mice,[593] transgenic plants such as tobacco[594,595] and corn,[596] and silkworms[597] have been successfully employed to produce human recombinant procollagens which avoids the problems related to variations between batches, interspecies transmission of disease and possible xenogenic immuno-responses induced by animal-extracted collagens.[598–600] However, the expression of fully functional molecules has been difficult due to the complex nature of procollagen synthesis.[601] Moreover, in all cases, the expression levels of procollagen have been very low and therefore have limited broad commercialization potential.[587,602,603] Moreover, recombinant collagens lack specific domains which are otherwise present in native fibrillar collagens,[564,604] which further compromises their biological function and reduces their use.

2.222.5. Future Perspectives

The use of xenogenic tissues and natural biomaterials in the skeletal system has been extensive. Future applications lie in how we can effectively overcome the current limitations in their manufacturing. A strategy to restore the instructive assembly of the natural scaffold is by the incorporation of signaling cues. This incorporation can be done by the use of functionalization strategies. Adding missing functionality to the

resultant manufactured biomaterial is an attractive option. This can be achieved by deciphering the linking strategies already existing in natural tissues. Natural enzymatic linkers can be synthesized using the advances made in peptide synthesis and click chemistry. However, much of the functionality can be achieved when basic fundamental transcriptomic signatures of various cell types, during their differentiation phases, are understood. Ultimately, the final EC matrix is a result of what the cells express. Hence, this critical piece of the puzzle needs to be deciphered to develop the ultimate biomaterial – the true EC matrix.

SMC	Smooth muscle cells
UDP	Uridine diphosphate
UDPG	UDP-glucose

2.223.1. Introduction

The development of biomaterials coincides with the beginning of surgery. The Indian surgeon Sushruta as early as 2800 years ago conducted advanced surgeries and used sutures made of cellulose from hemp and cotton. Cellulose was first isolated in 1838 from the cell walls of plants.[1] Since then, its structural importance and presence in other organisms has been further elucidated. In plants, cellulose provides structural integrity where it is found in conjunction with hemicelluloses, lignin, and other materials. The bacteria *Acetobacter xylinum* has been particularly noted for its production of cellulose in which it plays a protective role rather than being a load-bearing material. *A. xylinum* is a nonpathogenic obligate aerobic Gram-negative rod. It is a common contaminant of wine and beer and is found naturally on the surface of fruits and flowers where it produces a cellulose film.[2] This biofilm helps to retain moisture, protects the bacteria from UV radiation, and, in liquids, helps the bacteria stay near the oxygen-rich surface, thanks to its natural buoyancy.[2–4] On fruit, it has been shown that the biofilm promotes *A. xylinum* colonization while inhibiting colonization of competing organisms.[3] The cellulose produced by bacteria is pure, without contaminant molecules. This remarkable purity is combined with high water-holding capacity. Bacterial cellulose (BC) contains 99 wt% water and is essentially a hydrogel.[5] The architecture of the entangled nanoscale fiber network makes it mechanically strong (see Section 2.223.7). Taken together, all these unique properties of the BC network make it a very interesting candidate to be used for various biomedical applications (Figure 1).

2.223.2. Bacterial Cellulose: Growth

BC, like all cellulose, is a natural polymer synthesized from UDP-glucose (UDPG) monomers. Cellulose synthase is the enzyme that catalyzes the covalent attachment of these glucose subunits into a linear chain. In the process, UDP is cleaved off and the remaining D-glucose subunits are attached via β-1,4 linkages, forming β-1,4 glucan chains. In addition to the β-1,4 covalent bond between adjacent D-glucose monomers, each D-glucose subunit also hydrogen bonds with adjacent D-glucose monomers within its chain. As chains are brought into close proximity, interchain hydrogen bonding also occurs between the exposed hydroxyl groups of aligned chains (Figure 2).

A. xylinum is not limited to six-carbon sugars as substrates for cellulose synthesis. It can utilize a variety of molecules as carbon sources including hexoses, hexanoates, pyruvate, glycerol, dihydroxyacetone, and dicarboxylic acids.[3] The benefit of this diversity of usable substrates is that there is potential for growing BC in a variety of media, including biomass waste material. A wide range of alternative growth media has been investigated. Waste broth from beer culture, pineapple juice, coconut milk, konjac powder, and sugarcane molasses are some of the sources investigated in the past several years.[6–10]

Individual chain polymerization and subsequent association of multiple chains into larger microfibrils occurs in series. Cellulose synthase is thought to be located on the cytoplasmic membrane. Multiple chain synthesis sites are located in close proximity so that newly polymerized polyglucan chains associate in parallel, forming intermolecular hydrogen bonds. The method of extrusion from the cell differs in bacteria and plants. In plants, cellulose aggregates are extruded from rosette structures whereas in bacteria, they are extruded from a linear array of 50–80 extrusion pores running longitudinally along the side of each bacterium. In cellulose-producing bacteria, initial aggregates of 10–15 polyglucan chains form first.[3] These premicrofibril aggregates then assemble to form larger microfibrils. Microfibrils associate to form larger microfibril bundles, and bundles ultimately associate loosely to form the cellulose ribbon extending from each cellulose-producing bacterium. Bacteria replicate and continue 'spinning' cellulose until a dense intertwined mesh is created, thus enclosing and protecting the bacteria. The result of a colony of such bacteria-producing cellulose ribbons is a highly pure, nanofibrillar mesh composed of 99% water (Figure 3).[5]

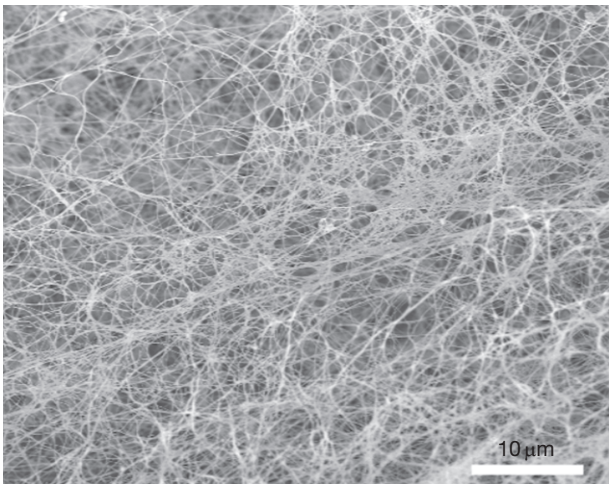

Figure 1 Bacterial cellulose: nanostructure.

2.223.3. Modification of Nanostructure

The polymerization of individual polyglucan chains and the ultimate crystallization of these large cellulose ribbons are coupled processes, occurring simultaneously and in linear physical connection.[3] However, the crystallization process can be disrupted by the addition of interfering molecules to

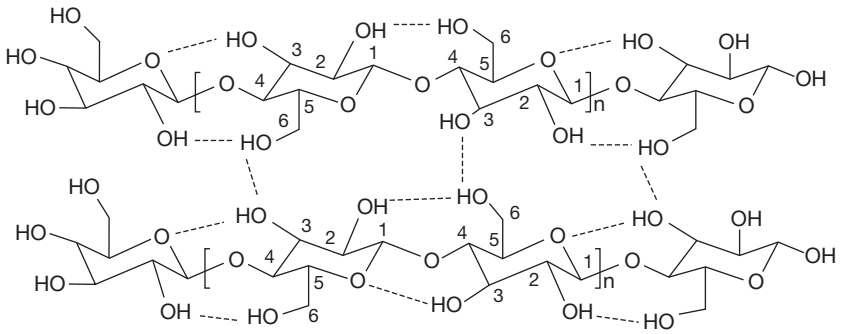

Figure 2 Cellulose, showing the hydrogen bonding network and the numbering of the atoms. Each glucose residue forms two intramolecular hydrogen bonds ($O_6 \cdots H–O_2$) and ($O_3–H \cdots O$ ring) and one intermolecular bond ($O_6–H \cdots O_3$).

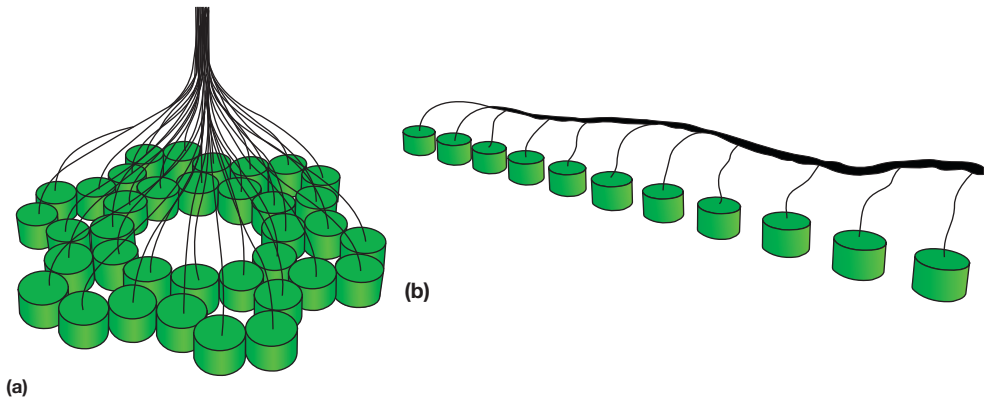

Figure 3 (a) Rosette-type terminal complex as found in algae and vascular plants. (b) Linear arrangement of cellulose extrusion pores, as found in cellulose-producing bacteria, forming a cellulose premicrofibril aggregate strand.

the culture medium (e.g., Congo red dye, calcofluor, carboxymethyl cellulose).[3,11,12]

There have been many efforts to modify the nanostructure of BC. One example is to supply different oxygen tensions. Watanabe *et al.* reported that a denser BC network formed in a static culture with a higher oxygen ratio (50%) than in air. BC nanofibrils branched in association with cell division, and those branches produced a ramified network. The length of the segments between branches varied from 700 µm at 10% oxygen to 200 µm at 50% oxygen tension.[13] It has been recently discovered that the synthesis of the nanofibril by bacteria can be involved in generating movement of the cell. By adding carboxymethylcellulose sodium salt (CMC) to the culture medium, bacteria moved faster in the culture medium, resulting in changes to the nanofiber compared to a normal cellulose nanofiber.[14]

2.223.4. Engineering of Morphology

One of the greatest advantages of BC is its ability to be molded into almost any size and shape during its synthesis without causing any significant alteration of its physical properties.

When cultured statically, BC accumulates at the surface of the culture medium as a pellicle.

The BC pellicle that is formed has a great number of almost parallel thin cellulose layers.[15] These layers propagate downward during culture. New layers always form at the upper film surface, resulting in a steady increase in the pellicle's thickness with time.[16] The pellicle can be used in its native state for several biomedical applications (see **Section 2.223.9**). It is also possible to reform the pellicle into desired shapes. For example, if the culture surface has a 'meniscus-like' shape, the resulting pellicle will be similar in appearance to a meniscus (**Figure 4**).[17]

Several patents and articles cover the production of BC tubes by utilizing different fermentation methods.[18–21] Many techniques use a surface that acts as a template for BC deposition and as a membrane for oxygen delivery. In some, the culture is encapsulated, which makes the BC network fill out the area between, for example, two glass cylinders, resulting in a tube-shaped BC network. Since the production techniques vary, the properties of the resulting tubes are not the same, even though they are all composed of a BC network.

2.223.5. Shaping in 3D Structure

A scaffold seeded with cells is generally considered the paradigm of tissue engineering. It has been found that when the scaffold has a nanoscale morphology, cell attachment, proliferation, and expression of matrix components are increased.[22] Compared with macroscale scaffolds, nanoscale scaffolds possess larger surface areas for the adsorption of proteins and present many more binding sites to cell membrane receptors.[23] BC fibrils are in the nanometer scale and are microscopically similar to collagen fibers.[24] This makes them interesting for use as a building block in scaffolds. The BC pellicle has too high a nanofibril density to be able to house cells other than in the outermost regions when acting as a scaffold for smooth muscle cells (SMCs).[24] The porosity can be altered with a

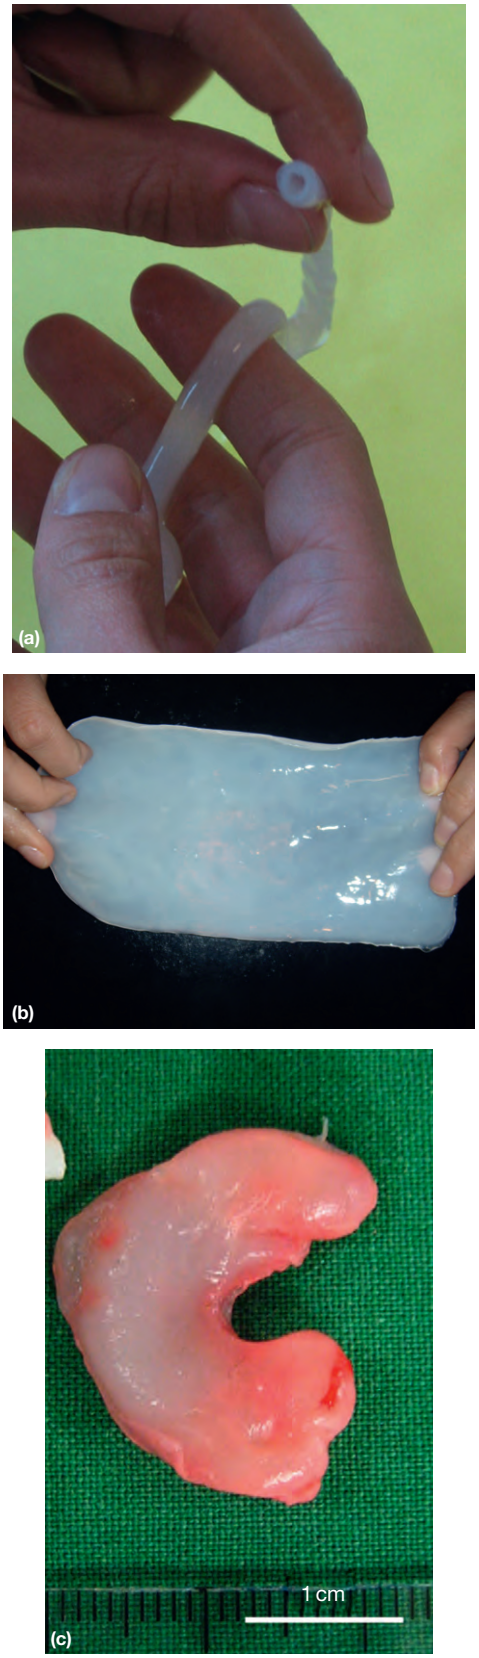

Figure 4 Bacterial cellulose in various shapes, tube to be used as vascular graft (a), membrane to be used as burn dressing (b), meniscus implant (c).

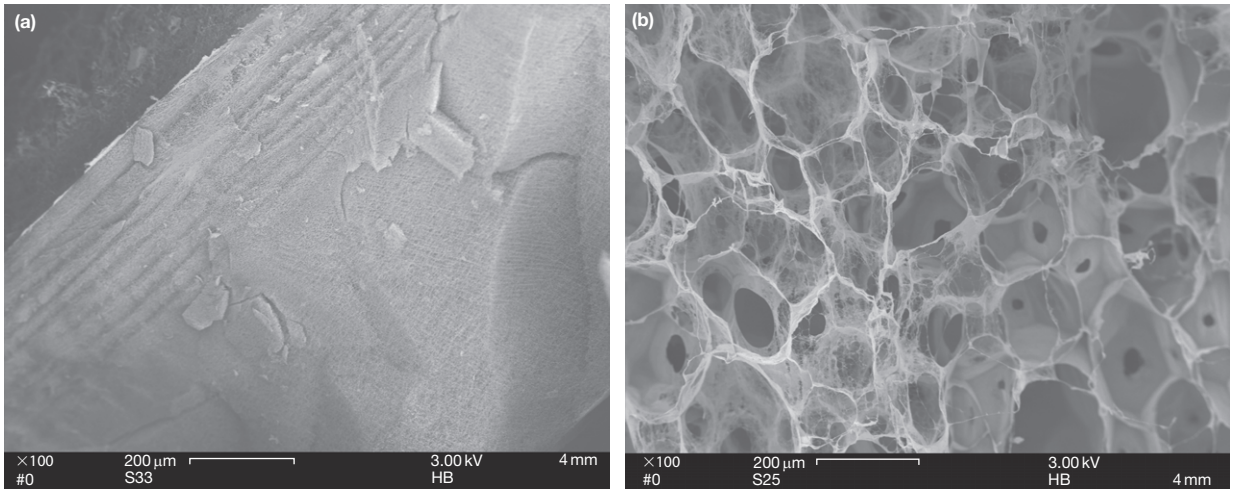

Figure 5 Scanning electron microscopic image of a pellicle and a porous bacterial cellulose (BC) network made with paraffin particles. The cross section of a BC pellicle is seen in (a) while (b) shows a scaffold made with paraffin particles in the size range of 300–500 µm. The porosity has greatly been altered with the help of the particle-leaching technique.

particle-leaching technique where paraffin wax particles are introduced into the culture, and removed when the culture is finished. This results in a microporous BC scaffold that can house SMCs (Figure 5).[24]

2.223.6. Biocompatibility

BC's high water content, around 99%, suggests that it can be seen as a hydrogel, although not by definition as it is not a network of polymer chains that are water soluble. Hydrogels are known for their favorable biocompatibility properties, largely due to little protein adsorption.

A biocompatibility evaluation of a BC pellicle has been made in Wistar rats by subcutaneous implantation and evaluation. At 1, 4, and 12 weeks, Helenius *et al.* reported that there were no macroscopic signs of inflammation, that is, redness, edema, or exudates, around the implanted BC pieces or in the incision at any time point.[25] No histological signs of inflammation in the specimens were found. Fibrosis, capsule formations, or giant cells were not detected around the implants. Instead, the rat connective tissue integrated very nicely with the BC structure at all the studied time points. Newly formed blood vessels were present around and in the implant at all studied time points. The formation of new blood vessels around and in a biomaterial is very important for the healing process and long-term success of a scaffold.[25] BC was further evaluated *in vivo* and *in vitro* by Mendes *et al.*[26] They found that BC induced a mild inflammatory response *in vivo*.

Genotoxicity evaluation has been conducted on BC nanofibers by Moreira *et al.* They reported that BC was not genotoxic under the conditions tested.[27]

Yamanaka *et al.* and Klemm *et al.* have reported data on BC blood compatibility.[19,20] BC was found to be blood compatible, although no systematic study has been carried out to elucidate BC properties toward blood. Klemm *et al.* further claimed to get endothelial cells to cover the lumen when they implanted microbial cellulose vessels, BASYC®, into a rat. As yet, there have been no studies on retention of endothelial cells on BC tubes or on endothelialization of BC tubes in large animal models.

Degradability of regenerated cellulose implants has been shown to be limited. The degradation is induced by chemical modifications that alter its ordered and rigid structure.[28,29] The degradability of BC has not been fully evaluated either *in vivo* or *in vitro*. Mendes *et al.* reported that subcutaneous implanted BC membranes remained intact for at least 90 days.[26] That is similar to what Helenius *et al.* have reported.[25]

2.223.7. Biomechanics

The bonding pattern between cellulose chains gives cellulose remarkable strength. Young's modulus in the plane of a thin BC sheet in the dry state has been reported to be >15 GPa, exceeding any previously tested polymeric film by more than 5 GPa, with tensile strength comparable to that of steel.[3,30]

The high Young's modulus has been ascribed to the unique supermolecular structure in which the microfibrils are tightly bound by hydrogen bonds (see Section 2.223.2). It is important to note that these studies have been conducted on dry films of BC. The reported tensile strength of BC in its wet state has been expressed in Newtons, which makes it difficult to compare results with other values for Young's modulus.[20,31] The Young's modulus in tensile load of wet BC gel has been reported to be 1 MPa, and the elasticity varies depending on sample preparation and probably also on fermentation method.[24,32] Another favorable property of BC is that it can be easily sterilized by autoclaving.

2.223.8. Cell Interactions and Migration

The high water content of BC makes the material a poor substrate for cell adhesion. The low irritation to the skin caused by BC, reported in the patents for wound-care products, is

probably due to some extent to the high water content, which might prevent adhesion to the healing skin and dressing.[33] Its less advantageous properties for cell adhesion have been addressed by Watanabe *et al.* when growing mammalian cells onto BC.[34] Adhesion was somewhat improved if the membranes were preincubated with proteins such as laminin, collagen, or fibronectin. The best results were obtained when the material was chemically modified and negative groups were introduced onto the surface. Watanabe *et al.* claim to have achieved an improvement of protein adsorption and thereby cell adhesion.[34] This is somewhat contradictory to common surface modifications, made to improve biocompatibility, where negatively charged groups are introduced precisely because they effectively decrease protein adsorption.[35] *In vivo* results of BC have, however, revealed good cell adhesion and migration into the material *in vitro*, using growth factors as an attractant.[24,25] Inducing porosity to the BC improves adhesion and migration of SMCs into the cellulose network.[36]

Other cell types have also been cultured on BC. Mendes *et al.* concluded that the material may prove useful as a scaffold for mesenchymal stem cells.[26] A cell proliferation evaluation has been conducted on BC nanofibers by Moreira *et al*. They used a proliferation assay to evaluate fibroblast and Chinese hamster ovary (CHO) cell proliferation on the nanofibers. A slight reduction in cell proliferation was revealed, although no modification in the cell morphology was observed.[27]

2.223.9. Biomedical Applications

Interest in BC as a biomaterial is not new; several products have been registered since the late 1980s (Biofill®, Gengiflex®). The use of microbial-derived cellulose in the medical industry has, however, been limited to liquid-loaded pads, wound dressings, and other external applications. There are several clinical studies by the BioFill company (BioFill Produtos Biotechnologicos, Curitiba, Pr Brazil) on BC in applications for regeneration of bone. In one case in which Gengiflex® was grafted with hydroxyapatite, a complete restoration of an osseous defect could be seen.[37] In 1996, Xylos negotiated exclusive licensing agreements with Johnson & Johnson to use their patents on cellulose-based wound-care products. Since that time, the company has been able to successfully obtain FDA approval for its product, XCell®.[38] XCell® is for external application (so far), Biofill® is partially dried BC, and Gengiflex® is partly modified BC.[15,33,39,40] However, BC has interesting properties in its wet, unmodified state. The versatility of BC allows it to be manufactured in various sizes and shapes depending on the product requirements. BC in different shapes has already been applied to treat several types of injuries. Sheets (or pellicles) of BC have been used as a barrier in the regeneration of periodontal tissue, to repair abdominal defects (peritoneum) and as a dura mater substitute.[37,41,42] Furthermore, chronic wounds and burns have been treated with BC sheets.[15,38] Attempts have been made toward regeneration of cartilage, bone graft material, and meniscus replacements.[4,17,20,37,40,42–47] Tubular-shaped BC has been suggested for use as a blood vessel replacement and for nerve surgery.[19,20] The utilization of BC vascular grafts has recently been reported.[48]

BC has also been used as a coating to reduce the coagulation effect on polyester vascular grafts and stents.[46,49]

There are several variables that influence the overall production process and performance of the final BC biomaterial, for example, choice of fermentation method, bacterial strain, media, and purification method. The commercialization of BC as a biomaterial will of course depend upon successful technical and economic solutions and market requirements.[43,50]

2.223.10. Future Outlook

This brief presentation of the unique properties of microbial cellulose probably raises the question of why microbial cellulose has not been used by industry. In fact, it has; however, certain hurdles have prevented its widespread use. These have included the need for better understanding of the biosynthetic process itself, optimizing the fermentation process, and enhancing cell proliferation and BC biosynthesis for more efficient, lower-cost production.[51]

In 1983 the Weyerhaeuser Co., in collaboration with Cetus, started process development, manufacturing, and marketing of microbial cellulose as a dough-like solid and a viscous liquid suspension called Cellulon®. The unique properties of BC mentioned earlier make it applicable in different fields, such as in the paper and textile industry as a binding and coating material and in the food industry to act as a thickener, stabilizer, texturizer, and/or calorie reducer. Despite the interesting properties of BC, Cellulon® never obtained commercial success, probably because cost reductions to make the product competitive with other biopolymers were never realized. The business was later sold to Kelco and has recently been purchased by Monsanto. Opportunities for expansion of microbial cellulose now exist; however, significant gains will be necessary in upgrading fermentation techniques.[43,51,52]

BC resembles human tissue in the sense that it is soft and is composed of highly hydrated nanofibrils with high mechanical strength. The material is versatile and can be manufactured in various sizes and shapes, depending on the product requirements. This makes it interesting to explore BC for use in several biomedical applications. Beyond controlling the size and shape of the BC, the microscopic morphology and even chemistry of the network can be altered in many ways.

A deeper understanding of network formation and various possibilities to control the direction of the extruded nanocellulose is important if we wish to tailor-make advanced 3D biomedical materials. Moreover, it is essential to screen the different strains of *A. xylinum*, to measure the specific dimensions of the nanocellulose fibers produced by each, and then to correlate this with the mechanical properties and porosities of the networks formed.

It is also important to elucidate the mechanism of the observed high biocompatibility of BC. How is the water bound in the network? How are fluids adsorbed and transported in the material? Also, knowledge of the durability and possible degradation of BC *in vivo* will be important for long-term implants. Can *in vivo* BC degradation rates be controlled? To conclude, there are several things to be learned about BC as

an implant, and collaboration between various disciplines will be necessary for successful implementation of BC as a medical material in the clinical setting.

Glossary

AFM Atomic force microscopy, one of several surface scanning probe tools used to image and assess the outer atomic levels of a surface with a cantilever.

Contamination Unwanted species adsorbed onto the surface of materials, originating from air (e.g., ubiquitous siliceous, hydrocarbon, and volatile surface-reactive species) or from the sample environment (aqueous adsorbates), or from the analytical methodology (vacuum oils, salts, fingerprints).

Evanescent field A surface-bound electromagnetic field decaying exponentially orthogonal to a surface and external to a medium, created from total internal reflection of coherent energy within that same medium.

Inelastic mean free path The average distance that an emitted photoelectron moves before experiencing inelastic collisions with another electron or nucleus of a material's constituent atoms, dissipating its energy within the material.

Sampling depth The surface penetration depth of analytical reporting for a specific surface analysis method.

SIMS Secondary ion mass spectrometry, a family of related methods that analyzes under UHV conditions secondary ion fragments sputtered from the surface of a sample by an incident primary ion beam.

SPM Scanning probe microscopy, the general family of scanning probe methods comprising many diverse modes of monitoring interactions of a cantilever tip with the outermost atoms on a surface.

SPR Surface plasmon resonance, one of several optical methods used to measure kinetics and amounts of adsorbing or desorbing species to a surface using surface-localized perturbations and attenuations in evanescent electromagnetic energy.

Surface zone The portion of a medium's surface region that is sampled by the chosen analytical method. This zone is highly variable, depending on the technique used, from outermost atomic levels (e.g., AFM) to a few atomic layers (static SIMS) to thousands of atomic layers (FTIR).

UHV Ultrahigh vacuum conditions used for surface analysis in which nearly all atmospheric components (gases, water vapor) are removed by pumping, leaving the sample to be analyzed in a desiccated state at or below 10^{-9} Torr.

XPS X-ray photoelectron spectroscopy, a UHV-based surface analytical method using incident X-ray interrogation of a surface to produce surface-emitted photoelectrons that are characteristic of surface elemental composition and chemical bonding species.

Abbreviations

AES	Auger electron spectroscopy
AFM	Atomic force microscopy
ATR-FTIR	Attenuated total reflection Fourier transform infrared spectroscopy
BAW	Bulk acoustic wave
BE	Binding energy
D	Dissipation factor
EELS	Electron energy loss spectroscopy
ESCA	Electron spectroscopy for chemical analysis
FPW	Flexural plate wave
FTIR	Fourier transform infrared spectroscopy
KE	Kinetic energy
LFM	Lateral force microscopy
NEXAFS	Near edge X-ray absorption fine structure
OWLS	Optical waveguide lightmode spectroscopy
QCM	Quartz crystal microbalance
QCM-D	Quartz crystal microbalance with dissipation monitoring
QSR	Quality system regulations
RMS	Root-mean squared
SAM	Scanning Auger microscopy
SAW	Surface acoustic wave
SECM	Scanning electrochemical microscopy
SEM	Scanning electron microscopy
SIMS	Secondary ion mass spectrometry
SH-APM	Shear-horizontal acoustic plate mode
SH-SAW	Shear-horizontal surface acoustic wave
SPR	Surface plasmon resonance
SSBW	Surface-skimming bulk wave
STM	Scanning tunneling microscopy
STW	Surface transverse wave
TIR	Total internal reflection
ToF-SIMS	Time-of-flight secondary ion mass spectrometry
TSM	Thickness shear mode
UHV	Ultra-high vacuum
XPS	X-ray photoelectron spectroscopy

3.301.1. Introduction

Widespread recognition that the surface of a biomaterial, employed either in a medical device or in an assay, is a critical determinant of the biological response to the material has led to the use of an array of surface analytical methods aimed at biomaterials surface characterization. In addition, surface characterization can be an important component of the fabrication protocol, design process, and performance evaluation of materials and devices used in any industry that involves macromolecular or cellular contact with synthetic materials. Elucidation of specific surface properties of a material is important for a number of reasons. First, materials surfaces interact with macromolecules (e.g., proteins, lipids, oligosaccharides) and cells in ways that influence subsequent biological responses (see **Chapter 4.403, The Innate Response to Biomaterials**; **Chapter 4.404, Adaptive Immune Responses to Biomaterials**; **Chapter 4.405, Leukocyte–Biomaterial Interaction *In Vitro***; **Chapter 4.406, Protein Interactions with Biomaterials**; and **Chapter 4.407, Bacterial Adhesion and Biomaterial Surfaces**). Second, because of interfacial thermodynamics, surface chemistry is distinct from that of the bulk material. Surfaces have intrinsic energy associated with the discontinuity of the interface, its asymmetry, and associated chemical properties from this unique environment. Surfaces actively minimize their free energy through continual processes of adsorption, restructuring, and chemical reactions, leading to a dynamic surface evolution through diverse physical and chemical responses. Surfaces are a challenge to understand fully because they change continuously with their environment and are readily contaminated: defining both kinetics and equilibrium in surface states is intrinsically problematic. Finally, the issue of analytical sensitivity is important: surfaces comprise a small fraction of a given material, limiting the amount of material interrogated by any surface analytical method. If a 'typical' single crystal surface density is 10^{15} atoms cm^{-2} ($\sim$0.2 nmol cm^{-2}), then surface analytical methods must be able to resolve this relatively minute amount of material in this specific zone from signals emanating from the bulk material. Performance requires both chemical selectivity and sensitivity – two common analytical figures of merit – to distinguish sufficient signals from a background and, importantly, in a specific, desired surface sampling depth.

This chapter presents a concise introduction to numerous common approaches to the comprehensive analysis of a biomaterial's surface. It is beyond the scope of this chapter to provide specific details of the various methods used in biointerface and surface analysis: entire books, monologues, and reviews are available to guide one further.[1–11] A wide range of surface-sensitive techniques are available to study the performance of materials and to aid in solving problems associated with devices fabricated from these materials in a biomedical context. For example, polymeric, ceramic, and metallic components of devices can be characterized both in terms of their surface chemistry and elemental composition with X-ray photoelectron spectroscopy (XPS or ESCA), Auger electron spectroscopy (AES), static and dynamic secondary ion mass spectrometry (SIMS), and attenuated total reflection Fourier transform infrared spectroscopy (ATR-FTIR). Rapidly evolving, diverse probe microscopy techniques such as scanning probe methods (i.e., atomic force microscopy, AFM) in various forms are used to characterize the outermost three-dimensional (3D) topography of a surface and much more that is associated with the atomic features of surfaces. Optical methods such as ellipsometry, optical interferometry and evanescent field methods, and surface plasmon spectroscopy and imaging methods[12–14] provide accurate information regarding the thickness of overlayers, adsorbed layers, or coatings on optically compatible or reflective materials such as metals and metal oxides. **Figure 1** shows a flowchart outlining the various surface analytical methods currently available to the biomaterials researcher. While all the techniques are not commonly

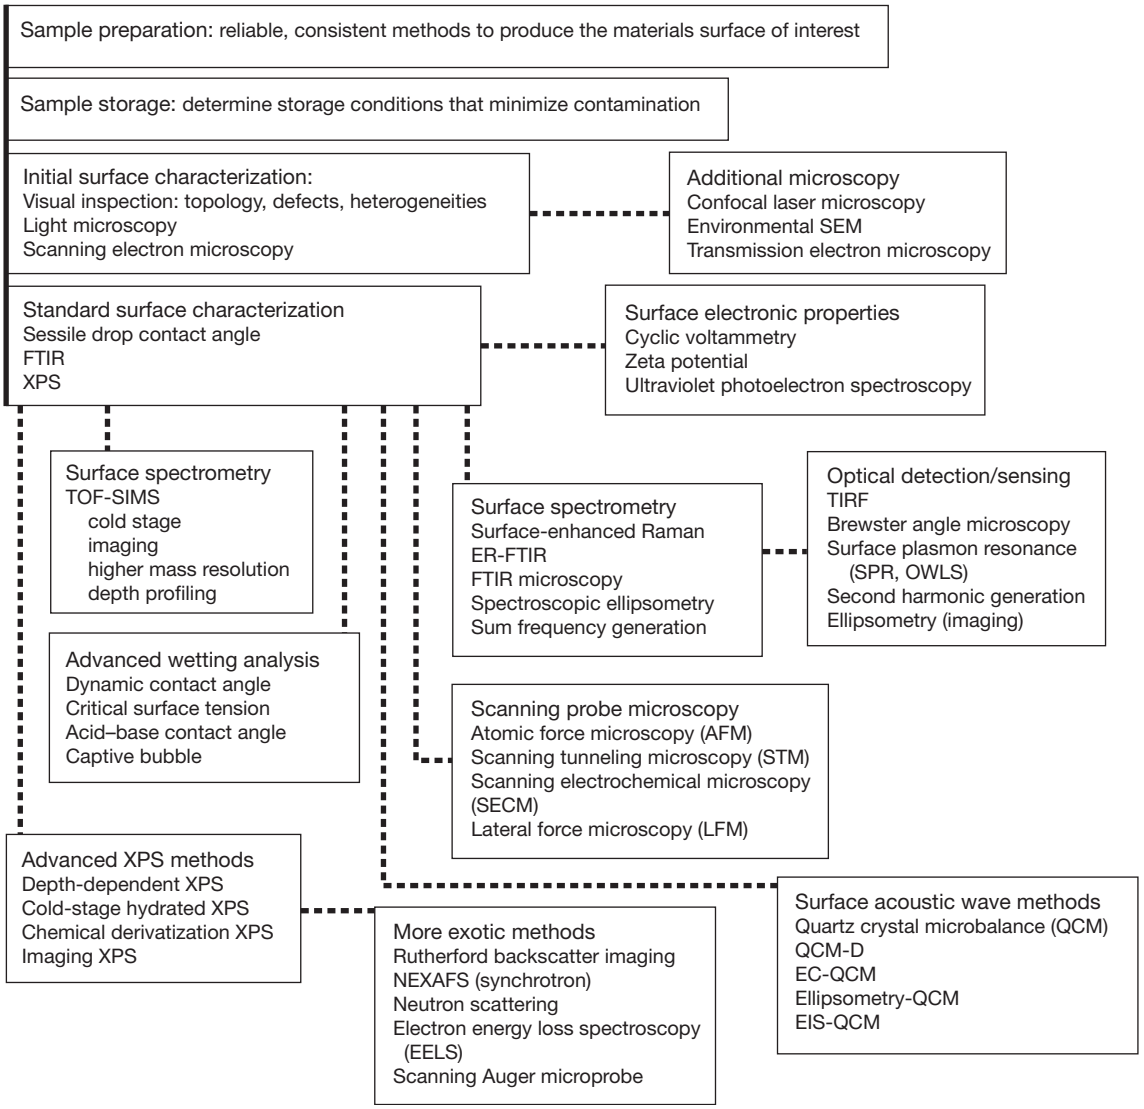

Figure 1 Methods flowchart for navigating various surface analytical approaches and instruments available for characterizing biomaterials. Adapted from Grainger, D. W.; Healy, K. In *Handbook of Biomaterials Evaluation*, 2nd ed.; von Recum, A. F., ed., MacMillan: New York, 1998; pp 115–141.

available at a single location, specialized surface analytical centers exist at industrial sites, many academic institutions, government research institutes (e.g., National Physical Laboratory, UK; NIST, ALS, PNNL, Sandia and Brookhaven, USA; CSIRO, Australia), and for-profit commercial analytical companies (e.g., Charles Evans, USA) that collectively utilize many of the methods detailed in Figure 1. The flowchart begins with relatively common and inexpensive surface analytical methods and moves to more exotic, specialized, and expensive techniques that are not often readily available. To understand the method of selection of certain techniques and the order of progression from one technique to the next requires an appreciation of the surface physical chemistry of the material, knowledge of a specific question that could be addressed by surface analysis, and some idea of the level of resolution required for the surface examination. For example, characterization of surface modifications to improve device performance, and identification of either contaminants or adsorbates requires the use of surface analytical equipment capable of detecting changes in surface chemistry and elemental composition at the outer nanometer level (i.e., 10 Å), while a general, comparative approximation between materials might require only a few inexpensive routine analyses of lower surface resolution and information content. It is critical to realize that because a surface is dynamic and many methods provide only partial information content at differing sampling depths with different resolutions, sensitivities, and selectivities, if one uses only one technique, one obtains only partial, incomplete information about the surface. A full understanding of the surface requires careful comparison and coordination of many complementary techniques that provide different information about the same sample.

3.301.1.1. Needs Assessment for Surface Analysis

A preliminary analytical approach is useful for all potential biomaterials surface characterization. A significant amount

of effort (and money) can be spared by making a few careful choices at the beginning of any analysis. The decision of when to employ these techniques depends on the type of information desired and the depth of the material surface from which the information should be collected. As it is rare for a single technique to provide sufficient information for complete surface characterization of a material, knowledge of how data from multiple techniques can be combined to generate a complete picture of the surface chemistry and structure is important.

3.301.1.2. Defining the Surface of Interest

Table 1 shows that each surface analytical method probes the 'surface zone' differently. This is shown schematically in Figure 2. Specifically, the depth of analytical interrogation (i.e., the sampling depth) and the type of analytical information returned must be considered when selecting methods. The surface-sensitive region for an ATR-FTIR experiment (up to ~2300 Å) is obviously not the surface zone analyzed by the atomic force microscope (top 10 Å) or a static SIMS experiment (top 10 Å). In addition, the type of information returned by each analysis is distinctly different. Regardless of surface depth resolution, the type of information required may dictate the sampling requirements (e.g., spectroscopic vs. surface energy vs. topology). Hence, one must decide the appropriate information to be gained from the surface analysis, and the method to obtain it. Appropriate questions to ask in this regard include

- How deep is the relevant surface of my biomaterial of interest?
- What methods probe this surface zone?
- What type of surface information is required? (e.g., compositional, energetic, dynamic, topological)
- What analytical environment is appropriate? (e.g., vacuum, ambient, or aqueous conditions)

In addition, quasistable surfaces (typically polymers) can exhibit lateral structural and chemical heterogeneities, as well as depth compositional gradients, confounded by the structural dynamics of intrinsic surface reorganization of these surface components either laterally or within the material's bulk. In these cases, methods that probe specifically at different zone depths or with different lateral spatial resolution would be better suited to the interrogation of these surface properties, which might not be accurately assessed by a general method. Protocols for the analysis of a specific surface may be developed by formulating specific objectives for performing surface characterization and by matching goals with techniques, cost, and access. Relevant goals for a typical surface analysis are provided in Table 2.

3.301.1.3. Sample Preparation and Handling for Surface Analysis

In vitro and *in vivo* biomedical devices are designed and tested to ensure reliability, consistency, and predictable performance. Quality control of surface composition and structure for all components in a biomedical device should be built into the quality analysis routine under a Quality System Regulations (QSR) mandate. Surface analysis should be performed on

Table 1 Surface analytical techniques commonly used for biomaterials characterization

Technique	*Physical principle*	*Measured quantity*	*Depth of analysis*	*Analytical sensitivity*
XPS (ESCA)	Photoelectron effect: incident X-rays induce photoelectron emission	Kinetic energy (eV) (or electron binding energy) of emitted photoelectrons	10–100 Å	0.1 at.%
AES	Incident electrons or X-rays cause emission of Auger electrons	Kinetic energy of Auger electrons (eV)	5–50 Å	0.1 at.%
SIMS	Incident primary ions emit secondary ions of different mass	Mass:charge (m/z) ratio of emitted ions	10 Å–1 μm	ppm
ATR-FTIR	Incident IR radiation is absorbed by surface molecules producing vibrations of interatomic bonds	Optical energy absorbance as function of wave number (or energy) characteristic of specific molecular vibrations	1–5 μm	1 mol%
AFM	Surface topography-induced deflection of a proximal cantilever is detected by reflected laser light and a photodiode	Quantitative three-dimensional images and surface physical properties in contact or noncontact modes of many types	Depth or lateral resolution: 1 Å	Atoms and molecules
SPR/OWLS	Backside incident laser radiation produces evanescent field at metal surface	Changes in maximum light reflectivity, intensity, or angle of reflected light associated with surface binding events; used to detect amounts or image adsorbates	Exponentially decaying optical field extending a few hundred nm away from metal surface	0.5–1 ng cm^{-2} adsorbate sensitivity
Ellipsometry	Detects changes in reflected coherent polarized laser light at an interface	Measures Δ and ψ that are then used to calculate film thickness and refractive index, and can be used to image surfaces	nm to μm	0.2 nm film thickness differentiation
QCM-D	Applied transverse propagating acoustic wave sensitive to adsorbing surface species and resulting viscoelastic properties of adlayer	Resonant frequency shift and impedance ratio (dissipation factor, D), proportional to mass loading	Few hundred nanometers	~ng cm^{-2} adsorbate sensitivity

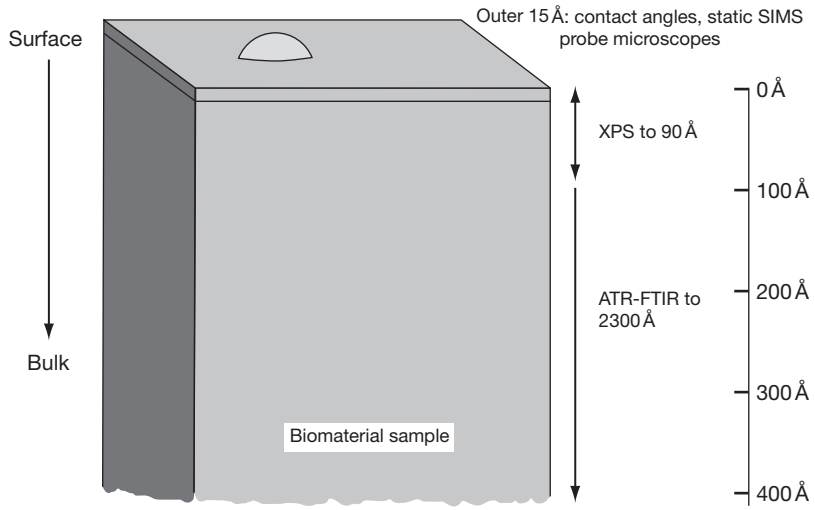

Figure 2 Schematic of an ideal biomaterial cross-section showing different surface analytical zones sampled by different analytical techniques. The surface analysis technique essentially defines the 'surface of interest' by the depth of its information retrieval and analytical reporting figures of merit. Adapted from Grainger, D. W.; Healy, K. In *Handbook of Biomaterials Evaluation*, 2nd ed.; von Recum, A. F., ed., MacMillan: New York, 1998; pp 115–141.

Table 2 Relevant goals for biomaterial surface characterization strategies

- Development of surface quality control criteria to monitor surface contamination and provide a means to establish the true identity of a biomaterial surface in context
- Monitoring surface-active leachables contained within a sample bulk that collect on biomaterial surfaces. Examples: plasticizers, polymer fillers, oligomeric or unreacted chemical species, catalysts, extrusion aids, mold-release agents, polishing compounds, and surfactant processing agents
- Assess the impact of sterilization protocols on surface chemistry and shelf-life
- Evaluate surface oxidation, degradation, corrosions, or chemical reactions over time in given environments
- Compare the effects of different biomaterial fabrication methods on surface properties. Molding and casting surfaces of different chemistries (e.g., metal, glass-ceramic, glass, ambient air) are well known to produce distinctly different surface properties in a given polymer film, metallic, or ceramic sample
- Correlate surface chemistry with biological responses, including activation of clotting factors, protein deposition, inactivation of immobilized enzymes and antibodies, cell and bacterial growth and phenotypes, macrophages activation, and fibrosis

samples in a state as close as possible to the state in which they exist in the actual device, subject to final packaging, and to the environment in which they are intended to be used. Once samples have been chosen, care should be taken to preserve the sample surface in its 'original' state. As most biomaterials are fabricated and manipulated under controlled but atmospheric conditions, certain levels of ubiquitous air- and water-borne contamination (hydrocarbons, water vapor, ambient siliceous species) should be expected – even clean rooms and hoods do *not eliminate* these adsorbates. If rigorous sample preparation and handling protocols are consistently followed, then ambient contamination should remain at relatively low and consistent levels. Common inadvertent, avoidable contaminants include human fingerprints (deposits of hydrocarbons and salts, typically sodium chloride), packaging or sealing materials (adhesive tape, parafilm, paper, or plastic wraps), and poor quality/contaminated solvents used for surface rinsing/cleaning. For example, many envelopes and copy papers have surface finishes (metal salts, clays) that abrade away and deposit onto a sample surface when they are placed in contact with the sample surface. Plastic bags frequently contain highly surface-active silicone oils and plasticizers (e.g., dioctyl phthalate is often detectable in any lab environment) that are readily transferred to a biomaterials surface. Therefore, sample storage or shipping protocols could substantially contaminate the surfaces being prepared and shipped for analysis.

An important 'first-step,' therefore, is to determine the cleanliness and reliability of all sample preparation, and handling and storage procedures/materials. The potential for contamination transfer to the biomaterials surface must be ascertained, typically by a time-dependent study of sample surface changes during storage and/or shipment. Commonly used clean storage containers include Fluoroware® twist-top single silicon wafer boats, acid-etched glass (borosilicate) dishes, cell-culture plastic ware (polystyrene), and zip-lock-type electron microscopy polyethylene bags. However, quality control and suppliers for these items are not guaranteed and checks should be run periodically to analyze for any variability in the surface composition of these materials. In addition, samples rinsed with alcohols or distilled water from common plastic laboratory squirt-bottles will often be contaminated by surface-active leachables introduced during the manufacturing of the squirt-bottles and thus these leachables will also be present in the rinsing media.

3.301.1.4. Sample Analysis Strategy

A common rule for best analytical results is that all conclusions regarding materials surface properties should be drawn from as many different analytical methods as financially and technically feasible. Therefore, conclusions drawn from any single surface data set are sure to be incomplete and possibly misleading. Several principles govern the selection of a surface analytical protocol. First, various biological environments intended for biomaterial applications are extremely heterogeneous and complex. Many surface analysis methods do not operate in conditions even close to biological complexity, or even simple hydration (e.g., ultrahigh vacuum (UHV) techniques including AES, XPS, and SIMS). Nevertheless, surface information provided by UHV techniques is often extremely valuable and useful, and can be correlated to biological performance even though the data are not collected under biological (i.e., aqueous) conditions.

The second guiding principle is that surface analysis data from many characterization techniques provide a logical, coherent, and integrated picture of the biomaterials surface. Contradictory data between several methods should be suspect and reconciled to avoid misleading or erroneous conclusions. An integrated approach allows a system of checks. Poorly reproducible data should be carefully scrutinized and checked by at least two alternative methods.

A third guiding principle is that all fabricated biomaterials surfaces are impure and imperfect. No chemical derivatization technique is perfect, no surface is without defects and heterogeneities at some scale, and all surfaces are contaminated to some degree. To date, no synthetic and fabrication expertise used in biomaterials development has resulted in ideal interfacial performance in any biomedical context. So, the more relevant, practical questions for surface analysis should focus on finding and relating the effects of ubiquitous, controlled levels of surface contamination and possible different defects present on all biomaterials to their observed biological reactions. Biological fluids, tissues, and cells respond to surface microenvironments (defects and heterogeneities). Identifying the types of surface properties, the chemistry, and structures, and how these influence biomedical device performance and consistency in a given application over time should be the goal.

A fourth important principle is that surface analytical methods have the potential to change a surface during the process of interrogation. That is, surface analytical techniques can damage or alter the surfaces being analyzed. Common examples are the sorption of probe liquid drops from wetting analysis into the material surface, loss of fluorine from fluorinated polymer samples exposed to nonmonochromatized X-rays under XPS analysis, and electron beam-induced reduction of metal oxides during AES analyses. Even state-of-the-art XPS X-ray sources can remove fluorine from certain polymers in some environments and induce oxidation of sulfur-containing compounds. Again, careful controls must assess the potential for generating misleading data from fragile/labile surfaces.

3.301.1.5. Surface Analysis Methods

The following sections survey some of the recommended methods and approaches to permit a thorough assessment of surface properties and compositions, and judgment of suitable criteria for either acceptance or rejection for a particular use. As every device or materials performance is context dependent, specific biomaterials surface properties that might promote or prevent certain biological responses are not described – only methods for surface analysis. Indeed, such understandings of surface design for specific biological performance remain premature and speculative, or at least empirical. General design rules for controlling surface-biological behaviors are often scientifically unfounded and their implications are dangerous to extrapolate. Nonetheless, early bio-surface adsorption events occurring spontaneously and rapidly upon exposure of a biomaterial to biological fluids determine subsequent biological responses, sometimes reflecting the relative 'biocompatibility' of this specific scenario (see **Chapter 4.401, The Concept of Biocompatibility** and **Chapter 4.402, Biocompatibility and the Relationship to Standards: Meaning and Scope of Biomaterials Testing**). These early interfacial events (occurring as fast as diffusional limitations dictate approximately microseconds) include adsorption of small solutes, salts, and organic molecules, then small proteins, and ultimately large proteins and cells to a biomaterial's surface (see **Chapter 4.406, Protein Interactions with Biomaterials** and **Chapter 3.311, Molecular Simulation Methods to Investigate Protein Adsorption Behavior at the Atomic Level**). Certainly, material surface parameters including surface composition, display of polar and apolar chemistries (surface energy), surface formal charge, hydrogen bonding, and topology are relevant to these critical events as reported by many past surface analysis studies.[1,2,4,5,8–11]

3.301.2. Ambient Analytical Methods

3.301.2.1. Contact Angle and Surface Energy Measurements

While many surface analytical methods require sophisticated equipment and expert operators, information on the outer few atomic layers of a material surface can be obtained with a relatively simple, inexpensive method called contact angle analysis. The three-phase intersection between a pure probe liquid of known surface tension, the biomaterial surface of interest, and ambient air (or gas bubbles) defines an angle in equilibrium: the contact angle. If the three-phase line is in motion, then the hysteresis between the reversible advancing and retreating angles of the line provides data on surface roughness, heterogeneity, and surface chemical mobility. Once defined, this angle can be related to solid materials interfacial free energies. Surface energy, in turn, is a reflection of the surface chemical and physical constitution – functional groups, polar or apolar species, and even acidic or basic chemistry, or topological features – in the material's outer 2–10 Å. Because hydrophilicity and hydrophobicity remain two important surface classifications correlating biological interfacial behavior, wetting analyses even in their crudest approximations are valuable surface interrogation methods. Interpretation of contact angle data depends on the suitability of certain assumptions regarding the three-phase scenario: misleading data will be obtained from misuse or ignorance of these assumptions.

Wetting analysis is perhaps the most used and also the most misused surface analytical method. Classic sources of information on wetting, capillarity, and surface tension are

recommended reading to understand the dynamics and thermodynamics of the three-phase line.[1,7,11,15,16] Because the three-phase line is sensitive generally to the outer atomic layers, this simple analysis, if done correctly, can provide surface energy information. Such contact angle analysis is also known as 'wetting analysis' due to the convention of using liquids to probe solid surfaces in air. In combination with other surface techniques mentioned in this chapter, contact angles provide a readily accessible, valuable first-line-of-analysis proven to be useful in virtually all areas of surface chemistry and engineering. As simple as this method appears, it is one of only few *in situ* techniques to characterize the aqueous–biomaterial interface.

The basis for contact angle or wetting analysis lies most often in the interaction of a liquid with a solid surface in the presence of a vapor. A liquid drop placed on a solid surface (a sessile drop) often will not wet the surface (i.e., spread spontaneously) but, instead, will remain as a drop having a definite angle of contact on the surface. The idealized interface is one between an ideal nondeformable smooth, clean solid, an infinitely deformable pure liquid, and a pure vapor. For this ideal scenario, the classic energy balance for the sessile drop in equilibrium on the surface is provided by Young's equation:

$$\gamma_{SV} = \gamma_{LV} \cos\theta + \gamma_{SL} \quad [1]$$

where θ is the three-phase contact angle, and the various interfacial free energies are given by γ_{SV} for the solid–vapor, γ_{SL} for the solid–liquid, and γ_{LV} for the liquid–vapor.

Contact angles can be interpreted in terms of Young's equation directly if the following assumptions are valid[1]:

- The solid surface is rigid and nondeformable (surface modulus of elasticity should exceed 3.5×10^5 dynes cm^{-2}). Gels and soft materials (e.g., biomembranes, surfactants, soft elastomers) often do *not* satisfy this assumption.
- The solid surface is immobile and cannot reorient in response to the liquid probe. Many polymer surfaces cannot fulfill this assumption.
- The solid surface is smooth (~0.1 μm root mean squared (RMS) surface roughness regime): optically or visibly featureless is generally acceptable. Most solid surfaces do not satisfy this assumption.
- The solid surface is homogeneous and uniform, lacking heterogeneous surface domains, patches, leachables, or contaminants. Unclean surfaces (i.e., all real surfaces and those tested ambiently) most frequently violate this assumption.
- The liquid phase surface tension is known and remains constant. Importantly, transfer of surface contamination and leachables to the liquid surface from either the solid or vapor phases will change the liquid surface tension. Temperature variations affect surface tension.
- The solid and liquid phases do not interact beyond the three-phase equilibrium (i.e., no surface swelling by the liquid, no extraction of the solid). Surface swelling violates this assumption.
- The spreading pressure for the liquid on the solid is zero, meaning that the liquid vapor does not adsorb onto the solid surface and change the solid surface free energy.

Contact angle hysteresis, inaccurate wetting, and invalid surface energy determinations result from scenarios where these assumptions are unfulfilled. Importantly, because most assumptions for ideal contact angle measurements are violated by actual measurement conditions, all contact angles measured must consider in their reporting and analysis the impact of these nonideal issues. True (reproducible, reversibly invariant) contact angle hysteresis in dynamic, mobile assays (i.e., Wilhelmy plate hysteresis-style) can be a useful diagnostic tool, but must be distinguished from hysteresis related to sample nonadherence to the assumptions listed above.

Several different methods have been developed for contact angle measurements[1,7,15]:

- Direct, microscopic measurements of the three-phase line for liquid drops in air, or vapor bubbles in bulk liquids, against solid surfaces.
- Dimensional determinations for drops on surfaces, allowing contact angle determination from well-known trigonometric relationships.
- Capillary rise of a liquid with a known surface tension within a small tube or capillary coated with the material of interest.
- DuNouy ring methods.
- Wilhelmy plate methods.

Many of these techniques are commercially available as turn-key, automated instruments. The Wilhelmy plate method can be adapted to nonplanar geometries, including cylindrical shapes relevant to catheters and tubing, fibers, and discs.[1,17]

Important differences between so-called static and dynamic contact angle measurements should be considered. If the solid–liquid interface is in motion, the measurement is dynamic and may not be at equilibrium. Wilhelmy plate hysteresis determinations are generally dynamic, although slow three-phase interfacial velocities can approximate static measurements. Immersion of the solid surface into the probe liquid produces an *advancing* contact angle, θ_A while emersion of the solid from the liquid produces a *receding* contact angle, θ_R. The difference between advancing and receding angles, $\Delta\theta$, is termed the contact angle hysteresis. A solid–liquid pair fulfilling all the assumptions listed above should exhibit only one contact angle and, therefore, no hysteresis. However, because most real systems cannot fulfill these assumptions, hysteresis is commonly observed and this information can be exploited. A critical assessment must always be directed at the source of hysteresis as two general types of hysteresis have been identified:

1. Thermodynamically stable hysteresis reproducible over many emersion–immersion cycles.
2. Kinetic hysteresis that changes with sample placement, time, and cycling frequency.

Interpretations of hysteresis must consider violations of the above-mentioned assumptions, including effects of surface heterogeneity (adsorbed contamination, domains), reactivity (i.e., polar, apolar interactions between probe liquid and surface), metastable surface structures and chemistries (reorganization, reorientation), surface roughness (texture, particle adhesion, pinholes, pitting), solid surface swelling and liquid penetration, adsorption of contaminants onto the liquid interface, and surface deformation (mobility). Only careful assessment of these interfacial factors in tandem with surface-sensitive knowledge from other analytical methods makes contact angle analysis a valuable surface characterization tool.

A popular extension of contact angle analysis is the determination of solid surface critical surface tension, γ_c, as originally described by Zisman's group.[18] This approach leads to an empirical determination of a solid surface energy related to the extrapolated solid surface free energy. Experimentally, a series of pure probe liquids of varying surface tension are applied as drops to the sample solid surface. Contact angles are assessed for sessile drops for test liquids that span a highly nonwetting (contact angle $\theta > 90°$, $\cos\theta \sim 0°$) to a highly wetting (contact angle $\theta \sim 0°$, $\cos\theta \sim 1.0$ for complete wetting) regime. When these data are plotted against the known liquid surface tensions, the critical surface tension is defined by the x-intercept at $\cos\theta = 1$ (complete wetting) from the liquid series. The method has proven useful for empirical correlations of solid surface energies with interfacial performance in various applications, including interesting relationships between materials bulk elastic modulus and γ_c. Values of γ_c for various polymers are tabulated in the *Polymer Handbook*.[19]

3.301.2.2. Ambient Surface Spectroscopy and Optical Waveguide Methods

Nondestructive, real-time label-free surface detection methods are attractive for monitoring interfacial reactions and adsorption events, mapping surface spatial reactivity and chemical patterning, and monitoring film thickness, even in aqueous and biological milieu. Figures 3 and 4 show several optical spectroscopic configurations. Several optical waveguide methods have shown nanomolar concentration (pg mm^{-2} mass) sensitivity for detecting adsorbates including proteins and cells, as well as applicability to a wide variety of biomaterials.[12–14] Label-free optical sensing is preferred, given the benefits of not introducing an extrinsic label to the adsorbate to detect it. However, optical compatibility between the analytical optical energy coupling and the material is required for detection, and intrinsic optically active signals from many molecules of interest are not strong, limiting utility in some cases. Regardless, these waveguide and evanescent methods are increasing in popularity and versatility, and have been commercialized in many different forms.

Most such analytical spectroscopy systems exploit evanescent electromagnetic fields directly external to a tailored waveguide to sense interactions with the waveguide surface (and often associated thin film). Optical sensing energy must be coupled into the waveguide, transmitted internally within the waveguide, and propagated such that internal reflection rules are satisfied to establish and maintain evanescent external fields.[20] In many cases, this must be accomplished within the biomedical test system of interest, that is, in the presence of a biomaterial coating on the waveguide and within a liquid flow cell or static aqueous milieu containing complex biological species in contact with the biomaterial-coated waveguide. The energy intensity and depth of sensitivity of the surface-bound evanescent field emanating from the waveguide into the external milieu depend upon many factors, including the input optical energy, the refractive indices of the waveguide and external media, and the refractive index of the adsorbing species.[14] In addition, the evanescent field intensity decays exponentially with distance from the waveguide surface, with

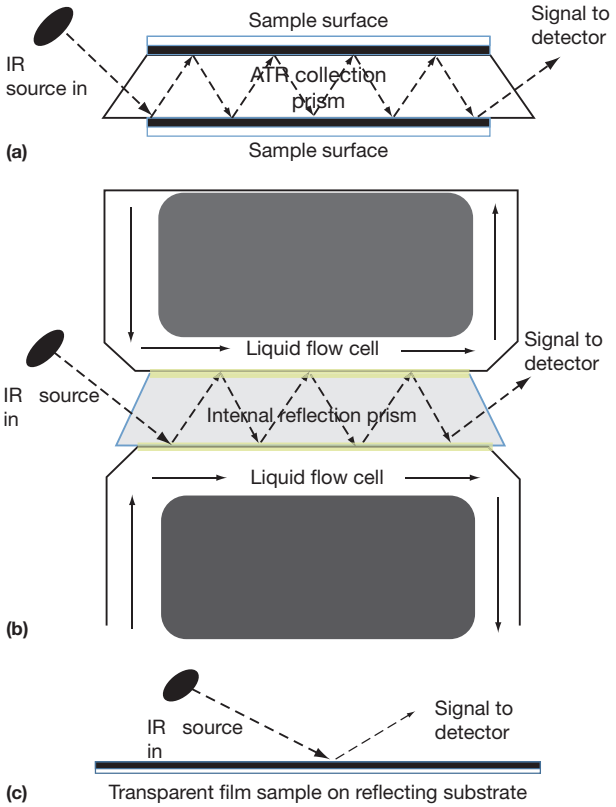

Figure 3 Modes of surface-sensitive measurement for infrared spectroscopic interrogation of biomaterials surfaces: (a) an attenuated total reflection (ATR) prism sandwiched by sample surfaces pressed against each prism surface, (b) ATR in a liquid flow cell with internal immersed collection prism, (c) grazing IR incidence external reflection off a surface in single-reflection mode.

a decay length of approximately $\lambda/2\pi$, where λ is the wavelength of the in-coupled optical energy. For an optical excitation wavelength of $\lambda = 500–800$ nm, which is characteristic of many common laser inputs, the evanescent field extends ~100–150 nm into the external milieu above the waveguide surface. This short evanescent field sensing distance provides the innate advantage that the waveguide-bound sensing field interacts with adsorbing material only in direct proximity to the waveguide surface, largely uninfluenced by species suspended in bulk solution. This improves the signal:noise ratio for adsorbate detection. This also presents the limitation that modifications to the waveguide surface (i.e., use of biomedical coatings or deposits) must be very thin and uniform on the waveguide for the evanescent field to penetrate with sufficient energy to produce a surface signal at the surface of the coating. The farther from the waveguide surface the target detection is desired, the (exponentially) weaker the bound evanescent signal is due to decay. Different designs for optical biosensors manipulate evanescent field properties to extend either well beyond or confined tightly to the waveguide surface. Improved detection sensitivity can be achieved by matching locations of largest biochemical binding to those waveguide zones of highest evanescent field intensity.[21]

(a) Surface plasmon resonance (SPR) backside illumination of a plasmon-active metal substrate, creating a front-side evanescent field capable of detecting surface-adsorbing species, (b) schematic description of SPR optical signal intensity as a kinetic function of the surface-adsorbate experiment, and (c) several common optical waveguide configurations for interfacial sensing using surface-localized evanescent field interactions and total internal reflection optical conditions.

3.301.2.3. Surface-Sensitive Infrared Spectroscopy

Infrared (IR) absorption spectroscopy is a classical bulk characterization method providing chemical information about the molecular structure of a material based on identifying characteristic vibrational bands of bonded units. IR interrogation of surfaces has been greatly enhanced by applying Fourier methods to enhance signal:noise ratios and resolution for generally weak IR vibrational signals associated with biomedically relevant species. Nevertheless, in many cases, FTIR of surfaces remains signal-limited, and certainly not very specific, as many characteristic IR absorption bands are shared among many species of interest. In addition, when a sufficient surface signal is obtained, the problem of distinguishing and resolving the specific surface analytical zone from bulk-derived IR signals is difficult due to the large IR sampling depth (up to a micron). Many actual FTIR 'surface analytical' configurations return information from thousands of molecular layers beneath the actual interface unless they are configured to remove this bulk signal.

Several different FTIR surface-sensitive modes of analysis have been developed for obtaining representative surface IR spectra.[22–25] Different commercially available sampling

'rigs' allow convenient access to spectroscopic analysis of material surfaces, adsorbate reactions, and kinetic events in aqueous media (Figure 3). Transparent films coated onto reflecting metal mirrors are successfully analyzed by grazing incidence external reflection geometries (Figure 3(c)), with acceptable signal:noise ratios even for monolayers of material.[26–28] Films can be dip-coated or cast onto metal substrates (e.g., gold mirrors) to produce these samples. Nonreflecting surfaces and powders can be analyzed in the diffuse reflectance mode.[24] Attenuated total reflection (ATR-FTIR) methods (Figure 3(a)–3(c)) have often been applied to biomaterials surfaces because hydrated and flow-cell samples in simplified aqueous solution can be analyzed using commercial components in an IR-active evanescent sensing mode extending several microns into the external medium. An IR-transparent prism (typically germanium, ZnSe, or silicon, Figure 3(a)) is used as a waveguide to propagate the analytical IR signal through the FTIR prism. IR internal reflection generates a localized evanescent electromagnetic field outside the prism. External samples or media placed adjacent to the prism surface are sampled by this evanescent field, producing IR absorption/IR spectra for all IR-active species within the evanescent field (Figure 3(a) and 3(b)). Acceptable signal:noise ratios often require high adsorbate surface coverages and intimate physical compression (close contact) of the sample against the prism surface, a problem for rough or rigid irregular samples or parts. An ATR-FTIR circle cell (flow cell, Figure 3(b)) has been used in the ATR mode to study protein interactions in real time with thin biomaterial films coated onto prisms.[29–31]

3.301.2.4. Ellipsometry

Ellipsometry in its diverse surface measurement formats represents a valuable optical technique for determining the thickness and surface density of overlayers on reflective materials (e.g., SiO_2, titanium, gold, aluminum, platinum, etc.). Organic films and polymers can also be studied with ellipsometry as model biomaterials if they are presented as a thin film on an optically reflective surface. The strength of ellipsometry lies in the technique's ability to report thickness and optical properties of either metal oxides, grafted organic molecules, or adsorbed proteins with good accuracy in a nondestructive manner.[32] Spectroscopic ellipsometry has found widespread use in the materials science community to determine the optical properties of unknown films, overlayers and materials, assess dissolution and swelling of thin polymer films, and analyze oxidation and corrosion of metals and *in situ* kinetics of macromolecular adsorption to materials in aqueous environments.[33–35] Spectroscopic ellipsometry has been employed in the biomaterials community using Cauchy optical models to interpret data to better reflect the physical interfacial situation, including film thickness and refractive index.[36]

Ellipsometry exploits changes in the reflected polarization of elliptically polarized light from an interface of interrogation. The ellipsometer actually measures the quantities 'del' (Δ) and psi (ψ), which are then used to calculate the index of refraction and the thickness of the layer interacting with the light. The quantity Δ is the change in phase difference between the parallel component and perpendicular component of light (with respect to the reflected plane) occurring upon reflection from either a surface or interface. By definition, ψ is the angle whose tangent is the ratio of the magnitudes of the total reflection coefficients, r_p and r_s.[37] Both Δ and ψ are functions of wavelength (λ) or energy and are used in the fundamental equation governing ellipsometry [2]:

$$\tan(\psi)e^{(i\Delta)} = r_p/r_s \qquad [2]$$

to calculate the total reflection coefficients, r_p and r_s. The total reflection coefficients are then used in conjunction with appropriate physical and mathematical models to calculate the parameter of interest, for example, adsorbed (protein) layer thickness and surface density. The accuracy of the physical parameters calculated depends on the model used to make the estimate. Thus, materials properties and other physical parameters determined by ellipsometry are inherently dependent on the physical model assumed by the user, its basis in reality, and the mathematical treatment of that model. A more complete review of the practical issues of ellipsometry is published,[33] and its theoretical aspects are treated extensively in textbooks.[37,38]

Use of ellipsometry in biomaterials science has been somewhat limited to protein adsorption kinetics and isotherm measurements of proteins from media containing only single proteins.[34,35] Recently, the scope of research employing ellipsometry has been broadened to include interactions of proteins with organic surfaces,[39,40] and the identification of the composition of proteins adsorbed to metals from human plasma,[41] or organic surface modifications.[42,43] Composition of proteins adsorbed to a surface was identified using an indirect immuno-ellipsometry technique to measure the increase in thickness associated with antibody binding directed toward specific proteins bound to the surface. A common problem associated with the measurement of overlayer thicknesses by ellipsometry is that the indexes of refraction ($N = n + ik$) of the layer and substrate need to be known *a priori* or determined simultaneously.[44] Accurate values of the index of refraction for proteins, thin polymer films, and organic layers are not usually available, so the researcher is left to estimate N. This problem is minimized by using a spectroscopic ellipsometer (commercially available), where plots of Δ and ψ as a function of wavelength (or energy) are used to accurately determine the optical properties of the layer, and calculate the parameter of interest from multiple wavelengths simultaneously. The accuracy of layer thicknesses and surface density in multilayer structures is also improved by making measurements with a spectroscopic ellipsometer.[45]

Imaging ellipsometry (IE), a powerful widely available tool for measuring thin films of many different materials adsorbed/deposited onto a substrate, combines the spatial resolution of optical microscopy with ellipsometry's thin film assessment capabilities. Interest in IE is surging, and it is now used for applications in biomedical surface imaging. Traditional IE is a qualitative technique; ellipsometry imaging shows surface topology variation mapped by optical changes. As a quasi-quantitative tool, changes in optical ellipsometry surface images can help elucidate lateral changes in film thicknesses or densities. IE overcomes spatial resolution limitations in normal ellipsometry that averages information over the fully irradiated spot size (typically 50–100 μm to >1 mm spots). Optics used in IE in combination with a CCD camera provide

spatial resolution to 1–2 μm, <0.1 nm thickness resolution (e.g., SiO_2 on Si) and real-time sample observation, providing unprecedented measurement control and analysis of sample homogeneity. In addition to taking measurements on multiple fields on a surface, IE can provide *n*, *k*, and thickness maps over the full field-of-view. IE also enables use of liquid flow cells for measurements in fluids using a standard reflective setup.[46,47]

3.301.2.5. Surface Plasmon Resonance and Other Total Internal Reflection Optical Sensing Tools

A distinct total internal reflection (TIR) optical (or evanescent field) sensing tool now very popular for *in situ* surface analysis of biomaterials utilizes surface plasmon resonance (SPR, **Figure 4(a)**).[48–57] Using backside optical excitation of surface plasmons in certain metallic thin films (particularly gold), incoming light guided to the metallic surface at the appropriate resonant angle and matched wavelength conditions excites a standing evanescent field propagating along both the metal and bound dielectric (i.e., biological) adlayer on the *opposite* metal surface. Adlayer optical changes from any adsorption or desorption events at this metal surface cause the optical resonance conditions to change, and this change can be used to follow the adsorption or desorption process (both kinetics and amounts) in real time under static or flow conditions. Two common methods are used to detect changes in the assay resonance conditions. One uses a fixed wavelength incident light source (i.e., a laser) and detects the intensity of the reflected light as a function of angle of light at the surface maintaining TIR. The other uses a multiple wavelength incident light source (i.e., white light) and detects the intensity of the reflected light as a function of wavelength. Since the resonance angle or wavelength is proportional to the optical properties of the adsorbed film, changes in those quantities can be used to determine amounts and kinetics of species adsorbing and desorbing from the metallic surface.

SPR sensing relies on the principle that any changes on the dielectric sensing surface will cause a shift in the angle or wavelength of the TIR light, followed in real time by a detector, to satisfy the plasmon excitation resonance conditions at the surface. Many SPR detection configurations and analytical instrumentation systems are commercialized[58–60] and perform versatile experimental tasks for mass sensing of biomolecules in liquid milieu adsorbed to or very near a biomaterial's interface.

As shown in **Figure 4(b)**, SPR reports kinetic changes in the mass of material adsorbed or desorbed from the metal surface within the evanescent field, but has no intrinsic chemical or biological specificity. Adsorption and desorption events can be monitored in flow cells, with addition of components, different milieu, and rinsing. Interfacial mass is indirectly reported as an optical SPR-instrument-specific unit and actual SPR mass must be converted using algorithms correlating the optical sensitivity of the instrument to the changes in the local refractive index and adsorbate-specific properties. The chemical and biological specificity must be introduced by modification of the metal surface (e.g., attachment of antibodies binding only specific species, labeling with resonance-enhancing probes or optically excitable dyes, or use of affinity ligands immobilized in a nonfouling surface background). Significantly, while SPR-derived rate constants are routinely reported for kinetic data, apparent surface binding or adsorption kinetics must be carefully interpreted in terms of mass transfer limitations imposed by the immobilized surface layer or matrix where surface interactions occur. Also, experimental conditions such as temperature changes that also change the resonance conditions must be controlled so that they do not confound measured changes in the SPR resonance angle or wavelength.

In other TIR sensor modes (**Figure 4(c)**), a resonant mirror (RM) configuration is used to create an evanescent field external to the sensing element (shown in **Figure 4(c)**). Again, optical resonance conditions are established in the waveguide that become changed by the adsorption of molecules on the external surface of the sensing surface. The RM TIR design is a 'leaky' waveguide strategy similar to SPR's Kretschmann prism configuration (e.g., **Figure 4(a)**), but differs in that the coupling of incident light through a prism is interfaced with a high-index dielectric layer, rather than a metal surface. The SPR design is married with the enhanced sensitivity of new waveguide structures to produce sharper resonance peaks than SPR, thereby increasing the sensitivity of the technique. Measurements made in real time using a flow cell configuration and adsorption or ligand–receptor interactions can be observed conveniently and rapidly in any number of environments. In addition, sensing surfaces can be chemically and physically modified with a number of known conjugation chemistries to yield interfaces with relevant chemical features for the biomaterials investigator.

Dual polarization interferometry (DPI) represents another evanescent sensing technique, first commercialized a decade ago (Farfield Group, Ltd., UK), that is now seeing increased application. DPI utilizes waveguide structures comprising stacked dielectric layers, with reference and sensing layers separated by a cladding layer (**Figure 4(c)**).[61] A top dielectric layer is etched to reveal the sensing layer so that two separate channels can be present on a single sensor chip. Laser light passed through the sandwiched waveguide structure produces an interference pattern detected by a CCD camera. Any changes in refractive index that occur at the surface as a result of adsorption alter the phase position of the fringes relative to the reference layer, are detected in real time, and deconvoluted to the amounts of adsorbed species. As opposed to reporting only relative changes in refractive index upon adsorption using one polarization, DPI's use of two optical waveguide polarization modes to determine both effective refractive index and adlayer thickness values provides distinct advantages over SPR, RM, and other optical sensor methods.

Optical waveguide lightmode spectroscopy (OWLS) also monitors changes in both transverse electric and magnetic polarization modes of optical excitation energy by adsorbing molecules. The optical thickness and the refractive index of thin and homogeneous adsorbed layers can be determined from the mode phase shifts and the absolute amount of adsorbed molecules is calculated based on the difference in refractive indices of adsorbed molecules versus external medium (solvent molecules do not contribute to detected mass). OWLS is sensitive ($\sim$1 ng cm^{-2}) and facilitates direct real-time monitoring of macromolecular adsorption to surfaces.[62]

Applications for these optical surface sensors are now being fully explored.[52,63,64] Sensing surfaces can be dip-coated, spin-coated, plasma modified, chemically derivatized, and serially exchanged. Quantification of adsorbed amounts, and binding and desorption kinetics are possible from both gas and liquid phases in flow/rinsing configurations. Tandem or synergistic surface-localized binding events can also be monitored. Fiber optic sensing waveguides for *in vitro* and *in vivo* analysis are widely reported for different applications and analytical capabilities.[65,66]

High-contrast SPR microscopy or imaging[67] has been proposed to increase the throughput of standard SPR sensors.[68–70] Imaging SPR once exhibited reduced sensitivity compared to conventional SPR but is currently capable of mapping surface topology using comparable mass/optical detection.[71] Twenty-micron lateral resolution for surface features several angstrom thick can be obtained. More recent work has demonstrated SPR imaging of DNA and protein monolayers on surfaces with applications to sandwich sensors, microarrays, and other protein-electrode-based devices.[72,73] Innovations to improve signal-based images using phase shift discrimination and angle scanning, and spatial arraying multiplex imaging techniques are now incorporated into commercial devices.[74] In addition, SPR and waveguide evanescent field fluorescence-based interfacial sensing and imaging applications are also reported to increase sensitivity and resolution.[75–77]

3.301.2.6. Scanning Probe Surface Imaging Techniques

As the tool of choice for nanometer imaging of surfaces, membranes, and molecules, the AFM now represents a diversified family of related scanning force microscopies (SFMs) with various unprecedented surface analytical capabilities.[78,79] SFMs are relatively new surface techniques (invented in 1986[80]), falling under the broader selection of 'scanning probe microscopies.' These surface profiling methods provide nondestructive quantitative topographical images of a surface with atomic-level resolution (well below the optical diffraction limit) on rigid, semisoft and soft materials, using several different force-feedback modes to produce surface images. These methods can also provide molecular-level resolution of 'shapes' or morphologies of biomolecules and some soft-modulus materials (e.g., membranes, polymer coatings, gels) attached to ultra-flat surfaces (see **Chapter 3.302, Atomic Force Microscopy** for further details).

AFM surface interrogation is performed by mechanical feedback from a stylus-like, microfabricated (commercial) cantilever probe held in contact with or very proximal to the surface while scanning in-plane in x and y directions. Laser tracking of the stylus interactions and cantilever surface trajectory scanning across the surface 'maps' the surface topology. Two AFM measurement modes are used: static and dynamic. In the static (or contact) mode, the AFM tip is placed in contact with the surface and 'dragged or pushed' in a scan to measure surface features directly by cantilever deflections. Constant force between the tip and the surface is maintained, using continuous rapid feedback from the laser tracking system.[71] Two piezoelectric translators adjust the z-axis of the sample while the sample is scanned laterally under constant probe force, termed optical lever detection,[80] used in most commercial instruments. In the dynamic mode (i.e., both noncontact and tapping measurement modes), the cantilever is oscillated at a desired frequency close to its resonance frequency, using external oscillator controls. Cantilever interactions with the surface change this oscillating frequency, both the amplitude and phase, producing the information base that yields the surface image.[81]

Significantly, scanning probe techniques can often be used in aqueous environments, an enormous advantage for biomaterials research where few methods provide this utility. Operating the AFM in a physiologically relevant medium such as water or buffered salt solutions turns out to be an advantage because in air capillary forces tend to distort the precision of the applied force.[80] AFM in particular is valued because it provides 3D topological information incomparable to other methods in these conditions. In addition, other cantilever surface feedback modes, including electrical potential, current, capacitance, frictional and affinity interactions, can map different surface properties. AFM has become the technique of choice for imaging synthetic biomaterials (commercial polymers, thin polymer films, ceramics, metal oxides, etc.), native biological materials (red blood cells, platelets, cell membranes, bacteria, bone, dentin, etc.), and patterned surfaces of all kinds. With these advantages, it also has disadvantages including its speed of surface scanning (several minutes per scan, leading to thermal drift problems), and image scan size: the AFM can image only a maximum height of $\sim$10–20 μm, and has a maximum scanning area of $\sim 150 \times 150$ μm. Image artifacts from AFM tip defects or contamination, along with the inability to measure sidewalls, overhangs, or narrow features where the tip geometry precludes surface size sampling, are also limitations of AFM. Even so, AFM images of microporous materials are possible.[82]

AFM has been used in numerous applications including structural characterization of organic thin films,[83] analysis of thin polymer films,[84] nanoscale tribology of polymer films,[85] protein adsorption onto mica surfaces,[81,86,87] measurement of the elastic properties of biological materials such as bone,[88] and monitoring of the demineralizing effect of conditioning agents on the structure of dentin.[89] AFM analyses on clinically available biomaterials include assessment of bone response to titanium implants with different morphology,[90] and analysis of a solvent extraction process on biomedical polyurethane morphology.[91–93]

3.301.2.7. Surface Analytical Detection Using Shear-Mode and Surface Acoustic Wave Oscillator Devices

Shear-mode and acoustic wave sensors exploit a sensing detection mechanism from an induced traveling mechanical (i.e., acoustic) wave in the sensor.[94,95] Acoustic wave propagation properties (e.g., wave velocity and/or amplitude) through or on the surface of a material responds to changes in the wave propagation pathway. Changes in wave velocity are monitored by measuring the sensor's wave frequency or phase change characteristics. These changes can be quantitatively correlated to corresponding events monitored by the sensor (i.e., surface adsorption). Acoustic wave and shear-mode devices as sensors use piezoelectric materials interfaces with an electrical pulse generator to generate their acoustic

wave. Piezoelectricity is characteristic of select materials that spontaneously and reversibly produce an electrical charge or field by an applied mechanical stress, or the reciprocal effect of applying an electrical field to a piezoelectric material to yield a mechanical stress. This piezoelectric property leads to their being named 'shear mode' oscillators: applying an oscillating electric field to the material creates a transverse mechanical wave that propagates through the substrate and then can be converted back to an electric field for measurement. Piezoelectric substrate materials possible for use as acoustic wave sensors and devices include quartz (SiO_2), lithium tantalate ($LiTaO_3$), and, in principle, lithium niobate ($LiNbO_3$), although rarely used. Each material exhibits specific advantages and disadvantages, involving crystal cost, their frequency-temperature dependence, and wave attenuation and propagation velocities. Quartz is versatile in that its temperature dependence can be selected by its substrate cut angle and the wave propagation direction such that ideally, temperature effects on wave propagation are minimized. Alternatively, a quartz acoustic wave temperature sensor may be designed by maximizing this effect. By contrast, lithium niobate or lithium tantalite, both exhibiting linear temperature dependences for all material cuts and propagation directions, cannot be exploited this way. Other piezo-active substrate materials include gallium arsenide (GaAs), silicon carbide (SiC), langasite (LGS), zinc oxide (ZnO), aluminum nitride (AlN), lead zirconium titanate (PZT), and polyvinylidene fluoride (PVDF).

Acoustic wave devices can be characterized by the mode of wave propagation through or on top of a piezoelectric substrate, distinguished by wave velocities and displacement directions. Two bulk acoustic wave (BAW) devices, all with transverse waves propagating through the substrate, are most commonly thickness shear mode (TSM) oscillators, and shear-horizontal acoustic plate mode (SH-APM) sensors. Alternatively, waves propagating on the surface of the substrate are known as surface waves. Surface acoustic wave (SAW) and shear-horizontal surface acoustic wave (SH-SAW) sensors, known also as surface transverse wave (STW) sensors, are the most widely used surface wave devices.

All acoustic wave devices can report their intrinsic sensitivity to wave perturbations from many different physical parameters. Any alterations in the propagating path characteristics over which the acoustic wave moves on or in the substrate produce a change in the output. While all such designs function in gaseous or vacuum environments, significantly, only a few devices operate efficiently in liquids. The TSM, SH-APM, and SH-SAW all generate waves propagating principally with shear horizontal motion and this does not dissipate appreciable energy into liquids. This facilitates their use in liquids without excessive wave damping. In contrast, the SAW sensor produces a substantial surface-normal displacement that radiates compression waves into the liquid above the surface, yielding excessive damping. Importantly, however, devices producing waves propagating at a velocity below the sound velocity in the liquid do not suffer appreciably from this damping. Other acoustic waves with attractive applications as sensors include the flexural plate wave (FPW), Love wave, surface-skimming bulk wave (SSBW), and Lamb wave.

3.301.2.7.1. TSM oscillator

The TSM is now better known as the quartz crystal microbalance (QCM) – the oldest and simplest SAW device, deployed for vapor sensing over 50 years ago and commercialized in many forms. The QCM typically consists of a thin disk of AT-cut (i.e., cut from quartz mineral piece at a 35.25° orientation to its optical axis) quartz with parallel circular electrodes, generally of evaporated conductive metal, patterned on both sides. Application of a voltage across these electrodes yields a shear deformation of the crystal due to the piezoelectric effect. This device is known as a resonator because the crystal resonates as electromechanical standing waves are created. Maximum displacement is at the AT-cut crystal faces, resulting in a device intrinsically sensitive to surface interactions. The QCM shear acoustic wave velocity depends highly on the quartz crystal properties, especially the stiffness (i.e., Young's modulus) and density, allowing these resonators to determine material-specific parameters not readily accessible using other sensors with direct transduction, such as SPR. Relationships between QCM crystal mass and its density allow prediction of the QCM resonant frequency variation associated with small mass increases at the QCM surface. This is based on the so-called Sauerbrey equation establishing a linear relationship between crystal resonant frequency and small mass increments, based importantly on the assumption that the mass deposited at the QCM surface is tightly or rigidly coupled to the crystal surface. Hence, the loaded crystal should simply behave as if it were a thicker crystal. Under these conditions, the effective crystal wavelength is increased, and consequently its resonant frequency decreases under such mass loading. As no energy dissipation occurs, this assumption will only be valid for thin, rigid, and uniform adsorbed surface films with similar acoustic properties to the bulk crystal material. QCM was originally used to measure metal thin-film deposition rates in vacuum systems, deployed in an oscillator circuit. The crystal oscillation frequency tracks the crystal resonance and directly reflects mass accumulation on the device surface in systems like these where the adsorbing layer is rigid and coupled to the QCM surface. This piezoelectric signal transduction in principle enables label-free detection of surface binding, adsorption and immobilization events in a variety of different applications, such as monitoring and characterization of protein adsorption, (bio)film deposition, detection of specific antigens, biomolecule binding kinetics, cell adhesion, and DNA detection.[94,95]

Importantly, certain adsorbing and assay conditions violate the Sauerbrey assumptions. Specifically, when the QCM is immersed in a fluid, as is often desired in biosensing applications, or when the surface-adsorbed layer or film has radically different viscoelastic, mechanical, or acoustic properties from the crystal sensor, mechanical wave energy is lost to the fluid phase through viscous coupling. In this case, the shear acoustic waves propagate from the crystal into the fluid, decreasing the sensor resonant frequency from (1) liquid damping proportional to the viscosity and density of the fluid and (2) exponentially decaying transverse shear wave energy dissipation into the bulk fluid, normal to the crystal surface, with a decay characteristic length depending on the crystal oscillating frequency. For example, a penetration depth (decay length) of 250 nm exists for a shear acoustic wave

propagating in water at a 5-MHz crystal frequency. Exploiting this same dependence of wave decay length on the crystal resonance frequency enables probing at different distances from the crystal surface and allows analysis of different 'layers' external to the crystal surface by measuring at the crystal frequency overtones. Importantly, crystal resonant frequency variations are also affected by changes in the roughness of the crystal surface, adsorbate heterogeneity, including nonuniform layers, solution permittivity and conductivity, and charged species near the surface. Many of these are serious limitations to QCM use in biological systems and must be treated differently.[94]

3.301.2.7.2. QCM with dissipation monitoring

The classic analytical treatment of surface adsorption using the Sauerbrey equation treats the sensor resonance frequency and its variation from adsorption as the sole experimental parameter. However, as the crystal resonance frequency is influenced by several factors that must be accounted for to accurately quantify analytes or kinetic adsorption data, and the 'rigid coupling' assumption does not often apply to adsorbed 'soft materials' such as many proteins, cells, lipids, and bacteria, alternatives to the Sauerbrey QCM treatment have been developed.[84] Significantly, impedance analysis enables a full description of the acoustic loading of the crystal surface and thus allows identification and elimination of interfering signals. Physically, impedance is the ratio of the applied voltage across the crystal and current flowing through the crystal between electrodes. In impedance analysis, the incident voltage versus the reflected sinusoidal voltage from the quartz crystal is measured within the resonant frequency, and the impedance magnitude and phase angle are calculated. The magnitude of the impedance provides a measure of signal attenuation, whereas the phase measures the lag between the applied field and the resulting displacement. Different SAW/QCM devices depend on the propagation of acoustic waves in a multilayer structure (i.e., crystal plus adsorbate layers). The acoustic load impedance reflects these changes, independently of whether these wave frequency changes result from actual surface mass accumulation, changes in the adsorbed material properties (e.g., swelling, softening, melting, or rigidity), or chemical (e.g., cross-linking) and physical (e.g., phase transition) changes. Dissipation monitoring in QCM, known as QCM-D and embedded in several commercial SAW instruments, employs on-board impedance analysis of QCM signals. Under conditions of low acoustic load, the impedance of the loaded QCM crystal surface can be expressed as an additional element in series with the equivalent circuit. That is, the impedance of the crystal mass loading under multiple layers is described as linear combinations of the impedance of each layer. Thus, when liquid is added or mass is deposited onto the crystal surface, new elements can be added to the model to describe the new overall impedance. This makes it possible to identify the effect of each of the layers simply by measuring the impedance in a stepwise manner as each component of the measuring sample (e.g., buffer, or target molecules) is added. The Q factor, defined as the ratio between the height of the QCM resonance peak and its width at half maximum in a given media, can also be obtained from impedance spectra. In physical terms, the Q factor represents the fractional energy stored and the energy lost in a single QCM oscillation. This is a quantitative measure for energy dissipation. However, the most commonly determined parameter to account for QCM dissipation is the dissipation factor, D, defined as the reciprocal of the Q factor.[94]

QCM-D improves on the traditional QCM capabilities with dissipation analysis, and enables real-time, label-free measurements of molecular adsorption and/or interactions on various surfaces in liquid media. In addition to sensing adsorbed mass with ng cm^{-2} sensitivity, measured as changes in quartz crystal frequency, the dissipation parameter (D) provides novel insights regarding the structural (viscoelastic) properties of adsorbed layers and their solvated states or of evolving soft matter properties. QCM-D has recently been coupled with real-time dual surface measurements using QCM-ellipsometry and QCM-electrochemistry and electrical impedance spectroscopy, and QCM-Raman spectroscopy. These tandem techniques enrich the information content available from each QCM assay.

3.301.3. Ultrahigh Vacuum Surface Analytical Techniques

3.301.3.1. Electron Spectroscopy for Chemical Analysis

Also known by the synonym XPS, electron spectroscopy for chemical analysis (ESCA) is the method of choice to provide high-resolution compositional information about biomaterials surfaces.[1,96,97] ESCA surface sensitivity results from the production of photoelectrons within a material, and the surface selectivity of their emission and characteristic analysis. X-ray excitation of a material produces classic photoelectron emission processes, resulting in the ejection of core-level electrons from atoms in a relatively deep surface zone (~μm), depending on X-ray energy. However, these ejected photoelectrons have kinetic energies ranging from 30 to 2500 eV, so their inelastic mean free path of travel within a material is about 0.5–3 nm for most materials. The inelastic mean free path is the average distance that an electron can move before experiencing inelastic collisions with another electron or nucleus of any atom in the material that results in loss of energy. As a result, very few photoelectrons created by X-ray-induced emission at depths >2–3 times the mean free path will leave the bulk material with their initial photo-emitted kinetic energy (KE). Photoelectrons produced at depths deeper than this undergo many collisions with atoms and electrons in the bulk and if they reach the ESCA energy analyzer, they will just contribute to the background signal. Owing to their strong interactions with matter, the intensity of photoelectrons decreases exponentially with the depth from the surface where they are created, meaning that XPS is most sensitive to the outer atomic level photoemission processes. This produces the ESCA sampling depth of ~10 nm for many materials. As each photoelectron KE is characteristic of the atom from which the electron was originally derived, all photoelectrons reaching the KE analyzer in ESCA are 'counted' and attributed to the abundance of their source atoms in the surface zone. All elements with an atomic number (Z) of 3 or greater create sufficient photoelectrons to be detected. Using ESCA, most elements can be detected to 0.1 at.% (atomic percent)

sensitivity, and relative atomic amounts are calculated for surface composition. ESCA methods allow access to a rich variety of data, as summarized in Table 3.

ESCA is based on photoemission of core- and valence-level electrons in an atom. Incident X-rays with energy ($h\nu$), usually monochromatic on modern systems, liberate core- and valence-level electrons with sufficient KE to escape from the material and pass through the vacuum chamber to the energy spectrum analyzer to determine their binding energies (BEs). The general form of the energy balance ($BE = h\nu - KE$) was proposed by Einstein in 1905. Additional terms (e.g., spectrometer work function) need to be included in the energy balance to account for the experimental conditions.[97] Figure 5 schematically shows the photoemission process along with a survey spectrum and high-resolution spectra acquired from poly(methyl methacrylate) (PMMA). Data are typically collected as survey spectra spanning the BE range of 0–1000 eV. Then high-resolution spectra may be collected in a region of interest to examine the fine structure of specific core-level peaks (e.g., carbon 1s, oxygen 1s, titanium 2p, etc.). The BE of the photoelectrons emitted depends on the atomic orbital from which they originated, the parent atom, and the chemical environment of the atom. A survey spectrum covering 0–1000 eV will contain photoemission peaks from all elements (excluding H and He) present in the surface of a material (up to 100 Å depth). Shifts in these ESCA peaks can be used to identify chemical state information of the atoms of this surface region.

Innovations in ESCA sampling methods include angle-dependent capabilities for depth compositional mapping,[98–100]

Table 3 Information obtainable from XPS analysis of the biomaterials interface

- Identification of all elements except H and He present in the outer 10 nm of a surface at concentrations exceeding 0.1 at.%
- Quantitative determination of approximate surface composition (±10%)
- Bonding information and molecular environments (oxidation states, bonding partners) in the surface zone
- Identification of unsaturated and aromatic species from satellite ($\pi \rightarrow \pi^*$) transitions
- Further information on surface-exposed organic functional groups using chemical derivatization methods
- Elemental depth profiles to 10 nm deep using angle-dependent XPS analysis or photoelectrons with different depths and depth profiling models
- Sputter depth profiling using various ion sources
- Lateral resolution of surface domains/heterogeneities using models applied to angular-resolved data, or using small spot imaging methods (~10 μm) and data handling models
- Identification of materials using valence bond spectra and bonding orbital information

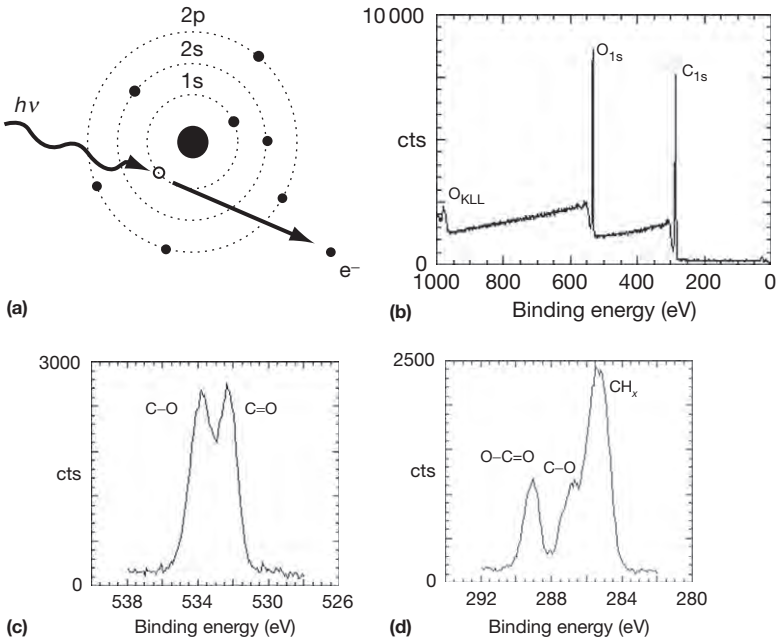

Figure 5 (a) Schematic of the photoemission process. An incident X-ray with energy ($h\nu$) liberates a photoelectron from an atom in the sample with sufficient kinetic energy to be measured by the analyzer. The binding energy (BE) of a photoelectron emitted from conducting sample in electrical contact with the spectrometer is described by the equation: $BE = h\nu - KE - \phi$, where ϕ is the spectrometer work function. Changes in binding energy (ΔBE) for a particular photoelectron (i.e., 2s) occur when the chemical environment changes. (b) A survey spectrum obtained from a poly(methyl methacrylate) (PMMA) sample using monochromatized Al K_α X-rays. Both photoelectrons (C 1s and O 1s) and Auger electrons (O KLL) are detected in the survey spectrum. High-resolution spectra of the O 1s and C 1s regions are shown in (c) and (d). Peaks due to the different oxygen and carbon species present in PMMA can be observed in the high-resolution spectra.

cryogenic freezing of volatile or hydrated specimens for UHV analysis,[101,102] surface spatial mapping of chemistry,[103–106] and surface derivatization reactions to identify functional groups[107–110] and new X-ray sources.[111] While standard sampled areas in a conventional ESCA instrument are millimeter in size or larger, the latest commercial instruments can analyze areas <10 μm in size. Both microprobe (focused X-ray source) and microscope (imaging detector) style ESCA instruments are available.[112–116] In addition, some microprobe style instruments can raster the X-ray beam across selected spots. The primary benefit of these new instruments is the capability of selecting smaller sample areas and 'mapping' surface chemistry in these areas. Disadvantages include a greater risk of sample damage due to a higher flux of focused X-rays (microprobe mode), X-ray exposure of the sample outside the analyzed area (microscope mode), a lower signal-to-noise ratio as smaller irradiated areas produce less photoelectrons (both modes), and significant charge neutralization problems on nonconducting samples. Submicron spatial resolution for biological samples is now possible with ESCA using synchrotron radiation soft X-rays (e.g., at the Berkeley Advanced Light Source).

Together, these ESCA methods offer numerous advantages for biomedical materials surface analysis. Parts or pieces of biomedical devices can be analyzed readily as retrieved, fabricated, or modified. In addition, ESCA provides the capability to evaluate hydrated specimens, to yield rich information on chemistries within a surface zone up to 100 Å deep, and to achieve relatively small sample destruction when using monochromatized X-ray sources. It has established precedents for numerous data interpretation modes, allows rapid sampling, and requires little sample preparation. Disadvantages include (1) the requirement for eliminating sample out-gassing in the UHV environment, (2) the need for access to specialized ESCA resources and expert operators with associated analytical costs, and (3) the potential for sample damage if extended analysis times are required. The first disadvantage can be greatly reduced using the cryogenic sampling methods mentioned above. The second disadvantage diminishes each year with the increased availability of these resources around the world.

Applications of ESCA to biomedical materials surface characterization and biocompatibility studies have been extensive. Studies of polymer surface dynamics,[1,117] protein adsorption to surfaces,[118] and analysis of commercially available materials and medical devices have been performed.[117–119] Inorganic materials have also been studied using ESCA. Orthopedic and dental applications include characterization of commonly prepared titanium implants,[10,120–122] contamination of dental implants from sterilization,[123] failure analysis of ceramic-to-metal bonding,[124] corrosion and oxidation of implants materials,[125–128] and characterization of dental amalgams.[129]

3.301.3.2. Secondary Ion Mass Spectrometry

SIMS is another UHV method that can supplement and augment surface analytical data available from ESCA.[130–138] This method produces a surface mass spectrum of surface species, analogous to long-standing bulk mass-spectrum techniques, using a primary ion beam impacting the surface to generate secondary molecular and ion fragments from the chemistry residing in the top few namometers of the surface of interest. A wide range of primary ion sources is commercially available. Initial SIMS experiments used rare gas ions such as Ar^+ and Xe^+ as primary ion sources. Then liquid metal ion sources using Ga^+ were developed for their improved imaging capabilities. Cs^+ ion sources have also been extensively used. Recent developments in cluster ion sources have significantly expanded the information that can be obtained from SIMS analysis.[139–141] Some of the commercially available cluster ion beams include C_{60}, Bi_3, and Au_3. Typical energies of the incident ion beam range from 200 eV to 30 keV. When the incident primary ion beam strikes the sample surface, ion energy and momentum transfer eject multitudes of different molecular, fragment, and atomic species from the surface zone. A small percentage (typically <1%) of these ejected species are positive or negative ions, which are collected and detected in an interfaced mass analyzer typical of mass spectrometers (i.e., measuring mass/charge ratio, m/z). With monoatomic primary ions, the flux of bombarding primary ions must be kept low (typical ion doses $<10^{13}$ ions per cm^2) to minimize surface etching and damage of surface chemistry. These conditions are termed static SIMS.[130,131] However, with the advent of cluster ion beams, such as C_{60}, that produce little residual surface damage (i.e., most of the material in the impact zone is sputtered away), the static SIMS requirements of low primary ion doses are no longer necessary. This has resulted in the new SIMS capabilities and analytical performance in surface molecular depth profiling and 3D imaging of organic and biological materials.[140,142–145]

The development of time-of-flight SIMS (ToF-SIMS) represented a major improvement in the method and now commercially available SIMS instruments capable of high mass resolution and imaging of surface species are widely available.[26,27,146] The ToF detection mass spectrometry configuration enables enhanced mass-measurement sensitivity and surface mapping of selected species into images. The advantages of SIMS plus enhanced mass-measurement capabilities mean that synthetic polymer surfaces and high mass adsorbates (proteins, contaminants, genetic material) can be analyzed on surfaces at high precision. Complex fragmentation patterns presented by macromolecule mass spectroscopy data are often difficult to interpret unless simpler model studies are performed as a basis for understanding fragmentation. However, newer multivariate statistical methods[147–151] improve enhanced analytical capabilities for both spectroscopic and imaging SIMS studies of organic and biological materials.

Information provided by SIMS analysis is shown in **Table 4**. This information is complementary in many respects to ESCA analysis and provides new, corroborative data from a different surface zone (see **Figure 2**). An example of ToF-SIMS analysis of PMMA, used frequently in bone cements and other biomedical applications, is shown in **Figure 6**. The negative (**Figure 6(a)**) and positive (**Figure 6(b)**) ToF-SIMS survey spectra along with high-resolution spectra (**Figure 6(c)**) demonstrate the ability to determine chemical species present at the surface with extremely high mass resolution. Since a focused primary ion beam is used to generate the secondary ions, it can be rastered across the surface to generate ion-specific images. **Figure 7** shows ToF-SIMS images from secondary ions that show the spatial distributions of chemical species on a surface.[145,152] In addition to chemical information associated with the

Table 4 Surface information obtained from SIMS experiments

- Surface sampling zone restricted to top 1–3 nm of material in the static mode
- Identification of hydrogen
- Molecular structure inferred from fragmentation patterns per mass spectrometry analysis
- Detection of higher molecular weight fragments (polymers, biopolymers)
- Useful for polymer, metal, and ceramic samples
- Applicable to devices and samples with complex geometries (e.g., powders, fibers, films, sponges, etc.)
- Spatial resolution of composition in imaging mode (<1 μm)
- High sensitivity to low surface concentrations (ppm to ppb for many atomic secondary ions)
- Molecular depth profiling and 3D imaging with cluster ion beam sputtering sources

outermost materials surface chemistry, recent work has demonstrated that SIMS is useful in identifying proteins adsorbed to interfaces.[152–154]

3.301.3.3. Auger Electron Spectroscopy

In AES, as in ESCA (XPS), energy deliberately directed to a surface (e.g., an electron beam or X-ray usually 2–20 keV in energy) ejects a core- or valence-level electron in an atom in the typical photoemission process. Subsequently, another electron from a higher energy level within this atom 'falls' into the vacated electron level. Two energy relaxation processes in this atom are then possible: an X-ray can be emitted from this electron relaxation, or a third electron can be ejected from the atom. The emitted electron in this latter process, shown in **Figure 8**, is an Auger electron, and is distinct from the ESCA photoelectrons. AES and scanning Auger microscopy (SAM) both use electrons as both the incident excitation source and the detected analytical signature. The process of Auger electron emission leaves an atom in a doubly ionized final state. A thorough discussion of the nomenclature used to describe Auger emission, instrumentation, and spectral interpretation can be found in the literature.[155,156]

AES and SAM are versatile techniques capable of characterizing the top few molecular layers (0.5–5 nm) with detection limits on the order of 0.1–0.5 at.%. In AES (and SAM), the KE of Auger electrons emitted from a parent atom is measured. All elements above He can be detected with either method. The strength of SAM is the excellent lateral resolution (<20 nm) obtainable with modern field emission electron sources. Owing to this excellent spatial resolution, SAM is routinely coupled with scanning electron microscopy and has found wide acceptance in the fields of biomaterials, microelectronics, catalysis, corrosion science, tribology, metallurgy, adhesion science, and oxidation of metals. Depth profiling measurements are made by monitoring the Auger signal intensities while eroding the sample by ion sputtering. The combination of surface sensitivity, excellent lateral resolution, and depth profiling capabilities allows SAM/AES to be used to investigate numerous phenomena associated with biomaterials fabrication, characterization, and performance testing. AES and SAM data are influenced by electron beam (incident electrons) interactions with the sample; so, considerable care must be taken to minimize electron beam-induced reduction or stimulated desorption of a sample, and in the case of depth profiling prevent ion dependent changes in peak shape and preferential sputtering of specific elements. The major drawback of these techniques is that they are limited in practice to the examination of inorganic materials, thin organic/inorganic coatings on base inorganic substrates, or inorganic coatings on organic materials. Comprehensive reviews of AES and SAM can be found elsewhere.[2,155] As a newer modification, Auger photoelectron coincidence spectroscopy (APECS) is now being developed as a surface analytical tool.

Standard AES analysis provides data describing the elemental composition of the near surface region, and possibly the chemical state of a particular atom. Data are typically collected as a survey spectrum spanning the KE range of 0–1000 eV; subsequently, high-resolution spectra may be collected in a region of interest to examine the fine structure of the Auger peaks. SAM studies provide the spatial distribution of the elemental composition, or the elemental composition at specific positions on a sample surface. AES and SAM have also been used extensively to analyze the surface of orthopedic and dental implants as a function of preparation,[120,157,158] surface modifications or bioactive coatings,[159,160] oxidation and corrosion of biomaterials,[127,128,161] implant failure,[162] and bone response to the implant.[90,163]

AES depth profiling measurements are useful in analyzing the thickness and composition of metal oxides on implant materials,[120,127,157,163] surface modifications such as ion implantation or bioactive coatings on metal surfaces,[160,161] and composition gradients at either a surface or interface. Quantitative depth profiling requires the use of a well-calibrated ion sputtering source to determine instrument parameters that minimize the interfacial depth resolution.[164] Furthermore, standards that model the actual sample are necessary to calibrate the ion sputtering rate. For example, an anodically oxidized titanium standard of known oxide thickness has been used to calibrate the sputter etch rate so that the oxide thickness of a titanium film exposed to a model biological environment could be measured.[127,128] Thorough discussions addressing quantitative depth profiling are given in the literature.[165,166]

3.301.4. Next Challenges: Nanomaterial Surfaces

Nanomaterials are the latest generation of new biomaterials, with novel properties and enormous potential for both *in vitro* and *in vivo* applications. Current increasing interests and use of engineered nanoparticles in both research and product development in biomedical areas has created substantial challenges for the surface analytical community to provide adequate tools for these materials. In a 2-nm diameter particle, over 60% of the atoms in particles of this size reside at their surface; specific surface areas for many of these nanomaterials are unprecedented (200–800 $m^2 g^{-1}$). Surface issues with these materials are indeed acute. As with all biomaterials, biomedical uses for nanomaterials also require full understanding of their properties and behaviors as they are synthesized, fabricated, applied, and as they age in a particular environment, process, or application. Accompanying this from the producer side is an increasing awareness of the need to understand the health,

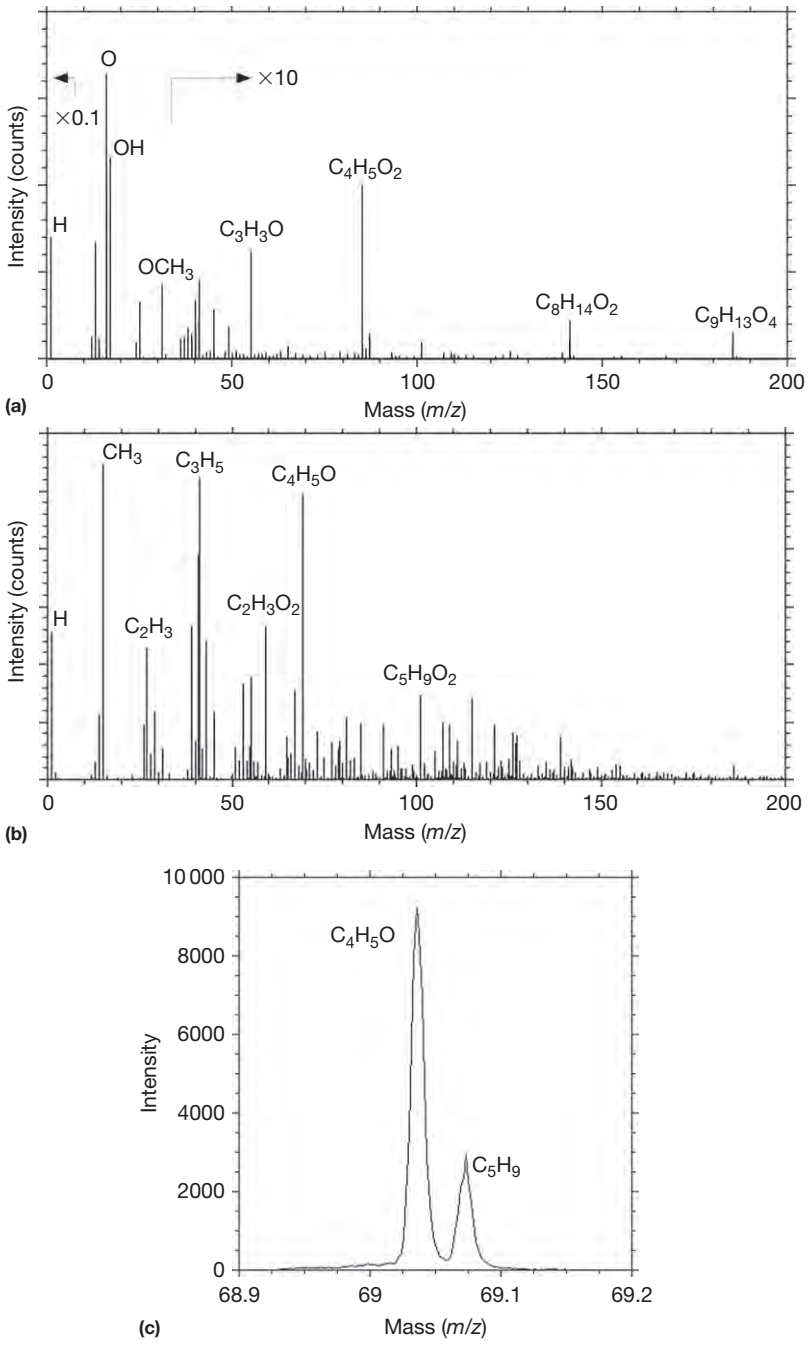

Figure 6 (a) Negative and (b) positive time-of-flight secondary ion mass spectrometry survey spectra of a poly(methyl methacrylate) (PMMA) sample for $m/z = 0$–200. Selected fragments related to the PMMA structure have been labeled. Examples in the negative ion spectrum include the methoxy peak at $m/z = 31$, the M – CH_3 peak at $m/z = 85$, and the 2 M – CH_3 peak at $m/z = 185$ (M = the PMMA monomer). Examples in the positive ion spectrum include the M – OCH_3 peak at $m/z = 69$ and M + H peak at $m/z = 101$. In some cases, multiple species are present at the same nominal mass. In (c), the high mass resolution spectrum for the positive $m/z = 69$ region shows both C_4H_5O ($m/z = 69.03$) and C_5H_9 ($m/z = 69.07$) are present.

safety, and environmental impacts of nanoparticles in all forms of possible interaction, both from consumers and regulatory agencies. Nevertheless, important physical properties required to understand the unique physical and chemical behaviors of many nanomaterials are unreported in research reports and apparently often go unmeasured, especially in biomedical conditions (*in vitro* or *in vivo*). Under these conditions, nanoparticles are often deliberately treated with surface-active stabilizing agents, and then exposed to many biological agents with surfactant or contaminants properties. The dynamics of interfacial structure–property relationships in these cases is unknown. None of these situations have methods sensitive enough to enable their direct analysis even in a dilute biological milieu. As a result, nanomaterials in their

operational conditions are often poorly characterized and, many times, their surface chemistry is not even adequately described. Increasingly, it is recognized that reports on the properties of nanoparticles and other nanomaterials are based on inadequate characterization, certainly not to the standards that historically have governed conventional biomaterials. Consequently, the validity of some conclusions correlating surface properties with performance, efficacy, function, and safety may be questionable. Development of surface analytical techniques to sufficiently characterize nanomaterials in biological contexts represents the next challenge.[167,168]

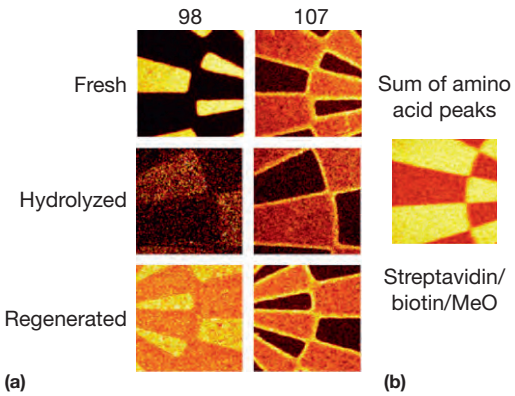

Figure 7 Time-of-flight secondary ion mass spectrometry (ToF-SIMS) images of hydrogel-coated glass slides with methoxy (MeO) and *n*-hydroxysuccinimde (NHS) pinwheel patterned surface chemistries. (a) Negative ToF-SIMS images of fragments from NHS ($m/z = 98$) and processing photoresist ($m/z = 107$) as the sample goes from fresh to hydrolyzed to regenerated. Note that the intensity of the photoresist residue (an organic contaminant on an organic surface) does not change significantly during this treatment sequence while the intensity of the NHS fragment does. (b) The NHS region of the NHS/MeO surface has been treated with an amine-terminated biotin molecule and then exposed to streptavidin. The positive ToF-SIMS image is a the sum of intensities from the amino acid fragments and shows the streptavidin only attaches to the biotin regions of the patterned surface. 3.301.5. Conclusions

Surface characterization of biomaterials has enjoyed a renaissance of development and technological improvement with the recognition that the material interface plays a key role in mediating biological response and reactivity. New methods are continually evolving, improving the capabilities to probe materials surfaces and their interfaces with biology in many new and valuable ways. While a variety of surface analytical methods are now available to the biomaterial scientist, each case of surface characterization must be carefully evaluated to match desired analytical information with the method(s) and their respective capabilities. Few techniques actually are able to provide surface data of direct relevance to the biological implant environment: few methods operate under water or in the presence of complex milieu such as serum. Instead, some of the more valuable methods (e.g., ESCA) often operate in high vacuum – far from the aqueous environment of biomaterial applications. At best, only simulated environments approximating biological sites (for example, the evanescent wave biosensors, environmental SEM or hydrated ESCA or SIMS) are currently available to address this gap between analysis and application environments. Much of a biomaterial's surface description, therefore, must be inferred and extrapolated from the environment of the surface in the analytical scenario (e.g., UHV) to the material site of application (aqueous). Because surfaces of many biomaterials are synthetic polymers or proteins capable of metastable states of surface relaxation and restructuring, analytical methods must account for possible 'chameleon-like' changes in surfaces (e.g., topology, chemistry)

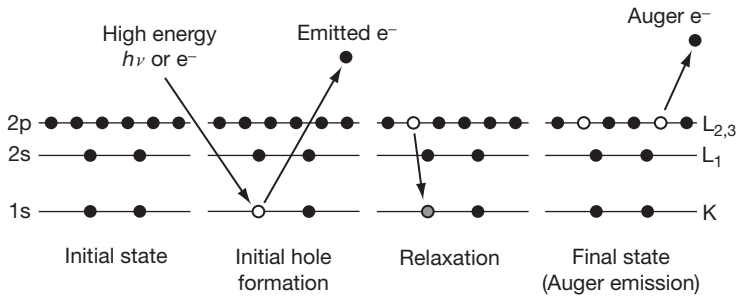

Figure 8 Schematic diagram of Auger electron emission process. The atom starts out with its full complement of electrons (far left). Then either a high-energy X-ray or electron beam is used to ionize a core or valence electron (ionization of a 1s or K electron shown, second from left). An outer shell electron then relaxes and fills the initial hole (relaxation of an 2p or $L_{2,3}$ electron is shown, second from right). The excess energy from the relaxation process is then either emitted as X-ray (not shown) or transferred to another electron which is then emitted (shown, far right). This is the Auger electron (shown as emission of an $L_{2,3}$ electron). The kinetic energy (KE) of the emitted Auger electron depends on the specific Auger transition that occurs (i.e., $KL_{2,3}\,L_{2,3}$ shown in this figure) and the chemical environment of the atom. It does not depend on the energy of the primary X-ray or electron beam used to create the initial hole as long as the beam has sufficient energy to ionize that electron. After emission of an Auger electron the atom has a charge of +2 due to loss of two electrons (the initial ionized electron plus the Auger electron). The energy balance for a $KL_{2,3}\,L_{2,3}$ Auger electron is $KE_{KL2,3L2,3} = BE_K - BE_{L2,3} - BE_{L2,3}$, where the first BE term represents the binding energy of the initial core hole, the second BE term represents the binding energy of the electron that fills the initial core hole, and the third BE term represents the binding energy of the electron that is emitted as an Auger electron.

between vacuum, air, and water environments. The more complete the knowledge of the material and its possible surface composition and physical chemistry, the more confident the investigator may be regarding the surface's reactivity in a biological setting. The fullest impact of surface analysis in the biomaterials field will be realized by coupling surface characterization to a broader set of disciplines common to biomaterials development. This sets the stage then for the biomaterials specialist to become adept with a number of scientific concepts regarding surfaces and their behavior. Comprehensive understanding of the influence of materials interfacial chemistry in biological systems will be derived from an ability to direct diverse principles of surface physics, surface analysis, materials science and engineering, surface electrochemistry, synthetic chemistry, and cellular and molecular biology to the application of biomaterials in specific sites.

Abbreviations

2D	2-dimensional
AFM	Atomic force microscope
BSA	Bovine serum albumin
EFM	Electric force microscopy
JKR	Johnson–Kendall–Roberts
LFM	Lateral force microscopy
mAb	Monoclonal antibody
MFM	Magnetic force microscopy
NHS	*N*-hydroxysuccinimide
pAb	Polyclonal antibody
PDMS	Polydimethylsiloxane
PE	Polyethylene
PU	Polyurethane
RMS	Root mean square
SAM	Self-assembled monolayer
SEM	Scanning electron microscope
SPM	Scanning probe microscope
STM	Scanning tunneling microscope
TEM	Transmission electron microscope

Symbols

A	Set point amplitude
A_0	Free amplitude of oscillation
d	The deflection of cantilever (nm)
E	Young's modulus (GPa)
E_s	Separation energy
F	Force (nN)
F_{adh}	Adhesion force (nN or pN)
h	Indentation depth (nm)
k	The cantilever spring constant (N/m)
r_{sp}	Ratio of set point amplitude and free amplitude of oscillation (A/A_0)
R	Tip radius (nm)
Z_{defl}	cantilever deflection (nm)
Z_{pos}	z-piezo movement (nm)
α	Half of the pyramidal angle of the indentor
β	= 2 for elastic deformation of a sphere and $(\pi/2)^2$ for pyramidal and conic shapes
Δ	Cantilever deflection at the point where the probe loses contact with the surface
ν	Poisson's ratio

3.302.1. Introduction

The atomic force microscope (AFM) is a member of a broad family of scanning near-field tools generally known as the scanning probe microscopes (SPMs). The primary distinguishing feature of SPMs is that the measurements are performed by bringing a small probe to close proximity with a surface, and the surface is then scanned, generating a contrast map. The first microscope in the SPM class was the scanning tunneling microscope (STM), invented by Binnig and Rohrer in 1981,[1] and the STM quickly demonstrated the imaging of surface structure with true atomic resolution.[1,2] Binnig and Rohrer were awarded the Nobel Prize in 1986 for the development of the STM. The STM uses the tunneling current between probe and sample to make maps of the surface structure, including the ability to resolve single atoms as noted. One central limitation of the STM is that the surface of the sample must be conductive. This limitation contributed to the development of the AFM in 1986.[3] The AFM uses a very sharp probe to measure and map the morphology of nearly any surface, without the limitation of conducting surfaces. This development quickly attracted the attention of the biophysical community and led to the development of a variety of high-resolution imaging techniques applicable to biological systems.[4–7] Although the initial emphasis of the AFM was primarily on improved imaging resolution in physiologic environments, it was soon recognized that the AFM had the capacity to be much more than just a high-resolution microscope. The possibilities for localized spectroscopic analysis, direct and selective surface modification, and molecular manipulation gave rise to a variety of technological breakthroughs across the realm of AFM use.[8,9]

One of the most important advantages of the AFM for biomaterials and biological applications is that measurement of samples can be performed under physiologically relevant conditions without complex sample preparations. This is significantly different from techniques such as the scanning electron microscopy (SEM) and the transmission electron microscopy (TEM), which generally operate under high vacuum, and must necessarily operate under high vacuum for very high-resolution imaging. Within the biomedical field, innumerable biological samples have been investigated, ranging from smallest biomolecules such as DNA,[10,11] proteins,[12,13] lipids,[14,15] and polysaccharides[16,17] all the way up to living cells[18–21] and tissues,[22,23] to name just a few. The focus of these studies is not just high-resolution imaging of structural properties, but also measurements of the mechanical, chemical, and functional properties[24] of these biological materials. Moreover, biological events can be observed in near real time by AFM, offering unparalleled opportunities for investigating dynamic, biochemical, and physiological processes while simultaneously acquiring structural and functional information on the materials,[25] for example, receptor–ligand interactions[26,27] and biological adhesion phenomena at material surfaces.[28]

The development of these AFM techniques has made a considerable impact across the many disciplines of biomaterials research.[25] Surface properties are known to play a major role in determining the host response to a biomaterial,[29,30] whether it be orthopedic, neural, vascular, or other soft tissues, as the molecular interactions occurring at the interface between material and host (protein adsorption, surface-induced thrombosis, cell–surface interactions, and tissue integration among others), are important determinants of the ultimate biologic response to a biomaterial.[31–33] The AFM provides unique opportunities for visualizing these and other surface-dependent cellular and molecular interactions in three dimensions, on a nanometer scale, and under physiological conditions. This chapter introduces the principles of the AFM techniques and their application to biomaterials research. Examples of selected studies of the structural properties of biomaterials as well as the dynamic biological properties and responses of biomaterials will illustrate the utility of the technique. Common concerns in optimizing AFM experiments as well as the future potential of the AFM in biomaterials research are also discussed.

3.302.2. Fundamentals of the AFM

3.302.2.1. Principles of AFM

Fundamental details of the AFM as related to instrumental aspects can be found throughout the literature.[34–36] This section briefly describes the most standard operating principles of the AFM and summarizes some of the common operating modes with examples of research that are likely to be of interest to the biomaterials scientific community.

The most common basic configuration of an AFM is shown schematically in Figure 1. The primary components of a typical system include a probe mounted at the end of a microcantilever that scans over the surface and detects a physical property that provides a contrast mechanism; a piezoscanner that controls the probe–surface separation and provides motion across the x, y, z directions, generally with angstrom-level accuracy; and a feedback electronic system that monitors and controls the probe near the surface. For topographic imaging, this control mechanism usually involves holding the probe at a preset vertical separation distance between the tip and surface. As the probe scans over the surface and interacts with the sample, the microcantilever deflects in response to some desired contrast

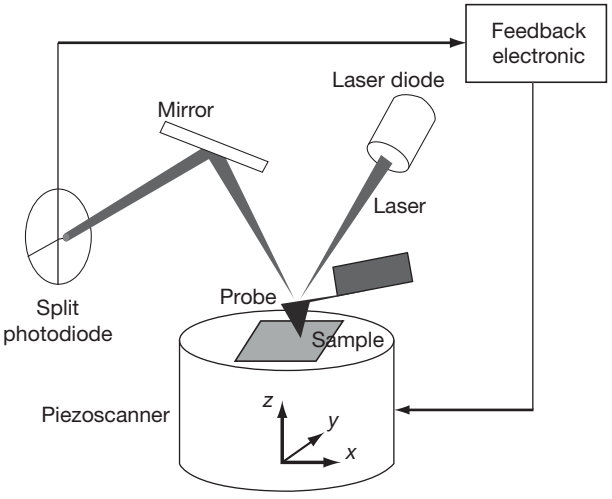

Figure 1 Schematic of the basic atomic force microscope configuration.

mechanism. The tip–sample interaction is commonly monitored by a laser beam targeted to the back of the cantilever. The beam is reflected toward a multisegment photodetector, configuring an optical lever which amplifies the sub-nanometer-level cantilever deflections. This interaction between the probe and sample is measured at each scanning point of a two-dimensional (2D) (X,Y) matrix, and when coupled with the recorded interaction forms a 3D reconstruction of the sample. In many designs, an optical microscope is coupled with the AFM to locate the position of the cantilever and to simultaneously acquire an optical image of the sample. Of course, some variations to this basic setup exist. For example, in some cases, the piezoscanner may directly raster the probe so that an optical system can be included in the setup. There are a multitude of variations and combinations of these systems, and the reader is encouraged to consult the literature for specific designs of interest.

The scanning probe is in large part the central component of the AFM, and serves as the method by which the various contrast mechanisms are achieved. The standard topographic imaging AFM probe consists of a sharp tip attached at the end of a flexible cantilever. The shape and sharpness of the tip are important in the ultimate resolution of the image obtained. The most common cantilevers are fabricated by photolithographic processes, using standard semiconductor materials such as Si, SiO_2, or Si_3N_4. The use of carbon nanotubes as ultrafine AFM probes represents a breakthrough in terms of resolution and accuracy.[37,38] Carbon nanotube probes, possessing a high aspect ratio and ultrasharpness, reduce the artifacts associated with imaging surface features.[39] Both standard semiconductor-based probes and carbon nanotube probes can be chemically functionalized, and nanotubes are sometimes regarded as important probes for biological applications of the AFM, particularly for the study of structural biology. However, a limitation of the ultrasharp tip is that the high pressures produced may damage delicate biological samples. Colloidal probes have been used for force and mechanical property measurements after attaching a sphere of known size to the end of the cantilever.[40] These spherical particles have a well-defined radius, can be glass, polymer, or other materials, and are often easy to modify with chemical functional groups or biomolecules. As a result, colloidal probes are often used to directly measure surface–surface interaction forces, colloidal interactions on the single particle–particle level, cellular mechanics, and adhesion forces under a variety of conditions.[40–43] AFM probes can be conductive, magnetic, or wear resistant, depending on the operation mode and the specific properties that one wishes to measure.

The appropriate choice of cantilever and probe is dependent on the imaging mode and the characteristics of surface features of interest. The stiffness of the cantilever should be as low as possible when the AFM is operated in contact mode to avoid damage to the sample, whereas in dynamic imaging modes, the higher spring constant values of the cantilevers may help reduce noise and instabilities. Commercially available silicon nitride and silicon probes may be satisfactory for many applications using contact and dynamic imaging modes, respectively. Another important criterion for choosing a probe is minimization or avoidance of the most common artifacts in imaging generated from the tip geometry, as illustrated in Figure 2.[44–47]

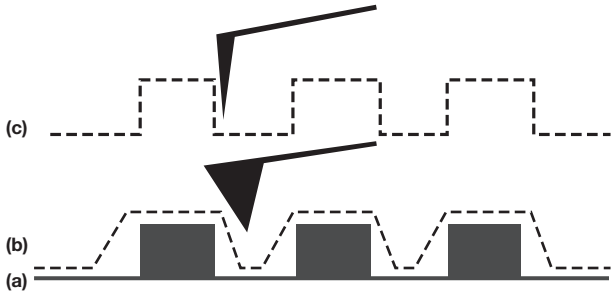

Figure 2 Artifacts can arise from atomic force microscope imaging as a result of the tip geometry. (a) The actual topography, (b) the image produced by a typical pyramidal probe showing an enlargement artifact, and (c) the surface as measured by an ultrasharp, high aspect ratio probe showing less enlargement.

The spring constant of the cantilever represents yet another important parameter of the AFM probe that should be considered, particularly for making measurements of interaction forces. Typical spring constants for commercial AFM cantilevers range from 0.001 to 100 $N\,m^{-1}$, enabling force sensitivity down to the piconewton level. Although manufacturers provide the nominal spring constants, actual spring constants are known to vary over wide ranges, even from the same batch of probes, with cantilevers fabricated from the same wafer varying by 10%. Fortunately, this issue was recognized early and techniques have been developed to directly measure the individual cantilever spring constants. These techniques can be grouped into three general categories: (1) dimensional models where theoretical models or semiempirical formulas are used to calculate the cantilever spring constants on the basis of their dimensions, geometry, and material properties[48,49]; (2) static deflection measurements where the spring constant is determined by loading the cantilever with a known force[50,51]; and (3) dynamic deflection measurements where the resonance behavior of the cantilever is related back to its spring constant.[52–55] Other methods may sometimes be used in specific situations; for example, the hydrodynamic drag force can be used to determine the spring constant of the colloidal probe cantilever.[56]

3.302.2.2. Contact Mode Imaging

As mentioned, a wide range of AFM operating modes can be used to examine different structure–property relationships under ambient or aqueous conditions. The most common (and original) mode of AFM imaging is termed contact mode. In this mode, the probe is brought into gentle contact with the sample surface so that the force between the probe and sample is repulsive. As the scanner gently traces the tip across the sample, the contact force causes the cantilever to deflect. Often, a Z-feedback loop is used to maintain a constant cantilever deflection, although for some high-resolution, small-area imaging applications, one might turn off this feedback loop. Images are created by recording the piezovertical position required to keep the force constant against the laser probe position if the feedback loop is on, or simply monitoring the cantilever deflection if the loop is off. Contact mode can be operated under aqueous environments, which remove the capillary forces seen in

ambient environments as a result of thin water films on probe and sample, thereby reducing the interaction forces and potentially minimizing tip-induced damage.[57]

Contact mode imaging is generally suitable for samples that are flat and rather rigid, for example, fixed cells, hard inorganic surfaces, metals, and common polymeric biomaterials such as polyethylene, PTFE, silicone, and polyurethane elastomers.[58] However, the shear forces applied to the sample during contact mode imaging can be sufficient to disrupt a delicate sample or sweep an adsorbed molecule to the periphery of the imaging area.[59,60] As a result, contact mode is often deemed unsuitable for reliable imaging of isolated proteins, live cell surfaces, or low modulus biomaterials under aqueous conditions.

When the probe scans the surface in contact mode, a torsion or twist of the cantilever arises from the lateral forces applied by the sample onto the probe, resulting in a deviation in the signal striking the two lateral segments of the photodiode. This operation mode is usually referred to as lateral force mode or lateral force microscopy (LFM),[61,62] and the torsion of the cantilever scanning across the surface yields information arising primarily from changes in surface friction (chemistry) and changes in surface slope (topography). To separate these effects, LFM and AFM images are often collected simultaneously. LFM allows identification of heterogeneities in materials, thin films, or monolayers at high spatial resolution, and illustrates the frictional properties of polymers,[63–65] although quantification of friction forces can be difficult. The use of a chemically modified probe to measure the difference between areas of a surface having distinct chemical properties is also referred to as chemical force microscopy.[66] This technique has been shown to be useful to map the chemical properties and even the different compositions of the surfaces of block copolymers.[67–69]

3.302.2.3. Dynamic Imaging Modes

3.302.2.3.1. Intermittent-contact imaging

As mentioned previously, contact mode imaging can result in the development of lateral forces associated with the raster scanning of the probe against the sample. To overcome this problem, a number of dynamic imaging modes have been developed.[70] One of the most commonly used of these is the intermittent-contact mode. A second piezoelement is used to oscillate the cantilever near its resonance frequency while the oscillation amplitude is monitored. The deviation of the magnitude of oscillation is measured as the cantilever approaches and contacts the surface. The cantilever's oscillation amplitude changes with sample surface topography, and a topography image is obtained by recording the feedback signal necessary to keep the amplitude of oscillation at a constant value. This intermittent-contact imaging is the most common dynamic mode, available on nearly all commercial instruments, and maps topography by lightly touching the surface with an oscillating probe tip. In this mode, the tip experiences both attractive and repulsive forces with the sample during oscillation,[71,72] and as the tip is only intermittently in contact with the sample, the lateral forces are greatly reduced.

Intermittent-contact mode can be performed in either ambient or aqueous conditions and has proved to be the most successful mode for high-resolution imaging of soft or delicate samples such as proteins and cell surfaces under aqueous conditions.[73–76] A representative example of proteins studied by intermittent-contact mode AFM on a surface is fibrinogen adsorption.[77] Fibrinogen is the third most abundant protein plasma in blood and plays a prominent role in platelet adhesion and development of surface-induced thrombosis. **Figure 3** shows images of fibrinogen on a hydrophobic graphite surface and hydrophilic mica surface, with both images obtained under phosphate buffer. The 3D trinodular structure of fibrinogen is clearly visible and the dimensions of adsorbed molecules can be measured.[73] The conformational structure of protein adsorbed on the material surface is known to be influenced by substrate surface property but also changed with adsorption time.[78,79] In the case of fibrinogen shown here, the operation of intermittent-contact mode in an aqueous environment provided the possibility to directly visualize the time-dependent conformational changes of this protein by measuring changes in the heights of the individual domains of the molecule.[73]

3.302.2.3.2. Force modulation and phase imaging

3.302.2.3.2.1. Force modulation

Force modulation and phase imaging comprise the second type of dynamic force microscopy. Force modulation imaging is a variation of the contact mode AFM technique, which can be used to identify and map differences in surface stiffness or elasticity.[80] The probe in force modulation mode scans in

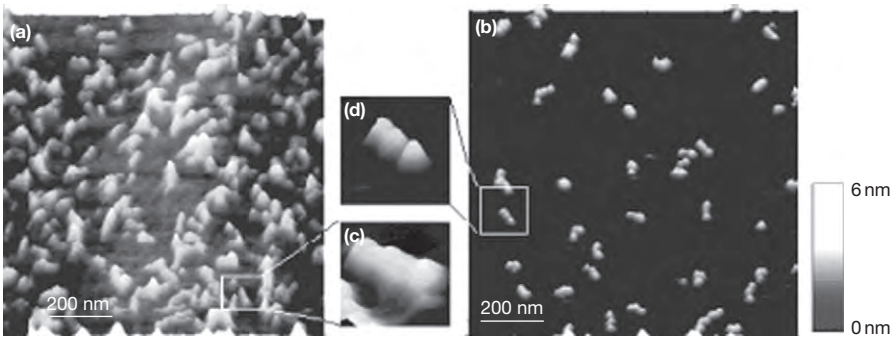

Figure 3 Molecular-scale atomic force microscope images of fibrinogen on (a) hydrophobic HOPG and (b) hydrophilic mica surfaces. (c, d) Higher magnification images of individual fibrinogen molecules illustrating the trinodular structure. The *z*-scale for (a) and (b) is 6 nm and 3 nm for (c) and (d). contact with the surface, but has a superimposed secondary vertical sinusoidal oscillation (modulation) that is significantly faster than raster scan. The force applied on the sample or cantilever is modulated so that the force is equal to that in contact mode. The variation (RMS) in cantilever deflection amplitude at the frequency of modulation can be used to obtain information on the mechanical properties of the sample. Topographical information is collected simultaneously with force modulation data. Force modulation has been used to characterize mixed composite and polymer blends as well as phase-separated block copolymers.[81,82]

3.302.2.3.2.2. Phase imaging

Phase imaging is a secondary imaging mode derived from the intermittent-contact mode that goes beyond the topographical data to characterize variations in composition, adhesion, friction, viscoelasticity, and other properties for a multitude of sample types.[70] Phase imaging monitors the phase lag between the periodic signal that drives the cantilever near resonance and the resulting oscillation of the cantilever. Changes in this phase lag are indicative of changes in the properties of the sample surface. Phase imaging has been a powerful tool in surface characterization of biomaterials, as the phase image is able to detect subtle chemical and mechanical variations in materials and can reveal more detailed surface properties than topography alone.[83,84]

An important application of phase imaging in biomaterials science is differentiating between the component phases of composite materials, including biomaterial stalwarts such as polyurethane (PU) copolymers.[85] PU materials are segmented block copolymers constructed from a mixture of 'soft' and 'hard' segments. These materials are frequently used in a variety of blood-contacting medical devices because of their desirable mechanical properties, fatigue resistance, and acceptable hemocompatibility for many applications, including circulatory support devices, vascular grafts, and heart valves.[86] **Figure 4** illustrates topographic and phase images of a PU material in an ambient environment.[87] The PU film surface appears relatively smooth across the $500 \times 500\text{-nm}^2$ scan area, with only a few occasional topographic features observed, whereas the distribution of the microphase structures can be clearly visualized from the phase image. In this image, high phase angle (light colors) represents the 'harder' regions, and these hard microphases appear as spherical or cylindrical features that are dispersed within a soft segment matrix. The lateral dimensions of the hard domains are 15–50 nm, similar in dimension to many plasma proteins such as fibrinogen.

Because phase imaging can be operated in physiological conditions, the technique provides an excellent opportunity for detection of dynamic reorientation in polymers during hydration. By collecting a series of sequential *in situ* phase images of a PU film following hydration in phosphate-buffered saline, hard domains were observed undergoing reorientation and enrichment at the surface.[88] It should be noted that the phase detection is affected by the force applied by the scanning probe to the polymer surface, which is presented by the ratio of set point amplitude and free amplitude of oscillation ($r_{sp} = A/A_0$).[89,90] **Figure 5** shows phase images of a PU material under increasing tapping forces.[87] At a very light tapping force (**Figure 5(a)** and **5(b)**; $r_{sp} = 0.95$ and 0.90, respectively), few phases are observed, suggesting the presence of a soft segment overlayer on the surface. As the imaging force increases (**Figure 5(c)** and **5(d)**; $r_{sp} = 0.85$ and 0.75, respectively), randomly oriented cylindrical and spherical structures are observed, indicating that hard domains are being detected in the subsurface region. This increasing tapping force can be used to sequentially probe deeper into a sample and to examine vertical sections.

AFM topographic imaging of adsorbed proteins is generally limited to smooth model substrates such as mica, graphite, silicon, and gold and polished metals. The inherent roughness of traditional biomaterial surfaces such as polymers has largely prevented observation of adsorbed proteins in topographic images. Phase imaging provides information on differences

in material properties of the surface, and offers the possibility to distinguish the adsorbed protein molecules from the underlying polymer surface. Holland and Marchant[91] reported imaging of fibrinogen molecules adsorbed on National Heart Lung and Blood Institute reference materials polydimethylsiloxane (PDMS) and low-density polyethylene (PE) *in situ* using phase imaging AFM. However, it was shown to be difficult to observe the individual proteins adsorbed on the microphase-separated polyurethane biomaterials because of the strong phase signal from hard and soft domains, and the comparable dimensions of fibrinogen and hard domains.

An alternative approach to detect protein adsorption on rough materials is to add a label to the proteins that can be detected by the AFM probe. For example, nanogold particles with well-defined dimensions are suitable for labeling proteins and are easily detected by AFM phase imaging. Figure 6 illustrates the topography and phase images of a PU film following adsorption of bovine serum albumin (BSA) conjugated with 6-nm nanogold particles. The protein-conjugated nanogold particles are detected in the phase image, allowing quantitative measurements of the labeled proteins to the different phases. The data showed that more proteins were adsorbed to soft regions of polymer, suggesting that the macrophase separation properties of polymer appear to be linked to local surface chemical properties (hard and soft domains) and proteins preferentially adsorb to soft segments. Similar gold label techniques were used by Eppell to monitor ligand binding to platelets using multiple microscopy techniques.[92]

3.302.2.3.3. Noncontact imaging modes

The final mode of dynamic microscopy to be discussed is noncontact AFM. Similar to the intermittent-contact imaging discussed previously, in noncontact imaging, the cantilever is oscillated near its resonance frequency, but in noncontact mode, the probe does not contact the sample.[93] As the probe tip approaches the sample, force gradients arising from van der Waals, electrostatic, or magnetic forces lead to shifts in the cantilever resonance frequency, which can be measured using either frequency or amplitude detection techniques.[94,95] The applications of noncontact AFM include electric force microscopy (EFM) and magnetic force microscopy (MFM). EFM provides the possibility for investigating the surface electrical characteristics, including localized charge distribution on surfaces and biomolecules,[96] surface potential, and doping profiles. MFM measures the gradient of the magnetic field of the material surface, and is mainly applied in magnetic data storage or micro-/nanomagnetic materials.

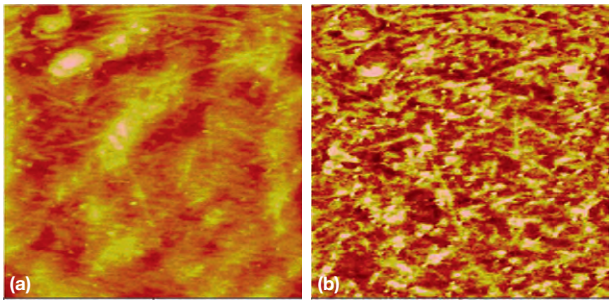

Figure 6 Atomic force microscope images of bovine serum albumin conjugated with 6-nm nanogold labels, adsorbed on polyurethane and imaged under PBS buffer. Gold beads are seen in both height (a) and (b) phase images. Quantification reveals a more than twofold increase in number of labeled proteins per unit area on the soft segment regions compared to the hard segment. 3.302.3. Force–Distance Measurement and Force Mapping

3.302.3.1. Force–Distance Curve

The interests of the biophysical and biomaterial communities in the potential of the AFM did not arise solely from the high-resolution imaging capabilities of this technique, but also because AFM offers the unique possibility of obtaining quantitative information on intra- and intermolecular forces at the single molecule scale.[8] This mode of operation is generally termed a force–distance measurement, and detailed interpretation and application can be found in the literature.[97,98] Briefly, the force curve produced by these measures shows the cantilever deflection measured as a function of the relative probe motion as it approaches and then retracts, or separates, from the surface. An example of a typical force–distance curve is shown in Figure 7. Starting from the right (position A), the probe is far from the sample and no interaction is detected. As the probe approaches the surface (moving toward the left side of the plot), long-range forces such as electrostatic and hydrophobic forces can be detected. When the probe reaches position B, the attractive force increases because of van der Waals forces, until the force gradient becomes greater than the spring constant of the cantilever and the probe jumps to contact with the sample (position C) with the cantilever bending downward (negative, or attractive force). After contact, the probe begins to compress the sample, and as the probe moves farther, an upward deflection of the cantilever (positive, or repulsive force) is measured. This contact region of the force curve can be used to measure the elastic properties of the sample. Eventually, the sample and probe begin separating. The cantilever deflection will move largely down the same path, although some hysteresis in the piezoposition might be expected.

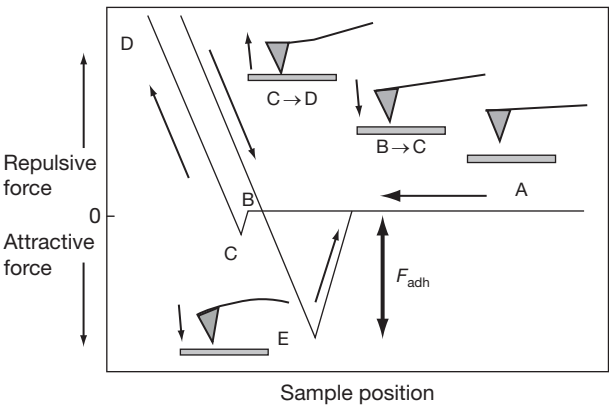

Figure 7 Schematic of a typical force–distance curve. The images illustrate typical cantilever deflections in each region of the curve.

Adhesion between the probe and the sample leads to an additional deflection of the cantilever downward until the adhesion force is overcome by the cantilever restoration force, and the probe separates from the surface. This additional downward deflection of the cantilever is the value that is most often measured as the adhesion force or debonding force. The AFM typically measures the cantilever deflection as a function of the z-piezodisplacement, which differs from the actual tip–sample distance. However, by subtracting the cantilever deflection from the z-piezomovement, the actual tip–sample displacement can be calculated (Figure 8).

A deflection–position force can be converted to a force–distance curve force via Hooke's law: $F = -kd$, where k is the cantilever spring constant and d is the deflection of the cantilever during imaging; thus, quantitative information on the interaction between an AFM probe and a surface can be extracted from force curves. Further, the AFM probe can be modified with specific functionalities, including chemical groups, ligands, proteins, and other biomolecules. This capacity enables the measurement of fundamental interactions between biological molecules such as proteins and a biomaterial surface,[99,100] and assesses ligand and receptor intermolecular bond strengths for cells on materials, for example.[101] Generally, long-range and short-range forces and the elasticity of the sample can be obtained from the approach portion of the curve, and intermolecular interactions such as adhesion force or debonding force measured from the retracting portion.

A variety of parameters can be obtained from the retracting portion of the force curve (Figure 8). The adhesion force (F_{adh}) is usually defined as the force at maximum cantilever deflection during separation from the surface. A pull-off or rupture length is the distance that the tip moves from the zero interaction force during separation to the position where the probe has separated and returned to zero deflection. The separation energy, E_s, is obtained by integration of the force holding the probe to the surface and the distance moved by the cantilever during probe separation from the surface. Each force at each point, $F_{s,i}$, is calculated for a scan split into n intervals, whereas the distance moved by the cantilever in each interval is $l = L/n$, where L is the total scanning distance between the start of approach and subsequent reversal. The total separation energy is thus calculated as the total area in the attraction-force region (shadow area in Figure 8) in a retracting curve as

$$E_s = \sum_{i=1}^{a} lF_{s,i} = -\sum_{i=1}^{a} lkd_{d,i}$$

3.302.3.2. Force Mapping

Maps of the distribution of intra- and intermolecular forces can be collected over the sample scanning area. Individual force curves are obtained at unique x–y positions on the sample, so that interaction forces can be measured at each location. This array of force curves forms a 3D force map, illustrating the distribution of any particular interaction of interest. For example, most simply, an array of adhesion forces extracted from force–distance curves would produce an adhesion map of the sample. Through selective modification of the AFM probe, this adhesion map can be tailored to isolate a particular interaction, thereby showing the distribution of an otherwise unknown entity. Figure 9 illustrates a schematic representation of adhesion mapping of proteins in a multicomponent protein layer on a material surface. In this case, the probe is modified with an antibody of interest, and interactions between the antibody-modified probe and the substrate demonstrate the presence of the desired antigen.

3.302.4. Nanoindentation and Measurement of Near-Surface Nanomechanical Properties of Polymeric Biomaterials

Information on the elasticity and other mechanical properties of a biomaterial surface or biological sample can be obtained from the approach, or compression, region of the force curve. Once the probe comes into contact with the surface, continued compression will lead to sample indentation. The indentation depth (h) can be calculated from the z-piezomovement (Z_{pos}) and the cantilever deflection (Z_{defl}) as

$$h = Z_{pos} - Z_{defl}$$

By measuring the amount of indentation at a given force, the local elasticity of the sample in terms of the Young's modulus

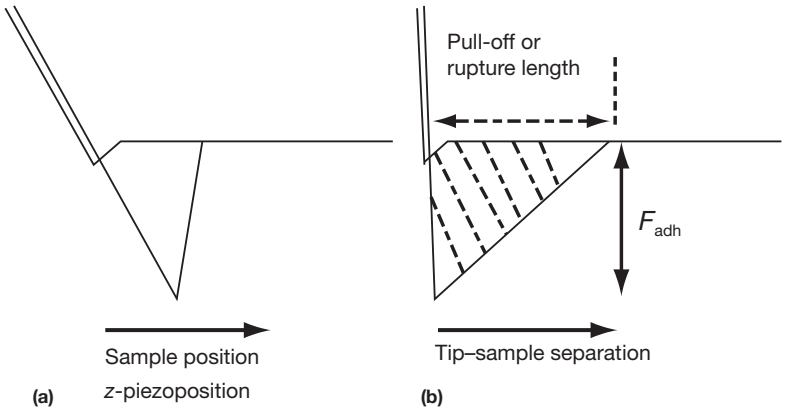

Figure 8 Conversion of a force curve (a) as a function of z-piezomovement and (b) as a function of probe–sample separation. The shaded area is used for calculation of separation energy.

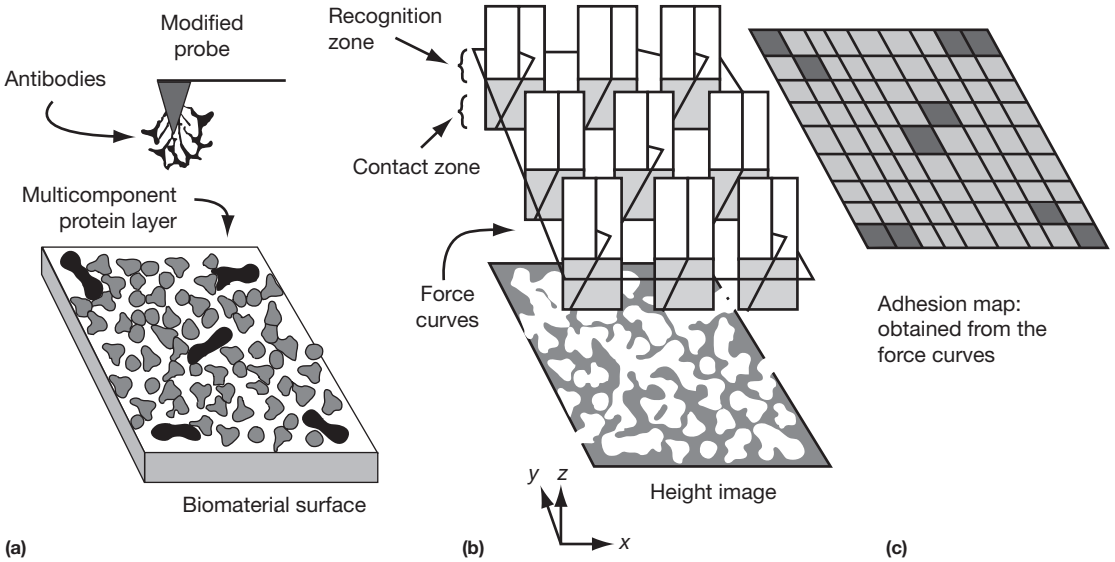

Figure 9 Schematic representation of adhesion imaging. (a) A functionalized probe scanning a multicomponent surface, (b) a topography image and array of force curves are obtained across the surface, and (c) an adhesion map is generated by calculating the strength of adhesion from individual force curves.

can be obtained from various classic models, including the Hertzian, Johnson, Kendall, Roberts, and Sneddon's.[102,103] Derivation of Young's modulus from the Hertzian model gives

$$E = \frac{3}{4}(1-\upsilon^2)\frac{k}{R^{1/2}}\frac{Z_{\text{defl}}}{h^{3/2}}$$

where v is Poisson's ratio, k is the spring constant of cantilever, and R is the tip radius, and the JKR model gives:

$$E = \frac{9}{4}(1-\upsilon^2)Rk\Delta\left[\frac{P_1}{3Rh}\right]^{3/2}$$

where $P_1 = (3P_2 - 1)[1/9(P_2+1)]^{1/3}$, $P_2 = (Z_{\text{defl}}/\Delta + 1)^{1/2}$, and Δ is the cantilever deflection at the point where the probe loses contact with the surface.

Sneddon's model accounts for the particular geometry of the indenter:

$$E = \frac{\sqrt{\pi}}{2\sqrt{2}\beta\tan\alpha}(1-\upsilon^2)k\frac{\Delta Z_{\text{defl},i,i-1}}{h\Delta h_{i,i-1}}\ (\text{pyramidal indenter shape})$$

$$E = \frac{1}{2\sqrt{R}\beta}(1-\upsilon^2)k\frac{\Delta Z_{\text{defl},i,i-1}}{\sqrt{h}\Delta h_{i,i-1}}\ (\text{parabolic indenter shape})$$

where $\beta = A_{\text{cros}}/A$, A_{cros} is the cross-sectional area of the indenter at the indentation depth h from the apex, β is equal to 2 for elastic deformation of a sphere and $(\pi/2)^2$ for pyramidal and conic shapes, α is half of the pyramidal angle of the indentor, and i, $i-1$ refers to the adjacent indentor displacements. Chizhik *et al.*[102] tested the elasticity of polyisoprene rubber, polyurethane, polystyrene, and polyvinylchloride by these models, and found that Sneddon's and Hertzian elastic models gave consistent results at indentation depths up to 200 nm, and were close to the JKR solution. The Hertzian model is relatively simple and does not require additional assumptions or measurements of interfacial energies as needed for the JKR theory. This model is often selected for calculation of elasticity of polymeric material[104] and cell surfaces.[105]

Figure 10 illustrates representative indentation and modulus curves for one region of a PDMS homopolymer surface as well as a segmented polyurethane material. In this example, the modulus is being measured at various indentation depths by looking at the local deformations of the cantilever as the probe compresses the surface. The PDMS is a uniform, single component polymer and used as a reference sample here. The data shows a uniform modulus down to approximately 50 nm indentation depth, and that the indentation curve increases with applied force in an approximately linear manner. The polyurethane material exhibits marked differences in the indentation depth and modulus profiles compared to the PDMS (Figure 10(b)). As the polyurethane copolymer contains both soft and hard phases, a nonuniform indentation depth curve is expected, and measurements of the indentation depth and modulus curves confirm a soft segment overlayer on the material surface, with the thickness of the soft overlayer being about 5–10 nm in this case. Once the soft segment overlayer is penetrated, hard segments with a high modulus are encountered in the sample.

As discussed previously, the AFM can be used to acquire an array of force–distance curves across the surface during scanning. Each force curve can be extracted and analyzed to produce a modulus profile as a function of indentation depth, as shown in Figure 10. By combining this depth sampling with an array of force curves across a small area, a modulus map for different subsurface depths was created, as shown in Figure 11. This figure illustrates the material modulus across a hydrated (1 h) polyurethane material at indentation depths of 3, 5, 7, 9, and 11 nm. The warmer colors in the maps represent higher modulus ('hard' segment regions) while the cooler colors represent lower modulus ('soft' regions). These modulus maps demonstrate the presence of an outer soft segment-rich layer for the 1-h hydrated sample, and as the sampling depth increases, more hard regions (higher modulus) are detected. Through measurements of polyurethane materials with

different hydration times, dynamic phase restructuring can be observed as changes in hard domain distribution.

3.302.5. Probing Molecular Interaction and Recognition Sites on Biosurfaces

The retraction, or separation, portion of force–distance curves allows measurement of a wide variety of interactions between a probe and a surface at or near the single molecule level. This ability enables measurements of the interactions of proteins and surfaces if the probe is appropriately modified with proteins of interest. Using this tool, one can explore the adhesion (adsorption) properties of proteins on material surfaces, or by using a probe modified with a specific functionality such as an antibody or a ligand, AFM allows detection or recognition of proteins and binding sites on biosurfaces (e.g., biomaterials, microbial cells). These techniques can be useful for studying the conformation, orientation, and activity of adsorbed proteins on surfaces.

3.302.5.1. Modification of AFM Probes

As AFM probes are generally fabricated from silicon-based semiconductor materials, there are a number of standard approaches available for probe–surface modification.[106,107] Chemically functionalized tips can be obtained by modifying their surface self-assembled monolayers (SAMs) terminated by specific functional groups. The SAMs can be formed on standard silicon and silicon nitride probes directly through surface modification with silane-based monolayers, or alternatively probes can be coated with a thin layer of gold so that alkanethiol-based systems can be used. These modified probes may be used to directly map surface chemical/physical properties, such as mapping the hydrophobicity of a surface,[108] or used as the substrates for subsequent biological modification.

Functionalizing of probes with proteins or other relevant biomolecules is an essential step for molecular interaction measurements.[109] The first functionalized biological AFM probe was used to measure the interactions between biotin and avidin.[110] The silicon nitride probe was incubated with biotinylated BSA solution overnight, and then the adsorbed biotinylated BSA was subsequently exposed to avidin. A second approach to preparing biological probes involves the use of the chemically modified probes. Proteins or macromolecules having thiol groups can be directly immobilized on gold surfaces, or biomolecules can be attached through standard coupling chemistries using, for example, carbodiimides and *N*-hydroxysuccinimide (NHS).[111] Amine functionalization[112] of probes allows for simple coupling approaches such as glutaraldehyde coupling, which has been

shown to allow proteins sufficient mobility and flexibility to rotate and orient themselves for binding and identification.[113]

Cells can be directly placed onto AFM probes for measuring interactions with surfaces. Bacterial cells have been immobilized using glutaraldehyde treatment to create covalent cross-links between the cells and the probe,[114] by attaching single cells using a small amount of glue,[115] or by physically adsorbing onto poly-L-lysine-coated tips.[116] Using any of these methods, the cells can be used to make measurements of interaction forces with surfaces, other cells, or immobilized proteins.

3.302.5.2. Measuring Adhesion Forces of Protein to Biomaterial Surfaces

Protein-modified AFM probes can be used to directly measure one of the most fundamental interactions in biomaterials science, the interaction forces between proteins and surfaces. Maps of these interactions can be used to determine the distribution of protein adsorption properties across a heterogeneous biomaterial surface, or to identify the location of protein adsorption/activity using biorecognition techniques. By combining the various techniques discussed so far in this chapter, it becomes possible to actually make direct measurements of the structure–function relationships in biomaterials. As an example, the compression region of the force curve provides information on material deformability or modulus, and at the same time, the separation region of the curve contains information on the adhesion of the probe with the surface at the same location. By combining techniques, the relationship between material microstructures (e.g., microphase structure in PU in this case) and protein interactions (the adhesion force) is obtained. Figure 12 displays the adhesion force map for an albumin-modified AFM probe, and the corresponding modulus map obtained simultaneously, for a hydrated PU film. In this figure, warm colors represent larger adhesion forces while cool colors indicate the smaller adhesion forces. The modulus map was generated from the compression region of the same force curves, and shows a distribution of hard and soft domains in the material. Strong correlations between the hard segment domains and low adhesion forces were clearly observed, as denoted by the white lines showing the overlay of the hard domain regions with the low adhesion force areas. The results provide direct evidence of decreased protein adhesion forces to the hard segment regions in PU, as one would expect on the basis of known material properties.

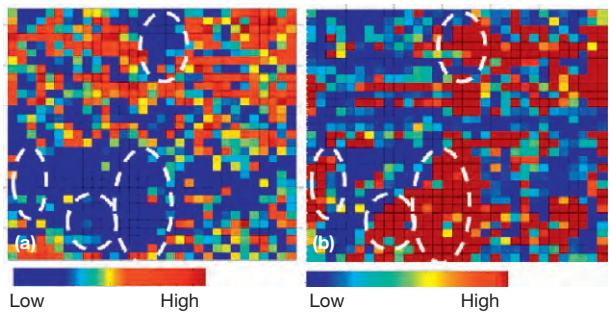

Figure 12 (a) Adhesion map and (b) modulus map of a polyurethane surface as measured by a bovine serum albumin-modified probe. Size: $500 \times 500\ nm^2$. Reprinted from Xu, L. C.; Siedlecki, C. A. *J. Biomed. Mater. Res. A* **2010**, *92*(1): 126–136.

3.302.5.3. Molecular Recognition of Proteins in Dual Component Protein Film

A critical step in using AFM to study protein adsorption at the molecular scale is the ability to detect specific proteins when numerous proteins simultaneously adsorb to the same material surface. Although molecular recognition of a specific protein might be feasible through topography alone on an ideally smooth surface, clinically used biomaterials have much rougher topographies, and it is difficult to detect proteins on these surfaces through standard imaging techniques, let alone identify different proteins.

Following the pioneering work on the biotin–avidin interaction, a variety of ligand–receptor forces have been measured at the single molecule level, including the forces between antibody and antigen for recognition purposes.[117] The group of Hinterdorfer and colleagues has led the way on this type of work, although their main emphasis has not been in the field of biomaterials. Antibodies are attached to probes using any of the methods described earlier, generating an AFM-based immunoassay with high spatial resolution, allowing for examination of multicomponent protein films on biomaterial surfaces without the tedious sample preparation necessary for

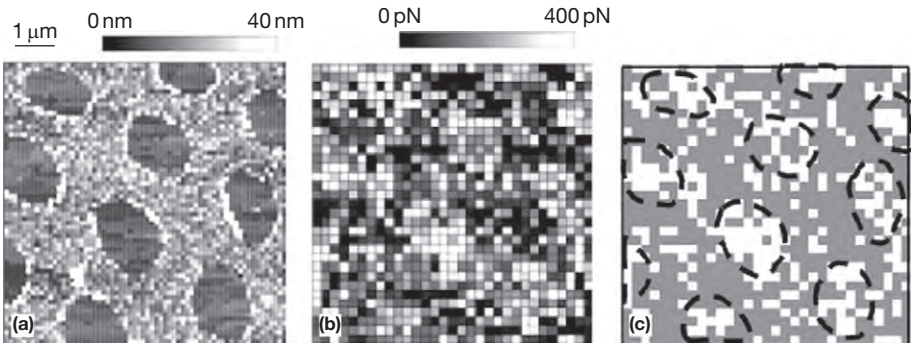

Figure 13 Images of microcontact printing patterned bovine serum albumin on mica after backfilling with fibrinogen. (a) Topographic image of the pattern, (b) adhesion map showing the interaction strength, and (c) binary recognition map showing fibrinogen recognition as white pixels and nonspecific interactions with bovine serum albumin as black pixels. Reprinted from Agnihotri, A.; Siedlecki, C. A. *Ultramicroscopy* **2005**, *102*(4), 257–268.

other techniques such as electron microscopy. Figure 13 illustrates an example of this work using proteins patterned into a known distribution. Albumin was patterned by microcontact printing on a mica surface, and fibrinogen was then allowed to adsorb into the nonpatterned areas (seen here as holes). An AFM probe coupled with a polyclonal antibody (pAb) against human fibrinogen was used to simultaneously measure both topography and interaction forces across the substrate surface. The adhesive force measured at each point is used to generate an adhesion map (Figure 13(b)) where the lighter regions showing higher adhesive forces correspond well with the holes in the height image, indicating the presence of fibrinogen in these regions. Control measurements were used to differentiate the nonspecific interaction of BSA and the antibody-modified probes from the specific fibrinogen–probe interactions, with that data being used to generate a binary recognition image showing the distribution of specific proteins (Figure 13(c)). This technique has subsequently been used to measure the distribution of fibrinogen on a series of PU biomaterials having different soft chemistry and hard segment contents.[87]

3.302.5.4. Measuring the Functional Activity of Adsorbed Proteins

The conformational structures and bioactivity of plasma proteins on biomaterial surfaces are important measurements for understanding the mechanism of biologic response to implants. While more traditional analytical techniques have been used to study the conformation, structure, and activity of proteins, these are generally not capable of providing the detailed level of information on proteins on surfaces under aqueous conditions, which the AFM can. Alternative approaches have used monoclonal antibodies (mAb) to detect the availability of specific functional regions in proteins.[78,118,119]

An example of the utility of combining probe microscopy with monoclonal identification techniques can be found in the study of fibrinogen. Fibrinogen is a central molecule in blood coagulation and thrombosis. It possesses three pairs of potential platelet-binding peptide sequences: two RGD sequences that are found in each of the Aα chains and a dodecapeptide sequence in each of the γ chains. There is ample evidence that the γ chain dodecapeptide sequence is the primary ligand for platelet binding to adsorbed fibrinogen. A commercially available mAb that recognizes the last 20 amino acids of the γ chain of fibrinogen (γ392–411) was coupled to an AFM probe, and interactions between this antibody-modified probe and fibrinogen were measured for a variety of substrates. Figure 14(a) illustrates the probability of the mAb against fibrinogen γ392–411 encountering the antigen in the platelet-binding region during any individual force measurement plotted as a function of fibrinogen residence time following exposure to a hydrophilic muscovite mica surface. The maximum likelihood of recognition occurred near 45 min, and decreased with increasing adsorption times. Time-dependent macroscale platelet adhesion measurements on the same muscovite mica substrates were carried out under similar experimental conditions.[120] Results illustrated in Figure 14(b) show that platelet adhesion similarly reaches a peak at ~45 min of fibrinogen residence time, correlating well with the molecular-scale AFM results and demonstrating the use of probe microscopy to measure protein function in single molecules.

3.302.6. Limitations and Perspectives

Despite the great potential of AFM in biomaterial research, there is still much to be improved for the AFM to be routinely used in applications beyond that of a characterization tool for surface topography. The outcome of AFM studies is dependent on several key factors, including the nature and quality of sample, the quality of probe used and methods for modifying/characterizing probe modifications, careful control of experimental conditions, the accuracy of data collection and robust methods for data interpretation, and attention to potential

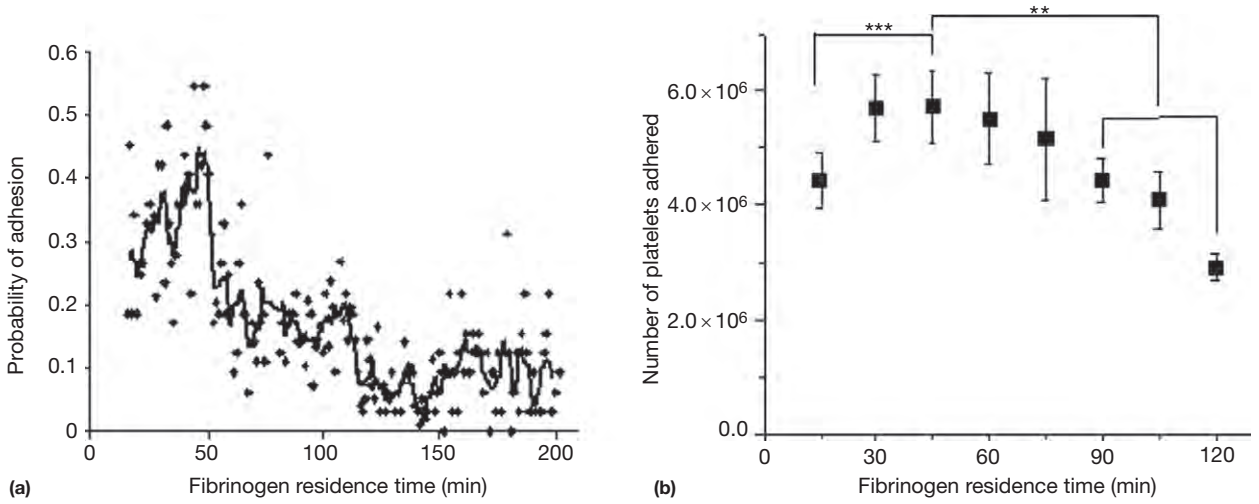

Figure 14 (a) Probability of interaction between a mAb against γ chain 392–411 and its antigen on fibrinogen measured by atomic force microscope. The solid line, the average of five points, is included for visualization purposes. (b) Platelet adhesion data from multiple experiments ($n \geq 6$ for each time point) showing changes in platelet adhesion as a function of fibrinogen residence time on mica substrates. Reprinted from Soman, P.; Rice, Z.; *et al*. *Langmuir* **2008**, *24*(16), 8801–8806.

artifact. Samples generally must be immobilized for scanning whether the sample is in an air or an aqueous environment. As a result, materials that are designed to minimize adsorption of proteins might not be suitable for AFM studies, a dichotomy in that these are the types of surfaces that are becoming increasingly important in biomaterials. While many studies of biomaterials are intended to understand how they influence biology, the immobilization of molecules either on the sample or on the probe may change the properties of these molecules in ways different from that in the biological environment. In force spectroscopy measurements, a modified probe may encounter the sample hundreds and even thousands of times, a situation vastly different from that found *in vivo* where it is usually an initial interaction that provides the impetus to biological response. Simple experimental factors such as probe loading force, loading rates, scanning rates, and contact time are all important parameters that affect the interaction forces and therefore may skew outcomes.[43,121] Experience is often necessary to understand how these factors affect the data obtained.

Although there are clearly important considerations to be kept in mind for all AFM work, the field has seen, and will continue to see, an increased use of novel, high-resolution AFM techniques for biomaterials science. Combinations of AFM with imaging and spectroscopic techniques[122,123] have greatly expanded the amount and types of data one can obtain simultaneously. AFM has become a routine surface characterization technique in many laboratories and research centers, and there has been a rapidly increasing use of AFM for characterization of the biologic responses to materials including cell–cell and cell–material interactions. With the development of micromachining and nanofabrication technologies, ultrasharp, ultrasensitive probes are being used more routinely, allowing more access to data that formerly required devoted facilities. As new developments in instrumentation and accessories continue to appear, it is also likely that the versatility of the AFM as a standard tool in biomaterials science will continue to progress.

3.303.1. Introduction

Researchers in the field of proteomics seek to apply unbiased methods to obtain a comprehensive understanding of complex mixtures of proteins. Traditional biochemical methods used to study proteins are well suited to address specific hypotheses but are biased by the use of specific antibodies or the labeling of single proteins. With traditional methods, high-quality information is gained about one protein at the expense of information about the multitude of other proteins in the sample. Unbiased methods instead seek to identify and quantify proteins that are exceptional under some set of experimental conditions, for example, proteins that adsorb well to a particular biomaterial. Identification of the observed proteins is an important goal of proteomics, which distinguishes the proteomics approach from the many methods that measure averaged properties of mixtures of adsorbed proteins, for example, ellipsometry, surface plasmon resonance, OWLS, quartz crystal microbalance, circular dichroism, attenuated total reflectance Fourier transform infrared spectroscopy (ATR-FTIR), etc. Proteomics typically combines electrophoresis, often two-dimensional (2D) electrophoresis, with mass spectrometry (see **Figure 1**). However, current technical limitations mean that proteomics approaches are far from comprehensive, and absolute quantification continues to be a major challenge. Methods continue to evolve, and it is likely that unbiased methods will eventually become the methods of choice to study proteins adsorbed to biomaterials.

3.303.2. Unbiased Analysis of Adsorbed Proteins by Polyacrylamide Gel Electrophoresis

In the field of biomaterials, several unbiased approaches were developed to study protein adsorption long before the field of proteomics emerged. In 1974, Lyman *et al*. eluted blood proteins from polyurethane, silastic, and Teflon FEP tubes exposed to blood in an *ex vivo* shunt model. Proteins were removed from the surfaces by incubation with 1% Triton X-100 for 2 days.[1] The proteins were concentrated and analyzed by alkaline polyacrylamide gel electrophoresis (PAGE). This type of PAGE leads to the identification of albumin, two α-globulin bands, two β-globulin, bands, and a γ-globulin band. The different surfaces had different amounts of albumin relative to the globulin bands. Surfaces with more intense albumin bands also showed decreased platelet adhesion, suggesting that surfaces that attract albumin have higher blood compatibility than those that attract the globulin proteins.

Limber and Mason subsequently examined proteins eluted from Cuprophane dialysis membranes that were coated with albumin or heparin and exposed to platelet poor plasma.[2] Proteins were eluted into flowing buffer, but continual desorption of adsorbed proteins was observed regardless of the length of the buffer wash. This may have been a result of the relative hydrophilicity of the substrates. A protocol was developed to elute proteins with a 250 ml buffer wash, then an elution with a 1% Triton X-100 solution to remove more tightly bound proteins, followed by another 1000 ml buffer wash and a

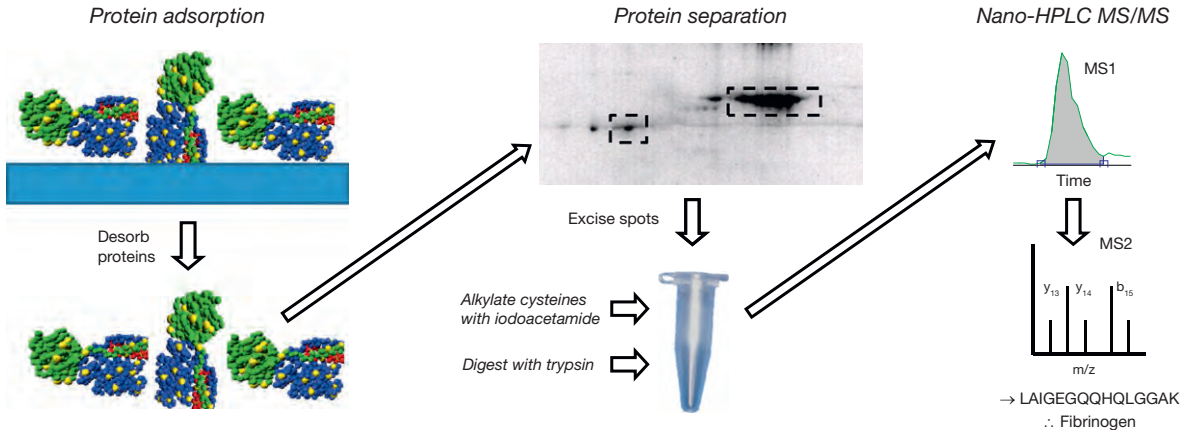

Figure 1 Workflow of a typical proteomics experiment to study protein adsorption. Many alternative protocols have also been developed, as described in the text.

second elution with Triton X-100. Up to seven protein bands could be observed by PAGE. However, only albumin and IgG could be definitively identified by immunoelectrophoresis, most likely due to the small amounts of protein present. The limited amounts of protein adsorbed to surfaces, typically about 200 ng cm^{-2} of surface area, and the difficulty in removing adsorbed proteins, still present challenges today.

Weathersby and coworkers enhanced these early techniques by radiolabeling proteins that had already adsorbed to surfaces.[3,4] Proteins were labeled with radioactive iodine and then eluted from the surfaces with 1% sodium dodecylsulfate (SDS) and sonication. The advantage of this method was the high sensitivity afforded by radiolabeling and the ability to detect noneluted protein. Proteins eluted from the surface were separated by SDS-PAGE. Identification of eluted proteins was based on molecular weights alone, as protein amounts were too low for Edman microsequencing. By comparing native and reduced gels, fibrinogen, IgG, and hemoglobin were identified based on the differences in peak locations following the disruption of disulfide bonds. However, six other major peaks could not be identified definitively. The relative change in the amount of each protein was measured on surfaces of different hydrophilicity (various copolymers of hydroxyethylmethacrylate (HEMA) and ethylmethacrylate (EMA). Some proteins were found to be more difficult to radioiodinate than others, complicating quantification of relative protein amounts. Further, a subsequent survey of a wide panel of surfactants revealed that a substantial fraction of adsorbed protein was not eluted.[5] Many of the proteomic methods in current use also rely on elution of adsorbed proteins prior to analysis, complicating interpretation of the results.

Unbiased methods may be used to demonstrate activation of the intrinsic coagulation cascade and the Vroman effect. Fibrinogen initially adsorbs to glass surfaces from plasma, but within a few minutes, can no longer be detected.[6] This process is known as the Vroman effect. Glass surfaces also promote the adsorption of Factor XII, which becomes more susceptible to enzymatic cleavage and activation upon adsorption.[7] Following enzymatic activation, Factor XIIa activates prekallikrein to form kallikrein. Kallikrein then may activate high molecular weight kininogen (HMWK). Activated HMWK binds to glass with high affinity and efficiently displaces fibrinogen.[8] To better understand this process, Brash and colleagues examined adsorbed human plasma proteins eluted from glass beads with 1 M Tris followed by 2% SDS and analysis by SDS-PAGE.[9] Most of the eluted proteins could not be definitively identified based on molecular weight alone. Immunoelectrophoresis demonstrated the presence of albumin, IgG, fibrinogen, and plasminogen, but the presence of other plasma proteins could not be confirmed. Bands consistent with intact fibrinogen were found in the 2% SDS wash, while bands consistent with plasmin-degraded fibrinogen were found in the 1 M Tris wash. In contrast, Factor XII-deficient plasma or plasminogen-deficient plasma had intact fibrinogen bands in the 1 M Tris wash. To better identify the proteins eluted from glass, Western blots were performed for 16 major plasma proteins. All 16 proteins were detected in the eluates by Western blot. Although degraded fibrinogen could be detected in normal plasma by Western blot, the proportion of degraded fibrinogen was highest in the 1 M Tris eluate. Compared to native plasma, Factor XII and HMWK eluted from the glass were found in their cleaved forms, indicating that they had been activated after contact with glass. Although Western blots allowed identification of the proteins eluted from materials, quantification of amounts of proteins relative to each other was not attempted. Due to the high sensitivity of the technique, bands on a Western blot may be undetectable on SDS-PAGE gels, while prominent bands on SDS-PAGE gels might not correspond to proteins examined by Western blot.

The large-scale Western blot approach was also applied to proteins eluted from hemodialyzers after clinical use.[10] The membranes consisted of poly(methyl methacrylate) (PMMA), cellulose acetate, saponified cellulose ester, or Cuprophane. Proteins were eluted with 2% SDS. Extensive degradation of many of the 16 proteins was observed, much more so than with human plasma *in vitro*, suggesting the presence of cell-derived proteases not present in platelet poor plasma. Little fibrinogen was present on PMMA membranes, while fibrinogen degradation products were mainly found on the other materials.

Large amounts of degraded complement protein C3 were found on all membranes. This was consistent with the activation of the complement cascade on the hemodialyzer units.[11]

3.303.3. Analysis of Adsorbed Proteins by 2DPAGE

The limitations of SDS-PAGE led to the use of 2DPAGE to better resolve plasma proteins (see **Figure 2**). 2D gel electrophoresis subjects proteins to isoelectric focusing prior to separation by SDS-PAGE.[12] In this way, hundreds of plasma proteins may be identified on a single gel based only on molecular weight and isoelectric point (pI).[13–15] Owen *et al.* used 2D electrophoresis in 1985 to examine proteins bound to extracorporeal membrane oxygenators (ECMO). On an ECMO that failed due to massive coagulation, hemoglobin and IgG were the most prominent proteins. A successfully used ECMO in the same patient revealed a large albumin spot in addition to hemoglobin and IgG.[16] Subsequently, Andrade and colleagues utilized 2D electrophoresis to detect heparin-binding proteins present in plasma.[17] Rather than eluting the proteins bound to heparin–agarose particles, depletion of proteins from plasma was measured. The adsorption kinetics of antithrombin-III, complement protein C3, Apolipoprotein (Apo) A-I, and Apo A-IV were quantified by observing the disappearance of spots corresponding to these proteins on 2D gels.

One of the drawbacks of unbiased proteomics techniques is the large amount of protein required for analysis. Assuming 200 ng cm^{-2} of adsorbed protein, 50 cm^2 of surface area would be required to obtain 10 μg of protein that is typically loaded in each lane of an SDS-PAGE gel. Even more protein is required for 2D gel electrophoresis. Thus, proteomic methods are more amenable to the analysis of high surface area materials, such as packed beds of microspheres. Not only is more surface area available, but the entire surface area may be exposed to a low volume of eluent, potentially eliminating the need to concentrate the eluted proteins prior to analysis. Thus, proteomic analyses of protein adsorption have largely focused on materials in the form of powders, fibers, microspheres, and nanoparticles.

2D electrophoresis has been used extensively to better understand the opsonization of microspheres and nanoparticles. Müller and colleagues used 2D electrophoresis to determine the effects of surface chemistry on protein adsorption and subsequent uptake by macrophages. Different polyethylene glycol (PEG)-based copolymer surfactants were adsorbed to polystyrene beads, and the more hydrophilic copolymers adsorbed, the less total protein.[18] Similar to previous studies, most of the proteins found in plasma were also found adsorbed to the nanoparticle surfaces. However, some proteins, such as albumin and haptoglobin were less abundant on the nanoparticle surfaces compared to plasma, while transferrin and Apo C-III were enriched. For most proteins, the adsorbed

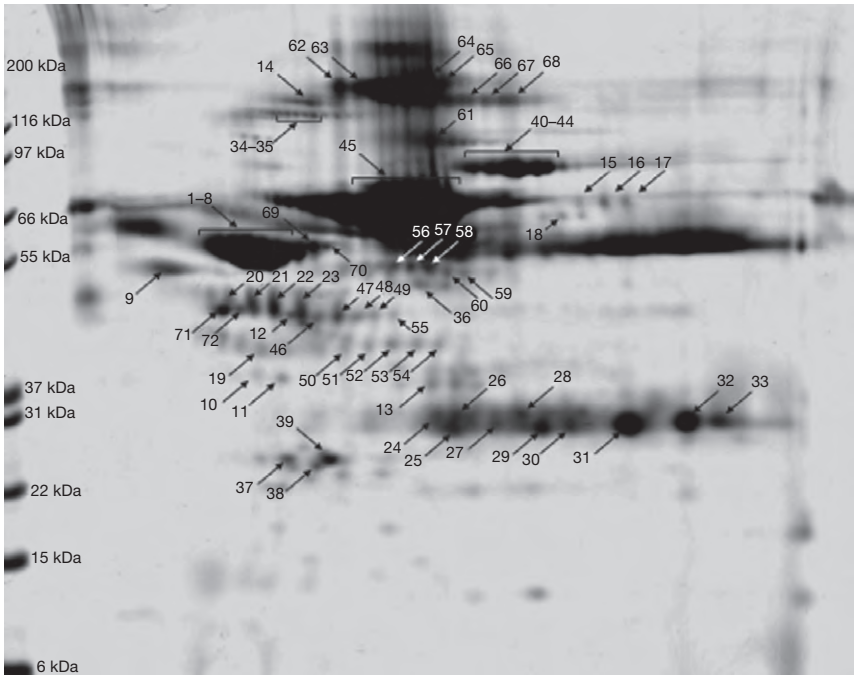

Figure 2 Two-dimensional gel electrophoresis of proteins eluted from an extracorporeal liver support device. Lower isoelectric point proteins are on the left side of the gel. Spots were cut from the gel and proteins in the spots were digested with trypsin. The peptide mixture was analyzed by matrix-assisted light desorption/ionization-time of flight/time of flight, with fragmentation of ions to allow identifications as in **Figure 3**. The largest spot (45) is serum albumin. Sixteen unique proteins were identified. The proteins that adsorbed to the device largely reflected the composition of proteins found in blood plasma. While the technique may, in principle, be used to determine the kinetics of protein adsorption, in practice, the throughput and cost of the method are still limiting factors. Copyright 2009 American Chemical Society.

amount was correlated with the hydrophobicity of the copolymer coating, but Apo A-IV and Apo E showed the lowest adsorption on the surfaces of intermediate hydrophilicity. PEG-based copolymer surfactants greatly lowered opsonization of polystyrene nanoparticles and increased circulation half-life.[19] However, proteomics analysis showed that protein adsorption still occurred on the so-called 'stealth' particles and that some proteins may actually be enriched on these surfaces. An extensive study of different PEG coatings on polystyrene microspheres revealed that the PEG coatings that were best able to reduce protein adsorption adsorbed slightly more albumin and Apo A-I, proteins that are not opsonins.[20] This suggested that hydrophilic coatings not only reduce protein adsorption but also recruit proteins that are not recognized by macrophages. Müller's group has published over 30 manuscripts characterizing protein adsorption to various particles, for example, emulsions,[21,22] iron oxide particles,[23] degradable PEG-containing microspheres, and nanoparticles,[24,25] polycyanoacrylate nanoparticles,[26] lipid–drug conjugates,[27] and transfection reagents.[28] Using similar methods, protein adsorption to liposomes was also studied by another group.[29]

LeRoux and colleagues used 2D electrophoresis to determine the mechanism by which PEG reduced uptake of polylactic acid nanoparticles by monocytes in plasma. Reduction of monocyte uptake due to the PEG coating was confirmed, yet the only differences in proteins adsorbed to the surfaces seemed to be Apo A-IV and Apo E.[30] In a later study by the same group, albumin adsorption to poly(D,L-lactide) nanoparticles decreased over the course of 60 min, while complement protein C3 adsorption increased dramatically.[31] This suggested that complement activation was initiated by the nanoparticles, consistent with previous work showing that complement promotes opsonization of these nanoparticles.[32] From the studies of Müller and LeRoux, it may be concluded that the protein composition in an adsorbed layer strongly resembles the protein composition of plasma, but PEG coatings reduce the total amount of adsorbed protein. However, the studies also suggest that the small differences observed between the adsorbed protein layer and the proteins in bulk plasma may be of tremendous importance in the biocompatibility of 'stealth' materials.

Müller and colleagues further used 2D gel electrophoresis to discover the mechanism by which some polysorbate-coated nanoparticles pass through the blood–brain barrier. The protein Apo E was found adsorbed to the nanoparticles in large amounts, which suggested a novel hypothesis for passage of these nanoparticles into the brain. The hypothesis was then experimentally validated, resulting in a novel discovery that may have not emerged using traditional methods.[33] Subsequently, another group found that PEG-polyhexadecylcyanoacrylate nanoparticles also crossed the blood–brain barrier. Using 2D electrophoresis and Western blotting, these nanoparticles were shown to also exhibit enhanced adsorption of Apo E.[34] Thus, unbiased approaches, when ideally practiced, may lead to the development of new hypotheses that may then be verified using more traditional methods.

In 1995, Feng and Andrade used 2D electrophoresis to analyze proteins adsorbed to powders of low temperature isotropic carbon (LTIC). The potential issue of nonelutable proteins was addressed by examining proteins that remained in plasma in the presence of the LTIC or silica powders. 2D electrophoresis allowed the identification and quantification of adsorption of 25 plasma proteins, inferred by the decrease in the intensity of spots on the gel due to adsorption to the powders. Twenty-one of the proteins had >50% depletion on silica at 12 h (with 1.5 m^2 surface area per 1.7 ml of plasma). All the proteins were >50% depleted on LTIC under similar conditions. Both materials adsorbed similar amounts of protein, about 200 ng cm^{-2} of total protein. The proteins with the highest surface activity could be discerned by using lower amounts of LTIC. The proteins that were >80% depleted under these conditions were Apo C, Apo E, complement protein C4, fibrinogen, α_2-HS-glycoprotein, α_2-macroglobulin, and plasminogen. On silica, the most readily depleted proteins were Apo C, Apo E, fibrinogen, and α_2-macroglobulin. After 5 min of adsorption on LTIC, the most depleted protein was fibrinogen. However, no Vroman effect was observed on either surface, as fibrinogen was still depleted at longer time points. This was inconsistent with many prior studies, as the silica surface would be expected to activate the intrinsic coagulation cascade leading to displacement of fibrinogen by activated HMWK. However, activation of the intrinsic coagulation cascade also results in the activation of plasminogen.[35] Activated plasminogen may have lead to fibrinogen degradation on the surface and in solution, reducing the intensity of the fibrinogen band on the 2D gel. This was consistent with the fibrinogen degradation products previously detected by Brash and colleagues.[9] Using similar methods, Rosengran *et al*. later analyzed the proteins depleted from plasma after exposure to ceramic particles (hydroxyapatite (HA), alumina, zirconia, and two bioactive glasses) along with proteins desorbed from the surfaces. Most of the major plasma proteins were found to adsorb to the surfaces, but Apo J (clusterin) was substantially depleted on all surfaces.[36,37]

Also in 1995, Stanislawski *et al*. used SDS-PAGE and 2D electrophoresis to examine protein adsorption to fibers used in ligament repair.[38] The fibers were made of polyarylamide, polyester (Dacron), polypropylene, or polylactic acid. After incubation with human plasma, the fibers were washed ten times with buffer and proteins were eluted from the materials with 3% SDS and 0.75% β-mercaptoethanol. Polyarylamide, the most hydrophilic material tested, exhibited a distinct pattern of adsorbed proteins compared with the more hydrophobic materials. In particular, a band at 115 kDa was present that was likely to be HMWK. The band was not present if HMWK-deficient plasma was incubated with the polyarylamide, although immunoblots failed to detect HMWK. Western blots demonstrated adsorption of fibrinogen, albumin, IgG, α_1-antitrypsin, transferrin, α_2-macroglobulin, prothrombin, Apo A-I, and Apo E. Some tightly packed bands on the SDS-PAGE gel were then resolved by 2D electrophoresis. Western blotting of the 2D gels allowed identification of the three fibrinogen chains, albumin, and the heavy chain of IgG. Nine other proteins were identified based on molecular weight and isoelectric point. Although HMWK may have been present on polyarylamide, no Vroman effect was observed. In fact, fibrinogen adsorption to polyarylamide was much higher than to the other surfaces, while Apo A-I adsorption was much lower. This agreed with previous reports that Apo A-I and fibrinogen adsorption are inversely correlated.[39]

Adsorption to hydrophilic surfaces has also been studied by proteomic methods. Magnani *et al.* used a two-step elution protocol to remove serum proteins adsorbed to glass, aminophase glass, and hyaluronic acid-modified glass. Proteins were eluted with 0.1% SDS followed by the sample buffer used for isoelectric focusing, containing 8 M urea, 4% CHAPS, and dithioerythritol. Using this protocol, over 1000 protein spots could be resolved on 2D gels. However, most of the spots on a 2D gel represent isoforms of the serum proteins with different amounts of glycosylation. The total number of unique plasma proteins has been estimated to be about 700.[40] Using manual processing, 30 unique proteins were identified by matching the spots on the 2D gels with those on a plasma protein 2D gel found in the Swiss-2DPAGE database (http://www.expasy.org). The most abundant proteins that adsorbed to glass and hyaluronic acid were albumin, α_1-antitrypsin, IgG, transferrin, fetuin, complement protein C3, and Apo A-I. Using similar methods, Berna *et al.* characterized adsorption of proteins to agarose-based chromatography resins in the presence of salts and sugars that promote protein phase separation.[41,42]

Materials commonly used in orthopedic implants are also amenable to proteomic analysis. In 2003, Sun *et al.* used 2D gels followed by Edman microsequencing to identify proteins adsorbed to titanium alloy, cobalt chromium molybdenum alloy, PMMA, and polyethylene particles, relevant to the failure of orthopedic implants.[43] Microsequencing resulted in the identification of only three proteins, albumin, α_1-antitrypsin, and Apo A-I. Albumin and α_1-antitrypsin were present as major peaks on all surfaces, while Apo A-I was only present on the polymeric surfaces. Using similar methods, Xie *et al.* found, in the course of studying proteins expressed by osteoblasts on hydroxyapatite (HA), that fetuin strongly adsorbed to the HA surface. This led to the development of a specific and novel hypothesis that adsorbed fetuin mediates osteoblast responses to HA. The researchers did not find that adsorbed fetuin affected osteoblast gene expression, but instead found that osteoblasts adhere normally to HA even in the absence of serum proteins.[44] However, this demonstrates how unbiased methods may lead to unexpected insights into complex biological responses.

3.303.3.1. Identification of Proteins by Mass Spectrometry

Mass spectrometry can greatly aid in protein identification. In 1999, Kingshott *et al.* studied proteins adsorbed to contact lenses using matrix-assisted light desorption/ionization-time of flight (MALDI-TOF) mass spectrometry. With this method, 2D gels were not necessary as the intact proteins were removed from the materials within the mass spectrometer. The proteins were adsorbed to the materials, washed, overlaid with light-absorbing molecules (matrix), and placed in the high vacuum of the MALDI-TOF. Whole proteins were removed from the surface upon exposure to laser light. Lysozyme was detected adsorbed to the contact lens after only 10 min in the eye.[45] In 2000, Oleschuk *et al.* used this method to analyze blood plasma proteins adsorbed to polyurethanes. The proteins were identified based on molecular weights observed in the mass spectra. Proteins as small as Apo C-I (6630 Da) and as large as IgG (150 000 Da) could be identified in a single spectrum. The limitation of the technique is the inability to measure absolute concentrations of the proteins. However, peak intensities are qualitatively related to adsorbed protein concentrations,[46,47] and albumin was found to be the most prominent peak, as expected.[48] Time-of-flight secondary ion mass spectrometry (TOF-SIMS) may also be performed on intact adsorbed proteins. By bombarding the adsorbed proteins with a beam of heavy ions, small fragments of the protein can be removed. On the basis of the differences in the ratio of the 20 amino acids in different proteins, the fragments can reveal the identities of proteins adsorbed to the surface (a detailed description is included in **Chapter 3.301, Surface Analysis and Biointerfaces: Vacuum and Ambient *In Situ* Techniques**).[49–52]

The major enabling technology that launched the field of proteomics was the use of mass spectrometry to identify protein spots on 2D gels following digestion of the proteins with proteases. Although quantification of protein amounts is still usually based on the intensity of the spot on the 2D gel, mass spectrometry allows identification of minor spots that previously would have only been the subject of speculation. In a typical protocol, spots on the 2D gel are cut out, washed to remove the protein stain, and then incubated with an enzyme such as trypsin. Trypsin cleaves proteins with high fidelity after lysines and arginines that are not followed by proline. By MALDI-TOF, a series of peaks are observed at different mass-to-charge (m/z) ratios, each corresponding to different peptides generated from the enzymatic digestion of the protein (a 'peptide mass fingerprint'). The sequence of the entire known proteome is available for download from the National Center for Biotechnology Information (NCBI). Prediction of the peptides that will be generated by proteolytic degradation of a particular protein is straightforward and performed automatically by a number of different software packages. The molecular weights of the predicted peptides may then be compared to peaks found in a MALDI-TOF peptide mass fingerprint.

In 2001, Derhami *et al.* used the sample buffer for isoelectric focusing, which contained dithiothreitol (DTT) and the surfactant CHAPS, to remove adsorbed serum proteins from titanium and tissue culture polystyrene. After 2D electrophoresis, spots were excised from the gel and digested with trypsin. The digest from each spot was analyzed by MALDI-TOF mass spectrometry. The peptide mass fingerprints were compared to predicted peptides of proteins found in a database with similar isoelectric points and molecular weights. Several proteins adsorbed to the materials were identified by MALDI-TOF, including α_2-HS-glycoprotein (fetuin), thrombospondin-1, α-fetoprotein, plasminogen, albumin, transferrin, and complement protein C3.[53]

If more than one protein is present within a spot, identification of the proteins by peptide mass fingerprints is more tenuous, but this may be overcome by further fragmenting each peptide ion in the mass spectrometer ('tandem mass spectrometry,' see **Figure 3**). In tandem mass spectrometry, a peptide mass fingerprint is obtained (a 'precursor ion scan'). Then a quadropole or ion trap is used to isolate ions at a particular m/z ratio, usually focusing on one of the more intense peaks in the precursor ion scan. The isolated ions are then fragmented, generally by collision with helium gas ('MS/MS scan'). Fragmentation by these collisions tends to occur at the peptide bond. Often, only one bond in the peptide backbone is broken, generating an N-terminal fragment and a C-terminal fragment referred to as *b* and *y* ions, respectively. The *b* and *y*

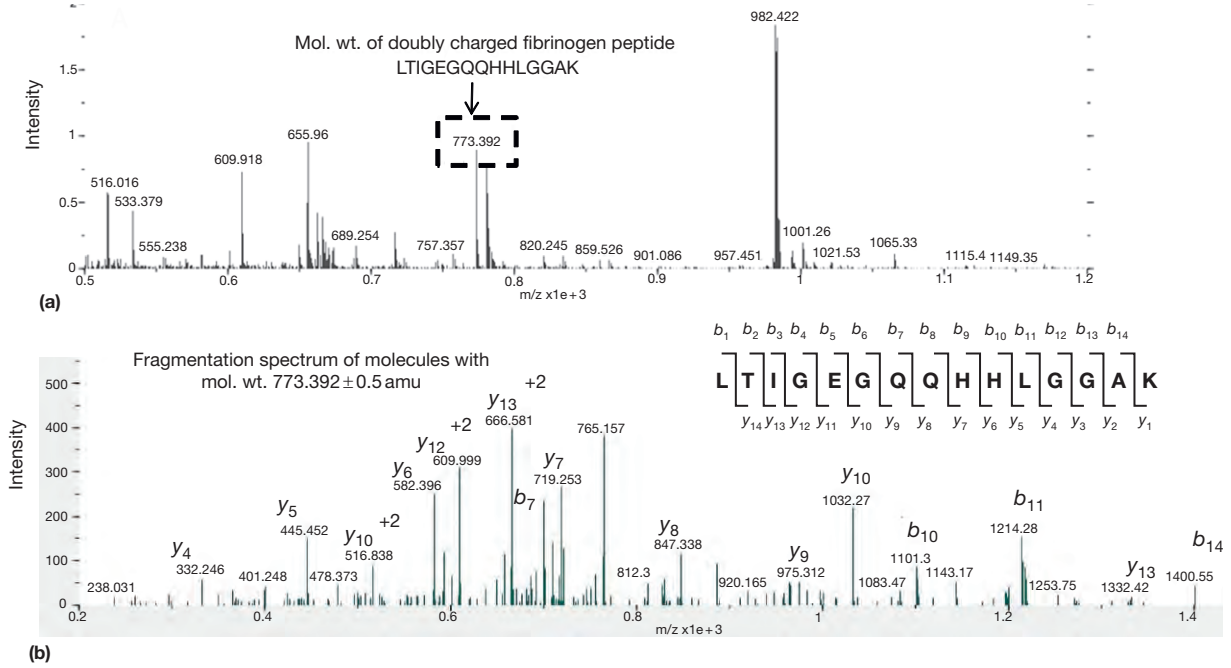

Figure 3 Protein identification by tandem mass spectrometry. A protein sample, often a band or spot following gel electrophoresis, is digested with the enzyme trypsin. The peptide mixture may be purified by high performance liquid chromatography run at extremely low flow rates. The eluent in some cases is directly electrosprayed into the mass spectrometer. (a) The peptides that enter the mass spectrometer may be detected in a 'precursor ion scan' (MS1 scan). The most intense peaks in the precursor ion scan are selected for fragmentation. In this example, a doubly charged ion (m/z 773.392) was selected and fragmented by collision with helium gas. (b) The fragmentation spectrum generated from the precursor ion peak shows peaks consistent with cleavage at different peptide bonds of the peptide with the shown sequence. While only some of the fragments are present, the assignment to this peptide can be made with high confidence. The *b* ions are fragments containing the N-terminus of the peptide, and *y* ions are the fragments containing the C-terminus of the peptide. The limitation of mass spectrometry is that while identification is robust, quantification is still challenging.

ions generated by fragmentation of a peptide yield a great deal of sequence information. In the ideal case, the full sequence of the peptide may be easily determined due to the presence of all possible *b* and *y* ions in the fragmentation spectrum. In real spectra, only some of the possible *b* and *y* ions are present. However, by matching the m/z of observed ions in the MS/MS scan with the masses of *b* and *y* ion predicted from peptides found in a protein database, assignments to a particular peptide may be made with extremely high confidence. Tandem mass spectrometry is not greatly affected by the presence of multiple proteins, since identifications are made of individual peptides at a narrow range of m/z, while peptides generated by trypsin have a wide range of m/z ratios. Nonetheless, high abundance proteins (e.g., albumin in plasma samples, actin, and histones in cellular samples) will generate intense peaks in the precursor ion scan and will dominate the scans selected for fragmentation. To increase the dynamic range of the measurement when multiple proteins may be present, peptides obtained from spots on the 2D gel may be separated by nanoliter-per-minute high performance liquid chromatography (nanoHPLC). Peptides separated by nanoHPLC enter the mass spectrometer over a range of times, increasing the ability to detect lower abundance proteins.

Kim *et al*. used tandem mass spectrometry to study plasma and serum proteins eluted from polypropylene, tissue culture polystyrene, poly(ethylene terephthalate) (PET), and polydimethylsiloxane.[54] The eluted proteins were first separated by 2D or SDS-PAGE gels. Bands or spots were sliced from the gels and treated with trypsin. The tryptic peptides were separated by nanoHPLC (run at 300 nl min) followed immediately by electrospray ionization and tandem mass spectrometry. Many of the same proteins found in previous studies were observed to be adsorbed to the different surfaces. However, one protein, serum amyloid P, was found to be one of the major proteins that adsorbed from serum onto the materials. The amount of adsorbed serum amyloid P increased over the course of hours to days of incubation with serum. On an SDS-page gel, serum amyloid P was identified along with Apo A-I and IgG light chain in the 20–30 kDa range after 7 days of incubation with serum. After 1 h, only IgG light chain was detected, while after 7 days in plasma, only Apo A-I was identified. Serum amyloid P had previously been demonstrated to bind to Fcγ receptors on leukocytes and opsonize particles for phagocytosis[55] It was hypothesized that adsorbed serum amyloid P promotes the attachment of leukocytes to biomaterials. Adsorbed serum amyloid P did in fact promote attachment and spreading of both monocytes and granulocytes onto the materials.[54] Similar methods were subsequently used to analyze proteins adsorbed to clinical low density lipoprotein (LDL) apheresis units. Seventy proteins were identified, including serum amyloid P.[56]

In recent years, characterization of protein adsorption to clinical devices by proteomics has become more common. Mares *et al*. used 2D electrophoresis and MALDI-TOF/TOF to study blood proteins adsorbed to liver support devices[57]

and polysulfone hemodialyzers[58] that had been used in human patients. MALDI-TOF/TOF is a type of tandem mass spectrometry and therefore yields high-confidence protein identifications. Some proteins were enriched by adsorption to the liver support devices: transthyretin, prothrombin, hyaluronan-binding protein, and plasma retinol-binding protein. Hyaluronan-binding protein is known to be upregulated by liver injury and is linked to protease activation. It was hypothesized that removal of this protein from the blood potentially could help to limit liver damage, but this was not experimentally verified. On the polysulfone hemodialyzers, ficolin-2, clusterin, and complement C3 were preferentially adsorbed. Ficolin-2 is an activator of the lectin pathway of the complement cascade. Along with the presence of complement C3 and clusterin (a C5b-9 inhibitor), a mechanism for complement activation on these membranes was suggested. The high abundance proteins from plasma such as albumin, transferrin, and α_1-antitrypsin were also present on the dialyzer units, consistent with an earlier proteomics study of cellulose diacetate and ethylenevinyl acetate hemodialyzers.[59]

3.303.4. Quantification of Protein Amounts by Mass Spectrometry

Tandem mass spectrometry is exceptionally adept at identifying proteins, but quantification of protein amounts by mass spectrometry continues to be a major challenge.[60] Generally, the intensity of ion peaks in the precursor ion mass spectrum is correlated with the concentration of the ion. However, in complex mixtures of proteins, unrelated peptides may elute from the nanoHPLC system at the same time, complicating the use of peak intensities from the precursor ion scan for quantification. Further, ionization is greatly affected by the presence of multiple peptides with different side chain chemistries,[61] making comparisons of amounts between different peptides quite difficult. The use of isotope-labeled internal standard peptides may help to account for differences in ionization efficiency.[62,63] However, this is limited by the availability of isotope-labeled peptides and proteins. In the absence of isotope-labeled standards, it has been found that simply counting the number of scans in which peptides from a particular protein are identified is a surprisingly accurate measure of protein concentration.[64] Further, the intensities of the *b* and *y* ions in the MS/MS scan are well correlated with protein concentrations and less sensitive to simultaneous elution of multiple proteins.[65] Strategies that combine these approaches are emerging which may improve the accuracy, precision, and dynamic range of mass spec-based quantification.[66] However, the current lack of quantification limits the usefulness of proteomics for the study of protein adsorption. Until then, radiolabeling remains the gold standard for quantification of protein adsorption.

3.303.5. Proteomics to Study Protein Denaturation on Surfaces

Adsorbed fibrinogen undergoes dramatic changes in conformation upon adsorption. The increase in surface area covered by each fibrinogen molecule is directly observable by atomic force microscopy (AFM) over the course of about an hour.[67] It has been proposed that resting platelets recognize two motifs on adsorbed fibrinogen, the α-chain 572–575 RGDS sequence and the γ-chain dodecapeptide.[68,69] The latter peptide is responsible for the aggregation of activated platelets in solution.[70] Binding of monoclonal antibodies suggests that the domains containing these peptides may undergo conformational changes following adsorption to surfaces.[71,72] A high-throughput proteomics method to detect exposure of protein domains upon adsorption may allow more detailed study of these processes.

The accessibility of side chain amino acids to reaction with chemical labels is commonly used to map protein structures.[73] Combined with mass spectrometry, the locations of the modified amino acids may be identified. Side-chain labeling methods may potentially reveal changes in conformation following adsorption to surfaces. Using a side-chain labeling approach, lysine groups on fibrinogen were reacted with NHS-activated biotin, following adsorption to PET microparticles.[74] Fibrinogen was eluted from the polymer and digested with trypsin. Using MALDI-TOF mass spectrometry, the presence of peaks corresponding to biotin-labeled peptides was used to estimate the extent of labeling, consistent with the exposure of these sites due to conformational changes that are more likely due to the slower kinetics of adsorption from low concentration solutions. Proteins adsorbed from less concentrated solutions had increased numbers of biotin-labeled peptides, and the two adhesion sites were only observed at lower solution protein concentrations.

Latour and colleagues utilized a tryptophan modification chemistry to probe conformational changes of adsorbed enzymes. Lysozyme or glucose oxidase was adsorbed to alkanethiol monolayers on gold. With lysozyme, tryptophan modification was lower on $-CH_3$ and –COOH surfaces compared to –OH and $-NH_2$ surfaces, and all surfaces had less labeling than the enzyme in solution. With glucose oxidase, tryptophan labeling was more extensive following adsorption. Circular dichroism could be applied to the protein-adsorbed self-assembled monolayers, and a decrease in helicity was correlated with tryptophan modification in glucose oxidase but not lysozyme. Activity of the enzymes adsorbed on the surfaces was also measured. A decrease in enzymatic activity was well correlated with a lack of tryptophan labeling of lysozyme, but tryptophan labeling was not correlated with the activity of glucose oxidase. The activity of glucose oxidase adsorbed on the $-CH_3$ and –COOH surfaces was actually higher than in solution. It was hypothesized that the tryptophans present near the active site of lysozyme are in a hydrophobic pocket that may orient toward the $-CH_3$ surface, decreasing activity. Tandem mass spectrometry was used to identify the tryptophan residues modified in lysozyme. On the $-CH_3$ surface, only one tryptophan was found to be labeled, which is far away from the active cleft of the enzyme. In solution, this tryptophan was unlabeled, but tryptophans near the active cleft were labeled.[75] Mass spectrometry thus could aid in deciphering the predominant orientations of adsorbed proteins. When proteins adsorb in preferred orientations, the side-chain labeling strategy may be useful to determine how conformational changes affect biological activity.

Future improvements in quantitative mass spectrometry may also allow characterization of preferred adsorbed orientations in complex mixtures of proteins.

3.303.6. Challenges of the Proteomics Approach

Despite the promise of proteomics for the study of protein adsorption, several limitations must be overcome. Ideally, proteomics should result not just in a large body of information, but to the emergence of novel, testable hypotheses. Unbiased approaches are difficult to reconcile with the cornerstone of the scientific method – the testing of specific hypotheses. Biased approaches are currently far superior to address specific hypotheses. Due to the wide range of concentrations of proteins in biological samples, proteomic methods are currently far from comprehensive. The most abundant proteins in biological samples, for example, albumin, actin, and histones, are often of little interest, yet dominate the signal from proteomic methods. Contamination of the sample with dust, skin, or hair may also result in a large signal from keratin. Proteins of great interest, such as growth factors, may be at concentrations that are far too low to detect without extensive purification, for example, by immunoprecipitation. However, the approach would then no longer be unbiased. Although proteomic methods are considered to be high throughput, the actual throughput may be relatively low. A typical sample run on nanoHPLC and a tandem mass spectrometer may require about 1 h of mass spectrometer time. To extensively characterize a single 2D gel could require days of mass spectrometer time, yielding typically only protein identification with no information on protein amount. Improvements in the throughput of mass spectrometers should greatly enhance the usefulness of these methods. Enhancement of the quantitative nature of mass spectrometry may also allow the methods to become competitive with radiolabeling. Compared to radiolabeling, proteomic methods are also challenged by the presence of adsorbed proteins that are difficult to elute. Elution of proteins from surfaces, particularly hydrophobic surfaces, will likely be incomplete.[76,77] On hydrophobic surfaces, the most highly denatured proteins that are most difficult to elute may also have the most biological activity due to more extensive conformational changes.

3.303.7. Conclusions

The use of unbiased methods has changed our understanding of the process of protein adsorption. It is clear that the proteins that adsorb to a surface largely reflect the proteins found in solution. Proteins such as Apo A-I, transferrin, and α_2-macroglobulin that are typically not studied by radiolabeling may be present in large amounts on surfaces. The impact of such proteins on biocompatibility, either directly or indirectly by affecting adsorption of active proteins, is unclear. However, the presence of a wide range of proteins should be taken into account to fully understand the role of adsorbed proteins in biological responses to materials. High-throughput, unbiased methods may lead to a comprehensive understanding of protein adsorption, although substantial method development will be required to surpass the quality of data obtained using traditional biochemical techniques.

Glossary

Boolean image Also binary image, a digital image with only two possible values for each pixel (commonly, '1' and '0').

Insertion device Array of spatially periodic magnets inserted into the straight section of the storage ring of a synchrotron source, different types are known: wavelength shifters, undulators, and wigglers; they all cause acceleration of the electrons in the storage ring which results in the emission of synchrotron light.

Multilayer monochromator Multilayer films for X-rays can be described as an extension of optical coatings to shorter wavelengths or of natural crystals to larger lattice spacings; a multilayer monochromator for X-rays selects a wavelength out of a polychromatic spectrum, commonly with an energy spread of a few percentage.

(Partial) Spatial coherence A property of a wavefront which allows for interference, that is, X-ray phase contrast within the content of this chapter.

Pixel Acronym for picture element which represents a value within an image interpreted as two-dimensional matrix (per definition, a pixel is shapeless).

Scintillation A subcategory of luminescence: ionizing radiation of high energy is converted into a flash of visible light photons.

Sinogram Also Radon transform, a visualization of the acquired raw tomographic data along the rotation angle which corresponds to one slice after the reconstruction.

Spatial resolution/point spread function Imaging detectors record an ideal point-shaped signal with a specific broadening, described with the point spread function (PSF); frequently, the width of the PSF is used as measurement for the spatial resolution of the detector (while the detector's pixel size needs to be adapted to the PSF according to Shannon's theorem).

Synchrotron light source The synchrotron itself is a cyclic particle accelerator based on synchronized magnetic and electric fields; frequently, electrons are accelerated close to the speed of light and then inserted into a storage ring where the light to be used is created when the electrons pass through magnetic fields (see as well insertion device).

Voxel Acronym for volume(tric) picture element which represents a value within, for example, a tomographic image interpreted as three-dimensional matrix (per definition, a voxel is shapeless).

X-ray phase contrast Also inline phase contrast, objects with negligible X-ray attenuation contrast can be visualized in terms of their edges when a source with a certain coherence is used for the illumination: the refraction of the X-rays at interfaces leads to an intensity modulation within the images.

3.304.1. Hard X-ray Microimaging

Since the discovery of X-rays by W. C. Röntgen more than a 100 years ago ('Über eine neue Art von Strahlen,' in: Secretary of the Physical-Medical Society, Würzburg, 1895), radiographic imaging has been established as one of the fundamental techniques for medical diagnosis. In addition, various other applications, for example, for nondestructive evaluation emphasize the high value of imaging the interior of an object without the need of damaging it.[1]

During in the 1970s, X-ray imaging was extended into the third dimension by combining radiographic images of an object taken from different angles: computed (axial scanning) tomography (CT).[2,3] Like radiography, CT established itself as a fundamental technique in medicine, and is presently extended by sophisticated contrast modes such as positron-emission tomography using different types of radiation, respectively.[4]

In the early 1980s, first successful approaches were reported in which CT was applied outside medical fields, for example, to study cracks in concrete.[5] In this case, the instrumentation development pushed the reachable spatial resolutions to the micrometer range: microtomography (μCT).[6,7] In the same decade, first publications were introducing μCT as performed using synchrotron light (SμCT).[8–13] During the 1990s, with the first so-called third generation synchrotron light sources starting operations, SμCT was established as a standard technique with spatial resolutions available up to the (sub-)micrometer range[14] and specific contrast modes.[15] This development has been well documented in the SPIE conference series *Developments in X-ray Tomography I–VII* and the corresponding proceedings. A detailed review on tomographic techniques for materials research and engineering using different contrast modes as well as radiation sources is given in Banhart,[16] specifically for synchrotron light sources in Graeff and Engelke.[13]

The content of this chapter is dedicated to *ex vivo* investigations performed using SμCT in the so-called absorption contrast mode. The specimens under investigation are human and sheep bone, taken several months after the implantation of bioceramic particles.[17] The following sections are dedicated to the introduction of the methods in a brief manner while results are presented in the following paragraphs.

3.304.1.1. Laboratory Approach

The basic principle of CT relies on the fact the interior mass distribution inside an object can be reconstructed from its radiographic projection images taken from different projection angles. Presently, various robust algorithms performing this task have been established as a standard solution, providing virtual slices of the analyzed object which arranged as a stack represent the volume image. One approach, known as algebraic reconstruction, formulates the problem as a set of independent equations to be solved via matrix operations. Other methods such as the filtered-backprojection algorithm or the direct Fourier inversion reconstruct a virtual slice by summation of the measured integral attenuation profiles in real or Fourier space.[18] An excellent description of the different basic principles of tomographic reconstruction was published by Kalender.[19]

The common scanning geometry known from medical CT keeps the patient fixed while the X-ray source and the detector are rotated around him to perform the CT scan.[4] For μCT, with the specimen commonly being small and of static nature, the X-ray source and the detector are fixed while the sample is rotated (see **Figure 1**). Consequently, demands on the mechanics are less extensive, especially for achieving a spatial precision in the (deep sub-)micrometer range.

With respect to the following section about synchrotron-based microtomography, two different beam geometries for full-field imaging have to be considered (see **Figure 1**): X-ray tubes emit the light in a broad cone or fan. The advantage of this cone beam geometry is that the imaging magnification and hence, the spatial resolution can be chosen by the distance between the sample and the X-ray source. But, this limits the maximum distance between the sample as well as the source in a practical manner: with the increasing distance the photon flux density decreases. Thus, the finite source size can deteriorate the achievable resolution by means of penumbral blurring. Furthermore, artifacts are introduced due to the incomplete projection data acquired when using a cone beam. Synchrotron light sources frequently deliver a nearly parallel beam. Here, the sample-to-detector distance can be extended up to several 100 m but the spatial resolution to be achieved requires a corresponding high resolving power of the X-ray detection scheme used.[4,14,16,18,20]

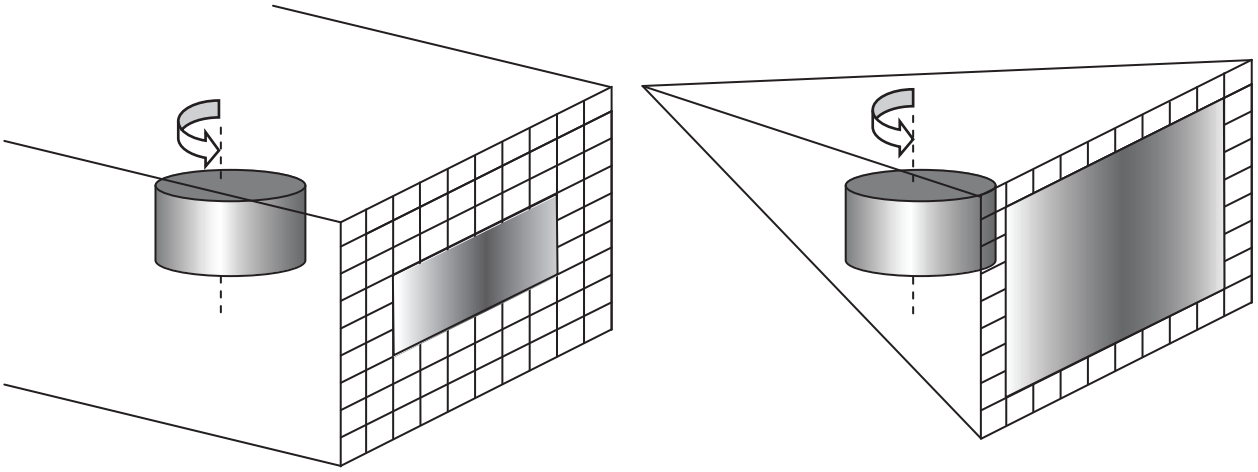

Figure 1 The two relevant beam geometries in full-field microtomography and radiography: parallel beam (left) allowing for large source-to-experiment distances but with high demands on the resolving power of the X-ray detector; the cone beam geometry (right) allows one to tune the imaging magnification via the sample-to-detector distance but is practically more sensitive to the finite source size extension.

The contrast in a standard laboratory μCT scan is given by the local X-ray attenuation behavior of the sample. This is in a first approximation related to the local density, the chemical components and the X-ray photon energy employed. The density-related material contrast is directly connected to the photon flux density available for imaging in a strongly nonlinear manner, for example, to double the detectable contrast an increase of the photons involved by a factor of four is required.[21,22] Additionally, for example, the X-ray photon energy used needs to be adapted for the individual sample as specific transmission values are optimal for the tomographic reconstruction.[13,23,24]

Full-field microtomography using laboratory X-ray sources is an excellent tool applied within a broad range of scientific and industrial fields. Successful approaches of μCT employed, for example, in bone research were already reported during the 1980s.[25–27] In the same decade, the demand for using the powerful synchrotron light sources with orders of magnitude higher than photon flux density for X-ray microimaging was formulated, since it would allow for pushing the limits of the achievable resolution in space and time.[7,14,28–31]

3.304.1.2. Synchrotron Light Sources

While laboratory X-ray tubes generate the light via accelerated electrons hitting a target, synchrotron light sources use electrons passing with relativistic speeds (close to the speed of light) through magnetic fields. Due to the magnetic field, the trajectory of the electrons is bent and as known from a classical dipole (antenna), accelerated electrons emit electromagnetic waves. The relativistic speed of the electrons deforms the dipole emission characteristic so that the light is emitted as a bundle in one direction tangential to the flight direction only. The speed of the electrons and their density as well as the magnetic field and the numbers of magnets roughly determine the emission spectra and photon flux density as well as the brilliance of the source.[32]

For imaging applications, the major advantages of synchrotron light sources in comparison with other sources are: the orders of magnitude higher than photon flux density, the almost parallel beam propagation and the coherence properties of the beam at the position of the experiment. As an example, see **Figure 2** in which the available monochromatic photon flux density of the imaging station located at the BAM*line* (BESSY-II light source of the Helmholtz Zentrum Berlin für Materialien und Energie GmbH, Germany) is compared with standard laboratory sources.[33,34] Other imaging stations at synchrotron light sources such as the European Synchrotron Radiation Facility (Grenoble, France) and the Advanced Photon Source (Chicago, United States) or SPring-8 (Hyogo, Japan) provide even much higher photon flux densities. The large amount of photons allows for using monochromators: monochromatic radiation employed for X-ray imaging increases generally the contrast while reducing artifacts.[35] A high photon flux density specifically allows for increasing the detectable density-related material contrast.[21,22] As mentioned in the previous section, due to the parallel beam the distance between source and experiment can be extended up to several hundred meters which suppresses the influence of the finite source size on the achievable spatial resolution. Another effect of this long distance is a certain coherence of the X-ray wave fronts at the position of the experiment, hence, interference effects can give access to more sophisticated contrast modes like the inline X-ray phase contrast or holotomography.[15,36–38] Other contrast modes such as the local chemical species distribution or the local crystal phase information are accessible when employing a scanning approach instead of the full-field imaging technique.[39] A detailed discussion about the advantages of using synchrotron light for μCT is given in Bonse and Busch[20] while the more general overview of the different contrast modes in combination with different radiation types is available, for example, by Banhart.[16]

The common design of a microimaging experimental station at a synchrotron light source is depicted in **Figure 3**, again using the BAM*line* as an example.[33,34] From the polychromatic radiation generated by the source inside the storage ring, a certain wavelength is selected via an X-ray monochromator. The light travels through a long vacuum pipe toward the

experimental hutch. Here, the sample is placed on a manipulator allowing for rotation, tilt alignments and translation. Behind the sample, a digital X-ray pixel detector is placed which records the light as transmitted by the specimen.

In Figure 3 an additional schematic is shown which displays the common indirect detection scheme applied for high resolution imaging with a parallel beam, based on the concepts of Hartmann *et al.*[41] and Bonse and Busch[20]: the luminescence image of a scintillator screen (powder or single-crystal) is projected via diffraction-limited visible light optics onto a camera (CCD or CMOS). Here, the maximum achievable spatial resolution is determined by the wavelength of emission of the scintillator as well as the numerical aperture of the objective used (Abbe's theorem). By introducing transparent thin single-crystal film scintillators, resolutions up to the (sub-)micrometer range can be reached as standard application.[14] The high resolution is only accessible at the expense of the field of view of the detector and its efficiency. In order to reach for a spatial resolution around 1 µm, pixel sizes below 0.5 µm have to be used, with the common 2048 × 2048 pixel CCD camera the remaining field of view is less than 1 mm^2. The required numerical aperture for this type of resolution reduces the depth of focus to a few micrometer in which the active layer of the scintillator screen has to fit. For example, at an X-ray photon energy of 15 keV a $Lu_3Al_5O_{12}$ (LAG) screen with the required thickness of 5 µm transmits 75% of the flux which therefore cannot be used for imaging.[40] Further increase of the resolution in the nanometer range can be achieved by employing X-ray optics.[42–44] This facilitated even studying structures as small as single cells.[45,46]

Commonly, access to experimental stations at synchrotron light sources is free of charge for scientific users. Experiments have to be approved after submitting proposals which are evaluated by independent committees. The beamtime is then allocated according to the availability and the ranking of the rated proposals.[47] A compilation of synchrotron light sources worldwide which operate microimaging facilities is listed in

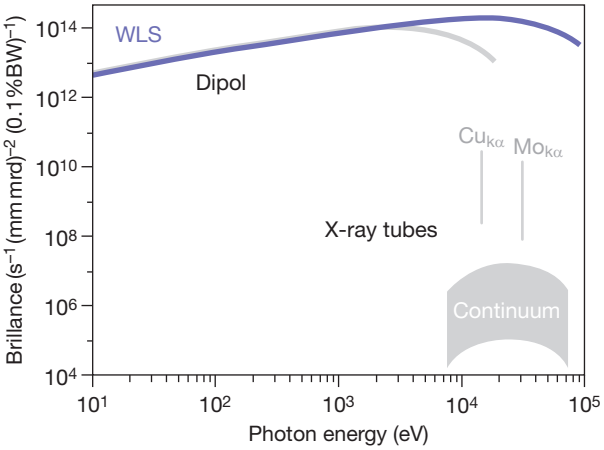

Figure 2 The available monochromatic photon flux at the BAM*line* imaging station of the BESSY-II light source (Berlin, Germany) in comparison with standard laboratory sources. 3.304.1.3. Quantitative Volume Image Analysis

Tomographic data sets are volume images in the sense of a three-dimensional matrix filled with values which, for example, can be considered as gray-scales for visualization purposes. Depending on the acquisition mode, these values represent, for example, the linear X-ray attenuation coefficient (μCT), density of metabolized isotopes (positron emission tomography), hydrogen concentration (magnetic resonance imaging), or the electron density (holotomography).

The first step in the analysis of a multiconstituent volume image is commonly the separation of morphological components (e.g., pores, bone, or bioceramic particles) into independent Boolean images. In such an image, pixels (picture elements, frequently called voxels for volume images) belonging to one phase are marked with a Boolean '1' while the remaining part of the image contains only '0.' In Figure 4, these steps are depicted via an example of cross-sections of a tomographic data set acquired *ex vivo* using synchrotron light showing a sheep bone specimen sampled 3 months after sinus floor augmentation with bioceramic bone grafting particles. Creating a Boolean image of the bioceramic is straight forward due to the excellent contrast and well-defined morphological structure. This Boolean image is used to remove the ceramic information from the original image which allows for separating the bone information from the remaining noise in a second step.[48] The crucial task of creating Boolean images, frequently called binarization, is one of the main challenges for the image analysis and subsequently, a broad range of techniques were developed, ranging from simple thresholds to sophisticated algorithms such as the watershed transformation or region growing in combination with a threshold hysteresis.[49,50]

Once a set of Boolean images is created, further data processing can derive quantitative results like spatial cross-correlations between different constituents in the image[51] or the Boolean images are used to determine properties of a structure based on numerical simulations.[52,53] In our case, the separated images are also the basis for high quality volume renderings as shown in Figure 4. Further details regarding the analysis and rendering of volume images are outlined in Schladitz and Ohser[54] and Ohser and Schladitz,[55] for example. Common software packages employed for the analysis and visualization of volume images, are MAVI by the Fraunhofer ITWM, Department of Image Processing[56] or, for example, VGStudioMax, see Reinhart *et al.*,[57] both are commercially available.

For bone histomorphometry, the standardization of nomenclature, symbols and units has already been performed.[58] These standards can then be applied when analyzing tomographic data sets of bone,[27,104] thus, it becomes possible to progress to bone histovolumetry when combining μCT with quantitative volume image analysis.[59]

3.304.1.4. Microtomography: Life Sciences, Biomaterials and Bone Research

While μCT for medical and clinical applications as well as life sciences in general is presently aiming for *in vivo* scanning of animals and humans,[60–62] the use of SμCT is more challenging in this context. This is due to dose issues,[63] but in addition because of the limited availability and high costs of beamtime at synchrotron light sources. The outstanding contrast accessible with SμCT as demonstrated for, for example, investigating breast tissue,[64] tumor tissue,[65] or cartilage,[66] however, emphasized the high value of these techniques as tool for medical diagnosis. For a review of selected biomedical imaging techniques using synchrotron light, the reader is referred to Baruchel *et al.*[67]

Successful imaging investigations based on utilizing synchrotron light have already been reported in various fields

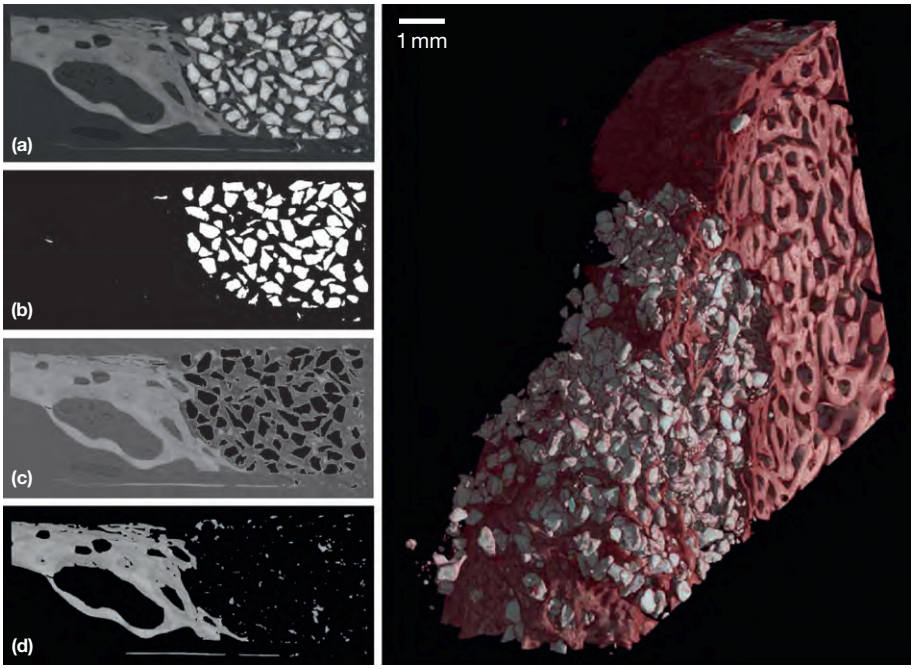

Figure 4 Left: from the gray-scaled image showing bioceramic particles after implantation for bone regeneration in sheep (a), through Boolean images of the individual material phases (e.g., ceramic particles, b) one can separate the gray-scale information of the different morphological components into independent images (c, d) which are the basis for high quality volume renderings as shown on the right. of the life sciences, such as biomineralization,[68] for studying endo- and exoskeletons[69] and biology, for imaging structure, function, and physiology of (living) organisms.[70,71] Due to the excellent contrast available, biomaterials have been studied with synchrotron-based microimaging for many years.[72–76] A few selected examples underscoring the high potential of synchrotron-based X-ray imaging with high resolution and in three dimensions are shown in **Figure 5**: the head of Forficula auricularia (Dermaptera),[71] a rat heart imaged with phase sensitive contrast[78] and newly formed bone onto the inner surface of a hydroxyapatite scaffold.[77] An example of a thorough comparative study of synchrotron radiation and laboratory X-ray sources for biomedical imaging (mammography) was published by Moeckli *et al.*[79]

Following the demonstration of the high potential of μCT for bone research,[26,27] SμCT was pioneered in this field already during the 1990s.[80] By virtue of the high density-sensitivity of the technique, it is excellently suited for the analysis of (trabecular) bone[81] or quantifying its degree of mineralization (see **Chapter 3.325, Imaging Mineralized Tissues in Vertebrates** and **Chapter 3.323, Magnetic Resonance of Bone Microstructure and Chemistry**).[82,83] The latter has also been applied for analyzing mineral concentrations in sound and carious enamel.[84] Other possibilities only available at synchrotron light sources include *in situ* investigations of bone under load to visualize crack formation[85] or *in vitro* studies of microgap formation between dental implants and their abutments.[86]

Recent developments, which also should be mentioned, are tomographic techniques using synchrotron radiation with very specific contrast modes for analyzing the local crystal structure[87] or chemical species distribution[88] of bone. Spatial nano-resolution in combination high density contrast has been achieved by ptychographic X-ray CT.[89] An outlook regarding synchrotron imaging contrast modes with micro- to nano-resolution to specifically study bone was published elsewhere.[90]

The widely nondestructive nature of μCT as performed by using laboratory or synchrotron sources also allows for an analysis of errors which arise when only classical (two-dimensional) techniques like histomorphometry of hard-tissue sections are applied for analyzing the amounts of newly formed bone rather than three-dimensional volumetric approaches (see **Chapter 3.313, Histological Analysis**). Already by comparing histological two-dimensional images with corresponding tomographic slices the strong effect of the sectioning of the specimens on the derived results can be demonstrated.[80] A first approach to quantify this effect using μCT with moderate resolution and contrast found discrepancies in the range of ±10%.[91–93] Recent studies with SμCT employing higher spatial resolution confirmed these observations, relating this effect both to the loss of substance which occurs during the sectioning as well to general limitations of histology originating from its two-dimensional nature.[59]

Exciting results are achieved when SμCT is used to study bone and biomaterials in a combined manner,[94] that is, the regeneration of tissue in a bony defect either around implants[95,96] or supported by ceramic bone substitute materials.[73] These studies are commonly performed *ex vivo* with animals, where biomaterials are implanted in artificial defects,

specimens taken after sacrificing and then analyzed using SμCT and additional techniques, as reported by Weiss *et al.*[73] An example for an *in vivo* clinical study using laboratory CT studying bone cement in the rat spine has been published by Wang *et al.*[97] Often these type of studies are referred to as *in vivo* studies, due to the fact that the performance of the biomaterials was evaluated using an *in vivo* animal model while *ex vivo* modes of analysis are employed subsequent to specimen retrieval.[98] The following two paragraphs focus on results achieved *ex vivo* as part of two studies with humans and with animals, where the response of bone to different bioceramic materials was imaged using synchrotron-based microtomography.

3.304.2. Comparative Animal Study of Bioceramic-Supported Bone Regeneration

3.304.2.1. Surgery and Specimen Retrieval

An animal study (DFG-grant: KN 377/3-1) was performed in order to investigate the osteogenic potential and biodegradability of various resorbable calcium phosphate bone grafting materials. The biomaterials studies included two rapidly resorbable calcium alkali orthophosphate ceramics, first a glassy crystalline material with the main crystalline phase $Ca_2KNa(PO_4)_2$ and small amorphous phase containing silica phosphates (material denominated GB9) and second a calcium alkali orthophosphate with the novel main crystalline phase $Ca_{10}KNa(PO_4)_2$ (material denominated 352i).

These bioceramics were designed for higher biodegradability compared to tricalcium phosphate, which was used as a clinically established reference material in the current study. All biomaterials included in this study had a mean particle size of 300–355 μm. The various test materials were implanted bilaterally in the sheep mandible and maxilla for 1, 4, 12, and 24 weeks and examined with respect to their potential to regenerate critical-size bone defects and their biodegradability.

In the maxilla, these materials were used for sinus floor augmentation which entailed close contact of a significant amount of the bone grafting material with the Schneiderian membrane, while close contact with the local bony tissue of the sinus floor was only present at the bottom of the defect (Figures 4 and 7). In order to prevent the migration

of fibroblasts into the implantation sites, which may potentially disrupt bone regeneration, the lateral access window to the sinus was covered with a titanium membrane. In this sheep study, an extraoral approach was chosen in order to access to the maxillary sinus. To this end, a lateral window was created.

In the sheep mandible chronicle critical-size membrane-protected defects as described by von Arx *et al.*[99] were applied. To this end, two premolars and molars were extracted and two rectangular defects 1.5 cm in width were created bilaterally. These were allowed to heal for 8 weeks, which was followed by removal of the granulation tissue and augmentation of the defects with the various bone grafting materials (**Figure 6**). The volume of the biomaterial granules inserted into the critical-size defects was about 1 cm^3. The defects were then covered with titanium membranes, thus applying the principle of guided bone regeneration.

After completion of the various implantation periods, the animals were sacrificed and the implantation sites with the surrounding bone tissue were retrieved for histological and synchrotron microtomographical analysis. The tissue blocks were fixed in an alcohol-based fixative Neofix^R (Merck KgaA, Darmstadt, Germany), then embedded in a resin, which contained methylmethacrylat and buthylmethacrylat. Prior to histological sectioning the embedded tissue blocks were examined with synchronton microtomography. This was followed by cutting 50-µm-thick sections using a sawing microtome and subsequent grinding and polishing of the sections, which were then used for histological, histomorphometric, and immunhistochemical analysis as described previously.[100]

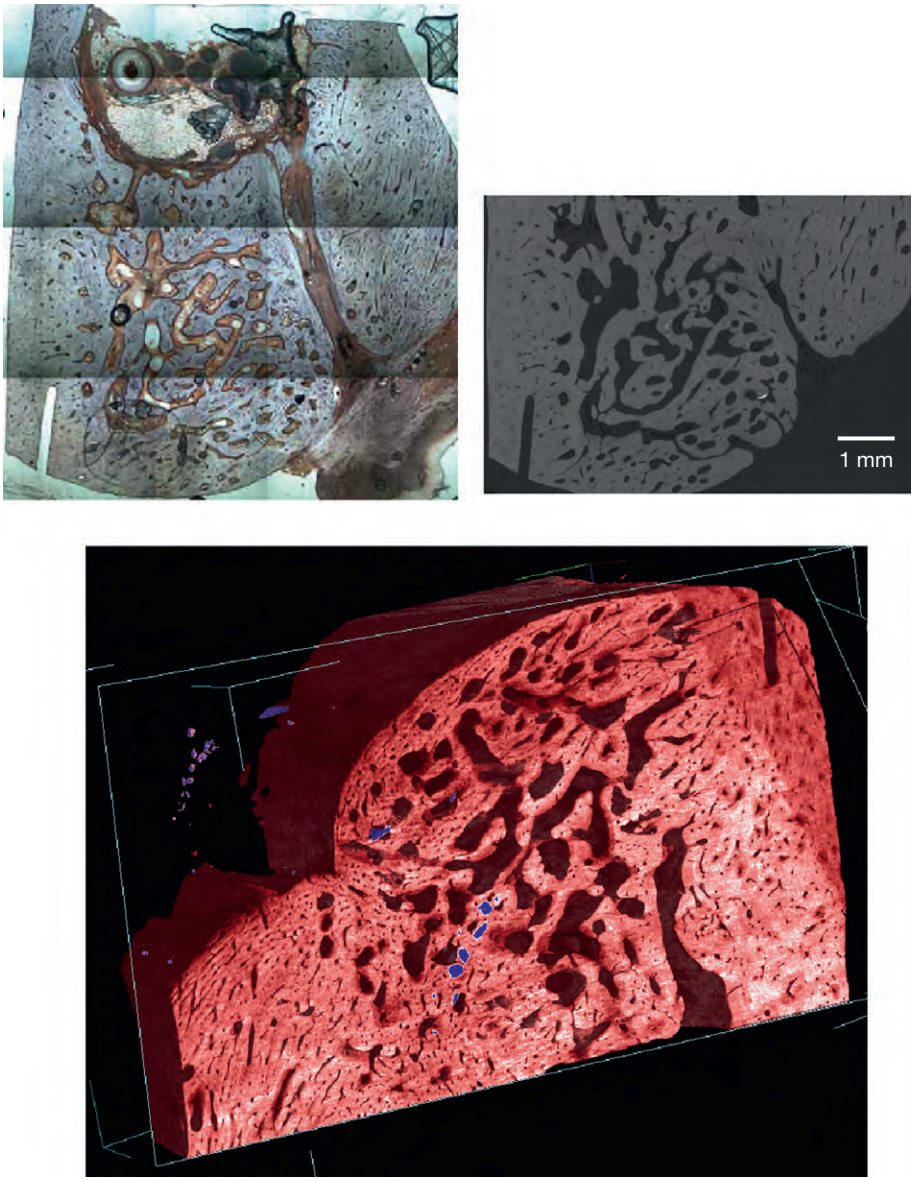

Figure 6 Specimen sampled 24 weeks after implantation of GB9 particles in the sheep mandible – top, left: histological section (bone in gray-blue, marrow spaces and areas staining positive for type I collagen appear in a brownish-red color), top, right: corresponding tomographic slice, bottom: volume rendering of the segmented tomographic data set (frontal cropped), residual bioceramic particles are distinguishable (deep blue).

3.304.2.2. Microtomography and Volume Image Processing

The microtomography experiments were performed at the BAM*line*, one of the hard X-ray beamlines of the BESSY-II light source (Berlin Electron Storage Ring Company for Synchrotron Radiation) at the Helmholtz Zentrum Berlin für Materialien und Energie (HZB), Germany.[33,34] The BAM*line*'s SμCT facility is operated by the Bundesanstalt fur Materialforschung und -prüfung (Federal Institute for Materials Research and Testing, Berlin, Germany) in cooperation with the HZB (Institute of Applied Materials). A detailed description of the experimental setup for microtomography can be found in Rack *et al.*,[34] a photo and a sketch of the imaging station is shown in Figure 3. The optimal X-ray energy for the tomographic scans was determined experimentally to be ~28 keV (monochromatic): assuming that the best contrast is given when the condition $\mu D = 2$ (μ: linear X-ray attenuation coefficient, D: sample diameter) is fulfilled, which equals to an overall X-ray transmission T by the sample of $T = 13.5\%$.[24]

For the experiments, the high resolution indirect detector was equipped with a nominal 10-μm-thick Gadox (Gd_2O_2S) scintillator powder screen because of its high stopping power and excellent photon yield. For the microscope objective, a Rodenstock 'XR-Heliflex' (focal length $f = 100$ mm, maximum $NA = 0.4$) was chosen in combination with a Nikon 'Nikkor 180/2.8 ED' ($f = 180$ mm) objective, resulting in a magnification factor of 1.8×. In the parallel section of the optical path, a diaphragm is placed to adjust the ratio of absorbed X-ray photons (Gadox) versus detected luminescence photons (CCD) and to compensate for defect focus. The optics project the luminescence image onto the back-illuminated CCD chip of a Princeton Instruments VersArray: 2048B (11 000:1 dynamic range with 1 MHz readout speed, 2048 × 2048 pixels, each 13.5 μm in size). The resulting effective pixel size is 7 μm which leads to a $14 \times 14\ mm^2$ field of view, large enough to investigate the usually $25 \times 12 \times 5\ mm^3$ sized specimen. In the radiographic projection the resolution was estimated to about 20 μm with the help of a copper edge (10% of the modulation transfer function). For the reconstruction of the tomographic images the filtered-backprojection algorithm is used via the ESRF software package PyHST.[101]

The absorption contrast in this microtomographic scans is determined by the local X-ray attenuation coefficient which mainly depends on the local density of the material as well as the atomic number of its elements. Here, the dependence on the X-ray energy can be omitted since a monochromatic beam is used. After the tomographic reconstruction, the resulting pixel values are translated into gray-scales and the whole volume data set can then be rendered in three dimensions. For the rendering, a commercial software package by Volume Graphics GmbH (Heidelberg, Germany) was used – VGStudioMAX.[57] In order to derive images which can be considered as an extension of histology into three dimensions, first the spatial information of the different material phases (bone and ceramic particles, *cf.*, e.g., Figure 4) was separated into Boolean images which contain only the morphological information of one phase. The algorithm applied is using a threshold hysteresis in combination with a region growing approach: an initial range of gray values, manually selected, is used to define, for example, what certainly is bone information within the image. In a second step, a broader range of gray values is selected, defining what might be the bone information. The algorithm extends in successive stages already identified bone phase with image pixels which are (i) direct neighbors of already identified bone and (ii) contain gray values within the above-mentioned second range. The algorithm terminates when no more pixels remain which fulfill these two conditions.[49] A further manual optimization of the input parameters is required, frequently performed by visual inspection of selected slides in gray-scales and Boolean. The results are volume images in which the very pixels associated with the bone information are marked as '1' and the remaining background is set to '0.' Once separated, the Boolean images can be individually cleaned from noise, for example, by using morphological transformations as well as being colored. A combined rendering of these individual volume images is shown in Figure 4, right side.

3.304.2.3. Results

Of the calcium alkali phosphate bioceramic GB9: two specimens were imaged, one sampled after 12 and one sampled at 24 weeks of implantation in the sheep mandible. The corresponding volume rendering of the 24-week sample is displayed in Figure 6 (bottom). Parts of the bony tissue are set transparent in order to give insight into the bony volume. At 24 weeks, only very few residual particles, which show excellent bone-bonding behavior, can be detected in the tomographic volume image (also after 12 weeks, only minor amounts of residual particles were distinguishable, data not shown here). Consequently, the GB9 ceramic supported bone formation and regeneration of the bony defect and then biodegraded rapidly, while new bone is formed, with hardly any residual particles remaining.

In order to validate our results, histological sections of the 24 weeks specimen were cut and prepared for immunohistochemical analysis. The corresponding section was identified (see below) and visualized using a light microscope in combination with a digital camera (Colourview III) and SIS Analysis software (Olympus, Germany) (see Figure 6 (top, left)). Here, the bone can be recognized by the gray-bluish color. Marrow spaces and areas staining positive for type I collagen appear in a brownish-red color. The volume data set of the 24-week sample was compared manually slice by slice with the histological image until the corresponding section was found (see Figure 6 (top, right)). No major differences between the detected bone structure in the tomographic image and the histological image are visible. Due to the density-related absorption contrast within the SμCT image it can be concluded that for this sample the bone is fully developed, that is, mineralized as all bony tissue detected in the chemical contrasted histological image is also visible in the tomographic slice.

The bone substitute material 352i, however, displayed a rather different behavior. A sample examined 12 weeks after sinus floor augmentation is depicted in Figure 7. In contrast to GB9 (see Figure 6) the majority of the ceramic particles are still present while only a small amount of newly formed bone becomes visible between the 352i particles. In addition, these particles show very limited bone-particle contact, that is, very poor bone-bonding behavior. Here, it is noteworthy that

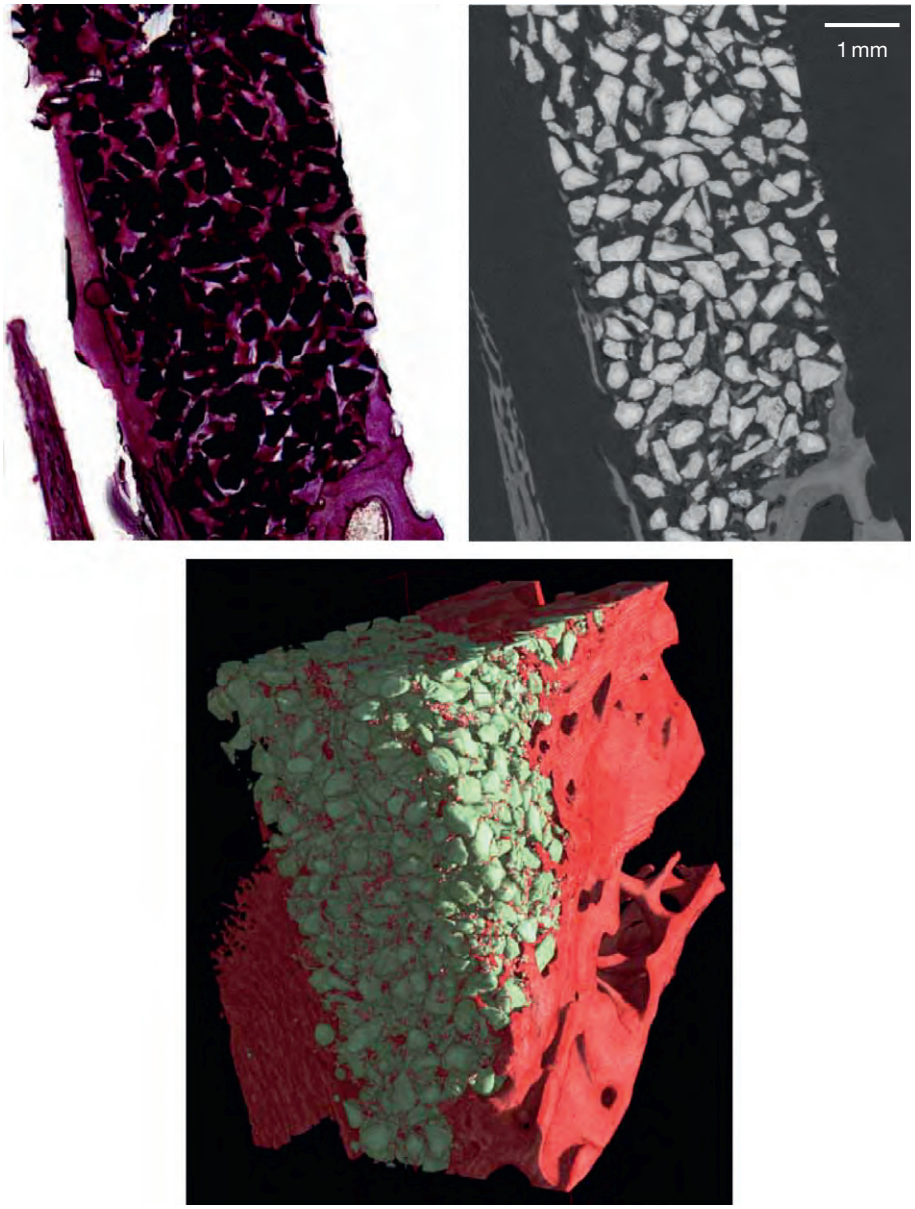

Figure 7 Specimen harvested 12 weeks after sinus floor augmentation with 352i – top, left: histologically prepared section (bone in cyan, ceramic particles black, soft tissue: scarlet red and light pink), top, right: corresponding tomographic slice, bottom: volume rendering of the segmented tomographic data set, bioceramic particles (white) are dominantly present in the augmented site (red). Adapted from Rack, A.; Zabler, S.; Müller, B. R.; *et al*. *Nucl. Instrum. Meth. Phys. Res. A* **2008**, *586*, 327–344.

these particles display a very limited biodegradability. At the same time, they only support limited bone formation at their surface, thereby resulting in a high soft-tissue particle contact and poor bone-bonding behavior. Again, to validate and also to extend the results derived from SμCT, histological sections were prepared (see Figure 7 (top)).

For comparison, the SμCT volume image showing bone and ceramic particles was sectioned and orientated so that the slice corresponding to the histological image becomes visible (*cf*. Figure 7). The amount of detected bone differs between the two images. When taking a closer look it becomes evident that the amount of bone visible in the lower right of the images is identical for both the tomographical as well as the histological image. This is bone tissue adjacent to the implantation site which was already present prior to implantation. However, in between the 352i particles a slightly greater amount of bone appears to be visible in the histological image when compared to the tomographical image. This appears to be newly forming bone tissue which is not fully mineralized. In the early stages of the bone formation, the tissue exhibits a lower degree of mineralization, thereby being less dense than a mature bone.[102] As a result it cannot be detected in the absorption contrast microtomography image due to its low density contrast whereas it is visible in the histological images. However, in the histological image, the considerable amount of soft tissue in contact with the bone substitute particles also becomes evident.

The use of microtomographic and histological images for characterizing the bone-regenerative capacity and biodegradability of GB9 and 352i facilitates analyzing the significant differences in how fast these materials degrade. With respect to the rapidly resorbable material, GB9 formation of mature and fully mineralized bone could be demonstrated after 12 and 24 weeks of implantation, whereas for the material 352i, limited bone formation and bone tissue with a low degree of mineralization was detected at 12 weeks.

By performing a qualitative comparison between a microtomographic slice and the corresponding histological section, the matching (or nonmatching) of the information collected by the two differing imaging techniques for a selected sample can be evaluated (see **Figure 6** vs. **Figure 7**). In case of a high level of congruence, the tomographic data set extends the capacity of hard-tissue histologic images into three dimensions. Hence, the bioregeneration of bone can be studied in a true spatial as well as nondestructive manner. The next section will underscore the value of the tomographic approach using hard X-ray synchrotron radiation to not only qualitatively but also to quantitatively determine the amount of bone regeneration in a given defect.

3.304.3. Bone Regeneration After Sinus Floor Augmentation in Humans

3.304.3.1. Surgery and Biopsy

In order to study bone regeneration in the human case, the effect of two particulate tricalcium phosphate materials (porosity 35% and 60%, respectively) on osteogenic marker expression and bone formation was evaluated in biopsies sampled 6 months after augmentation of the sinus floor.[103] This was in addition to examining the biodegradability. Two of these patients were selected for SμCT-analysis. Sinus floor augmentation was performed using β-tricalcium phosphate (TCP) particles with either 35% porosity (TCP, grain size 1000–2000 μm, product label: Cerasorb, Curasan AG, Kleinostheim, Germany) or 60% porosity (TCP-P, grain size 1000–2000 μm, product label: Ceros, Mathys AG, Bettlach, Switzerland).

Sinus floor augmentation elevation was carried out under local anesthesia. A staged surgical approach was used in which dental implant placement is performed 6 months after sinus floor augmentation. This was due to the fact that the height of the residual alveolar process was only 1 mm in the posterior maxillary region. Then the newly created space between the maxillary alveolar process and the elevated Schneiderian membrane was filled using a mixture (4:1 ratio) of β-TCP particles and autogenous bone chips. X-ray images were taken postoperative which allowed to examine the volume of the augmented sinus floor directly after sinus floor elevation as well as to determine volume alterations after the healing period of 6 month, that is, prior to implant placement.[59]

The dental implant placement as well as biopsy sampling were also performed in local anesthesia. One biopsy from each patient was harvested utilizing a trephine burr (2.75 mm inner diameter and 3.50 mm outer diameter), at one of the dental implant sites, in which the height of the original residual alveolar crest prior to augmentation was ~1 mm and the depth of the implant bed prepared after augmentation was roughly 12 mm (after augmentation). The biopsies were 2.5 mm in diameter and roughly 8 mm in length. Specimens underwent histological, histomorphometric, and SμCT examination. They contained the grafted area as well as the native alveolar crest of the sinus floor, which was ~1 mm in height. We would like to note that the residual native crest was not included in any analysis.

For the histological as well histomorphometric analysis, a novel technique which facilitated performing immunohistochemical analysis on undecalcified hard-tissue sections as described previously was used.[100,103] In brief, samples were fixed immediately in an ethanol-based fixative Neofix^R (Merck KGaA, Darmstadt, Germany) commonly for 3 days at room temperature. This was followed by infiltration and dehydration. Then the specimens were embedded in a resin, which was composed of metylmetacrylate and *n*-butyl-metracrylate to which benzoyl peroxide (BPO catalyst, Merck KGaA, Darmstadt, Germany) and polyethylene glycol 400 (Merck KGaA, Darmstadt, Germany) and 1.5 ml *N*,*N*-dimethyl-*p*-toluidine (Merck KGaA, Darmstadt, Germany) were added. Samples were polymerized in polyethylene vials. This resin was selected because it maintained the antigenicity of the tissue and at the same time also provided adequate material properties for cutting the 50-μm-thick sections with a sawing microtome. After polymerization, the blocks were removed from the vials and excess resin was trimmed away. Both tissue blocks, which contained the entire biopsy cylinders, underwent SμCT scans prior to histological sectioning and histomorphometrical evaluation. Further details on the SμCT scans are given in the next section.

Following the tomographic data acquisition at the synchrotron light source the resin blocks which contained the biopsies were glued to acrylic slides (Plexiglas GS 209, Rohm GmbH & Co. KG, Darmstadt, Germany) by applying an epoxy resin based two-component adhesive (UHU GmbH & Co. KG, Buhl, Germany). Fifty microns sections were then cut with a Leitz 1600 sawing microtome (Leitz, Wetzlar, Germany). These sections were then grounded and polished. Prior to the immuno-histochemical staining, deacrylation of sections was done by immersion in toluene, xylene and acetone. Subsequently the sections were rinsed in distilled water and placed in *Tris*-buffer (pH 7.4). Immunohistochemical staining was then performed as described previously,[103] Mayer's haematoxylin was used as a counterstain.

Histomorphometric analysis was performed on pairs of 20–30-μm-sections which were ~150 μm apart. Both sections were measured semiautomatically using a light microscope (Olympus, Hamburg, Germany) in combination with a digital camera (Colourview III) and the SIS Analysis™ software (Olympus, Hamburg, Germany). Additionally, a square area of 6.25 mm^2 was defined within the longitudinal plane of each specimen. For both biopsies, the surface area that consisted of bone and the area that consisted of graft material were measured in square millimeters. Additionally, the area fraction of bone, as well as the area fraction of grafted material, was analyzed as a percentage of the total area and were averaged. Because there were no histomorphometric discrepancies between both sections of each biopsy specimen, one section was chosen as a representative for the later SμCT comparison in the following sections.

3.304.3.2. Microtomography and Volume Image Analysis

Like in the previous section, the microtomography experiments were performed at the BAM*line* of the BESSY-II light source (Helmholtz Zentrum Berlin für Materialien und Energie (HZB), Germany), see as well Görner *et al.*[33] and Rack *et al.*[34] A photograph and a schematic of the imaging station are shown in Figure 3. The optimal X-ray energy for the tomographic scans was determined experimentally to be ~20 keV (monochromatic): assuming that the best contrast is given when the condition $\mu D = 2$ (μ: linear X-ray attenuation coefficient, D: sample diameter) is fulfilled, which equals to an overall X-ray transmission T by the sample of $T = 13.5\%$.[24]

For the indirect detector, a 50-μm-thick cadmium tungstate ($CdWO_4$) single-crystal scintillator glued on top of a 0.5-mm-thick yttrium–aluminum garnet substrate ($Y_3Al_5O_{12}$) was chosen. Its luminescence image is projected onto the CCD chip of a Princeton Instruments camera VersArray:2048B with an effective 9× magnification (leading to an effective pixel size of 1.5 μm and a real spatial resolution of ~4 μm) using a Rodenstock 'TV-Heligon' (front objective, $f = 21$ mm, maximum $NA = 0.5$) in combination with the Nikon 'Nikkor 180/2.8 ED' ($f = 180$ mm). The choice of the pixel size was determined by the dimensions of the sample (2.5 mm in diameter) as well as the finite size of the CCD sensor (leading to a $3.2 \times 3.2\,mm^2$ field of view). In order to achieve a good reconstruction quality, 1500 projection images were recorded for each SμCT scan of one of the specimens. For the reconstruction, the filtered back projection algorithm[18] was applied utilizing a software package which was developed by the SciSoft group of the European Synchrotron Radiation Facility (ESRF) – PyHST.[101]

Due to correspondingly short detector-to-sample distance chosen, the contrast in the acquired SμCT images is dominated by the absorption, common phase contrast edge enhancements are only slightly present. This is as well due to the spatial resolution of the employed indirect detector setup as well as the coherence properties of the BAM*line* (~165 μm horizontal source size). Similar to the previous section, the contrast of the fully developed mature, that is, mineralized bone was used to create Boolean images of the bone phase by applying a region growing algorithm in combination with a threshold hysteresis (*cf.* example images in Figure 4). While in the sheep study, the focus was on the volume renderings, in case of the human specimens, we consider a quantitative approach in order to compare the two-dimensional histological results with the volumetric analysis performed via SμCT. Therefore, for the specimens investigated, a histologic section as well as a SμCT image was acquired. Manual scanning of the tomographic data set in meridional and sagittal orientation allowed us to find the slice in the volume image which corresponds to the histologic section (see, e.g., Figure 8). Plain voxel counting in the Boolean slice which shows the same information as the histologic section gives access to the two-dimensional bone density. The same procedure when applied to the whole volume image determines the true three-dimensional bone density. Thus, it opens to the possibility of comparing histologic results with a truly three-dimensional approach in a quantitative manner.

3.304.3.3. Results

A scan of the central portion of a human specimen which shows regenerated bone after augmentation with Cerasorb particles (β-TCP with 35% porosity) is depicted in Figure 8. In the top portion the histological image as compared to the SμCT slice containing the same information is shown. Below the volume rendering of the complete data set, sectioned along the same slice which corresponds to the histologic section. The three-dimensional visualization shows the new bone which formed in conjunction with degradation of the TCP particles. The newly formed bone was predominantly a lamellar bone with different degrees of mineralization – higher degrees in the central areas (light red colored) and lower degrees in the marginal areas of the regenerated bone (dark red colored).

As described in the previous sections, two-dimensional histomorphometric image analysis was performed on the histological image in a manual manner. Histomorphometrically the bone area fraction was determined to be 53.3%. From the Boolean image of the corresponding tomographic slice a value of 54.9% was calculated. The absolute difference of only 1.6% between the two results underscores the good correspondence of the information gathered by microtomography and histomorphometry in terms of contrast. Consequently, this facilitates using tomographic data to measure the real bone volume fraction in a three-dimensional manner. The volume image analysis after processing the SμCT data set showed 48.8% of the entire volume of the central portion of the biopsy to consist of newly formed bone 6 months after sinus floor augmentation. So, the measurements of the bone volume determined by calculating it via the three-dimensional SμCT data differed from the values of the bone area fraction (histomorphometry) by 8.5%.

Concerning the second specimen, a scan of a human biopsy after augmentation with Ceros particles (β-TCP with 60% porosity) is shown in Figure 9. Again, in the top portion the histological image is shown as compared to the corresponding SμCT slice. In the bottom portion of the image, a volume rendering of the complete data set is depicted, sectioned along the slice which is shown in the top portion of the figure. Here, 6 months after sinus floor augmentation the volume image shows different degrees of mineralization of the newly formed bone, clearly visible in terms of different shades of red. Residual β-TCP particles are clearly visible (blue color). When taking a comparative look on the three-dimensional images shown in Figures 8 and 9 it becomes evident that the TCP-P (Ceros) bone biopsy specimen exhibits a tightly-meshed bone pattern with increased density. This is associated with a decreasing volume of bone marrow spaces and the yet unmineralized fibrous matrix. Furthermore, residual particles of the degrading ceramic material display good bone formation at their surface, that is, good bone-bonding behavior.

Identical to the Cerasorb specimen, two-dimensional image analysis was done manually on the histological section. In this case, the bone area fraction measured histomorphometrically was 38.8%. Here the two-dimensional image analysis of the tomographic data as transformed into a Boolean image revealed a bone area fraction of 39.0%. Like in the previous case, both methods of two-dimensional analysis delivered similar results. Hence, it was possible to progress

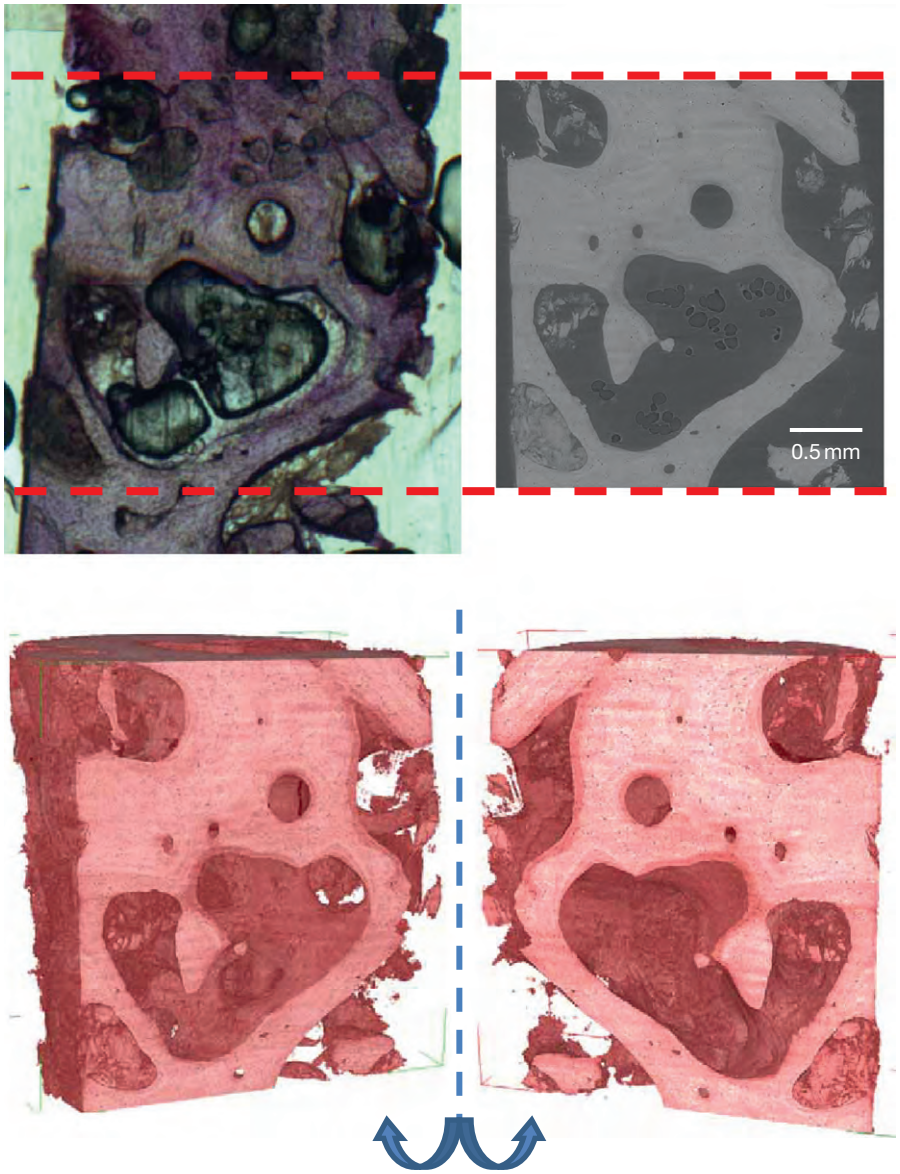

Figure 8 Human bone biopsy sampled 6 months after sinus floor augmentation with Cerasorb particles (35% porosity) – top: histologically prepared section (left, bone in violet-blue, bone marrow spaces and soft tissue in brownish-gray) and corresponding tomographic slice (right). Bottom: volume rendering of the complete tomographic image, sectioned along the slice representing as well the histological information. Adapted from Stiller, M.; Rack, A.; Zabler, S.; *et al*. *Bone* **2009**, *44*, 619–628.

then to measure the real three-dimensional bone volume fraction based on the Boolean image of the SμCT data set. In this case, the data processing resulted in a value of 36.3% for the bone volume fraction of the examined portion of the biopsy. The difference between the bone area fraction measured using conventional histomorphometry versus the bone volume as determined by SμCT is 6.5% and therefore less compared to the case in which the less porous β-TCP was used and in which a more cancellous pattern of bone regeneration pattern was observed.

But, in both cases it became evident that the application of only classical two-dimensional methods for analysis like histomorphometry is associated with significant errors in the results. By applying synchrotron-based microtomography with its widely nondestructive manner, three-dimensional nature, as well as high contrast, it is possible to progress to histovolumetry which allows for a more precise analysis of, for example, bone regeneration.

3.304.4. Summary

Synchrotron-based microtomography is an established technique available at various synchrotron light sources worldwide (see Table 1). The combination of high resolution with high signal-to-noise ratio and different contrast modalities renders SμCT as an excellently suited analytical tool for studies in biomedical fields such as bone research and hard-tissue research.

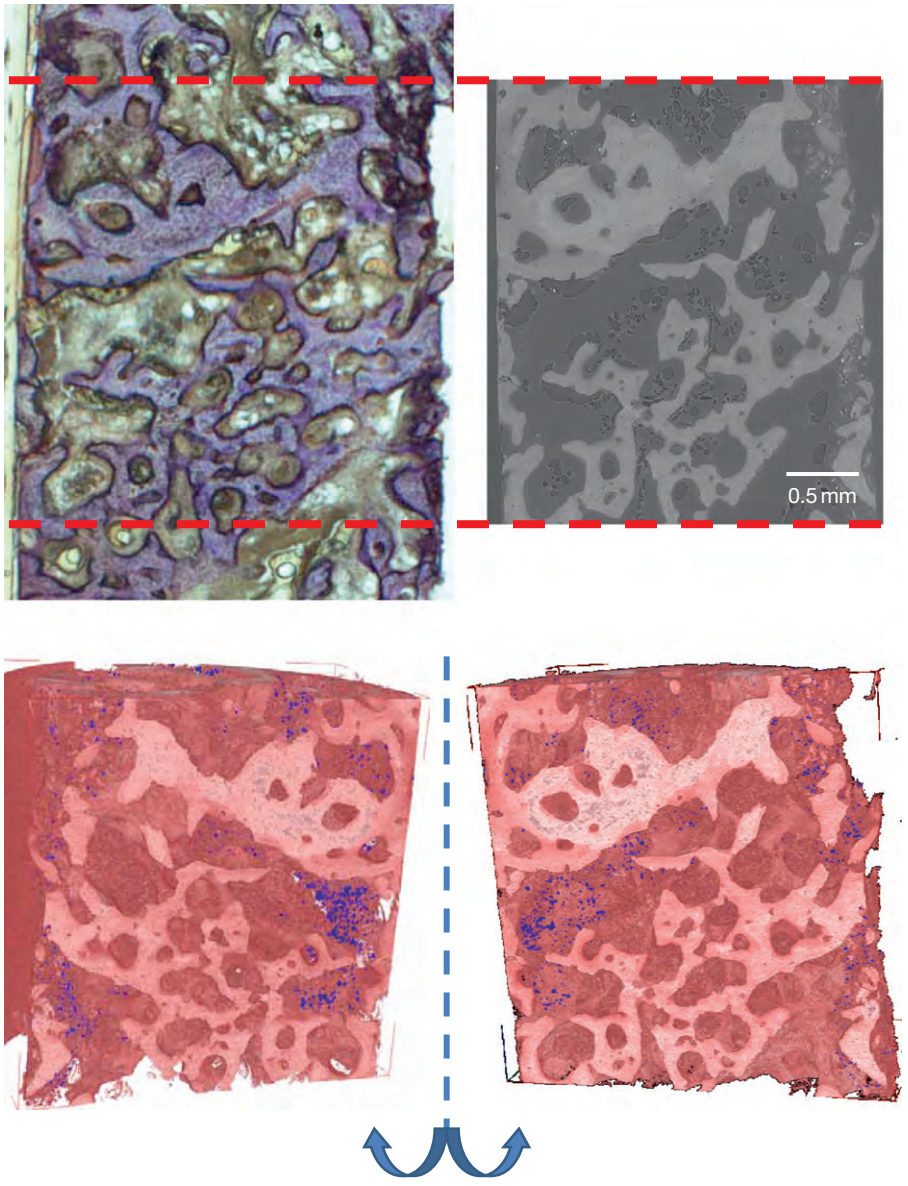

Figure 9 Human bone biopsy sampled 6 months after sinus floor augmentation with Ceros particles (60% porosity) – top: histologically prepared section (left, bone in blue, bone marrow spaces and soft tissue in gray, residual particles black) and corresponding tomographic slice (right). Bottom: volume rendering of the complete tomographic image, sectioned along the slice representing the histological information. Residual bioceramic particles are detectable (deep blue color). Adapted from Stiller, M.; Rack, A.; Zabler, S.; *et al*. *Bone* **2009**, *44*, 619–628.

Countless successful applications have been published in recent years, a selection of which has been outlined in the first section of this chapter.

The analysis of bone regeneration supported by different bioceramic materials using SμCT has been described as one of the many potential applications in the field of biomaterials research. Here, comparing bioceramic compositions with different resorbability in the context of an animal study showed that based on the qualitative agreement between histological sections and corresponding tomographic slices, SμCT can be considered as an extension of the classical histology into three dimensions. In addition to the three-dimensional approach, SμCT compared to the sectioning of specimens provides information in a widely nondestructive manner. The increased reliability of the achieved results was demonstrated in a second study, in which quantitative analysis was employed to compare the amount of regenerated bone as analyzed using histomorphometry to the results yielded by SμCT in combination with volume image analysis. A significant difference with respect to the amount of bone determined was demonstrated. Consequently, so-called histovolumetry needs to be considered for future studies in order to verify, qualify or falsify the results based on classical two-dimensional techniques.

Besides the high potential of synchrotron-based imaging techniques, a drawback will remain which is the limited beamtime available and the high costs of synchrotron light. Therefore, this analytical tool, will be dedicated to the analysis of selected specimens and cases. A fact, which is not going to be

changed within the near future, despite the many light sources which have recently started operations.

For the future, two main developments are supposed to open new possibilities for biomedical and biomaterials research using synchrotron light. One is based on the extended resolution capabilities when X-ray optics are employed. Hierarchical imaging showing, for example, the structure of a specimen on the macroscopic, microscopic, and nanoscopic scale combined with different contrast modalities (multimodal imaging) will be a goal only to be reached when synchrotron light sources are employed. Furthermore, a second development is the increased data acquisition speed which will push further for *in situ* examination of specimens in combination with time-resolution.

Acknowledgments

We like to acknowledge the support of J. Goebbels, B. R. Müller, T. Wolk, and G. Weidemann (BAM) during the data acquisition at the BAM*line*, G. Berger, R. Gildenhaar (BAM) for developing and fabricating the calcium alkali orthophosphate bone substitute materials, Ch. Koch, H. Seeligmann, I. Borchert, A. Besnarek, and A. Kopp (Charité) for the histologic sections, T. Weitkamp (ESRF) for the tomographic slices of the rat heart, O. Betz (Universität Tübingen) for the tomographic image of the head of Forficula auricularia (Dermaptera) and F. Peyrin (ESRF) for the volume rendering of the hydroxyapatite scaffold with newly formed mouse bone. Parts of this work were founded by the German Research Foundation (DFG-grant no. KN 377/3-1).

OA	Osteoarthritis
PACVD	Plasma-assisted chemical vapor deposition
PVD	Physical vapor deposition
THR	Total hip replacement
UHMWPE	Ultra-high molecular weight polyethylene

3.305.1. Introduction

Degenerative joint disease is recognized as an increasing problem for society as a direct result of an ageing population. More than 700 000 primary total hip and knee replacements are performed each year in the United States, and demand for the surgery is expected to double in the next 10 years. When a person has joint pain and joint immobility, the main concern is the relief of that pain and the return to a healthy and functional lifestyle. The degeneration of joints often makes surgical repair or replacement necessary. Most of the implants used in orthopedics usually utilize a surface modification method such as protective, hard, or bioactive coatings to improve reliability and long-term performance.

Osteoarthritis is the degeneration of the articular surface of the joint. The word arthritis literally means joint inflammation. There are two basic and separate causes of arthritis, inflammation, and mechanical damage. Mechanical damage is related to osteoarthritis where either a limb fracture or prolonged mechanical overload initiates degradation of the articular cartilage. Osteoarthritis is the most common form, and the hip is one of the common joints affected by this. It is a degenerative process, which directly results in the wearing out of the articulating cartilage on the joint's surface. Over time, the joint surfaces slowly deteriorate until the underlying bone is exposed. Exposed bone results in a painful joint when it moves and bears weight. As a result, hip pain and stiffness increase and the bones articulate without the load-distributing effect of the cartilage.[1] Other hip problems that produce similar symptoms include rheumatoid arthritis and avascular necrosis (injury and loss of blood supply to the bones).

Osteoarthritis (OA), also known as degenerative joint disease, is a painful and debilitating condition that affects many people, including the relatively young. It is said to be the most common musculoskeletal disorder affecting the western world. Overall OA affects 13.9% of adults aged 25 and older

and 33.6% (12.4 million) of those older than 65; an estimated 26.9 million US adults in 2005. In OA of the hip, the most common surgical treatment is some form of hip replacement (or arthroplasty). In Australia, in the period from September 1999 to the end of 2007, there were just over 125 000 primary total hip replacement (THR) surgeries, almost 90% of them for OA.[2] THR has been described as an orthopedic success story, enabling hundreds of thousands of people to live fuller, more active lives. Despite the success of THR it has been observed that it is not so suitable for younger patients who wish to return to a more active lifestyle.[3]

The probability of survival of THRs in younger patients is around 80% after 10 years and drops to 50% after 20 years. Therefore, patients under 50 years old would be likely to outlive their implants.

Hip resurfacing (HR) is proposed as a bone-conserving alternative for younger, heavier, and more active patients for whom a total hip replacement is less suitable. Despite its popularity, and increasing acceptance and use by orthopedic surgeons, there still remains controversy and disagreement over whether it should be used or not.[4,5] One of the main concerns is the incidence of early, postoperative, hip fracture.[6,7] The other main cause of failure of HR is loosening of the femoral implant.

In Australia, in the period from September 1999 to December 2007, there were almost 11 000 HR with 150 revised because of femoral fracture and 89 because of loosening.[2] There are several anatomical and surgical parameters that affect the incidence and likelihood of hip fracture and loosening.

As early as the 1960s and 1970s in Europe, Charnley, Scales, McKee, Ring, and Muller developed either metal–polyethylene (M–PE) bearings for total hip replacements (THR) or all metal (M–M) cobalt–chromium–molybdenum (CoCr) heads and cups.[8]

Currently, bearing surfaces for hip joints fall into two broad categories. Firstly, the so-called *hard-on-soft* combinations in which hard materials such as metal or ceramic implants articulate against polyethylene. Secondly, the so-called *hard-on-hard* bearing surfaces in which the same hard components articulate against themselves. New bearing surfaces are being sought, which give significant reductions in both the volume of wear debris generated and its effect on the body.[9]

3.305.1.1. Why Surface Engineering?

The release of particulate matter derived from THRs is important in determining the long-term survival of the prosthesis. Polyethylene debris derived from a M–PE coupling appears to cause the most pronounced tissue reaction. Phagocytosis of wear debris induces an inflammatory reaction associated with the release of cytokines and other inflammatory mediators. Once osteolysis has occurred, it tends to progress and may ultimately lead to failure of the implant. Consequently, it is appropriate to consider the use of bearing surfaces with a greater resistance to the production of osteolytic wear debris, such as metal-on-metal and ceramic-on-ceramic systems.[10]

Wear in metal-on-metal components is known to consist of two distinct phases. A relatively high-wear running-in phase followed by a steady-state phase when the wear rate is relatively constant and much lower. Metal-on-metal components have given good clinical results but there are still concerns over long-term exposure to elevated levels of metal ions.[9]

Surface engineering of the metallic bearing surface offers an alternative approach to reduce metallic wear debris in metal-on-metal bearing couples for hip prostheses. Fully surface-engineered bearing systems are used to reduce the wear rates for metal-on-metal prostheses and to minimize the generation of wear debris and the release of metal ions. After 2 million cycles in a physiological anatomical hip joint simulator test, it has been shown that the wear rates of full surface-engineered (surface-coated) prostheses were at least 23-fold lower for the heads and 6-fold lower for the inserts than the traditional clinical metal-on-metal prostheses, which leads to at least an 18-fold reduction in the overall wear rates.[11]

3.305.2. Coating Techniques

Coatings offer the possibility of modifying the surface properties of surgical-grade materials to achieve improvements in performance, reliability, and biocompatibility. Techniques such as physical vapor deposition (PVD), chemical vapor deposition (CVD), metal–organic chemical vapor deposition (MOCVD), electrochemical vapor deposition, thermal or diffusion conversion, and sol–gel processing have been used to produce both micro- and nanocoatings.

3.305.2.1. Plasma Coating of Calcium Phosphates

Hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$, is widely accepted as a biocompatible material, which resembles the mineral component of bone and teeth.[12,13]

Since the early 1980s calcium phosphates have been used as porous coating materials on a range of metallic implants for orthopedic and maxillofacial applications.[14,15]

This was initiated to compensate for the poor mechanical properties of porous bulk calcium phosphate materials and utilize the excellent mechanical properties of the metallic substrates.

Over the years, a large number of coating methods have been investigated, ranging from thermal processes to sophisticated ion implantation methods, to produce calcium phosphate coatings, but plasma spraying has been the only commercial method widely applied to metallic implants.

A mixture of amorphous and crystalline phases results from the spraying process leading to variable solubility, dictated by the amount of the amorphous phase. While some manufacturers prefer a more crystalline coating, others prefer faster dissolving amorphous or calcium oxide containing coatings.

The advantage lies in the supply of calcium and phosphate ions that stimulate bone tissue growth toward the surface. However, a good balance must be reached between the solubility and the bone growth rate to allow good mechanical bonding and properties at the implant–tissue interface. Pure hydroxyapatite coatings are now being substituted by chitosan/hydroxyapatite composites[16] to improve bone adhesion or by fluorohydroxyapatite coatings to improve bone integration.[17]

The ideal environment for bone growth is established whereby metal ion release is reduced, good mechanical interlocking is established, and a bioactive surface is available.[18]

Thermal spraying is a well-established technology for forming hard coatings on selected component substrates. The coating material is heated in a gaseous medium and projected at high velocity as molten droplets onto a substrate surface. Upon impact, the droplets become flattened, heat is transferred to the cold substrate and the droplets solidify rapidly to form the 'splat.' Powders, rod, and wires can be used as feedstock materials.[19,20]

Thermal processing of hydroxyapatite has been controversial. The complexity of plasma processing requires a high degree of skill to ensure that the desired product is deposited. Every particle travels through the heat source and is subjected to a unique processing environment dictated by the thermokinetic history of the particle. Several approaches are being used to provide a reproducible environment. Axial powder delivery, unlike transverse delivery, provides injection directly into the heat source.

Several thermal processing routes can be employed depending on the materials and desired coating. These include plasma spraying, high velocity oxyfuel (HVOF) spraying, detonation flame spraying, and flame spraying. Plasma spraying can be carried out in an ambient atmosphere (atmospheric plasma spraying, APS), under vacuum (vacuum plasma spraying, VPS), or under controlled atmospheres, such as nitrogen. Plasma spraying uses a direct current arc to produce gas plasma, although other sources, such as radiofrequency-generated plasmas can be used. Each is capable of producing coatings of thickness ranging from a few microns to a few millimeters. The high-temperature decomposition during plasma spraying impedes the deposition of hydroxyapatite coatings.[18]

A narrow particle size distribution provides each particle with a comparable heat history. Atmospheric plasma spraying causes turbulence that introduces cold pockets into the spray stream. Turbulence can be reduced by plasma spraying in a vacuum or with a flame.

The control of particle melting leads the way to predictable solidified droplet microstructures. Electron microscopy has long been a useful technique to visually identify the appearance of the deposit. Micro-Raman provides the ability to assess the chemical bonding within each flattened droplet. Micro-X-ray diffraction, available at synchrotron light sources, provides an analysis of the crystal structure. Nanoindentation testing, also known as depth-sensing indentation, is ideally suited for measuring hardness and elastic modulus of droplets or thin films/coatings and will be discussed later in this chapter.

3.305.2.2. Nanocrystalline Coatings

Nanocrystalline coatings with grain sizes in the nanometer range are known to exhibit superior hardness and strength. The search for nanostructured coatings is driven by the improvement in nanocoating techniques and the availability of various kinds of precursor materials and sources.

Coating is a technique for the surface modification of the base material in order to enhance the physical and/or mechanical performances of tools and structural components. Existing PVD and CVD processes for preparing microcrystalline coatings can be used to produce nanostructured coatings by modifying the processing parameters or by using feedstock powders having nanograined structures. In addition, conventional plasma spraying and high velocity oxygen fuel thermal spraying are viable high-rate deposition techniques to produce nanocrystalline coatings using nanosized feedstock powders.

Hard ceramic coatings have attracted increasing attention due to their potential applications in cutting and forming tools, bearings, engine parts, and seals. Hard coatings improve the durability of substrate materials in hostile environments against abrasive wear, to prolong the component life. The ever-growing need for superior materials to withstand severe operating conditions has driven the search for superhard coatings with hardness values above 40 GPa.[21–23] Until recently, hardness enhancement in a single layer could only be achieved by introducing mechanical stresses into the coatings. The limitations of conventional coatings due to inferior hardness, elastic modulus, and poor oxidation stability are overcome by nanocomposite hard coatings such as nc-TiN/α-SiN_x, which consist of nanocrystalline TiN and a noncrystalline tissue phase of SiN_x, which are mutually immiscible. The improved mechanical properties of these nanocomposites can be explained by their nanostructure. Nanocomposite thin films exhibit hardness values significantly exceeding the microhardness that is given by the rule of mixture. Several research groups have reported on various superhard coatings with hardness exceeding 40 GPa. However, there is a distinguishable difference between superhard films where the high hardness values originate from the high compressive stress induced during the deposition by energetic ion bombardment and a second 'family' of coatings for which the hardness is due to the nanostructure arrangement.[22] Superhard nanocomposite thin films are at the early stage of development and appear to have a wide range of applications.

Although many different coating techniques and their modified versions exist, we will briefly explain only three basic methods. There are a number of review papers that cover each in more detail.[24,25]

3.305.2.2.1. Physical vapor deposition

Deposition of thin films by PVD techniques has found widespread use in many industrial sectors. State-of-the-art magnetron sputtering processes allow the deposition of metals, alloys, ceramic, and polymer thin films onto a wide range of substrate materials. Therefore, it is used in many coating applications, for example, metal-working industry, biomedical applications, and optical or electrical components. There is an increasing demand for coatings with tailored and enhanced properties such as high hardness, wear and corrosion resistance, low friction, and specific optical or electrical properties as well as decorative colors, and often, complex combinations of those properties are required.

PVD is a versatile synthesis method and is capable of preparing thin film materials with structural control at the atomic or nanometer scale by careful monitoring of the processing conditions. PVD involves the generation of vapor phase species either via evaporation, sputtering, laser ablation, or ion beam. In most PVD-based processing approaches, it is not possible to uniformly coat nonplanar substrates without sophisticated substrate translation/rotation or the use of multiple, spatially distributed sources. This arises because the vapor atoms are created in high vacuum that results in nearly collisionless vapor transport to the substrate. As a result, only regions in the line-of-sight of the vapor source are coated.[26]

3.305.2.2.2. Chemical vapor deposition

CVD of films and coatings involves the chemical reactions of gaseous reactants on or near the vicinity of a heated substrate surface. This atomistic deposition method can provide highly pure materials with structural control at atomic or nanometer-scale levels. Moreover, it can produce single layer, multilayer, composite, nanostructured, and functionally graded coating materials with well-controlled dimension and unique structure at low processing temperatures.

Furthermore, the unique feature of CVD over other deposition techniques such as the non-line-of-sight-deposition capability has allowed the coating of complex-shaped engineering components and the fabrication of nanodevices and composites. The versatility of CVD has led to rapid growth in the use of functional devices and it has become one of the main processing methods for the deposition of thin films and coatings for a wide range of applications, including refractory ceramic materials used for hard coatings and metallic films for protective coatings.[27]

3.305.2.2.3. Sol–gel nanocoating method

Sol–gel-derived nanocoatings are one of the preferred thin film production methods due to the relative ease of production and the inexpensive equipment utilized. The advantages of the process are based on its ability to form a physically and chemically pure and uniform coating over complex geometric shapes and the potential to deliver exceptional mechanical properties.

By definition, a sol is a suspension of colloidal particles in a liquid. A sol differs from a solution in that a solution is a single-phase system, whereas a sol is a two-phase, solid–liquid system. Colloidal particles can be in the approximate size range of 1–1000 nm; hence gravitational forces on these particles are negligible and interactions are dominated by short-range forces and surface charges.

Reducing their surface charge can modify the stability of the sol particles. If the surface charge is reduced sufficiently, 'gelation' is induced and the resultant product is able to maintain its shape without the assistance of a mould. Gels are regarded as composites, since they consist of a solid skeleton or network that encloses a liquid phase or excess of solvent. Depending on their chemistry, they can be soft and have a low elastic modulus, usually obtained through controlled polymerization of the hydrolyzed starting compound. In this case, a three-dimensional network forms, resulting ultimately in a high molecular weight polymeric gel. The gel can be thought of as a macroscopic molecule that extends throughout the solution. The gelation point is the time taken for the last bond in this network to form. This gelation can be used to produce nanostructured monoliths, powders, platelets, or nanosized coatings, depending on the process applied. Shrinkage problems are the main concerns in monolithic structures.

Sol–gel processing is unique in that it can be used to produce different forms, such as powders, platelets, coatings, fibers, and monoliths of the same composition, merely by varying the chemistry, viscosity, and other factors of a given solution. Furthermore, the range of different compositions that can be produced includes single oxides, mixed oxides, and nonoxides such as nitrides, borides, and chlorides.[28]

The advantages of the sol–gel techniques are numerous; it is nanoscale; it results in a stoichiometric, homogeneous, and pure product owing to mixing on the molecular scale; high purity can be maintained as grinding can be avoided; it allows reduced firing temperatures due to its small particle sizes with high surface areas; it has the ability to produce uniform fine-grained structures; it allows the use of different chemical routes; and it is easily applied to complex shapes with a range of coating techniques, including dip, spin, and spray deposition.[29–31]

Furthermore, sol–gel coatings have the added advantages that the costs of precursor materials are relatively unimportant, owing to small amounts of material requirements. Shrinkage for a number of coatings, depending on the chemistry, is fairly uniform perpendicular to the substrate and the coating can dry rapidly without cracking. A single layer coating is ~70–100 nm. Several layers can be applied, but cracking is typically an issue when more than four layers are applied, even with alternating sol gel deposition and sintering.[31–34]

Sol–gel film deposition also offers the advantage over other film depositions techniques in that thickness, pore volume, size, and surface area can be relatively easily controlled by synthesis methods or chemistry. Significant research has been conducted on the design of hard coatings with excellent strength, hardness, and toughness characteristics. One of the design concepts is based on the formation of multilayered gradient structures or superlattices having a difference in the elastic modulus between the layers. The thickness of each layer is in the nanometer range and a number of methods are used to produce multilayered films with desired nanohardness values. Another design approach utilizes the formation of single-layer nanocomposite coatings with microstructures comprising nanocrystallites embedded in an amorphous matrix.[35]

3.305.2.3. Diamond-like Carbon

Diamond-like carbon (DLC) has been the focus of extensive research in recent years due to its potential application in many technological areas. The combination of low friction, wear resistance, high hardness, biocompatibility, hemocompatibility, and chemical inertness makes it suitable for a number of applications ranging from the coatings of stents, heart valves, orthopedic components, and prostheses in the biomedical industry.[36,37] DLC and doped DLC have been investigated extensively for possible biomedical applications. It has been demonstrated that doping with elements such as Si, N, F, Ca, and P improves the properties of DLC such as biocompatibility, infection resistance, and mechanical properties.[38–41] DLC films have been used to coat the surfaces of blood-interfacing prostheses. A number of different deposition technologies have been described for synthesizing DLC films.[42] The most common deposition technique used is RF-based (13.56 MHz) plasma-assisted chemical vapor deposition (PACVD). This technique allows high-quality DLC coatings to be deposited onto complex-shaped items at low temperature (**Table 1**).

3.305.3. Thin Film Mechanical Testing: Methods

With the ever increasing demands imposed by the use of bioimplants and devices, novel techniques are required to assess their mechanical reliability. Methods for ascertaining mechanical properties and adhesion have been stimulated by developments

Table 1 Thin film mechanical properties of some common thin films showing according to their deposition techniques, nanoindentation hardness, and Young's modulus values

Thin film material	*Hardness (GPa)*	*Elastic modulus (GPa)*	*Deposition process*	*References*
Hydroxyapatite	1.5–5.0	60–100	Microplasma spraying	84
Hydroxyapatite	2.5–3.0	65–140	PLD	19
Hydroxyapatite	4.5–5.2	100–120	RF magnetron	20
DLC	20–47	180–415	PLD	85
DLC	10–16	70–120	RF magnetron	86
DLC	16	150	PACVD	36
DLC-Si	12–16	110–150	PACVD	36
DLC-F	6–16	80–150	PACVD	39
DLC-SiO_x	11–16	100–150	PACVD	40
DLC-TiO_x	10–16	160–130	PACVD	38
TiN	15	250	CVD	87
TiN	25–27	250–280	FAD	21
TiO_2	17–18	200–210	FAD	88
TiO_2	4–7	–	PACVD	89
ta-C	34–42	295–345	FAD	90
ZrO_2	14–18	180–225	FAD	91
ZrO_2	6–12	120	Sol–gel	34,71
nc-TiN/α-SiN_x	40	300	FAD	21
SiO_2	2.5 $\pm$ 0.27	13.6 $\pm$ 0.4	Sol–gel	92
$ZrO_2/Al_2O_3/ZrO_2$	10.4$\pm$ 0.8	240 $\pm$ 22	Sol–gel	30

This table is designed to give some examples of the work carried out in the field. In most if not in all studies different thicknesses on and a number of different substrates were used. FAD, Filtered arc deposition; PACVD, Plasma assisted chemical vapor deposition; PLD, Pulsed laser deposition; RF magnetron, radio frequency magnetron; CVD, Chemical vapor deposition; SOL, Sol–gel deposition.

of bio-inspired coatings (i.e., hydroxyapatite) on metallic substrates, as discussed in the previous section. Methods to quantitatively determine the mechanical properties of these thin coatings on substrates or free-standing films are required. There have been constant improvements and developments in equipment capable of extracting the properties of the structure or film and also the adhesion of the coating to an underlying substrate.[43]

In general, we typically think of thin films in terms of their electronic, magnetic, or optical properties but many such devices are limited by their mechanical properties. Furthermore, for medical devices that are mainly used in very harsh physiological environments, it is extremely important to understand mechanical properties. A common definition of thin films is based on the substrate thickness and geometry, which influence the mechanical, and in general, physical properties.[44]

In biomedical applications, implants are usually much thicker than the thin film coatings applied to them. Some of the new generation coatings can be from a few nanometers in thickness up to a few millimeters thick. The question arises, can a 30–50 μm plasma-sprayed coating be classified as a thin film coating?

In the context of biomedical applications, coatings greater than 1000 μm should be considered 'thick' or 'macrocoatings', 1–1000 μm as 'thin film coatings' or 'microcoatings' and below 1 μm should be considered 'nanocoatings.'

An overview of some of the most widely used test methods for measuring mechanical properties and adhesion performance of micro- and nanocoatings on substrates pertinent to biomedical materials development is given. These methods can broadly be divided into the measurement of (i) coating properties and (ii) adhesion properties, although there may be some overlap with some techniques. For an excellent and comprehensive compilation of methods for studying film adhesion, the reader is referred to Lacombe.[45]

3.305.3.1. Instrumented Nanoindentation

The starting point and method of choice by many practitioners in the biomedical field for measuring the mechanical properties of coatings and implants is nanoindentation. The methodology and instrumentation have developed in leaps and bounds over the years and it is now considered a simple and effective means of obtaining meaningful measures of hardness, *H*, and Young's modulus, *E*, of coatings. The main requirements for obtaining the best possible results with such testing are in sample preparation, calibration of equipment and corrections for thermal drift, initial penetration, frame compliance, and indenter tip shape.[46–53]

In macro/microindentation, a load is applied and then removed and the area of the residual impression is measured.[54] By contrast, in nanoindentation, a set load (in the mN range) is applied to the indenter in contact with the specimen. As the load is applied, the penetration depth is measured (nm range). At maximum load, the area of contact is determined by the depth of the impression and the known angle or radius of the indenter. The result is a load–displacement curve as shown in **Figure 1** for pure hydroxyapatite, which yields contact pressure or hardness and Young's modulus from the shape of the unloading curve using software based on the model and indenter type (pointed, i.e., Berkovich, Vickers, Knoop, or spherical).[47] Likewise, different types of loading and unloading methods can be used to extract desired properties as a function of depth of penetration.[32,33,48,55] The application

of nanoindentation can also be directed toward the measurement of residual stress and film adhesion from direct indentation or transverse scratching as described by Fischer-Cripps.[48]

3.305.3.2. Adhesion and Wear Test Methods

Adhesion testing is necessary to ensure the coating will adhere properly to the substrate to which it is applied. Many techniques have been employed for adhesion measurement of films and coatings as demonstrated by Mittal.[56] The most popular test methods for measuring the adhesive bonding to substrates include pull-off, cross-cut, indentation scratching (increasing load), and pin-on-disk.

3.305.3.2.1. Pull-off testing

This is perhaps the most common method to determine the strength of a bond between a thin film and a thick substrate. Many types of configurations have been proposed[57] using universal testing machines or dedicated tensile testers. The main requirements are that the alignment of grips and sample fixture is precise to ensure uniform loading and that the adhesive used to bond the sample to the fixture is sufficiently strong (stronger than the bond strength of the film–substrate) and does not penetrate the interface of interest. The bond strength is determined from the critical load required to separate the film–substrate contact area. The main advantage of this technique is its versatility and applicability to a wide range of coating–substrate systems. It can be used for both soft flexible coating as well as hard brittle ones. The weakness in typical pull testing is the wide variation in data. One must perform multiple tests on a given sample and statistical analysis to obtain reliable quantitative data. In biomaterials, pull out is a more common mode of failure of a bone implant than bone fracture. Pull out may not necessarily occur at the interface between bone and coating, but instead between the metal and the hydroxyapatite coating.

3.305.3.2.2. Scratch testing

Scratch testers such as that shown in Figure 2 use a small diamond stylus or hard metal (WC; normally 200 μm radius), which is drawn across the coated surface at a constant velocity at increasing load. The load on the diamond causes stresses to be increased at the interface between the coating and the substrate, which can result in delamination or chipping of the coating. The load at which the coating first delaminates is called the critical load and is a measure of coating adhesion. Coating failure can be determined from load and the distance at which delamination begins using microscopy, or from the change in friction or using an acoustic emission sensor. In addition to the critical load, the applied normal force, the tangential (friction) force, and the penetration depth are obtained.

Figure 3 shows the typical cracking and delamination that occurs on scratching a hard titania coating on a polycarbonate substrate.

Analyzing scratch test results is difficult due to the complex stress states involved and the broad array of damage processes that can occur depending on film thickness and the mechanical properties of the film and substrate. The test is sensitive to loading rate, stylus shape, environment (humidity), and scratch speed. Thus, it is difficult to relate the critical load to film adhesion.

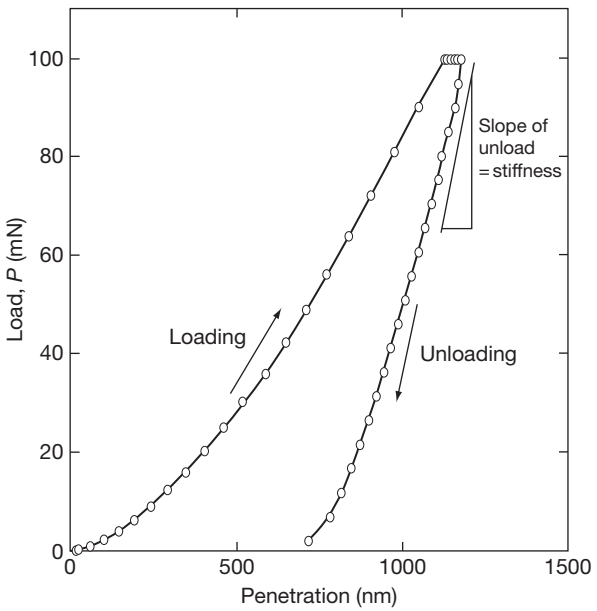

Figure 1 Indentation load–displacement curve for a pure hydroxyapatite using a Berkovich indenter ($H = 9.9$ GPa, $E = 110$ GPa).

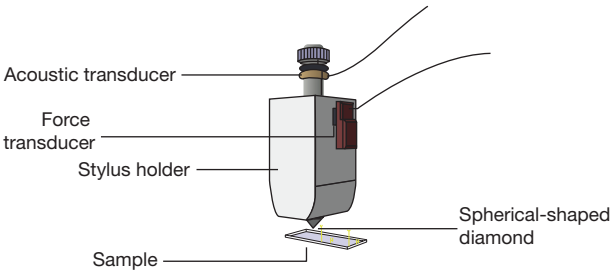

Figure 2 Typical scratch testing device (based on the Quad Group Inc. Romulus III universal test equipment).

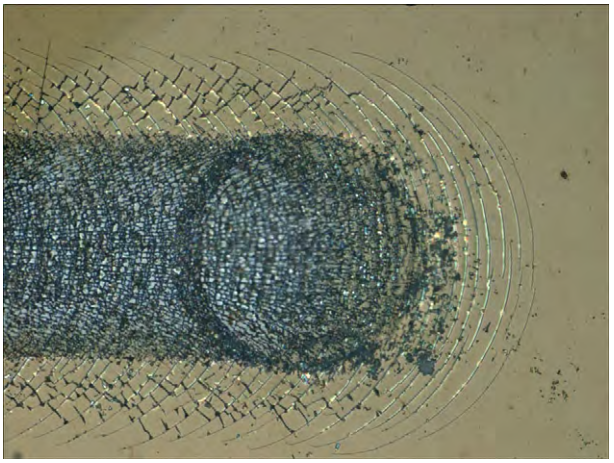

Figure 3 Scratch damage in a titanium oxide coating on a polycarbonate substrate. Horizontal field of view is 400 μm.

3.305.3.2.3. Pin on disk

Pin-on-disk tribometers are used to determine the friction coefficient and wear resistance of surfaces. The tester consists of a pin (normally a ruby, WC, or metal sphere) under a static load in contact with a rotating sample. The test can be run for an extended period of time either in air or a simulated body environment to provide information on the degradation of the coating with time (sliding distance). Similar devices that are used in biomaterials research are pin-on-plate type wear testing machines, such as the Ortho-Pod instrument (Advanced Mechanical Testing, Inc., Watertown, MA). This has six stations for the pins with independent servo-controlled variables that correspond to rotary motion of both the plate and the pins and the normal load applied to each of the six pins. The pin rotation feature gives this machine the ability to generate pin–plate sliding motions that are typically not available on standard pin-on-disk machines. The Ortho-Pod is an excellent tool for testing implant materials whose wear characteristics depend upon various sliding directions (crossings) as well as load, in either dry or a fully lubricated environment (serum or other fluids).

3.305.3.3. Microtensile Testing

In microtensile testing, the coating is deposited on a tensile coupon, which can then be pulled in a universal testing machine or specialized device that can be placed under an optical microscope or in a scanning electron microscope (**Figure 4**). The damage evolution in the coating can be viewed *in situ* or *ex situ* after application of specific strains. The method is suitable to determine properties of thin or thick coatings on a variety of ductile substrates.[58–62]

This type of test is advantageous in that the stress field is uniform and small specimens can be used. Likewise, using optical or scanning electron microscopy to view the damage *in situ* during loading offers useful insights into material failure mechanisms.[63,64] The drawback with such tests is that for analysis of the coating behavior, the residual stress and Young's modulus of the coating are required by other means, such as from curvature measurements (see later) and nanoindentation, respectively.

Thin brittle coatings on ductile substrates when uniaxially stressed produce parallel cracks in the coating layer perpendicular to the tensile axis and normal to the interface. These cracks generally extend along the width of the sample and increase in number with additional elongation, leading to a decrease in the crack spacing. For some systems, cracks may also be accompanied by localized delamination of the coating from the substrate. Ultimately, the delamination of the coating signals the end of the lifetime of the coated system. For softer and more compliant films, cracking can be irregular and film debonding reduced substantially. The drawback with these semibrittle films is that quantitative analysis cannot be performed.

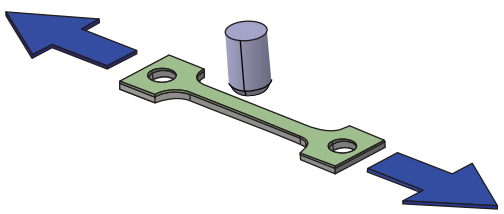

Figure 4 Schematic of the *in situ* tensile test specimen pulled while viewing with optical microscope.

In situ tensile tests provide insights into fracture and delamination processes and for ranking the practical adhesion performance of different coatings. The film debonding behavior is key to the reliability of film–substrate systems, particularly where mechanical loading and chemical interactions are encountered. For films that crack and debond in a controlled fashion, one can use linear elastic fracture mechanics relations to extract intrinsic film properties (strength and fracture toughness) and interfacial adhesion characteristics.[65–67]

Zirconia films (both nano and macro) have been produced by a number of different methods and are of great interest for variety of orthopedic applications. The phase transformation in bulk zirconia has been found to be a clinical concern in femoral heads of THA due to the unexpected failures observed in early 2000.[8,68] However, zirconia nanocoatings of 70–100 nm thickness are not affected by the dilation due to phase transformations and behave differently from their bulk forms.[34] As a result, a wide range of different deposition techniques for zirconia have been proposed. Characterization techniques also proved that adhesion of these coatings to a number of metallic biocompatible substrates and new generation femoral components has been extremely good.[69]

As an example, microtensile testing was used to determine the mechanical properties and adhesion characteristics of surface-modified pure titanium metal substrates coated with a sol–gel-derived alkoxide-based zirconia to improve its wear properties and corrosion resistance is briefly described. In addition to microtensile testing, tribological pin-on-plate wear tests were also carried out for assessment of wear properties.

The morphology, adhesion, and tribological properties of the zirconia sol–gel coating on as-polished and 25 V anodized titanium surfaces were compared.[70] The anodization of titanium involves the formation of a thin, compact, oxide layer, which improves the wettability for further coating. These samples were spin coated with zirconia, yielding 100 nm thick films. The nanocoatings were prepared by alkoxide sol–gel chemistry, using techniques and protocols developed in an earlier work, and were examined with X-ray diffraction and scanning electron microscopy.[34,71]

Interfacial adhesion properties were measured using the tensile test as described above. The tribological properties were investigated using an Ortho-Pod machine, with commercial grade ultra-high molecular weight polyethylene (UHMWPE) pins (3/8 in. diameter) that can articulate in number of different combinations against opposing coated and control specimens. The UHMWPE pins were used in a bovine serum environment. The amount of wear was measured gravimetrically and wear features were observed using SEM. Preliminary Ortho-Pod results indicate a lower wear rate on the anodized titanium substrate in comparison to the as-polished substrate. The calculated H statistic of 38.563 indicated that indeed there are statistically different wear rates among the groups ($p < 0.001$). No *post-hoc* analysis is available to test for differences between individual groups – the Kruskal–Wallis approach simply provides a ranking of best to worst. In this light, the four best performing surfaces were, from best to worst, surfaces Cp Ti

once coated with ZrO_2, uncoated anodized Cp Ti, uncoated Ti6Al4V samples, and uncoated Ti6Al4V anodized samples.

Table 2 shows the film properties and interfacial adhesion energies for the as-polished and anodized titanium substrate. The film properties are essentially equivalent but the anodized layer has improved the interfacial adhesion of the zirconia film to the substrate by a factor of about 7.

The fracture toughness of the films depends on the integrity of the film, the bonding to the substrate, interphases between coating and substrate, and the nature of the substrate itself. The production of a homogeneous solution is necessary to ensure good mechanical properties for the film as well as protection of the substrate. No cracking of the coatings were observed for any of the preparation conditions. Bonding to the substrate was also found to be good for all films, as evidenced by the lack of any severe spalling in all samples (Figure 5). The pattern of fracture lines on the sample in Figure 5 are through thickness cracks initiated mainly by slip bands from the substrate deformation. The tortuous crack paths shown demonstrate good fracture toughness and adhesion of the nanocoatings.

3.305.3.4. Bending Tests

Three- and four-point bending methods have been used to characterize the interfacial fracture between dissimilar materials and films on substrates, and to quantitatively evaluate the interfacial fracture energy. The thicknesses of these substrates are usually much smaller than their lateral dimensions, so that simple beam bending mechanics can be applied to describe their elastic response.[72]

A fracture-mechanics-based method for four-point bending developed by Charalambides and coworkers[73] for interfaces between dissimilar materials has been applied in many areas including biomaterials research successfully[74–78] to measure interface fracture energy. The method requires a bend bar of the coated substrate with a notch machined in the coated layer as shown in Figure 6. As the bending moment increases a crack initiates from the notch and propagates to the interface. For a sufficiently weak interface bond, the crack deflects and propagates along the interface. The interfacial fracture energy is given in eqn [1]:

$$\gamma = \frac{21P_c^2 l^2\left(1-\nu_s^2\right)}{16E_s b^2 h^3} \qquad [1]$$

where b is the specimen or beam width, h is the total thickness, l is the moment arm (distance between inner and outer loading lines), P_c is the critical load for stable crack propagation, and ν_s and E_s are Poisson's ratio and Young's modulus of the substrate, respectively. This method has the advantage that the interface fracture energy is independent of the crack length as long as the crack tip is not too close to the precrack or the loading points.

Table 2 Zirconia film properties and interfacial fracture energies for as-polished and anodized titanium substrates

	As-polished pure Ti	*Anodized pure Ti*
Zirconia film strength (MPa)	480 ± 50	530 ± 50
Zirconia film fracture toughness (MPa $m^{1/2}$)	0.34 ± 0.02	0.37 ± 0.05
Interfacial fracture energy (J m^{-2})	4 ± 0.8	30 ± 0.8

3.305.3.5. Bulge and Blister Testing

In bulge and blister testing, the film–substrate system is pressurized with gas or a fluid through a hole in the substrate. The height of the resulting hemispherical bulge in the film is then measured by optical microscopy or an interferometer. The pressure and deflection height can be used to provide information on elastic, plastic, and time-dependent deformation. In blister testing the pressure is increased until the film starts to debond from the substrate. The interfacial energy can be determined from the critical pressure for debonding as shown in eqn [2][79]:

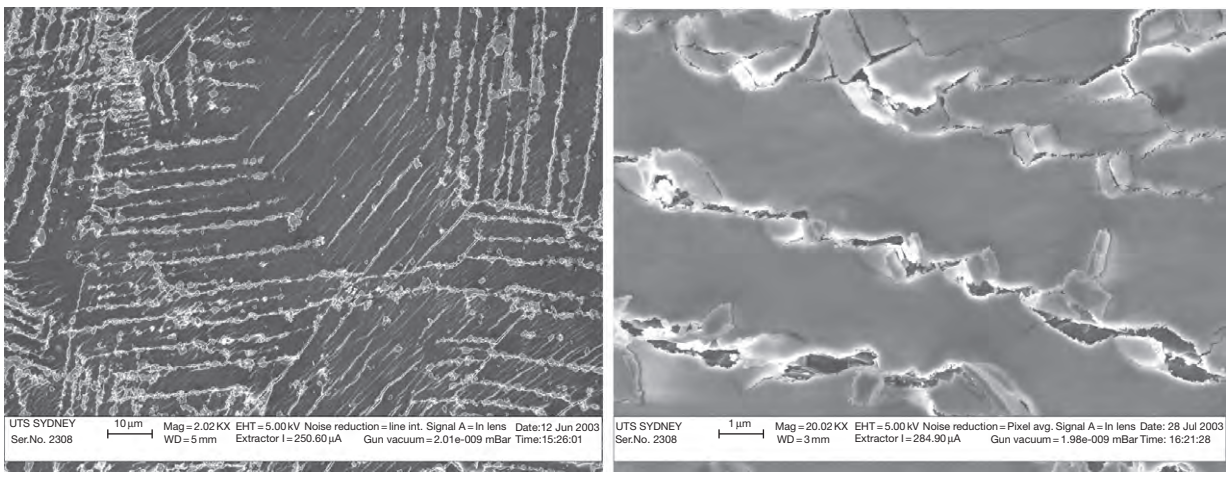

Figure 5 Scanning electron microscopy images of the sol–gel-derived zirconia-coated titanium alloy substrate after tensile testing showing the parallel micro-cracks in the coating which are dictated by the shear bands in the substrate (left, scale 10 µm) and at higher magnification the torturous path of the crack propagation within the film that is still well adhered to the substrate (right, scale 1 µm). Sample strained to about 10%.

$$\gamma = \frac{p^2(3 - v_f^2)r^4}{16E_f t_f^3} \quad [2]$$

where p is the applied pressure, r is the radius of the hole, E_f is the Young's modulus of the film, v_f is the Poisson's ratio of the film, and t_f is the film thickness.

3.305.3.6. Stress Measurements

The evaluation of the stress in a coating due to deposition and or temperature can be crucial in regards to mechanical stability. The stress in a film is made up of the following components (eqn [3]): intrinsic (deposition, mode of growth, structure), thermal expansion mismatch between film and substrate, and externally applied stresses[80]:

$$\sigma_f = \sigma(\text{intrinsic}) + \sigma(\text{thermal}) + \sigma(\text{external}) \quad [3]$$

Substrate curvature is a simple method requiring a stylus profilometer capable of long scans, generally no less than 10 mm length, or by using a phase shifting interferometer. The advantages of using an optical method such as interferometry are high accuracy of about 6 nm, substrates with curvature of up to 3 μm are acceptable, and rapid and straightforward to use. Furthermore, the substrate needs to be sufficiently thin for adequate measurement of the curvature. The stylus profilometry method requires careful and precise placement of the sample, so that a cross scan in the x- and y-directions is made on the surface (preferably both sides) before and after coating. A second method of measuring the curvature of substrate is by using a phase shifting interferometer (Figure 7).

The stress in the coating (intrinsic+thermal) can be determined using the Stoney formula without prior knowledge of the coating properties. The information that is required is coating thickness, substrate thickness, and Young's modulus. Stoney's equation[81] shows the relationship between the change in the radius of a coated and uncoated substrate and the corresponding stress in the layer (eqn [4]):

$$\sigma = \frac{1}{6}\left[\frac{1}{R_f} - \frac{1}{R_i}\right]\frac{E_s}{(1 - v_s)}\frac{t_s^2}{t_f} \quad [4]$$

where R_i is the radius of curvature before coating, R_f after coating, E_s and v_s the modulus and Poisson's ratio of the substrate, t_s the substrate thickness, and t_f the film thickness. Assuming that the scan length L of the substrate is much greater than the final bow B of the substrate, the radius R can be calculated using eqn [5].

$$R = \frac{L^2}{8B} \quad [5]$$

Compressive stress in the film leads to a convex deflection, whereas tensile stress results in concave deflection (as shown in Figure 8). The reader is referred to the text by Freund and Suresh,[82] which provides a comprehensive resource on stresses in films.

Measurements can be made *in situ* during deposition or thermal treatment with optical means by interferometry or deflection method (cantilever beam) using a low power laser. Likewise, elastic strain in films can be measured by X-ray diffraction from the change in crystal lattice d-spacing, from which the stress can be determined, given knowledge of the Young's modulus and strain-free lattice spacing (which may be unknown in many cases).[83]

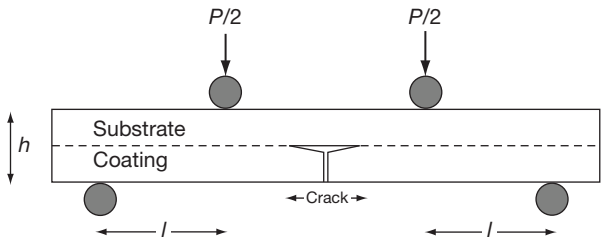

Figure 6 Schematic of the four-point bend delamination method.

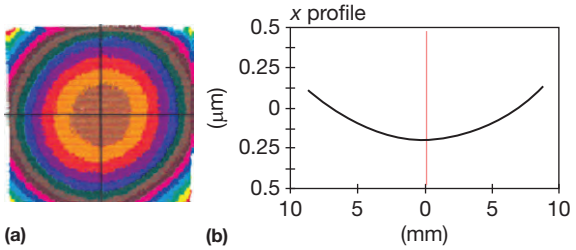

Figure 7 (a) A typical interference pattern (obtained by using a phase shifting interferometer) of the curvature of Si substrate coated with a film with tensile stress and (b) showing the curvature profile in the x-axis.

3.305.4. Concluding Remarks

In the biomedical field, the surface modification of metallic materials aims to inhibit wear, reduce corrosion and ion release, and promote biocompatibility. Surface coatings offer the possibility of modifying the properties of a component, and hence, improve both performance and reliability.

To date, many deposition methods have been used to produce wear-resistant, bioactive, and/or protective corrosion-resistant coatings on various substrates.

Many of the common barrier and corrosion-resistant coatings use plasma or thermal spraying, while several more recent techniques that have been used include PVD, plasma MOCVD, electrochemical vapor deposition, and sol–gel processing.

Microcoatings (30–50 μm) applied by plasma methods have produced in specific instances a range of problems. However, thin nanoscale coatings avoid problems associated with thermal expansion mismatch with metallic or ceramic substrates.

The term sol–gel is currently used to describe any chemical procedure or process capable of producing ceramic oxides, nonoxides, and mixed oxides from solutions.

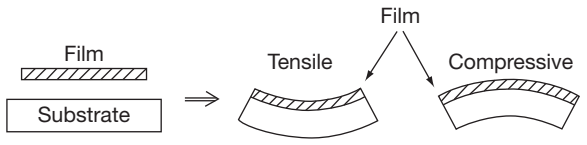

Figure 8 Film strained in tension results in tensile stress or strained in compression results in compressive stress.

Sol–gel-derived ceramic nanoscale coatings (40–200 nm) show promise due to their relative ease of production, ability to form a physically and chemically uniform coating over complex geometric shapes, consolidated at relatively low temperatures, and their potential to deliver exceptional mechanical properties and wear resistance due to their nanocrystalline structure.

The mechanical properties of biomaterial coatings and the substrate (implant) are strongly dependent on the film microstructure and deposition process as well as on the influence of interfacial constraint. These properties can differ from the bulk, and accurate measurement techniques are essential for determination of the properties of the coatings. In particular, better techniques are required for quantitative measurements of hardness, friction, adhesion strength or particularly the coating–substrate interfacial fracture toughness. Nanoindentation and microscratch measurements are essential tools for characterizing submicron coating properties, and further understanding of mechanical processes involved in these and other tests will help in obtaining valuable information, as well as in identifying their limitations. Likewise, the advent of microfabrication/machining technology and lithography has allowed micron-sized samples and free-standing films to be produced and tested *in situ* using SEM and/or TEM. In addition, theoretical modeling approaches are essential for progress in understanding thin film–substrate interfacial behavior which may lead to better choice and design of thin film–substrate materials selection.

The relationship between materials surface properties and biological responses is one of the major issues in biomedical materials research. Surface modification by thin film deposition has become a valuable tool for research aimed at understanding how structural and chemical surface properties influence material–biosystem interactions. As better understanding is achieved, one can expect that surface modifications for the purpose of controlling tissue response will open up avenues for developing new and superior implants and medical devices in a more systematic manner and at a faster rate than at present. This is possibly where the greatest potential of surface engineering lies in this field.

Bone–implant interactions, in addition to biological factors, are influenced by functionally applied multiaxial forces and biomechanics. The ultimate understanding of biological systems can only be achieved with appropriate nanoscale mechanical properties of biogenic structures and the influence of the nanostructures and nanoloading on these biological systems.

Our push to measure and determine thin film mechanical properties at the nanoscale will inevitably open new avenues in understanding the influence of stresses and micro/nanodeformations in the growth and repair mechanisms of biologic systems to allow us to use new materials, systems, and tools in tissue regeneration.

Acknowledgments

The authors thank Dr. Richard Roest for his contribution on nanocoated zirconia films and Drs. Tony Murphy and Phil Martin for their critical proofreading of this chapter.

3.306.1. Introduction

The mechanical characterization of biological tissues and biomaterials is of utmost importance in clinical medicine. However, there is a paucity of information regarding the role of mechanics of biomaterials associated with clinical treatments. Biological tissues and biomaterials used *in vivo* oftentimes have small dimensions or are composed of hierarchical structures with important features at the nanometer to the millimeter scale. A technique that can probe mechanical properties at these scales has the potential to address numerous questions that are relevant to the biomedical community. Nanoindentation, also known as instrumented or depth-sensing indentation, involves the application of a controlled load to the surface to induce local surface deformation. With a typical working force range of 1 μN to 500 mN and a displacement range of 1 nm to 20 μm,[1] this technique, originally developed for the metallurgical thin films community, has become a commonplace tool for the measurement of nano- and microscale mechanical properties of tissues and synthetic biomaterials. Because of its small probe size, nanoindentation can be used to measure local material properties in small, thin, and heterogeneous samples. This allows testing of specimens that are unsuitable for traditional mechanical testing techniques, such as biopsy specimens or tissue samples from small animals. Nanoindentation is also useful for measuring mechanical properties of microstructural features within bulk samples of biomaterials/tissues, characterizing the properties of individual constituents within composite or heterogeneous samples, or mapping mechanical properties across a sample surface. As a result, nanoindentation is emerging as a valuable mechanical testing technique for biomaterials.

A simplified schematic illustration representative of many instrumented indentation systems is shown in **Figure 1**.[2,3] Commercially available systems include MTS (Oak Ridge, TN), Hysitron (Minneapolis, MN), Micro Materials (UK), UMIS (CSIRO, Australia), and CSM Instruments (Switzerland). Force is often applied using either electromagnetic or electrostatic actuation, and a capacitive or inductive sensor is typically used to measure displacement. Regardless of the operational differences, the raw force and raw displacement data for these systems are generally coupled due to the leaf springs, and in fact, a plot of the raw force as a function of the raw displacement with the tip out of contact is characteristic of the spring stiffness.[4]

3.306.2. Overview of Nanoindentation Technique

3.306.2.1. Measurement of Elastic Modulus and Hardness

The most common application of nanoindentation is to measure the basic mechanical properties such as elastic modulus and hardness of small volume samples.

The analysis of force–displacement curves produced by instrumented indentation systems is often based on the work by Oliver and Pharr.[3] Their analyses were in turn based upon Sneddon's theoretical work[5] for the penetration of a flat elastic half space by different probes with particular axisymmetric shapes (e.g., a flat-ended cylindrical punch, a paraboloid of revolution, and a cone). Consider the case of the elastic contact for a cone and a flat specimen. The force and the indenter displacement are given by Sneddon's equation:

$$P = \frac{2}{\pi} E^* \tan\alpha h^2 \qquad [1]$$

in which P is the maximum force, E^* is the reduced modulus, α is the indenter cone half-angle (Figure 2), and h is the displacement of the specimen-free surface beneath the indenter.

The reduced modulus is determined by the elastic modulus and Poisson's ratio (which is the ratio of transverse contraction strain to longitudinal extension strain in the direction of the stretching force) of sample and indenter based upon the following relationship

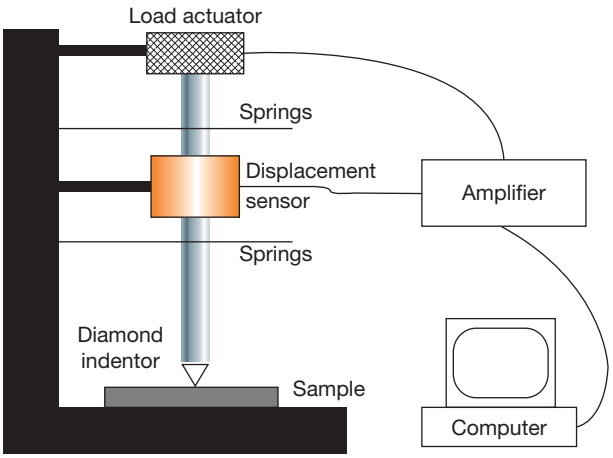

Figure 1 Schematic illustration of an instrumented indentation system.

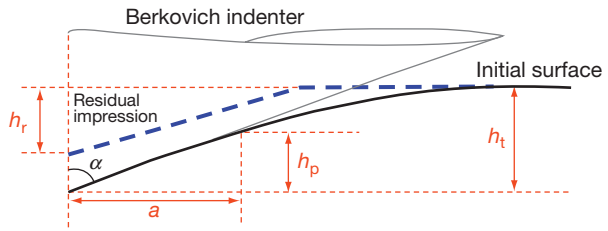

Figure 2 Schematic illustration of an equivalent axisymmetric contact between a Berkovich indenter and a flat specimen. h_t is total penetration depth, h_p is contact depth, h_r is final unloading depth (residual depth), α is the indenter equivalent cone half-angle, and a is the equivalent contact radius of the indenter at maximum load.

$$\frac{1}{E^*} = \frac{(1-\nu^2)}{E} + \frac{(1-\nu_i^2)}{E_i} \qquad [2]$$

where E, E_i and ν, ν_i are elastic modulus and Poisson's ratio of the sample and indenter, respectively.

Taking the derivative of P with respect to h in eqn. [1], it now becomes

$$\frac{dP}{dh} = 2\left[\frac{2}{\pi} E^* \tan\alpha\right] h \qquad [3]$$

where dP/dh is defined as the contact stiffness, S, which is a very important quantity in the analysis of nanoindentation test data.

The displacement of the indenter and the radius of the circle of contact are related by

$$h = \frac{\pi}{2} a \cot\alpha \qquad [4]$$

and since $A = \pi a^2$, it is straightforward to obtain

$$E^* = \frac{1}{2}\frac{dP}{dh}\frac{\sqrt{\pi}}{\sqrt{A}} \qquad [5]$$

The last equation applies to the elastic contact of any axisymmetric indenter (such as a sphere, cone, and cylindrical punch) and allows the combined elastic modulus of the indenter and the specimen to be calculated from the contact stiffness and the contact radius. The contact stiffness can be measured experimentally. The contact radius can be found from the contact depth, h_p, and the geometry of the indenter as $A = \pi a^2 = \pi(\tan\alpha h_p)^2$. The contact depth, h_p, is related to the deformation behavior of the material and the shape of the indenter, which can be obtained from[3]

$$h_p = h_t - \frac{\varepsilon P}{S} \qquad [6]$$

where S is the contact stiffness and ε is a function of the particular tip geometry. (For example, the flat-ended cylindrical punch has the value of 1, paraboloid of revolution has the value of 0.75, while cone-shaped tip has the value of $2(\pi-2)/\pi$).

These elasticity-based analyses are normally applied to the unloading data of an indentation measurement, assuming the unloading behavior of the material is characterized by elastic recovery only. In general, the relationships between penetration depth, h, and force, P, during unloading can be represented in the form

$$P = \alpha(h - h_r)^m \qquad [7]$$

The parameter α contains geometric constants, the sample elastic modulus E, the sample Poisson's ratio ν, the indenter elastic modulus E_i, and the indenter Poisson's ratio ν_i; the parameter h_r is the final unloading depth (Figure 2); and m is a power-law exponent (typically with a value between 1 and 2) that is related to the geometry of the indenter. Once an appropriate fit of the unloading indentation force–displacement curve (see Figure 3) is obtained, the derivative, dP/dh, determined at the maximum loading point (h_{max}, P_{max}) is used to determine the contact stiffness S. With the knowledge of elastic modulus and Poisson's ratio of diamond, which are ~1000 GPa and 0.007, the elastic modulus of the sample can be calculated from eqns. [2] and [5].

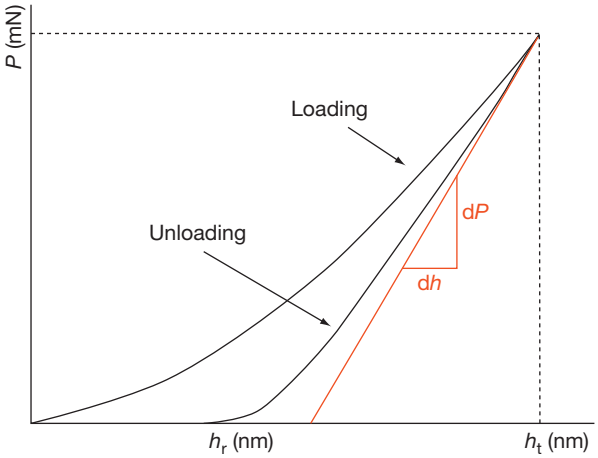

Figure 3 Schematic diagram of indentation force–displacement curve with the unloading stiffness S at the maximum force illustrated.

The hardness H of a solid is defined as its resistance to local plastic/permanent deformation. The simplest method to determine H, or the contact pressure, is to press a hard indenter of known geometry and to divide the applied load P by the contact area A produced by the indentation, $H = P/A$. The indentation hardness parameter originated with dead weight loading and optical measurement of the indentation residual impression.[6] Good examples include most microhardness tests (e.g., Vickers hardness test), in which the elastic recovery of the material coupled with difficulty in determining the edge of the impression may influence the measured size of the residual impression. In nanoindentation testing, the residual indent impression is frequently too small to be measured optically, and is not measured, but the area is inferred from the assumption that the residual area is the same as the contacted area at maximum load, A_c, which is in turn calculated from the indentation depth h_t (eqn. [2]). The contact hardness (H_c) can then be defined as the hardness at peak load[3]:

$$H_c = \frac{P_{max}}{A_c} = \frac{P_{max}}{\pi(\tan\alpha h_t)^2} \quad [8]$$

where α is the indenter cone half-angle and h_t is the total penetration depth (**Figure 2**). For a Berkovich indenter, α is 70.3°.

Obviously, both elastic and plastic deformations contribute to the total contact at peak load.[7] The aforementioned analysis was originally derived for metals[6] in which the elastic deformation was negligible compared with the plastic component. However, for most biomaterials, elasticity or viscoelasticity is significant and important for their performance. The classic contact hardness is not an accurate basis to describe the resistance to local plastic/permanent deformation of these materials. Based on a contact hardness model assuming 'springs in series' for elastic and plastic deformation,[8] Oyen developed a parameter to express the plastic deformation component of a material using indentation hardness testing.[9]

In her analysis, Oyen pointed out that both elastic (h_{El}) and plastic (h_{Pl}) deformations contribute to the total contact displacement (h_t) as mechanical elements in series such that the displacements sum

$$h_c = h_{El} + h_{Pl} \quad [9]$$

The known form of the elastic load–displacement relation is[5]

$$P_E = \alpha_2 E' h_{El}^2 \quad [10]$$

and α_2 is a constant dependent upon indenter geometry and is 4.4 for a Berkovich indenter,[10] E' is the plain strain modulus ($E' = E/(1-\nu^2)$), where ν is Poisson's ratio) and P_E is the elastic load component. Similarly, the plastic load–displacement relation is

$$P_P = \alpha_1 H h_{Pl}^2 \quad [11]$$

where α_2 is again dependent upon indenter geometry and is 24.5 for a Berkovich indenter, P_P is the plastic load component, and H is a term quantifying resistance to permanent deformation.

Knowing that for elastic and plastic elements in series the loads are equal ($P_E = P_P$), the contact hardness can be written by combining eqns. [8]–[11][8] as

$$H_C = \frac{1}{\alpha_1((\alpha_2 E')^{-1/2} + (\alpha_1 H)^{-1/2})^2} \quad [12]$$

by which the resistance to plastic deformation, H, can be extracted from the indentation hardness. Also, the proportion of elastic and plastic deformation can be calculated. A simple analysis for bone and teeth reveals that plastic deformation resistance H of mineralized tissues is three to six times higher than the apparent indentation hardness and plastic deformation of these biomaterials only occupies ~50% of the total indentation deformation.[9]

The effort associated with the plastic deformation resistance during the generation of nanoindentation data may also be considered from the energy point of view.

Mechanical work done or energy consumed is defined as the product of force and displacement. Therefore, the area below the loading curve in the load–displacement (P–h) diagram (**Figure 3**) corresponds to the total energy spent pressing an indenter into the material, U_T. The area below the unloading curve corresponds to the elastic energy recovered from the system during unloading, U_E. Their difference, $U_P = U_T - U_E$, (the area between loading and unloading curve), expresses the unrecoverable energy, consisting of the work spent in plastic deformation or other irreversible processes (e.g., cracking), and stored elastic energy associated with the residual stresses caused by the resultant impression. All these energies can be easily calculated from P–h curves. However, since all these values correspond to a particular test with special values of load and depth, it is more informative to normalize them. This is typically done by determining the ratio of the unrecoverable energy to the total energy

$$U(\%) = U_P/U_T \times 100 \quad [13]$$

and is used to normalize the energy expenditure of each test. This value may also be denoted as the 'plasticity index' to characterize the plasticity or nonlinear response of the material. This U_P/U_T ratio ranges from 0 for an ideally elastic material (all energy is returned on unloading) to 1 for an ideally plastic material (no energy is returned). In addition, the

concept of 'work of indentation'[1,11] is considered as the basis for analysis. The energy to create a unit volume of indentation is called the 'work of indentation' and is given by

$$W = \frac{U}{V} \quad [14]$$

in which U is the energy used to create the indentation volume, V, on the surface of the sample. During loading procedure, the energy used to create the volume, V_T, at maximum load should be U_T. After unloading, the residual impression with the volume V_R is a reflection of unrecoverable energy, U_P. The volume of indent produced by a spherical indenter is a segment of a sphere which can be calculated with the following equation:

$$V = \frac{\pi}{3}h^2(3R - h) \quad [15]$$

As there is a geometrical relationship between contact radius, a, contact depth, h, and tip radius, R, namely

$$R = \frac{h^2 + a^2}{2h} \quad [16]$$

eqn. [15] can be rewritten as

$$V = \frac{\pi}{6}h(h^2 + 3a^2) \quad [17]$$

in which h is generated from the analysis software and contact radius, a, is calculated using a tip calibration function, $a = f(h_P)$, established with fused silica.

For a Berkovich indenter, the volume of an equivalent conical shape was determined by using the nominal indenter face angle of 70.3°. Therefore, the volume can be calculated from

$$V = \frac{1}{3}\pi a^2 h \quad [18]$$

in which contact radius, a, is calculated by

$$a = \eta \tan \alpha h_p \quad [19]$$

with η being the area function ratio between a perfect indenter ($\eta = 1$) and the actual indenter.[12]

For the residual impression V_R after unloading, h in the aforementioned equations is the residual depth, h_r, of the indentation (see **Figure 2**). The calculation of the residual volume V_R is based on Stilwell and Tabor's observation,[13] who assumed the elastic recovery in the horizontal direction is small enough so that the radius of residual impression is the same as the maximum contact radius of the indentation, a, in eqns. [16] and [17]. With U_P and V_R values, the plastic work of indentation ('true hardness' defined by Sakai), W_P, values can be calculated with eqn. [14].

The method has been applied on the investigation of dental enamel.[14]

3.306.2.2. Instrument Calibration

As a delicate measuring system working at small displacement and using very light forces, calibration is essential for nanoindentation to acquire repeatable and reliable results. Although most manufacturers provide details of calibration procedure of the system in the software of the user's menu, little discussion of calibration related to nanoindentation can be found in the literature. Basically, for a nanoindentation system, calibration should be done from the following different aspects before the machine becomes suitable for any real testing.

3.306.2.2.1. Basic calibration of force and depth measurement systems

For the purpose of accuracy of the data, it is important that both the force and displacement sensors are properly calibrated against traceable reference standards. Calibration of the instrument is normally done at the time of manufacturing and not by the end user.

3.306.2.2.2. The determination of the load frame compliance, C_f

Consideration of the load frame compliance (defined as $C = h/P$) effects is critical for accurate interpretation of force–displacement response. Apart from the load frame, the compliance is influenced by the specific indenter tip used. The displacement output readings and the effect are equivalent to a spring in series with the load train and depend linearly upon the load applied. Prior to calibration (i.e., C_f is unknown), the measured displacement, h_{total}, is a combination of displacement of the load frame, h_f, and displacement of the sample, h_s. Treating the system as two springs (the load frame and the sample) in series under a given force, P, $h_{total} = h_f + h_s$. Dividing both sides by P,

$$C_{total} = C_f + C_s = C_f + \frac{\sqrt{\pi}}{2E^*}\frac{1}{\sqrt{A}} \quad [20]$$

Usually, the load frame compliance, C_f, can be calibrated by using reference samples with known elastic modulus and Poisson's ratio. With the concept of compliance and known geometrical details of the indenter, eqn. [20] can be rewritten as

$$\frac{dh}{dP} = \frac{1}{2\tan\alpha E^*}\frac{1}{h_p} + C_f \quad [21]$$

Typically, a series of indentation measurements are made on a single reference sample, and a plot of dh/dP against $1/h_p$ is linear with an intercept given by C_f. The choice of the reference sample should be made with an objective of maximizing contact stiffness (minimizing C_s) so that C_{total} is dominated by C_f. Thus, relatively large indentation forces and depths are normally applied to a reference material that either has a high modulus or exhibits significant plastic deformation, that is, a sample that has a high ratio of E/H.

3.306.2.2.3. Indenter tip shape calibration

The analysis equations for nanoindentation testing rely on the dimensions of the indenter being ideal, since the projected area of the impression is calculated from the depth and the geometry of the indenter. However, for sharp indenters, the tip of the indenter is usually rounded. For spherical indenters, the actual radius can be either larger or smaller depending on the quality of manufacture. To account for these variations in indenter geometry, a 'tip' correction, or area function, is needed to apply to the results. The objective of tip shape calibration is to estimate the cross-section area of the indenter tip as a function of distance from the apex. Usually, a series of indentation measurements are made on a single reference sample to

cover a large range of force and penetration depth data. At any given force, P, the contact area, A, is the cross-section area of the indenter tip at a distance, h_p, from the tip apex. For each indentation, from load–displacement curve, A and h_p can be calculated by eqns. [5] and [6], respectively. With sufficient number of measurements over a range of h_p values, a tip shape function, $A(h_p)$, can be determined by fitting the A versus h_p data, typically using a multiterm polynomial fit of the form

$$A(h_p) = B_o h_p^2 + B_1 h_p + B_2 h_p^{1/2} + \ldots \quad [22]$$

in which B_0, B_1, . . ., B_n are constant coefficients determined by the curve fitting. Ideally, B_0 should be equal to $\pi \tan^2 \alpha$ (for a conical indenter) representing the perfect tip, while additional terms attempt to account for deviations from ideal geometry, such as blunting of the tip.

An alternative approach in the software of some instruments uses a simple ratio between the actual contact area (A_h) versus the theoretical contact area for a perfect sharp indenter tip ($A_t = 3\sqrt{3} \tan \omega h_p^2$) where ω is the indenter apical angle. That is

$$\eta(h) = A_h / A_t \quad [23]$$

The value of $\eta \sim 1$ for large depths of penetration, whereas for shallow depths, the magnitude of η increases as $h \to 0$, especially for blunter tips with larger equivalent indenter tip radii.[12] The latter authors also point out the influence of pile-up and sink-in about the edges of the impression on the determination of the contact area.

3.306.2.3. Indentation Stress–Strain Relationship

As mentioned earlier, the instrumented indentation technique has become a popular method to measure the mechanical properties of different biomaterials. However, most investigators use a sharp tip such as a Berkovich indenter from which the hardness and elastic modulus may be determined. Relatively few investigators choose a spherical tipped indenter. Theoretically, a sharp tipped indenter does not allow the transition from elastic to plastic behavior of a material to be deduced because these indenters produce a nominally constant plastic strain impression. A spherical tip, in contrast, with increasing depth of penetration, develops increasing contact stress with load, the mechanics of which will now be considered, so that the elastic to plastic transition response and the determination of the contact stress–strain property of a material may be investigated.[15,16]

The use of spherical tipped indenters has a long history for characterizing metallic materials.[17] Tabor[6] found a simple empirical relationship between contact pressure or hardness and contact strain (contact radius/indenter radius, a/R). This approach and the relationships between hardness and true stress as well as contact strain and true strain have been an area of further study such as that by Matthews[18] and have been analytically confirmed by Hill *et al.*[19] Recently, Lawn and colleagues[20–23] have investigated the behavior of dental ceramics with a spherical indenter. The latter research has mainly concentrated on the macroscale damage mode of brittle material and multilayer structures.

Besides the Oliver and Pharr[3] method discussed earlier for the determination of the hardness and elastic modulus mechanical properties of materials, Field and Swain[24] developed an alternate method to analyze force–displacement data using a spherical tipped indenter. Later, Oliver and Pharr[25] and Suganuma and Swain[12] verified the equivalence of the two approaches.

The models chosen to interpret the indentation data were that of Hertz,[17] Oliver and Pharr,[3] and Tabor.[6] Unfortunately, on a microscale level, it is impossible to produce a perfect polished diamond spherical indenter with a constant radius. In the case of a spherical tipped indenter, Hertz's analysis provides an elastic contact relationship between indenter and samples (see **Figure 4**).

The radius of contact circle, a, can be calculated as[17]

$$a^3 = \frac{3}{4}\frac{PR}{E^*} \quad [24]$$

in which $\frac{1}{E^*} = \frac{1-\nu^2}{E} + \frac{1-\nu'^2}{E'}$, E, E' and ν, ν' are Young's modulus and Poisson's ratio of specimen and indenter (usually diamond), P is the contact load, and a is the contact radius.

The total depth of penetration, h_t, is given by

$$h_t^3 = \left(\frac{3}{4E^*}\right)^2 \frac{P^2}{R} \quad [25]$$

Contact pressure, P_m, can be calculated by the definition of the pressure,

$$P_m = \frac{P}{\pi a^2} \quad [26]$$

Hertz also established the simple relationship between the elastic total displacement into the sample, h_t, and the contact depth, h_p,

$$h_t = 2h_p \quad [27]$$

Combining eqns. [24] and [26], the relationship between the contact pressure, P_m, and the contact radius, a, is

$$P_m = \left(\frac{4E^*}{3\pi}\right)\frac{a}{R} \quad [28]$$

where E^* is the reduced modulus and R is the nominal radius of the indenter tip. This expression establishes the linear relationship between contact pressure and contact strain, a/R, during the elastic loading of a material.

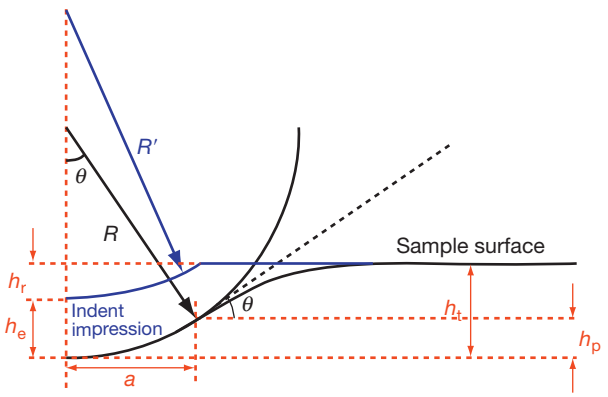

Figure 4 Schematic illustration of contact between a spherical indenter and a flat specimen.

In the case of a conical tipped indenter, Tabor[6] showed that

$$\varepsilon_r \approx 0.2 \tan\theta \quad [29]$$

$$\sigma \approx P_m/3 \quad [30]$$

are appropriate expressions for representative strain, εr, and stress, σ, where θ is the angle between the indenter flank and the original surface. Matthews,[18] on the other hand, suggested that the divisor in eqn. [30] should be 2.8 rather than 3.

For spherical indentation, strain increases continuously with indentation impression depth, and an appropriate equivalent expression is

$$\varepsilon_r \approx 0.2a/R \quad [31]$$

where for small θ, $\tan\theta \approx \sin\theta \approx a/R$.

The approach of Tabor, namely the H–a/R curve generated for a material, is generally regarded as the contact stress–strain curve.

In the case of elastic–plastic response of materials to pointed indenters, Oliver and Pharr[3] recommended a simple method to fit the nanoindentation P–h unloading curve (see eqn. [7]). This method applies to all axisymmetric indenters, including spheres. With this equation, the elastic contact stiffness, dP/dh, can be calculated from the upper portion of the unloading data.

There is a constant relationship between the elastic contact stiffness, dP/dh, the projected area of contact, A, and the reduced or indentation modulus, E^*,

$$\frac{dP}{dh} = \beta \frac{2}{\sqrt{\pi}} E^* \sqrt{A} \quad [32]$$

in which $A = \pi a^2$ and β is a constant dependent upon indenter shape. For a spherical indenter, $\beta = 1$.

In this context, by assuming that the elastic modulus, E, of a material is known, the radius of contact area, a, at a certain loading force, can be calculated from eqn. [32], namely

$$a = \frac{dP/dh}{2E^*} \quad [33]$$

At the same time, a relationship between the indenter radius, R, contact radius, a, and contact depth h_p, can be derived from Figure 4,

$$a = \sqrt{2h_pR - h_p^2} \quad [34]$$

By combining eqns. [33] and [34], it is not difficult to show[28]

$$\frac{a}{R} = \frac{\frac{dP/dh}{E^*} h_p}{\left(\frac{dP/dh}{2E^*}\right)^2 + h_p^2} \quad [35]$$

Based on the definition of hardness, H,

$$H = \frac{P_{max}}{A} \quad [36]$$

the nanoindentation system can record the P–h response of a material from which P_{max}, h_p, and dP/dh may be automatically calculated. Thus, a relationship between H–a/R curve of the sample may be determined.

Because of the inevitable deviation of the tip shape from that of a sphere, the real radius of the tip at different contact depths may not be as constant as the nominal value reported by the manufacturer. Therefore, a better method is required to avoid using the parameter of tip radius, R, in the calculation.

From Figure 4, it is not difficult to show that the contact area of a spherical indenter with a specimen can be described by the h_p–a curve. The tangent angle of this curve, θ, may also be easily calculated from the derivative of the function $h_p(a)$. Moreover, to facilitate calculation, the equation of the curve can be expressed as $a = f(h_p)$ and its derivative (da/dh) as $a' = \tan\beta = f'(h_p)$, in which β is the tangent angle of the curve. In this way, the stress–strain curve of any material can be acquired by collecting P and h_p data alone. For $\theta + \beta = 90°$, $\tan\theta$ can be calculated as

$$\tan\theta = 1/\tan\beta = 1/f'(h_p) \quad [37]$$

Contact pressure, H, can be calculated as

$$H = \frac{P_t}{A} \quad [38]$$

in which $A = \pi a^2$ and $a = f(h_p)$. With eqns. [37] and [38], the stress–strain curve (H–$\tan\theta$ curve) may be calculated. Another geometrical relationship evident from Figure 4 is

$$a/R = \sin\theta = 1/\sqrt{(\tan^{-2}\theta + 1)} \quad [39]$$

By a combination of eqns. [37] and [39], an effective indenter radius, R, may be determined. The elastic modulus of the sample may be calculated from eqn. [33] as

$$E^* = \frac{dP/dh}{2a} \quad [40]$$

With the help of the known tip shape function $a = f(h_p)$, the elastic modulus of any sample can be measured with nominally spherical tips by using only h_p and dP/dh data.

Although the indentation stress–strain is an empirical relationship as the actual stress and strain about an indentation impression has severe gradients, it is not surprising that some investigations have shown that the nominal stress–strain curve from this approach did not superimpose with standard uniaxial stress–strain curves.[26] Therefore, it might be wiser to retain the values of H and $\tan\theta$ in the results to avoid misunderstanding that the plots are standard stress–strain curves. However, using the same method, the H–$\tan\theta$ curves enable comparison between different materials and are indicative of stress–strain behavior. The method has been applied to the measurement of stress–strain relationship of human enamel and dental materials.[27,28]

3.306.2.4. Measurement of Fracture Toughness and Residual Stress

3.306.2.4.1. Fracture toughness

Indentation methods have been used for many years to determine the fracture toughness of brittle materials. The most popular method uses a Vickers indenter and micro- to macro-indentation-based loads (1–500 N). For brittle materials, radial/median crack patterns form around the indenter, and from the size of the radial cracks or the remaining strength of the indented object, the fracture toughness may be estimated. This approach was initially proposed by Palmqvist[29] to determine the fracture toughness of hard metals (WC–Co alloys).

Follow-up studies by a number of authors led to the development of a basic understanding of the median radial fracture response about pointed indenters.[30–32] The most widely used approach to determine fracture toughness is that by Anstis *et al.*[33] There have also been many other expressions for the determination of the critical stress intensity factor (K_{1c}) based upon Vickers indentation tests. A critical review of the various expressions and their validity for the determination of toughness for brittle ceramics and glasses is given by Ponton and Rawlings.[34] More recently, Quinn and Bradt[35] have drawn attention to the fact that Vickers indentation-derived values for fracture toughness may be at variance with standardized values from classic methods. However for many situations, such as localized phases and small samples, traditional methods are not appropriate for the determination of fracture toughness.

Lawn *et al.*[31] described the evolution of a half-penny median/radial crack system in the far field of a sharp indenter. Based upon this analysis, it is possible to derive a simple relation between the measured radial crack length, c, the hardness, H, the elastic modulus, E, and the fracture toughness of a material, namely

$$K_{1c} = \kappa \left(\frac{E}{H}\right)^{1/2} \left(\frac{P}{c^{3/2}}\right) \qquad [41]$$

where κ is given by

$$\kappa = \Psi(\cot \phi)^{2/3} \qquad [42]$$

ψ is an empirical constant and ϕ is the equivalent conical angle of the indenter geometry; for a standard Vickers indenter, κ is 0.016. This approach was shown to be suitable for a wide range of brittle materials.[33] Recently, Leonardi *et al.*[36] have developed a fracture-mechanics-based analysis to determine κ and ψ for both wedge and point force approaches to the crack extension about triangular pyramid indenters.

Nanoindentation typically uses a Berkovich indenter tip that only generates three radial cracks rather than four as for the Vickers indenter. Dukino and Swain[37] compared the fracture toughness of a number of brittle materials when measured with a Vickers and Berkovich indenter. In all instances, the size of the radial cracks with the three-sided Berkovich indenter was ~ 10% larger than for the Vickers indenter at the same load. These authors also developed a specific expression to account for the difference in the number of cracks and also because the radial cracks were shallow surface cracks rather than median/radial cracks as is the case for a Vickers indenter at moderate loads.

More recently, researchers have used sharper corner cube indenters to evaluate the fracture toughness of brittle materials at loads commensurate with nanoindenter systems.[38,39] Scholz *et al.*,[39] using an atomic force microscopy (AFM)-based nanoindenter system, were able to derive the fracture toughness of materials from submicron-sized radial cracks. A typical set of data generated by these authors is shown in **Figure 5**. The value of the constant κ was found to be slightly dependent upon the ratio of the crack size to the residual hardness impression size and varied from 0.022 to 0.028. The extension of this approach, although not with nanoindenter loads, has been undertaken on bone[40] and dentine.[41]

Another approach to estimate the fracture toughness of brittle materials has used the force–displacement response

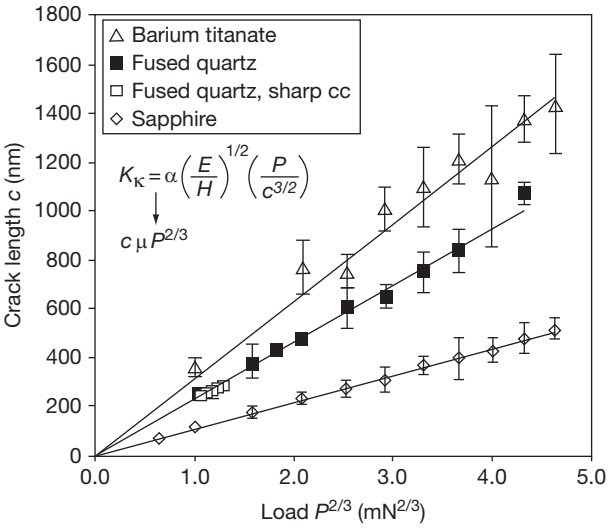

Figure 5 Measured crack lengths for a number of materials using a cube corner indenter and AFM-based nanoindenter system. Derived from Scholz, T.; Schneider, G. A.; Munoz-Saldana, J.; Swain, M. V. *Appl. Phys. Lett.* **2004**, *84*, 3055–3057.

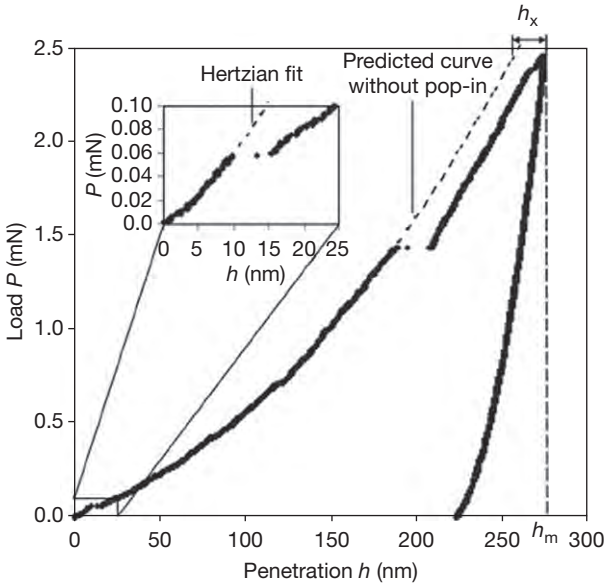

Figure 6 Force–displacement curve for a sharp (tip radius ~ 70 nm) corner cube indenter being loaded into barium titanate. The first pop-in event at low load (see insert) is associated with the transition from elastic to elastic–plastic behavior and the second pop-in is associated with crack formation about the indenter. The additional penetration associated with radial crack formation is h_x.

of a corner cube indenter to determine the fracture toughness. Specifically, often pop-in events are observed during indentation of brittle materials with a sharp indenter. Field *et al.*[42] developed an approach that used the additional pop-in displacement associated with radial crack formation to quantify the K_{1c}. This was further extended by Scholz *et al.*[39] who identified there were two pop-in events during indentation, as shown in **Figure 6**. The response prior to the first pop-in was associated with the Hertzian elastic response of the slightly

rounded cube corner indenter tip (radius ~70 nm). At a critical contact pressure, the material around the indenter tip yields and the first pop-in occurs. With increased loading, the material behaves in an elastic–plastic manner, which is predictable based on the hardness and elastic modulus of the material.[43] At a critical load, radial cracks are formed about the indenter and the second pop-in event occurs. This additional displacement with the second pop-in is associated with the crack opening displacement that is related to the size of the cracks, the elastic modulus, and fracture toughness of the material.[42]

3.306.2.4.2. Residual stresses

The presence of residual stresses in a material may have an influence on the hardness, and on the extent of radial crack extension around the impression in the case of a brittle materials indented with a sharp indenter. There have been a number of studies that have explored the influence of residual or applied stress on the hardness of metallic materials.[44] These studies generally have considered the presence of biaxial tensile or compressive stresses; the situation becomes more complex in the case where uniaxial stresses are present. The latter creates a nonaxially symmetric deformation problem. In addition, residual stresses in materials, except for low yield stress metallic materials, are generally small compared with the magnitude of the hardness, and as such, the perturbation of yield stress or hardness by their presence will be minor. A critical analysis and experimental procedure to quantify the residual or applied stresses on the hardness or to determine the residual stress from change of hardness is given by Suresh and Giannakopoulos.[45]

The presence of residual stresses is more apparent on the extent of radial crack extension around the residual impression. Marshall and Lawn[46] developed a simple analysis of this problem. The presence of residual or applied tensile or compressive stress on the surface of the material being indented introduces an additional term in the expression for the stress intensity factor, as given by eqn. [41]. A complete 2D fracture mechanics analysis of this problem was also developed by Lawn and Marshall[47] for a number of cases which included linear and parabolic stress distributions. For the situation where the indentation crack size is small compared with the gradient of stress, the expression for the stress intensity factor is composed of two terms:

$$K_{1c} = K_{Ind} + K_{App/Res} \quad [43]$$

where K_{Ind} is the indentation stress intensity factor given by eqn. [41] and $K_{App/Res}$ is the stress intensity factor for a crack in the residual or applied stress field and is given by

$$K_{App/Res} = Y\sigma_{App/Res}\sqrt{c} \quad [44]$$

where Y is the shape factor for a half-penny surface crack and $\sigma_{App/Res}$ is the applied or residual stress present. Combining eqns. [41], [43], and [44] we have

$$K_{1c} = \kappa\left(\frac{E}{H}\right)^{1/2}\frac{P}{c^{3/2}} \pm Y\sigma_{App/Res}\sqrt{c} \quad [45]$$

The second term in eqn. [45] may be positive or negative depending upon whether the stresses on the surface are either tensile or compressive, respectively. The aforementioned approach has been used to determine the tempering residual stresses developed in veneering porcelains as a consequence of rapid cooling.[48,49] Kase and Rowcliffe[50] used this approach with a corner cube nanoindenter to plot the stress field about indentation impressions in soda lime glass.

3.306.2.5. Indentation Creep

Viscous response of natural biomaterials plays an important role in their function to bear and distribute force, especially for bone, and has attracted considerable attention.[51–56] Jäger[52] summarized the characteristics of typical viscous deformation of biological tissues as (1) the force necessary for deformation depends on the deformation rate; (2) force–displacement hysteresis occurs during loading and unloading; (3) application of a (constant) force leads to transient and/or permanent creep; (4) after removing the deformation force, there is stress–relaxation/recovery.

Restricted by measurement methods, the limited viscosity, and temperature range over which natural biomaterials operate, the viscous responses, especially creep behavior, are difficult to quantify. For metallic and polymeric materials, traditional tensile and/or compressive tests are used to investigate the creep response of a specimen. Two main problems limit the usage of these methods for biological materials such as enamel or dentine. Firstly, these tests need multiple identical specimens and are time consuming to conduct. Secondly, the accuracy of these methods depends on the creep response of the material. For small samples with limited creep, such as enamel, it is not very reliable. Torsion[55,56] and three-point bending tests[51] were used to measure the relaxation and the elastic modulus and shear modulus of bovine bone. Furthermore, because of the anisotropic property of natural biomaterials, the loading direction must be controlled. This limitation, along with the size of teeth, severely restricts the usage of bulk methods for the evaluation of dental tissue. In the field of biomaterials, only limited indentation creep tests have been done on biological hard tissues.

Indentation creep tests are a powerful technique for studying the rheological properties and relaxation dynamics of different materials such as metals,[57] polymers,[10,58,59] and other materials.[60,61] Lucas and Oliver[57] reviewed the depth-sensing creep tests and recognized four types: (1) indentation load (at fixed displacement) relaxation tests, (2) constant rate of loading tests, (3) constant-load indentation creep tests, and (4) impression creep tests. The most common method is the constant-load indentation creep test, which records the change of the depth with time.

In some nonlinear solids, especially power-law creep materials, the mechanical response depends upon the strain rate, $\dot{\varepsilon}$, namely[1]

$$\sigma = K\dot{\varepsilon}^m \quad [46]$$

where K and m are material constants and m is the creep rate sensitivity. This equation is derived from Norton's finding that $d\varepsilon/dt = (\sigma/\sigma_c)^n$, where ε, σ, t are strain, stress, and time, respectively and σ_c, n are material parameters.[62]

The complex stress state beneath an indenter tip requires a somewhat different approach to evaluate the creep response generated. Because of geometrical similarity for conical and pyramidal indenter tips, the Berkovich tip has a constant effective strain value; from Tabor's empirical relationship, the effective contact strains

are $\varepsilon_r \approx 0.2 \tan \theta$.[6] Therefore, the strain rate of an indentation test can be extracted from the h–t curve as the indenter displacement velocity divided by the plastic depth of penetration[63]:

$$\dot{\varepsilon} = \dot{h}/h \qquad [47]$$

where the indentation rate $\dot{h} = \mathrm{d}h/\mathrm{d}t$. Strictly speaking, h should be the contact depth of indenter, h_p. However, to facilitate the measurement and calculation, total displacement, h_t, is generally used in this equation. By assuming a constant ratio of h_p/h_t, which is what is commonly observed for most materials including enamel, the use of ht instead of h_p will not significantly influence the final results.[64]

Another independent analysis derived from the definition of hardness also supports the concept of strain rate dependence in eqn. [47].[57] As has been mentioned in eqn. [8], the definition of contact hardness, H, can be written as

$$H = \frac{P}{A} = \frac{P}{ch^2} \qquad [48]$$

where H is hardness, P is the load, h is the contact depth (and total depth, h_t, is often chosen), and c is a geometrical constant of the indenter (24.5 for perfect Berkovich tip). Equation [48] can be differentiated and reorganized into

$$\frac{\dot{h}}{h} = \frac{1}{2}\left(\frac{\dot{P}}{P} - \frac{\dot{H}}{H}\right) = \dot{\varepsilon} \qquad [49]$$

in which $\dot{\varepsilon}$ is the strain rate defined in eqn. [47]. This equation suggests that, during the holding period of a creep test, because the force is kept constant ($\dot{P} = 0$), strain rate $\dot{\varepsilon}$ is expressed by $\dot{h}/h$. This conclusion is the same as eqn. [47].

Based on the aforementioned analysis, the creep behavior and the creep rate sensitivity, m, of material can be calculated from the depth–time (h–t) curve of the creep test at maximum load. By fitting and determining the differential equation of the h_e depth–time (h–t) curve, the indentation rate $\dot{h} = \mathrm{d}h/\mathrm{d}t$ needed by eqn. [47] can be calculated. From eqn. [48], the contact pressure (hardness, H) can be acquired. Therefore, creep rate sensitivity value of the sample can be read from the logarithmic plot of $H - \dot{\varepsilon}$ curve. The method has been applied to human enamel research.[64]

An alternative approach for the time-dependent properties may be described in a more classical way, such as universal rheological models, consisting of springs and dashpots (Figure 7). The parameters in these models can be obtained by fitting the time course of indenter penetration by a creep function, depending on the material, indenter shape, and loading history (see, e.g., Mencik *et al.*[65]).

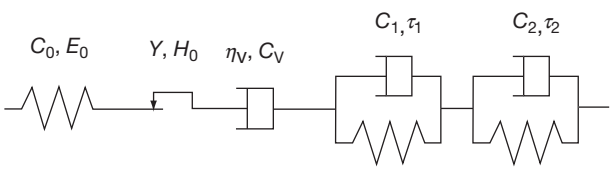

Figure 7 Viscoelastic–plastic model 'spring + plastic element + dashpot + 2 Kelvin-Voigt bodies'. C_0, C_1, and C_2: compliances; E_0 and H_0: instantaneous elastic modulus and hardness; c_v: viscous compliance; τ_1, τ_2: retardation times.

The relationship between indenter load and the depth of penetration into elastic or viscoelastic material under monotonic loading can be expressed generally as

$$f[h(T)] = K\psi(P, J, t) \qquad [50]$$

where f is some function of the indenter shape and penetration depth, K is a constant characterizing the indenter geometry, and Ψ (P, J, t) is a function depending on the load magnitude and history, on material parameters, and on time.

3.306.2.6. Other Factors that Influence the Accuracy of the Results

1. Environmental conditions may have significant effect on nanoindentation test results. Thermal drift and mechanical stability are two main issues to consider. Because the nanoindentation displacement sensor is sensitive to sub-nanometer displacements, any thermal expansion of the indenter, indenter shaft, and specimen as a result of temperature changes during a test can be incorporated into the test results. The thermal expansion need only be very small to make a significant effect. For example, an indentation test lasting 1 minute to a penetration depth of 100 nm can easily be in error by more than 10% if the change in displacement sensor output due to thermal expansion is 10 nm over that minute. For this reason, the temperature of the system and the sample must be very well controlled and maintained throughout the test. It is always good to allow the indenter and newly installed sample some time to reach thermal balance before starting the test. Also, any environmental vibration that is transferred to the system may influence the displacement accuracy of the test. Therefore, sufficient vibrational damping is important to ensure the mechanical stability of the whole system.
2. The viscous properties of the sample have significant influence on the results as well. This is because the compliance method, on the analysis of force–displacement data, (as described in **Sections 3.306.2.1–3.306.2.3**) is based on the assumption of elastic–plastic, isotropic sample materials.[3,25] Polymeric biomaterials and tissues often exhibit viscoelastic or time-dependent behavior. These characteristics can lead to errors in modulus determination using the compliance method. The most readily observed effect of viscoelasticity on indentation is creep, or a sinking of the tip into the sample under a constant load. In cases where creep behavior dominates the elastic response of the material, a 'nose' is observed on the indentation unloading curve, as illustrated in **Figure 8**.[66] In short, it was found that when loading is followed by unloading without a hold at peak load, displacement increases slightly in the initial portion of the unloading phase, because the creep rate of the material is initially higher than the imposed unloading rate. This phenomenon results in a negative slope in the initial unloading region (**Figure 8(a)**), making it impossible to use the compliance method to measure modulus as well as overestimating the hardness. To eliminate this creep-induced nose effect, Briscoe and colleagues[66] incorporated a 10 s hold period at peak load into their applied load–unload functions in order to allow the material to approach equilibrium prior to unloading. The effect of this hold period on

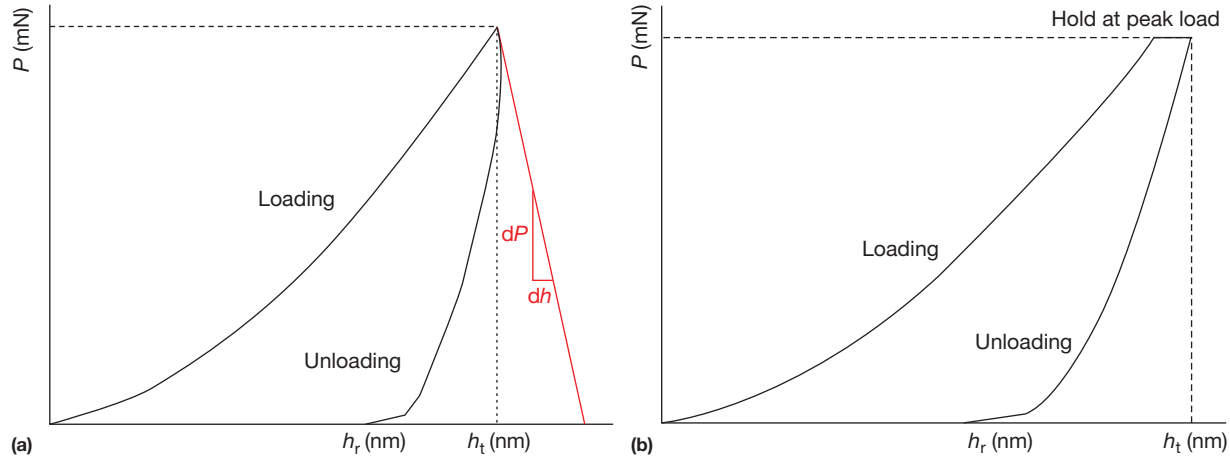

Figure 8 (a) Illustration of the nose effect resulting from indenting a viscous material. (b) Illustrates the elimination of the nose effect by adding a hold period at peak load.

load–displacement data is illustrated in **Figure 8(b)**. This same approach has been used in many indentation studies of biomaterials, with different hold periods to allow the creep rate to dissipate prior to unloading.[67,68] An appropriate hold time should be selected based on the creep and unloading rates used in the experiment. More details about indentation creep have been discussed in the previous sections.

More recently, Guidoni *et al.*[69] also investigated the possible role of indentation recovery during unloading on the unloading slope compliance during testing of bovine enamel. Using the compliance method, these authors found that a threefold change in E modulus occurred depending upon whether tests were conducted wet or dry using a cube corner indenter. However, when the same samples were tested using blunter indenter tips, differences of <20% were observed. The major differences in the case of the cube corner indenter between wet and dry were considered to be associated with significant pile-up about the indenter for the dry specimen.

3. As with most biomaterials function under conditions of complete hydration, the history of sample storage will influence the mechanical behavior of the biomaterials. It has long been recognized that, for biological samples, E and H of the specimen is significantly affected by the hydration status. In bovine femur cortical bone, dehydration increased E in osteonal tissue and interstitial lamellae by 15.4% and 9.7% (when using a Bekovich indenter), respectively, which was attributed to the fact that drying contracts the individual fibrils in the tissue.[70] Another study of bone specimens reports increases in indentation moduli of 11–28% after dehydration, with further increases after embedding in resin.[71] An investigation of human enamel under different environmental conditions also showed substantial changes in elastic modulus, hardness, and creep response after ethanol dehydration, water rehydration, and dry.[72] These studies demonstrate the importance not only of testing fully hydrated specimens but also of avoiding prolonged dehydration during sample preparation and testing. Other studies illustrate the importance of selecting an appropriate storage medium and time. It was demonstrated that storage of dentin and enamel specimens in Hank's balanced salt solution (HBSS) maintained the low load corner cube-derived mechanical properties, while storage in deionized water or $CaCl_2$ solution resulted in a decrease in modulus and hardness that was attributed to demineralization of the surface.[73] Observation on dog trabecular bone reveals that long-term storage in epoxy (3–6 months) increased the E of the specimen significantly (26%), which was attributed to the increase of modulus of embedding resin, desiccation of the bone tissue, and hardening of the porous space in the tissue.[74]
4. The method of surface preparation can also affect mechanical properties, as surface roughness can have a significant impact on the measurement of modulus using nanoindentation.[75] For mineralized hard tissue, the most common sample preparation methods are microtome sectioning and mechanical polishing. A comparison of these two preparation methods prior to testing lamellar bone specimens illustrated that, depending on the thickness of the specimen required, the surface preparation methods can significantly influence the roughness and resultant mechanical properties of the specimens.[76] Usually, to minimize errors arising from surface roughness, biomaterials are polished (usually down to a 1 μm or even finer particle size) prior to indentation.[77,78] It has been suggested that indent penetration depths then be chosen such that the surface roughness (Ra) is <10% of the total penetration depth.[79]
5. A feature evident with many materials evaluated using nano- and microindentation is the presence of the so-called indentation size effects (ISE). This effect is generally seen using pointed indenters, but does occur with spherical indenters, where the hardness decreases with increasing load. On the other hand, for metallic and ceramic materials, the elastic modulus of a material is usually considered invariant with contact size, and this is one aspect that should be confirmed initially when size-dependent effects are observed. There have been a number of explanations rationalizing ISE developed over the past 5 decades for metallic and ceramic materials, which have been critically reviewed.[80]

6. For the measurement of thin film, the thickness of the film and the properties of the substrate material have influence on the nanoindentation results. Details have been discussed in **Chapter 3.305, Biomedical Thin Films: Mechanical Properties** by Ben-Nissan *et al.*

3.306.3. Application of Nanoindentation to Biomaterials

Nature endows different natural hard materials unique structures, which offer potential for the development of biomimetic materials. The nanoindentation technique provides the ability to explore the mechanical properties, including anisotropy of these naturally designed biomaterials, in respect to their multiple hierarchical microstructures. The use of nanoindentation for characterizing the properties of biological materials has been well reviewed elsewhere.[81–83] It is impossible to cover the whole literature database within a few pages in this chapter. Therefore, here we illustrate the application of nanoindentation research on human enamel.

As the hardest organ of our body, teeth must retain their shape as well as resist fracture and wear during load-bearing function for the life of an individual. Teeth experience a range of loading situations[84]: firstly, they contact directly other objects and/or opposing teeth; secondly, they encounter normal and sliding contact loading resulting in wear, and thirdly, unlike bone, damage of teeth is not repairable. To meet all of these functional requirements, teeth have evolved with a unique hierarchical microstructure. What is the relationship between the hierarchial microstructure and the excellent mechanical behavior of the natural biomaterials? Nanoindentation becomes a basic tool to explore this area. Numerous nanoindentation investigations have been conducted on human teeth, as they do not readily lend themselves to more conventional property evaluation procedures.

3.306.3.1. Elastic Modulus and Hardness of Enamel

The mechanical tests to determine the elastic modulus and hardness of enamel have experienced several stages of development from the macroscale to the micro- and nanoscale over the last few decades. Due to the size limit of human enamel samples, it has been difficult to perform macroscale tests. Therefore, most recent investigations on the mechanical properties of human enamel have been done using nanoindentation.[27,73,79,85–94] These micro- and nanoscale investigations revealed some very interesting features of this natural ceramic-like biocomposite.

Firstly, the high mineral level (about 96 wt%) as well as the unique microstructure of enamel contribute to its high mechanical properties.[79,86,95] The stiffness of a composite material like enamel is a combination of the stiffness of its multiphase components and associated microstructures; the inorganic-hydroxyapatite (HAP) crystals and organic tissues which may be considered as a fibrous composite model.[96]

Secondly, the hardness and elastic modulus of enamel were found to be a function of enamel rod alignments.[27,79,92] The measured elastic modulus varies with the direction of load application relative to the apatite crystals of enamel. Higher elastic modulus values were generated when the force is applied parallel to enamel rods, as the deflection will be resisted primarily by the aligned crystals in that direction within the rods. In the perpendicular directions, the displacement will be influenced more by the less stiff organic tissue surrounding the crystals, thereby resulting in lower elastic moduli. The rod orientation dependence is also seen in a numerical uniaxial loading 3D finite element analysis simulation of enamel.[96] This also explains the discrepancy in the elasticity data of the localized values of enamel rod and interrod regions. The interrod region was reported to have hardness and elastic modulus of about only 25 and 50%, respectively of the values of the core region of the rod.[88]

Thirdly, the mechanical properties of the enamel are intra-tooth site dependent. The inner enamel near the dentino-enamel junction (DEJ) has on average a reduced hardness and elastic modulus values by typically 26% compared to the outer enamel.[86,89] The size of enamel rods decreases with distance toward the DEJ; consequently, the volume fraction of softer protein-rich interrods has a twofold increase, which undoubtedly contributes to a decrease in composite hardness and stiffness.[92]

Lastly, recent systemic nanoindentation investigation on sound enamel of permanent teeth with different tips and various loads reveals that the elastic modulus of enamel does not have a constant value but a noticeable size effect dependent on the indentation contact areas.[27] This behavior is shown in **Figure 9**, which illustrates a consistent decrease in elastic modulus with an effective contact diameter for all indenters. This shows that the elastic modulus, in the case of enamel, is a function of the contact area and the effective volume of the contact stress field from which the elastic modulus is determined, irrespective of what type of indenter tip is used. This can be rationalized by the unique rod–interrod microstructure of the biocomposite, in which the nanohardness and elastic modulus of the interrod region were respectively 73.6% and 52.7% lower than those of the rod.[88] Upon consideration of the rod structure of enamel, with increasing peak load during nanoindentation, more and more prism-sheath units are involved in the indentation stress field and contribute to the measured nanoindentation elastic modulus (**Figure 10**). Due to the reduced modulus of the protein-rich sheath region,

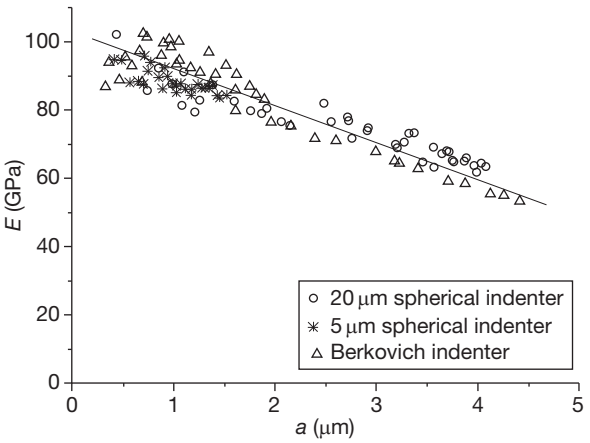

Figure 9 Elastic modulus, E, of human enamel parallel to the rod axis plotted against contact radius, a, for the three different indenters.

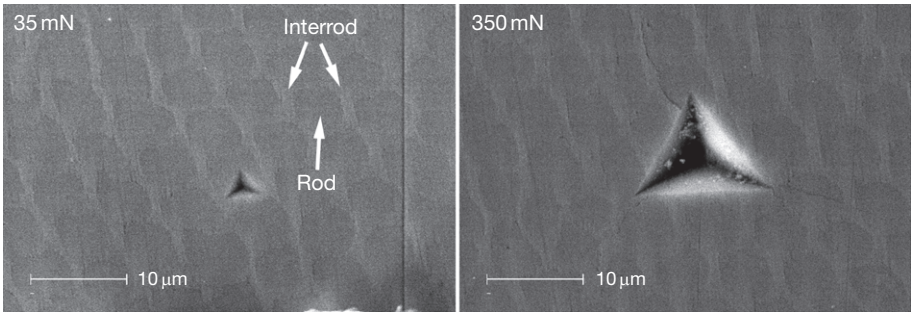

Figure 10 Indenter impressions from different peak loads are compared and also with the rod-like features within the enamel. (a) Shows that under a load of 35 mN, the Berkovich impression was located within one prism unit. In contrast, (b) illustrated that a 350 mN load generated a much bigger impression with the same indenter now covering more than three prism units.

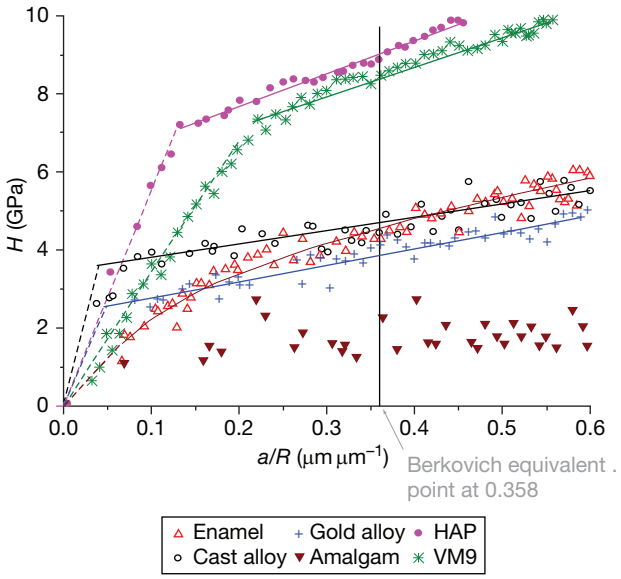

Figure 11 Indentation-derived stress–strain (H–tan θ) relationships of different dental restorative materials and enamel. Solid lines represent plastic part and short dotted lines represent the elastic part of materials, which were calculated from the Hertz equation [25].

the more the sheath area becomes involved in the deformation field, the lower the stiffness of the measured area. This may also partially assist in explaining the wide range of elastic modulus reported in other investigations and wider standard deviations from AFM-based nanoindentation tests.

3.306.3.2. Stress–strain Relationship of Enamel

With the method described in Section 3.306.2.3, nanoindentation stress–strain relationships for enamel have been evaluated,[27] and some interesting results were found.

As shown in Figure 11, enamel exhibited smooth stress–strain curves without a prominent elastic–plastic transition point. This is mainly caused by the unique composite rod structure of enamel and its organic-rich interrod region, which enables it to be more deformable and less damage prone than pure HAP. In the case where the indentation force was parallel to the prism (rod) direction, the yield behavior was primarily determined by shear deformation of the very thin protein 'glue' between the individual apatite crystallites. In the case of the load perpendicular to the axis of the enamel rods, the loaded rods deflect under the force because the contact load is supported not only by the rod structure but also by the more deformable and thicker interrod structure surrounding the rods.

A comparison of indentation-based stress–strain curves generated with small spherical tipped indenters for a range of dental materials is shown in Figure 11. Enamel was found to behave more like a metallic material than a ceramic. A comparison with dense HAP, which is the main component of the enamel, indicated that enamel had much lower stress–strain response. This suggests that the minor organic components in enamel influence the mechanical behavior of this highly mineralized biocomposite significantly. From this point of view and the aforementioned results, traditional criteria of dental material selection based on elastic modulus and hardness may not be appropriate for choice of restorative materials which can protect opposing teeth from excessive attrition. The nanoindentation stress–strain evaluation should also be involved in future dental restorative material selection and development studies.

As proposed in Section 3.306.2.1, the plastic deformation resistance can be extracted from nanoindentation data by either a hardness approach[9] or an energy approach.[14] For enamel, plastic energy expenditure ratio, U%, from eqn. [13] begins at 30% and has a monotonic increase with the contact strain, tan θ, with no obvious elastic part (Figure 12). In contrast, HAP showed a linear U%–strain part for strain values <0.5 and the curve started from 0%. Although the major component of the two materials in Figure 12 was very similar, enamel had a slightly higher energy dissipation ability (~10%) than HAP at the same strain level.

A question arising from Figure 12 is, where has the extra energy in enamel dissipated? If we initially consider the apatite crystals, their very small size would have near theoretical strength, ~10% of the shear modulus of ~10 GPa. The mean contact stresses for enamel do not approach this value and only in the vicinity of the tip in the case of the Berkovich indenter may such stresses be achieved. Hence, it is not considered that energy loss by conventional dislocation-based plastic deformation of the inorganic phase is important for enamel. Therefore, the focus of the discussion is centered on the role of the organic protein components between and surrounding HAP crystallite rods.[28]

Spears in a finite element numerical model of the elastic response of enamel cited the elastic modulus of HAP crystals and organic tissues as 114 and 4.3 GPa, respectively.[96] Moreover, AFM nanoindentation[88] also reinforced the argument that the protein-rich sheath between the rods has a lower elastic modulus and hardness than the apatite containing cores of rods: the nanohardness and elastic modulus of the sheaths as reported earlier were 73.6% and 52.7% lower than those of the rods, respectively. The nanoindentation curves shown by Ge *et al.*[88] showed that sheaths exhibited more energy absorption than rods. White *et al.*[97] also established that mineral apatite crystals had a microhardness ~1.8 times greater than human enamel. These studies indicate that the minor components of enamel, namely protein and water, have a profound softening/plasticizing effect. Other possible mechanisms responsible for the greater energy loss include fracture of the apatite crystallites, deformation of the very thin protein layers between the crystallites within the prisms, or deformation of the protein and movement of fluid in the nanoscale porous structure.

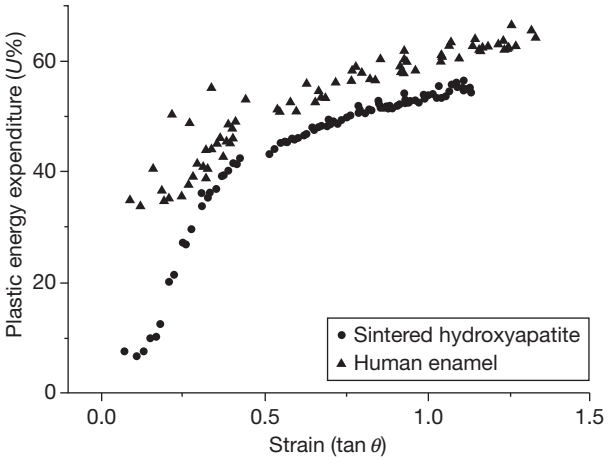

Figure 12 Comparison of plastic energy absorption ability between enamel and dense hydroxyapatite based on indentation data generated with a nominally 10 μm spherical indenter.

It was argued by He and Swain[14] that higher energy expenditure behavior of the enamel was primarily related to the minor organic components. Three different mechanisms were considered to potentially contribute to the measured energy absorption, namely fluid flow within the sheath structure as proposed by Fox,[98] protein 'sacrificial bond' extension as proposed by Smith *et al.*[99] for nacre and Fantner *et al.*[100] for bone, or nanoscale friction within sheaths associated with the degustation of enamel rods as considered by Macho *et al.*[101] Further work is required to more quantitatively assign the energy loss observations to these or other mechanisms.

3.306.3.3. Creep Behavior of Enamel

In recent investigations,[64,102] the creep behavior of enamel was described and compared with dental materials by a one-step nanoindentation loading–unloading method with a Berkovich indenter. Samples were indented at the maximum force of 250 mN with a one-step loading method. Holding time at maximum load was 900 s for all tests. During one-step unloading, another holding at 5 mN was activated. This unload-holding time was 900 s as well.

In Figure 13, the relative penetration depth, h'_t, was calculated by subtracting the initial depth at the beginning of the holding time from the increasing depths with time during the holding period at maximum and minimum loads. Creep data, while holding at maximum load, exhibited increasing penetration depth with time for most of the investigated materials (Figure 13(a)). Pure titanium showed the greatest extent of creep followed by enamel. In contrast, the indentation creep depths of dense HAP were very limited (<0.025 μm during the 900 s holding period). Such limited creep response, ~0.03 nm s^{-1}, is within the system thermal drift stability range and implies that the viscous properties of HAP materials are negligible compared with their elastic–plastic properties.

At the minimum-load holding period (named *backcreep* period), the recovery was prominent only for enamel but remained within the instrument's stability range (<0.03 nm s^{-1}) for other samples (Figure 13(b)). The displacement rate and limited backcreep of HAP (~0.03 nm s^{-1}) and

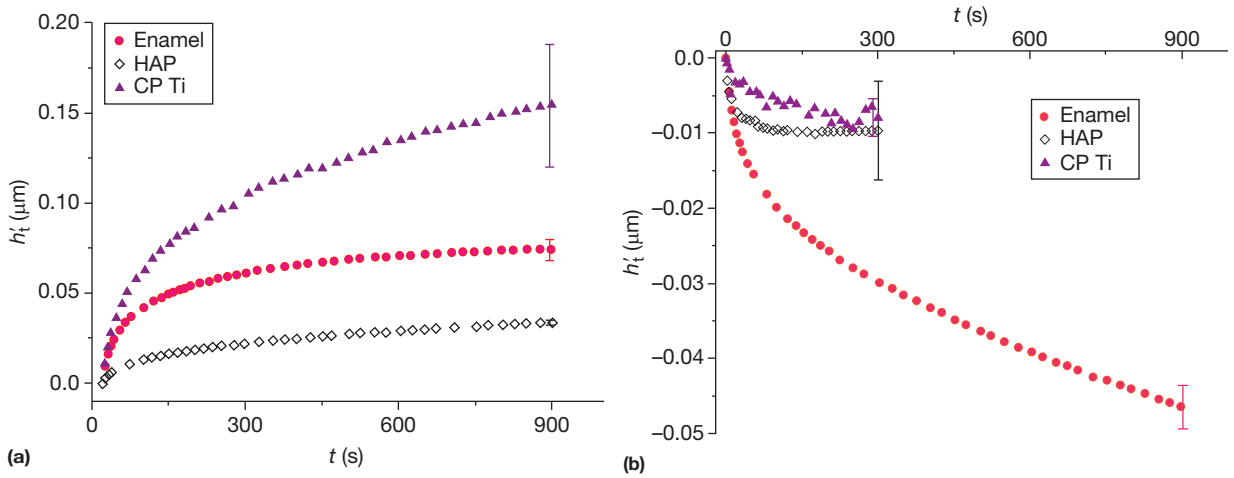

Figure 13 Indentation depth against time, $h'_t - t$ curves generated with a Berkovich indenter of (a) creep at 250 mN and (b) backcreep at 5 mN of different materials.

titanium ($\sim$0.02 nm s^{-1}) were all within the limit of system thermal drift. Therefore, only enamel exhibited significant backcreep response.

This phenomenological result implies that enamel and some dental metallic materials all exhibit creep behavior but with different characteristics. This indicates that different mechanisms are responsible for such behavior. The viscoelastic behavior of enamel may be considered as follows: first, the proteins and other organic (and water) components within enamel may be regarded as a biopolymer. Viscoplastic properties of these biopolymers stem from the configurational rearrangements, disposition, and interaction among the macromolecules in both their short- and long-range network interactions.[103] Under indentation load, high stresses around the indenter tip cause a rapid redistribution response of the structure, while in the lower stressed regions more remote from the tip, long-range interaction response is slow due to the time-dependent macromolecular rearrangement. Upon unloading, because of the memory effects associated with the cross-linked network, the molecules have a tendency to return to their initial form and positions.[103] In the case of indentation, the surrounding elastically deformed hinterland about the residual impression provides an additional driving force for such backcreep deformation. These factors result in the recovery of the indentation impression being also time-dependent. Second, proteins within enamel may behave similar to the recovery domain bond within many proteins, called a 'sacrificial bond.'[104] Rief *et al.*[104] also noted that the longer the delay before the next application of force, the more reformation or recovery of the bond occurred during relaxation; refolding of protein domains was also observed during this process. Similarly, proteins within the organic-rich sheath and between the apatite crystallites of enamel may have a similar function and response as those in bone.

In short, this reversible viscoelastic property of enamel may help teeth redistribute the localized high contact/impact stresses resulting from chewing forces, especially the high localized contacts from asperities/small hard particles trapped between teeth. Also, sliding wear between teeth and food particles may introduce high local tensile, compressive, and shear forces around the sliding contact area. This reversible inelastic property may be vital to limit damage accumulation and prevent excessive wear in enamel.

3.306.3.4. Nanoindentation of Caries Lesions

Nanoindentation has also been employed by researchers of structures that have experienced human diseases. Dental caries may be defined as a bacterial disease of calcified tissues of teeth and is characterized by demineralization of the inorganic and destruction of the organic substance of the tooth.[105] Due to its long history and wide prevalence, dental caries has attracted considerable attention of both clinical practitioners and researchers.

From a materials science point of view, caries and precaries or precavitated lesions (e.g., white spot lesions (WSLs) in clinic) would be anticipated to have markedly inferior mechanical properties than their healthy counterparts. By considering the aforementioned hierarchical microstructures of both enamel and dentin, and the natural procedure of acid invasion and mineral dissolution, the changes of mechanical properties may have certain characteristics, which may be able to help us understand the formation and development of the lesion so that remineralization treatments may be developed. In this field, nanoindentation is obviously a powerful tool.

Recently, a nanoindentation characterization of artificially generated WSLs has been reported.[106] After a certain period of time soaking in a mild acidic solution, sound teeth samples showed certain degrees of subsurface demineralization. The partially demineralized lesion areas had lower elastic modulus and hardness than sound areas, due to the loss of mineral crystals. On the surface of these natural lesions (WSLs), a harder, less demineralized surface layer up to 50-μm thickness was found (unpublished data).

Another recent nanoindentation on WSLs (unpublished data) exhibited a number of specific mechanical property features: (1) there is a rapid gradient and reduction in mechanical properties from sound enamel to the WSL body; (2) the body of the lesion appears inhomogeneous with some islands that show higher or lower elastic modulus and hardness; (3) the surface layer of the lesion showed higher elastic modulus and hardness than the lesion body. Moreover, the reduction of elastic modulus and hardness of natural WSLs was considered as a consequence of mineral loss. Therefore, a correlation analysis of elastic modulus and mineral density was performed on the natural WSL samples. Mineral density were measured and calculated from the gray value of calibrated micro-CT images.[107] By taking the mineral density of sound enamel ρ_{sound} as 3.0 g cm^{-3}, the porosity of every indented lesion point can be calculated with the equation: Porosity $= \rho_{lesion}/\rho_{sound}$ and correlated with the elastic modulus of that point (**Figure 14**). An exponential relationship was found to fit the data very well and the result can be related to Rice's minimum solid area model for porous materials.[108] In addition, recent high resolution electron microscopy observation provided direct evidence on the dissolution and pore formation of enamel HAP crystals as a consequence of caries degradation.[109]

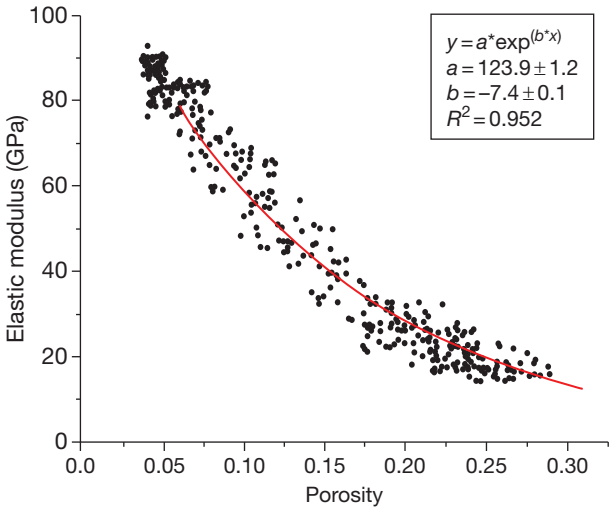

Figure 14 Nanoindentation-derived values of elastic modulus plotted against the mineral porosity of white spot lesion sample determined from quantitative micro-CT.

Developmental defects of dental hard tissues, mainly including amelogenesis imperfecta (defects of enamel) and dentinogenesis imperfacta (defects of dentine), are others conditions where nanoindentation has application. The etiology of these developmental defects is complex, including genetic, environmental, and systemic factors. Amelogenesis imperfecta has two subtypes: hypoplastic type (defective matrix production) and hypomineralized type (defective maturation/mineralization).[105] In general, most of these defective enamel and dentine tissues have less mineral and higher organic contents. Theoretically, from Spears' finite element model,[96] the change of the mineral/organic ratio of the composite will decrease the mechanical properties of the nature biocomposite significantly. In recent nanoindentation investigation, the hardness and elastic modulus of the hypomineralized enamel were reported as 0.53 ± 0.31 and 14.49 ± 7.56 GPa, respectively, which are much lower than the sound counterpart.[110] Similarly, another nanoindentation mapping showed that the hardness and elastic modulus of the hypomineralized region ranged from 0.07–1.7 to 3.2–40.9 GPa, respectively, which are less than a quarter of that of the normal enamel.[111] It was also suggested that this reduction is not only due to variations in mineralization, but more likely from differences in the apatite crystalline and crystal orientations of the hypoplastic enamel. Moreover, a newly published report showed that hypomineralized enamel also exhibited a profound elastic modulus size effect upon nanoindentation, as described in **Section 3.306.3.1**, but the decreasing trend was more significant than sound enamel.[112] The accompanying transmission electron microscopy (TEM) observations illustrated thicker interrod structures, with higher levels of organic content surrounding the HAP crystals within both rod and interrod regions.[112] By employing Spears' finite element model, the inferior mechanical properties can be reasonably explained in respect of the microstructure of the hypomineralized enamel.

3.306.4. Summary

In conclusion, nanoindentation provides a powerful way to explore the mechanical properties of biological materials in respect to their hierarchical microstructures. The nanoindentation investigations on natural biomaterials have contributed significantly to biomimetics and the development of new composite materials. However, as a newly developed technique, some aspects regarding the special properties of biomaterials need further development and investigations. These include:

1. Nanoindentation investigation of viscoelastic–plastic properties of biomaterials. As stated previously, viscous behavior of the material may generate a 'nose' effect on the force–displacement curve upon unloading and affect the accuracy of the result. How to resolve the problem needs more theoretical and experimental research.
2. Nanoindentation of fluid-filled porous structures.
3. Investigation and characterization of creep properties of biomaterials by nanoindentation. Unlike the uniaxial tests, nanoindentation generates a complex stress field on the sample. Procedures to adequately quantify the creep ability of materials by nanoindentation need further consideration.
4. Indentation size effects (ISE). Usually, this is a term related to metallic and ceramic materials related to hardness. However, as illustrated in this chapter, biomaterials may present similar size effect on the elastic properties due to the hierarchical microstructures. How to interpret and apply the results containing size effects becomes a question for further research on biomaterials.

Glossary

Alendronate (also alendronic acid) Is a bisphosphonates drug used for osteoporosis.

Anabolic agent Substance which stimulates the formation of new bone. One of the most common anabolic agents is the parathyroid hormone (PTH) which regulates the levels of calcium in the serum. The use of anabolic agents is common in therapies against osteoporosis.

Antiresorptive therapy A type of medical treatment used against osteoporosis which inhibits bone resorption. Antiresorptive therapies are often based on bisphosphonates.

Bone quality Various skeletal factors which contribute to bone strength in addition to bone mass. For example, bone quality includes bone microarchitecture, bone material properties, bone remodeling.

Colles' fractures (also Colles fracture) Distal fracture of the radius in the forearm with dorsal posterior displacement of the wrist.

Compact bone (also cortical bone) A common type of bone which forms the outer shell of most bones. Compact bone is much denser and has different mechanical properties than trabecular bone.

Osteocyte A type of bone cell found inside the mineralized bone matrix. It is located within a small hole called osteocyte lacuna. Osteocytes can communicate with each other through cell processes which run inside small channels called canaliculi. Osteocytes are believed to act as sensors which transform mechanical inputs into biological signals.

Osteoporosis One of the most prevalent bone diseases which increases bone fragility and, consequently, fracture risk. Osteoporosis is accompanied by a decrease in bone mass and by a deterioration of bone microarchitecture

leading to a general decrease in bone quality. Osteoporosis is most common in women after menopause (so-called postmenopausal osteoporosis), but also develops in men.
Teriparatide A form of parathyroid hormone (PTH) used in the treatment of osteoporosis.

Trabecular bone (also cancellous bone and spongy bone) A common type of bone which is found, for instance, inside the vertebral body and at the end of long bones. Trabecular bone is highly porous and it is composed of small struts called trabeculae.

3.307.1. Introduction

Bone is the most frequently investigated biological material and finite element analysis (FEA) is currently the computational tool most commonly used for the analysis of bone biomechanical function. FEA has been used in bone research for more than 30 years and has had a substantial impact on our understanding of the complex behavior of bone.[1] Bone is structured in a hierarchical way over many length scales[2] and this chapter reflects this hierarchical organization. In particular, we focus on the applications of FEA for understanding the relationship between bone structure and its mechanical function at specific hierarchical levels. A better understanding of the relationship between structure and mechanical function is supposed to be important for the current trend of (bio)materials design, where the structure of biological materials is considered as a possible source of inspiration.[3] Furthermore, an improved understanding could lead to more successful approaches in the prevention and treatment of age- and disease-related fractures.

FEA has been extensively used in bone research for a variety of purposes. This chapter does not attempt to give an in-depth review of all the FE studies in the bone field. Neither do we consider traditional aspects directly related to the design and analysis of orthopedic implants; for this topic, the reviews of Prendergast[4] and Wirth *et al.*[5] can be consulted. In addition, we limit our review by only considering bone from a 'static' point of view; hence, time-dependent processes such as bone adaption and healing are not included. FE simulations in the field of bone remodeling and adaption have been recently reviewed by Gerhard and colleagues,[6] whereas FE studies on bone healing have been collected by Doblaré *et al.*[7]

In this chapter, the basic concepts of FEA are briefly discussed in Section 3.307.1.1. The reader looking for a more exhaustive description of the principles and numerical implementations of FEA is referred to classical textbooks.[8] Afterward, we focus on some specific levels of bone hierarchical structure, ranging from the macroscale to the nanoscale. At each level, the most common FE modeling strategies are introduced. Depending on the hierarchical level, different research questions have been investigated with FE simulations: from more clinically oriented issues connected with bone quality (e.g., predicting bone strength at the radius) to more fundamental problems (e.g., basic mechanisms of damage accumulation in mineralized collagen fibrils).

At the macroscopic or organ level (Figure 1(a)), bones have quite different shapes that relate to their specific functions and loading conditions. Bones are loaded through direct contact within joints and through the action of muscles and tendons; hence, the resulting loading scenarios can be very complex. Nevertheless, a proper and accurate description of the boundary conditions is fundamental for meaningful calculations of physiological tissue loading, and this can be done only when whole bones are represented. Furthermore, the effects of bone diseases such as osteoporosis become specifically apparent at the organ level where they can cause spontaneous fractures. In Section 3.307.2, FE studies on whole bones are reviewed focusing on the specific locations that are most prone to osteoporotic fractures, which are the femur, radius, and vertebra.

At the mesoscale, the next hierarchical level with typical dimensions of hundreds of micrometer, trabecular bone can be distinguished from compact bone (Figure 1(b)). Trabecular bone is found at the ends of long bones (e.g., in the femoral head or in the distal radius) and inside the vertebral bodies; it has a porous nature and it is composed of small rod-like and plate-like struts. The mechanical behavior of trabecular bone,

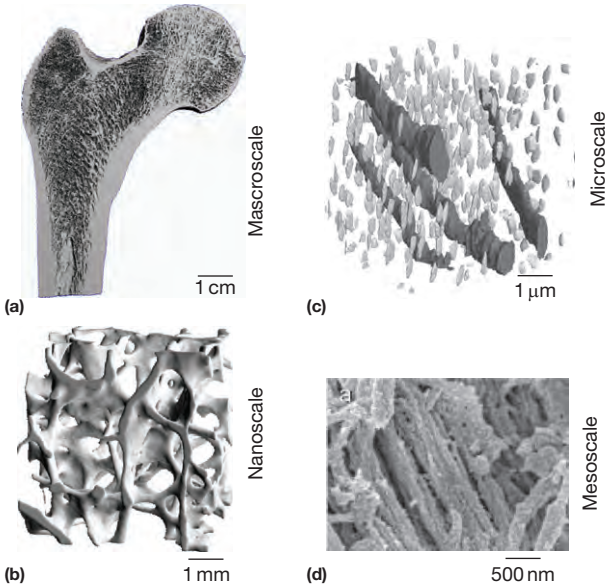

Figure 1 Schematic overview of the hierarchical levels of bone considered in this chapter. (a) At the macroscale, a microcomputed tomography (μCT) image of a section across the femur shows the trabecular core as well as the compact cortical shell around it (image courtesy of Thomas Mueller, ETH Zurich, Zurich, Switzerland). (b) At the mesoscale, close-up on the three-dimensional microarchitecture of a trabecular bone sample coming from the femoral head and imaged with μCT. (c) At the microscale, the main ultrastructural features of cortical bone (canal network and osteocyte lacunae) are visible with synchrotron radiation nanocomputed tomography. explored with FE strategies, is reported in Section 3.307.3. The extent of this section reflects the considerable amount of literature focusing on trabecular bone. In fact, trabecular bone has been extensively characterized for mainly two reasons. First, bone loss and architectural deterioration occurring in osteoporotic patients primarily weaken the trabecular network. Second, trabecular bone is a natural material that efficiently combines low weight with high mechanical performance: hence, the study of the relationship between architectural and mechanical properties (e.g., stiffness, strength, and failure modes) could be inspiring for biomaterial applications.

Compact or cortical bone appears dense at a level of hundreds of micrometer, but considering a higher magnification (3–5 μm), several ultrastructural features such as the osteocyte lacunae and the canal network can be distinguished (Figure 1(c)). The influence of such features on the mechanics of bone tissue at the microscale as assessed by FE is explored in Section 3.307.4.

At the material level, the basic building blocks of bone are a soft but tough protein matrix and stiff but brittle mineral crystals (Figure 1(d)). The relative geometrical arrangement of the two components influences the stress transfer between mineral and collagen as well as the propagation of cracks in this composite material. FE applications at the nanoscale are reviewed in Section 3.307.5.

3.307.1.1. The Finite Element Analysis

Due to the application of external loads, internal forces (stresses), and deformations (strains) are generated inside a structure. The magnitude and direction of stress and strain are influenced by various aspects including magnitude and direction of the loading conditions, shape and internal architecture of the structure, and local material properties. The transmission of forces from the boundary of an object to the inside of that structure is well described with a set of partial differential equations that constitute the so-called boundary-value problem. From a mathematical point of view, the elastic problem can be formulated by considering a three-dimensional body of volume V, delimited by a surface S into a coordinate system x_i ($i = 1, 2, 3$). The body is subjected to some prescribed displacement on its boundary and to external forces which can be point loads f_P, surface loads f_S, or volume loads f_V. A coordinate system is also attached to the body. Due to loads and boundary constrains, the body will deform and the strain tensor $\boldsymbol{\varepsilon}$ can be computed by differentiating the displacement vector $\boldsymbol{u}(\boldsymbol{x})$ (small strain assumption):

$$\varepsilon_{ij} = \frac{1}{2}\left[\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right] \qquad [1]$$

The diagonal components of the strain tensor ($i = j$) represent the relative length variation along the directions of the coordinate system whereas the nondiagonal components ($i \neq j$) express the relative angle variations between two faces initially parallel to the directions of the coordinate system. Considering a linear elastic constitutive behavior, the relationship between the stress tensor $\boldsymbol{\sigma}$ and strain tensor $\boldsymbol{\varepsilon}$ is given by:

$$\sigma_{ij} = C_{ijkl}\varepsilon_{lk} \qquad [2]$$

The diagonal components of the stress tensor ($i = j$) represent the area-normalized force acting along the directions of the coordinate system and perpendicular to a considered infinitesimal area, whereas the nondiagonal components ($i \neq j$) describe the area-normalized force acting along the directions of the coordinate system but parallel to an infinitesimal area. If the material is isotropic, only two independent material properties are needed to describe the material mechanical behavior and the stiffness matrix $\boldsymbol{C}$ becomes:

$$\boldsymbol{C} = \frac{E}{(1+\nu)(1-2\nu)}\begin{bmatrix} 1-\nu & \nu & \nu & 0 & 0 & 0 \\ \nu & 1-\nu & \nu & 0 & 0 & 0 \\ \nu & \nu & 1-\nu & 0 & 0 & 0 \\ 0 & 0 & 0 & 1/2-\nu & 0 & 0 \\ 0 & 0 & 0 & 0 & 1/2-\nu & 0 \\ 0 & 0 & 0 & 0 & 0 & 1/2-\nu \end{bmatrix} \qquad [3]$$

where E is the Young's modulus and ν the Poisson's ratio.

The constitutive equation (eqn [2]) has to be solved under two constraints. First, the equilibrium condition on the stress tensor states that (assuming $f_v = 0$):

$$\frac{\partial \sigma_{ij}}{\partial x_j} = 0 \quad \text{in } V \qquad [4]$$

Second, the strain field must satisfy the compatibility relations to assure the existence of a displacement field:

$$\frac{\partial^2 \varepsilon_{ij}}{\partial x_k \partial x_l} + \frac{\partial^2 \varepsilon_{kl}}{\partial x_i \partial x_j} - \frac{\partial^2 \varepsilon_{ik}}{\partial x_j \partial x_l} - \frac{\partial^2 \varepsilon_{jl}}{\partial x_i \partial x_k} = 0, \quad i,j,k,l = 1,2,3 \qquad [5]$$

Equations [2], [4], and [5] can be combined into a single equation for the displacement:

$$(\lambda+\mu)\frac{\partial}{\partial x_i}\left(\frac{\partial u_k}{\partial x_k}\right)+\mu\frac{\partial^2 u_i}{\partial x_j^2}=0 \qquad [6]$$

λ and μ are the Lamè coefficients defined as:

$$\lambda=\frac{E\,v}{(1+v)(1-2v)},\quad \mu=\frac{E}{2(1+v)} \qquad [7]$$

Equation [6] is a second-order partial differential equation that describes the displacement field inside a three-dimensional object. Only in very simple cases it can be solved analytically; in most of the situations encountered in bone research, geometries, loading conditions, and material properties are complex, and numerical solutions of the elastic problem are needed.

The FEA is the most adopted numerical procedure for solving boundary-value problems. The finite element method (FEM) does not directly attempt to discretize eqn [6]; instead, it is based on alternative formulations of the elastic problem such as, for instance, the potential energy method or the principle of virtual works. Such formulations are preferred since they can be solved directly using simple linear matrix operations and indirectly when used in combination with powerful minimization methods. Considering the potential energy principle, it states that a mechanical system is at equilibrium when its total potential energy reaches its minimum value. The total potential energy Π is obtained by summing up the total strain energy inside the system and the work done by the external forces W:

$$\Pi=\frac{1}{2}\int_V \boldsymbol{\sigma}\boldsymbol{\varepsilon}\,\mathrm{d}V-\int_V \boldsymbol{u}\boldsymbol{f}_\mathrm{V}\,\mathrm{d}V-\int_S \boldsymbol{u}\boldsymbol{f}_\mathrm{S}\,\mathrm{d}S-\sum_P \boldsymbol{u}\boldsymbol{f}_\mathrm{P} \qquad [8]$$

The formulation of the total potential energy given in eqn [8] is valid for a continuum system whereas for FEA a discrete implementation is required. The basic idea of the FEM is to discretize a complex structure into small elements with simple shapes. The size of the elements must be chosen according to the length scale of interest. The elements are interconnected through nodes situated at specific locations within the elements and at the elements boundaries. The displacement field inside each element is assumed to be a function of the displacement of the nodes; the displacement functions, also called shape functions, are generally linear, quadratic, or cubic. The first step in the discretization procedure is to substitute the continuum displacement vector $\boldsymbol{u}$ with the nodal displacement $\boldsymbol{U}_\mathrm{N}$. The displacements of the nodes are the main unknowns of the FEM. The displacement and the strain within each element ($\boldsymbol{U}_\mathrm{M}$ and $\boldsymbol{\varepsilon}_\mathrm{M}$, respectively) can be calculated as a function of the nodal displacement by introducing the shape-function matrix $\boldsymbol{S}_\mathrm{M}$ and the strain-displacement matrix $\boldsymbol{B}_\mathrm{M}$:

$$\boldsymbol{U}_\mathrm{M}=\boldsymbol{S}_\mathrm{M}\boldsymbol{U}_\mathrm{N} \qquad [9]$$

$$\boldsymbol{\varepsilon}_\mathrm{M}=\boldsymbol{B}_\mathrm{M}\boldsymbol{U}_\mathrm{N} \qquad [10]$$

The stress inside each element $\boldsymbol{\sigma}_\mathrm{M}$ is defined based on the element strain $\boldsymbol{\varepsilon}_\mathrm{M}$ and on the element constitutive properties reported in the constitutive matrix $\boldsymbol{D}_\mathrm{M}$:

$$\boldsymbol{\sigma}_\mathrm{M}=\boldsymbol{D}_\mathrm{M}\boldsymbol{\varepsilon}_\mathrm{M} \qquad [11]$$

Similar to the displacement, all the forces acting within each element can also be transformed into equivalent forces acting at the nodal points, which must be in equilibrium with the boundary stresses and with all the loads acting on the element ($\boldsymbol{f}_\mathrm{P}$, $\boldsymbol{f}_\mathrm{S}$, and $\boldsymbol{f}_\mathrm{V}$). Inserting eqns [9]–[11] into eqn [8] and putting together all the force terms into a global force vector $\boldsymbol{F}$ and all the displacement terms into a global displacement vector $\boldsymbol{U}$, eqn [8] becomes:

$$\Pi=\frac{1}{2}\boldsymbol{U}^\mathrm{T}\boldsymbol{K}\boldsymbol{U}-\boldsymbol{U}^\mathrm{T}\boldsymbol{F} \qquad [12]$$

where $\boldsymbol{K}$ is the so-called global stiffness matrix. The minimum value of the total potential strain energy of the finite system is computed by imposing:

$$\frac{\partial\Pi}{\partial\boldsymbol{U}_i}=\begin{bmatrix}\dfrac{\partial\Pi}{\partial\boldsymbol{U}_1}\\ \vdots\\ \dfrac{\partial\Pi}{\partial\boldsymbol{U}_N}\end{bmatrix}=0,\quad i=1,\ldots,N \qquad [13]$$

which leads to the following system of N algebraic equations (in three dimensions N is equal to three times the number of nodes in the system):

$$\boldsymbol{K}\boldsymbol{U}=\boldsymbol{F} \qquad [14]$$

With the FEM, the problem of solving a second-order partial differential equation [6] is reduced to the easier task of solving a set of algebraic equations.

In FEA, two typical drawbacks resulting from the element discretization should be mentioned. First, the displacement functions can very well represent the displacement field within each element but may give rise to discontinuity in the displacement between adjacent elements, therefore violating the compatibility criterion. Second, equilibrium is computed and ensured only at nodes where equivalent forces are considered; inside the elements, equilibrium requirements are often violated. Therefore, the solution obtained with FEA is approximate and concepts such as accuracy and validity should be considered. The accuracy of a FE model quantifies how close the model output is to the real solution of the boundary-value problem. Since the real solution is not known, the accuracy can be estimated with a so-called convergence test: the size of the element is decreased and a new solution is obtained and compared with the old one. From a mathematical point of view, if the element size approaches zero, the numerical solution will converge to the correct solution. The model validity, a fundamental issue unfortunately often disregarded, tells to which extent the results of the model can represent or can predict the behavior of the investigated mechanical system. The validation of a model is often performed by comparing model predictions with experimental results. Where the accuracy of a FEA can be quite easily assessed, it can be challenging (and sometimes even not possible) to verify the validity of a FE model.

3.307.2. Macroscale: Whole Bone

The natural ability of the skeleton to withstand loads can be greatly compromised in case of bone diseases such as

osteoporosis. A fundamental task of bone research is to provide tools for improving the prediction of bone strength, ideally *in vivo* and at the organ level. Nowadays, the main diagnostic method to assess fracture risk connected with skeletal disorders such as osteoporosis is to measure *in vivo* the amount of bone. This is often performed with a technique called dual-energy X-ray absorptiometry (DXA), which estimates from the quantity of the adsorbed radiation how much bone is present.[9] The result of DXA measurements, corrected by body size, is the bone mineral density (BMD) characterizing with a single scalar value the bone under investigation. According to the instruction of the World Health Organization (WHO), a reference value of BMD for healthy people as a function of age is established and variations of 2.5 standard deviations or more below this value define an osteoporotic individual.[10,11] When thinking at the intricate structure of bone (**Figure 1**), it is obvious that there are several limitations in estimating bone mechanics, and in particular, bone strength using BMD only. Estimating the probability of fracture with BMD does not identify all the people at risk and does not tell who will and who will not have a nontraumatic fracture.[10] The poor predictive power of BMD is also evident from the effects of antiresorptive therapies where the significant reduction observed in fracture risk has almost no correlation with the small increase in BMD.[12–14]

Two computational approaches have been employed for estimating the mechanical behavior of bone (primarily bone strength) at the organ level: continuum-level FE (or continuum FE) and microstructural-level FE (or continuum FE) (μFE). Those methods are based on three-dimensional virtual reconstructions of the skeletal system which can be obtained nondestructively with computed tomography (CT) or magnetic resonance (MR) imaging.[15,16] The development of FE simulations in bone research has run parallel to the improvement in the resolution of imaging systems based on X-rays and MR. *In vivo* scanners for the whole body based on quantitative CT (QCT) have a resolution of about 1 mm. QCT measures the specific external shape of bones and gives estimations of BMD but it does not include microstructural details (i.e., at the level of individual trabeculae) which are only visible in the submillimeter range. For the extremities of the musculoskeletal system, scanners with higher resolution have been developed. Peripheral QCT (pQCT) initially had a resolution of about 170 μm and nowadays high-resolution pQCT (HR-pQCT) can resolve bone microstructure with a voxel size of 80 μm.[17] The widely spread desktop micro-CT (μCT) system, used in bone research starting from the 1990s,[18] is now capable of resolving bone structure even at the submicrometer range but requires small bone samples. In animals, the feasibility of performing *in vivo* μCT was first demonstrated in the rat proximal tibia using synchrotron radiation,[19] and was used to depict bone loss after OVX.[20] The recent introduction of desktop μCT systems for *in vivo* scanning of small animals[21,22] with resolution better than 10 μm has opened the way to more practical and better accessible systems.[23]

3.307.2.1. Continuum-Level FE

Continuum FE models are commonly based on QCT imaging. In continuum FE different degrees of material complexity such as inhomogeneity, anisotropy, and nonlinearity can be introduced within manageable computational time. Elastic moduli for continuum-level FE elements are commonly derived from BMD values through empirical conversions,[24] which however, are still quite controversial.[25] It has been demonstrated that continuum FE, based on QCT images, can give better predictions of bone strength than BMD.[26,27] For the skeletal locations where only QCT imaging is clinically feasible, such as femur and vertebra, continuum FE could be considered the actual state of the art computational method to predict bone strength *in vivo*. The method has a great potential to become a valuable tool in cross-sectional studies, where bones of different healthy and osteoporotic individuals are scanned and compared; conversely, it might not be precise enough to track more subtle changes in bone stiffness and strength in follow-up studies, where the very same skeletal regions of the same patient is followed over time.[16] It has been suggested that a possible cause for the nonperfect ability to predict bone strength from QCT-based FE models is the lack of information on bone microstructure. By definition, continuum FE models do not represent the internal microarchitecture of bones; hence, features such as the orientation of individual trabeculae or the thin cortical shell surrounding the trabecular core cannot be resolved. However, these structural aspects could be fundamental for a better understanding of the mechanisms of deformation and failure of bones. The use of more refined FE models, which accurately represent bone microarchitecture, might be a way to overcome this problem and therefore to better predict bone failure.[16] Increasing the complexity of the material behavior is considered another possible strategy to compensate for the lack of microstructural information.[28]

3.307.2.2. Microstructural FE

During the last two decades, a novel approach to investigate the mechanical properties of bone, which takes into account bone microarchitecture has been developed. The approach combines three-dimensional imaging with FE and is referred to as microstructural FE (μFE) analysis or voxel FEA. The strategy normally adopted to exploit high-resolution images for FE simulations is to directly convert each image voxel into (typically) a brick-shaped element.[28–30] Alternatively, image processing algorithms (e.g., marching cube) are adopted to generate smoother meshes of tetrahedral elements.[31] Obviously, as a result of the voxel-to-element conversion approach, the resulting μFE models are made up of a very large number of elements: an entire human vertebra can possess up to 60 million elements and 200 million degrees of freedom.[32,33] Special solving strategies have been developed for such large systems. The element-by-element method,[30] for instance, exploits the fact that all elements are identically shaped bricks for making very efficient use of the memory. More advanced numerical methods based on the concept of preconditioners have been recently introduced for large parallel computer architectures.[28,34] Currently, the maximum number of degrees of freedom that can be analyzed in μFE is about 1 billion and, when using supercomputers, the solution time required can range from minutes to a few hours depending on the number of CPUs and the complexity of the model.

The tissue properties normally adopted in μFE are quite simple: it has been shown by comparison with biomechanical

testing that isotropic and linear elastic material models give very accurate predictions (for small deformations) of the apparent mechanical behavior of bone samples and of whole bones.[16,35,36] Even if the tissue modulus is assumed isotropic, the directional dependence of bone mechanical properties emerges automatically due to the directional nature of the trabecular network. The role of tissue properties as well as of nonlinearity in the material behavior will be discussed in more details when specifically considering trabecular bone (Section 3.307.3.2). Another advantage of μFE is the possibility to calculate stress and strain locally, in the individual trabeculae; this knowledge can be fundamental to understand bone adaption in healthy and osteoporotic conditions.[33,37]

In the following three sections, some examples of continuum FE and μFE studies focusing on whole bones will be presented. Three locations of the musculoskeletal system which are often subjected to osteoporotic fractures[38,39] will be considered: the femur (Section 3.307.2.3), the radius (Section 3.307.2.4), and the vertebra (Section 3.307.2.5). For each of these regions we will not attempt to give an exhaustive review of the literature, instead, some significant applications of FE simulations will be discussed. Our aim is to give the reader an idea of the current state of the art applications of FE in bone research, including advantages and potential pitfalls.

3.307.2.3. Femur

One of the musculoskeletal sites where osteoporotic fractures are most frequent is the femur and in particular the femoral neck.[39] The femur is also one of the most studied bones of the skeleton. It was by looking at the trabecular arrangement inside a human femur that, more than a century ago, the first thoughts on bone remodeling and adaption were made.[40] Hence, it may not be surprising that the first FEA of a whole bone reported in literature was performed on a femur.[41] Since the original work of Brekelmans,[41] FE studies have been extensively used to assess the mechanical properties of human femurs, with a special interest in predicting failure characteristics as well as stresses and strains at the tissue level in healthy and osteoporotic conditions.

3.307.2.3.1. Continuum FE models

Continuum FE models take in consideration the specific shape of the femur but do not model the internal architecture. This method has been often employed to study femoral fractures: it has been shown that continuum FE performs better than BMD in quantifying bone strength, with R^2 values typically ranging from 0.75 to 0.83.[42,43] Keyak and colleagues[43] used linear continuum FE, with geometry and material properties automatically generated from QCT scans, to investigate the prediction of fracture locations. Several human femurs ($N = 18$) were tested under two different loading conditions: single-limb stance and fall to the side. The model could predict different fracture locations for the different loading scenarios; however, the agreement with experimentally determined failure locations was limited to 72% and 67% for stance and fall loading case, respectively. In a subsequent study, the model was refined by including nonlinear material behavior (an elastic region, a perfectly plastic region, and a strain-softening phase were considered).[44] The nonlinear properties improved the strength prediction ($R^2 = 0.92$) but also resulted in a huge overestimation of stiffness. Considering failure properties, one obvious question is which type of failure criterion for bone tissue can better identify the risk of fracture? Schileo and colleagues[45] combined subject-specific continuum FE models and experimental mechanical testing to compare the performance of a failure model based on maximum principal strain versus stress-based criteria in predicting the failure patterns of human femurs. The authors considered only three femurs and a single loading condition; nevertheless, the results clearly indicated that a principal strain criterion better identified the level of failure risk and the location of fracture. The use of a failure mode based on strain is supported by experimental data showing that the failure strains of bone tissue appear to be fairly constant.[46]

Currently, QCT-based continuum FE models appear to be the best technology to determine femoral bone strength *in vivo*. However, no technological standard exists for quantifying bone fracture from FEA. More experimental data on bone failure characteristics is needed to justify or adapt currently incorporated bone fracture mechanics models in the FE analyses. With that in place continuum FE seems to be a promising approach towards a clinical implementation of patient-specific strength prediction in the femur.

3.307.2.3.2. μFE models

The femur has been analyzed with μFE simulations also with different aims than strength prediction. In particular, this methodology has been used to explore the link between microstructural changes occurring with osteoporosis and their impact on the load distribution at the tissue level. This aspect is quite important in view of the ability of bone to adapt to its mechanical demands. It is not clear to which extent bones are adapted to normal or habitual loads of daily life and, therefore, how dangerous are nonhabitual or error loads, for instance originating from accidents or during sport activities.[37] In addition, the adaption mechanism might differ in healthy and osteoporotic conditions. Researchers have tried to answer those issues by focusing on the analysis of local stress/strain distributions in healthy and osteoporotic bone under different loading scenarios.[33,37,47] One study of van Rietbergen[37] analyzed the stress and strain distributions inside an healthy and an osteoporotic human femur with high level of details. μCT images of a region of about 100 mm in length (including the femoral head and neck) at a resolution of 80 μm were converted into μFE models which had approximately 96 millions of elements (Figure 2(a) and 2(b)). Cortical and trabecular bone were modeled with different tissue moduli (22.5 and 15 GPa, respectively) and proper boundary conditions were applied to simulate the maximum load occurring during the stance phase of walking. The simulations showed that the mean tissue strain was almost 1.7 times higher in the osteoporotic femur compared to the healthy one (520 and 304 mean microstrains, respectively) (Figure 2(c) and 2(d)). Additionally, the tissue of the osteoporotic specimen was less uniformly strained, as shown by its broader strain distribution. Interestingly, osteoporotic bone presented a higher percentage of tissue both high-loaded and low-loaded than healthy bone. Finally, the authors observed that by reducing the external load by approximately 41%, the mean strains in the two femurs

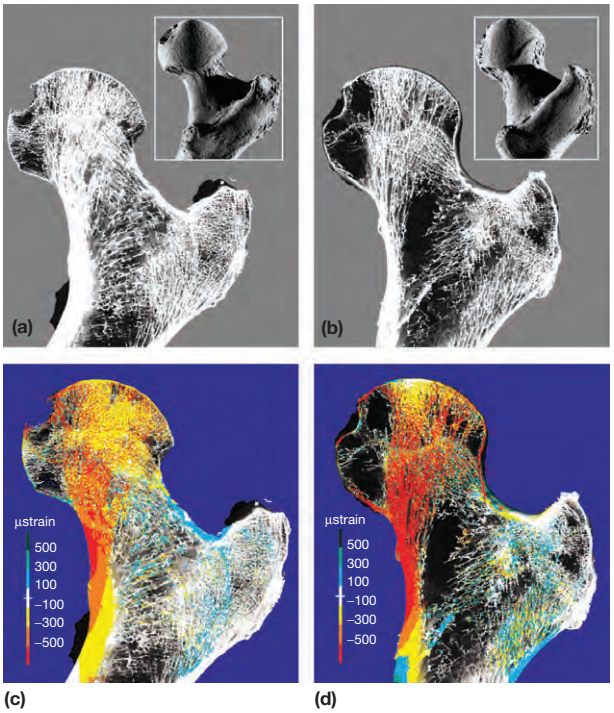

Figure 2 Three-dimensional reconstructions of a healthy (a) and osteoporotic (b) proximal femur. Sections across the femurs as well as the entire models are shown. A large hole can be seen in the (b) osteoporotic femur, devoid of any trabeculae; contour plots for the principal strains at the tissue level inside the healthy (c) and osteoporotic (d) human femur. The strains were computed with micro-finite element analysis (element size 80 μm). For loading conditions the stance-phase of walking was assumed. In the color map, negative values (from yellow to red) correspond to compressive strains and positive values (from blue to green) to tensile strains. The loading patterns in the two femurs are similar; however, higher strains both in tension and compression are present in the osteoporotic femur. Adapted from Van Rietbergen, B.; Huiskes, R.; Eckstein, F.; Ruegsegger, P. *J. Bone Miner. Res.* **2003**, *18*, 1781–1788, with permission.

were quite similar, hence suggesting that osteoporotic bone might be adapted to lower load levels. A similar approach based on μFE was followed by Verhulp *et al.*[47] to characterize the tissue stresses and strains for nonhabitual loads. More specifically, the authors simulated and analyzed a fall to the side onto the greater trochanter for the same healthy and osteoporotic femurs used by van Rietbergen *et al.*[37] In this study the relative contribution of cortical and trabecular bone in taking up the load was also calculated. This estimation was done by measuring the ratio of the elastic energies stored in the two bone compartments was alos calculated. The μFE calculations indicated that both for healthy and osteoporotic femur, the anatomical location subjected to the highest strain was always the cortex of the femoral neck. Also for the case of a fall to the side, broader distributions of the strain energy density (SED) were found for the osteoporotic femur. However, the relative amounts of strain energy stored by the inner trabecular bone in the two models were comparable (67.8% and 70.3% for the healthy and osteoporotic femur, respectively). Similar strain distributions in the two femurs were obtained if the loading force acting on the osteoporotic femur was reduced by 39%. Surprisingly, this values is very similar to the one reported by van Rietbergen for physiological loading configurations.[37] This fact may indicate that the relative weakness of the osteoporotic femurs compared to the healthy one does not depend on habitual or nonhabitual loading conditions. A limitation of these two studies was that only one healthy and one osteoporotic sample were considered. It would be interesting to test to what extent the findings are valid when analyzing femurs from a more heterogeneous population with different degrees of osteoporosis.

3.307.2.4. Radius

Fractures at the distal radius are very spread among osteoporotic individuals. They have less severe consequences than femoral fractures but cause great pain and often require surgical interventions. In addition, those fractures are also considered good indicators of an increased probability of having other fractures in the future at different skeletal locations.[48] Similar to other bones, the prediction of fracture risk at the radius has been based on the measurement of BMD. However, this approach presents several limitations, as discussed at the beginning of Section 3.307.2. Not only from a clinical, but also from a technological point of view, the radius is an interesting anatomical site because it can be imaged *in vivo* with high-resolution techniques such as pQCT and HR-pQCT; having such *in vivo* detailed measures makes image-based μFE the preferred computational method for assessing and predicting the stiffness and, more important, the strength of this skeletal region. For this reason, in this section we will only consider studies were μFE has been used in combination with pQCT or HR-pQCT to investigate the mechanical behavior of the radius.

3.307.2.4.1. μFE models

One of the first aims of μFE studies based on pQCT of human radii has been to determine whether a correlation exists between common regions of fractures observed in clinical practice and locations of high mechanical stresses or strains computed with μFE. A study of Ulrich and colleagues[48] focused on a distal radius of a healthy volunteer, which was imaged along with the two adjacent carpal bones, at a resolution of 165 μm. Bone tissue was assumed to be linear elastic with an isotropic tissue modulus of 10 GPa and the model had about 1.6 millions of elements. The inclusion of the carpal bones and of a cartilage layer between these bones and the radius was done in an effort to improve the boundary conditions for modeling high impact forces resulting from a fall. In fact, the loading scenario at the distal radius is quite complex, and the relative fraction of load coming from the carpal bones (scaphoid and lunate) depends on the specific position of the hand and it is still not too well characterized. Ulrich *et al.*[48] considered different loading scenarios, corresponding to the same applied maximum force of 1000 N and showed that the ratio of the forces acting on the carpal bones had a strong influence on the stresses and strains inside the radius. A quite interesting result was that for all load cases, the location of highest SED absorption was always in a region adjacent to the articular surface. This region well corresponds with locations where radius fractures are observed in clinics.[49] The study of Ulrich *et al.*[48] was probably the first attempt to

estimate tissue-level stress and strain in a living human subject. Subsequently, Pistoia and coworkers[50] investigated the influence of image resolution on the predicted mechanical behavior of bone with μFE. The study showed an excellent correlation between elastic moduli calculated from the pQCT-based models (165 μm) and those calculated from high-resolution μCT (28 μm) based models ($R^2 > 0.95$). They also investigated failure properties and, in particular, strength prediction.[36] For that purpose they combined linear elastic μFE based on pQCT scans with experimental mechanical testing. In the study, 54 human arms from cadavers were scanned with pQCT (voxel size 165 μm) and then tested until failure in a simplified experimental configuration adopted to reproduce the Colles' fractures. The ultimate (or failure) load was defined as the maximum force measured in the experimental tests. Failure loads were also estimated with linear elastic μFE by computing the force required to have a certain percentage of bone tissue loaded beyond the tissue yield strain, which was assumed at 7000 microstrains.[51] The best correlation ($R^2 = 0.75$) between experimentally and computationally determined failure forces was obtained when 2% of the tissue resulted loaded beyond the yield point. The predicted ultimate force, however, was always overestimated by approximately 30%. From a technical point of view, the resolution of the FE analysis could be a first source of inaccuracy. In fact, the voxel size of the first generation *in vivo* systems, like the one used in the study of Pistoia,[36] is 165 μm. This could lead to overestimating trabecular thickness (Tb.Th).[52] Such models would overestimate bone failure loads because, for the same applied load, a network with thicker trabeculae will experience less strain. Clearly, strength prediction is hampered here by the adopted methodology of deriving failure, which is a highly nonlinear phenomenon, from linear elastic analyses. An improvement in failure prediction is foreseen with increasing the resolution and with the inclusion of nonlinear properties in μFE.

Assessing bone strength and fracture risk with HR-pQCT is obviously more promising than with normal pQCT and BMD because of the higher degree of details obtained at the microstructural level. *In vivo* HR-pQCT images of the whole radius are not accessible since in clinical practice only a section of the radius is scanned. If the entire geometry of the radius is not available, one potential concern is whether μFE studies based on only subregions are able to predict bone strength. Additionally, it is not clear which type of boundary conditions should be applied to such subregions since the load transmission from the joint is not taken into account. In two recent works, Mueller *et al.*[53] and Varga *et al.*[54] have explored those issues. The study of Varga *et al.*, for instance, was based on 21 radii which were scanned at 82 μm isotropic voxel size using HR-pQCT. Two different subregions of 9 mm were virtually cut and analyzed with μFE. The first subregion was located in the standard position adopted for clinical scanning at a distance of 9.5 mm from the endplate. The second location was more distal and in contact with the endplate (**Figure 3(a)**). Isotropic and homogeneous tissue properties were used (Young's modulus of 15 GPa and Poisson's ratio of 0.3) and boundary conditions were imposed to simulate compression tests. Concomitantly, experimental mechanical test-to-failure were performed with a setup adopted to reproduce Colles' fractures (**Figure 3(b)**).[55] The strength estimation with FE was done with the threshold method, introduced by Pistoia[36] and previously explained. The authors reported high correlations between experimental and computed strength for both regions ($R^2 = 0.96$ and $R^2 = 0.92$, for the most distal and for the standard location, respectively). From these results, it can be inferred that FE analysis based on single subregions seems very promising for predicting bone strength and, surprisingly, the role of the boundary conditions might be only of second order.

If μFE based on high-resolution images of the radius has to become the standard clinical tool for assessing bone strength and fracture risk, two important issues need further discussion. First, appropriate mechanical procedures to directly estimate bone strength needs to be identified and standardized. Second, the reproducibility of such procedures has to be quantified. The first aspect has been explored by MacNeil and Boyd.[56]

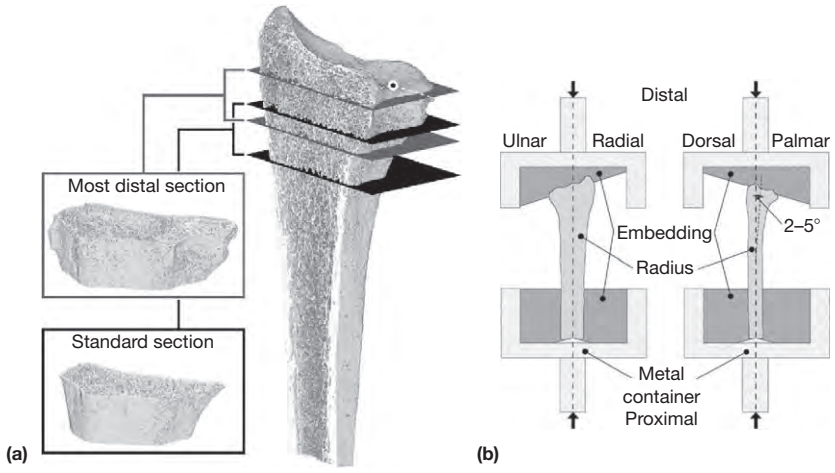

Figure 3 (a) Location of the two regions selected on HR-pQCT of the distal radius. The standard region is measured 9.5 mm away from the endplate whereas a new location is selected more distal and in contact with the endplate. (b) Schematic representation of a setup for mechanical testing of human radii. The specific testing configuration is chosen to reproduce Colles' fractures. Adapted from Varga, P.; Pahr, D. H.; Baumbach, S.; Zysset, P. K. *Bone* **2010**, with permission.

The authors considered the role of various μFE modeling assumptions (e.g., homogenous vs. heterogeneous tissue modulus, linear and nonlinear material behavior) on the simulated strength. μFE models with a homogeneous tissue modulus were compared versus models where the modulus varied locally according to the attenuation values of the CT. Additionally, both linear and nonlinear simulations (using an asymmetric, bilinear yield strain criterion) were run. Direct mechanical compression testing was also performed to have a gold standard value for failure strength. The experimental dataset was not the entire radius but several specimens of approximately 9 mm in thickness cut from several locations in human cadaver radii. The samples were scanned with HR-pQCT (82 μm voxel size) and then tested in uniaxial compression. A typical μFE mesh had approximately 7 millions of elements and was solved in an average of 2.6 h. Also in this study, the apparent elastic properties estimated with linear μFE correlated highly with failure strength, and the correlation was only slightly higher when local tissue moduli were assigned based on CT-attenuation values than when an homogeneous modulus (6.8 GPa) was used ($R^2 = 0.98$ and $R^2 = 0.97$, respectively). The nonlinear analysis was as well in excellent agreement with the experimental strength ($R^2 = 0.95$) and, additionally, it could capture the behavior of the tissue beyond the yield point. Reproducibility of the μFE-based mechanical assessment is the second important aspect which has been investigated by several authors.[57–60] A useful parameter to define the reproducibility is a measurement of the precision error, previously introduced for bone densitometry measurements.[61] Stiffness and strength computed with μFE based on HR-pQCT seems to be highly reproducible, with reported precision error in the range 0.48–2.93%.[59]

In conclusion, considering the recent developments in high-resolution imaging, where the microarchitecture of the distal radius can be easily quantified *in vivo* with a resolution of approximately 80 μm, it is foreseen that μFE based on HR-pQCT imaging might, in the future, be used as a tool for the analysis of bone quality and fracture risk in patient populations.

3.307.2.5. Vertebra

Several FE models of the vertebra have been developed over the last 15–20 years.[62] In analogy with radius and femur, *in silico* research on human vertebrae has been driven by the need for having accurate predictors of strength and risk of fracture which could replace the use of BMD.[63] It is well known that fractures connected with osteoporosis occur frequently in the vertebral body and that increased bone fragility could even lead to a spontaneous collapse of the vertebrae.

3.307.2.5.1. Continuum FE models

In terms of *in vivo* strength assessment and prediction, the current computational state of the art employs continuum FE in conjunction with QCT. This methodology can provide better estimates of vertebral compressive strength than QCT alone. Crawford and colleagues,[26] for example, compared the FE-based bone strength and the QCT-based bone strength against gold standard strength values assessed with experimental tests. In their study the authors considered 13 human vertebral bodies which were scanned with QCT (0.674 mm pixel size). The QCT voxel values were converted into elastic moduli (along the vertical direction) using a simple linear correlation between elastic modulus and mineral density.[64] The material behavior was assumed transversely isotropic and the remaining elastic constants were derived accordingly. The resulting FE models were heterogeneous at the material level: microstructural details were not directly considered but the models were able to detect lower Young's modulus in the core of the vertebra, which reflects the presence of the porous cancellous bone (Figure 4). The vertebral strength was positively correlated with the FE measures of strength ($R^2 = 0.86$) and only poorly correlated with BMD values ($R^2 = 0.53$). Although the study has several limitations, it is one of the first works that has demonstrated the better performance of FE models with respect to correlation-based QCT methods in predicting vertebral compressive strength. Improvement in the prediction of the mechanical behavior (also considering off-axis loading) can be obtained by employing more complex material laws. Chevalier *et al.*[65] used a calibration method to derive local bone volume fraction (BV/TV) from BMD values and a fabric-based model[66] was adapted to convert local voxel volume fractions into elastic values. With this novel procedure, each element of the FE model carries information on local elasticity as well as on the anisotropy of the trabecular network. The prediction of the ultimate force from the FE models was again linearly related to the experimental values ($R^2 = 0.77$) but this time the slopes and intercepts of the linear regression equation

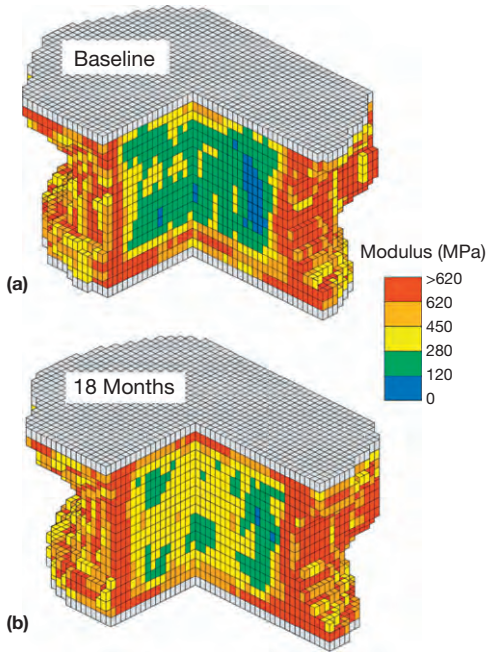

Figure 4 Continuum-level finite element models of a lumbar vertebra scanned *in vivo* with quantitative computed tomography (QCT) (a) at the base line and (b) after 18 months of anabolic treatment. Each element in the FE model is assigned a different Young's modulus based on the gray values of the QCT. The osteoporotic treatment alters the distribution of density within the vertebra, as seen by comparing (a) and (b).
Adapted from Keaveny, T. M.; Donley, D. W.; Hoffmann, P. F.; Mitlak, B. H.; Glass, E. V.; San Martin, J. A. *J. Bone Miner. Res.* **2007**, *22*, 149–157, with permission.

were not significantly different from 1 and 0, respectively. This is an important result which means that FE can predict bone strength in an absolute sense, without any need of additional correction factors. In the same study, the authors also extended the use of continuum FE for investigating the location and accumulation of damage during different applied loads. For this purpose, a newly developed constitutive law for elasticity, plasticity, and damage was employed.[67] It could be shown that, independent from the loading modes, damage accumulation always occurred in the vertebral core, where trabecular bone is located.

Recently, the FE framework based on QCT has been used to evaluate the effectiveness of various osteoporotic therapies.[68–70] In all the investigated scenarios the FE approach provided more information on the effects of osteoporotic treatments than only BMD. For instance, Keaveny and coworkers[70] compared the effect of an anabolic agent (teriparatide) versus an antiresorptive therapy (with alendronate) in a study on human patients. A total of 53 subjects were considered and QCT scans were taken before starting the treatment and after 18 months of treatment. For all the subjects the compressive strength of the L3 vertebra was assessed with continuum-level FE modeling (Figure 4). The two treatments changed BMD and strength in a quite different way: the median percentage increase for the anabolic agent was significantly greater than for the antiresorptive one (13.0% and 4.9%, respectively). In addition, the anabolic agent increased the vertebral strength not only by increasing BMD but also by altering the distribution of density within the vertebra. In conclusion, FE studies have been able to overcome the limitations of BMD in discriminating vertebral fracture and can more precisely evaluate the effects of treatments.

3.307.2.5.2. μFE models

μFE methods require high-resolution images, which are currently not available *in vivo* for the vertebra. However, this technique has been fundamental to understand the micromechanical behavior of vertebral bone and also bone adaption in healthy and diseased situations.[32,33,71–73] Two novel studies[32,71] explored the relative contribution of the cortical shell and of the vertebral core in the mechanical properties of the vertebra. For these studies, 13 human vertebrae were scanned with μCT (voxel size 60 μm) and the corresponding specimen-specific FE models (with more than 13 million elements) were generated. An automated image processing procedure was developed to identify and digitally separate the cortical shell; compression tests were simulated with and without the cortical shell. Despite its thin nature (average thickness of 0.38 ± 0.06 mm), the shell had a predominant role in the load transfer mechanism: at the narrowest section of the vertebrae, the shell carried between 38 and 54% of the load.[32] Such improved understanding of the biomechanics of the vertebra may be beneficial for identifying changes occurring with aging, diseases, and after clinical treatments.

3.307.3. Mesoscale: Trabecular Bone

As described in Section 3.307.1, a distinction is made between cortical and trabecular bone. Trabecular bone, also called cancellous bone, is found at the end of long bones as well as in the spine. It has a complex internal network of small rod-like and plate-like struts called trabeculae. Depending on the specific location, trabecular bone can have quite different microarchitectures, even within one subject (Figure 5(a)). In addition, even at the same location cancellous bone can have a variety of densities and morphologies among different individuals depending on age, genetics, and disease-related aspects (Figure 5(b)). The mechanical properties of trabecular bone, which also vary a lot with anatomical location, age and disease, depend on three main factors: apparent density, internal microarchitecture, and local tissue properties. For the same apparent density, a large variability in stiffness and strength has been reported which might be due to the specific role of microarchitecture and of material properties. A better understanding of the interplay among these three factors is of high importance, especially for the clinical assessment of bone fragility and fracture risk as well as for the design of new scaffolds and implants for osteoporotic bone. In fact, bone fractures associated with osteoporosis, occur frequently in anatomical locations dominated by trabecular bone, like the femoral head, the vertebral body, and the radius (Section 3.307.2). The complex mechanical behavior of trabecular bone has been extensively investigated with computational models based on FEA for the last 20 years. In particular, two different types of modeling approaches have been considered.[46] The first approach, more conceptual and based on cellular solids theories, will be reviewed in Section 3.307.3.1; the second one, more recent, adopts μFE combined with high-resolution images and it will be introduced in Section 3.307.3.2.

3.307.3.1. Conceptual Cellular Solids Modeling

The main philosophy of the cellular solids approach is to reduce the complexity of the trabecular network while still being able to describe its most relevant micromechanical aspects. The reduction in complexity is carried out by mapping only certain aspects of the trabecular network into simplified two- or three-dimensional lattice models. The microstructure of a cellular solids model is often composed of a collection of elements (or beams) which have in general the same shape but different length and thickness. The elements can be regularly arranged in space (e.g., periodic honeycombs) or can have a more random distribution (e.g., Voronoi honeycombs). From a computational point of view, such models can be efficiently solved with coarse-grained FEA based on beam elements. In short, compared to continuum-level FE and μFE models, each beam inside a cellular solid structure is modeled with special purpose elements called beam elements which allow only for specific deformation modes (typically bending, stretching, and shear deformations) and therefore can greatly reduce the number of degrees of freedom of the models. In addition, with such idealized representations of the trabecular architecture, it is feasible to introduce controlled variations in given architectural parameters and to assess their impact on the mechanical performance. In this section, we will focus on the main questions related to bone research which have been addressed with cellular solids modeling.

3.307.3.1.1. Role of architectural disorder and defects

The architecture of trabecular bone is neither completely regular nor random[2] and cellular solid models have been used to

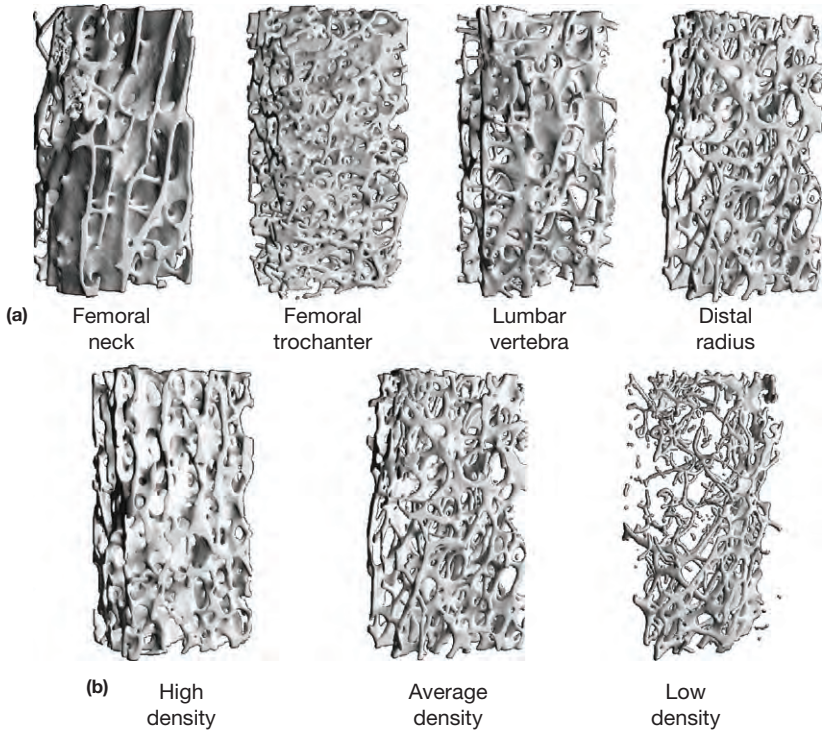

Figure 5 Three-dimensional microcomputed tomography reconstructions of trabecular specimens from various skeletal locations (a) within the same individual and (b) at the same location (distal radius) among different individuals. Within the same subject, trabecular bone can have quite different relative densities and microarchitectures: from very dense plate-like structure (e.g., femoral neck) to a combination of rod-like and plate-like network (e.g., distal radius). At the same skeletal location, the microarchitecture of trabecular bone is subject-specific and it is influenced by factors like age and health status. Dense trabecular specimens are often seen in young and healthy people, whereas with aging or osteoporosis the trabecular network becomes coarser and the plates transform into rods. Data courtesy of Felix Eckstein, Ludwig-Maximilians-University Munich, Germany.

investigate the effect of different degrees of randomness (or disorder) on apparent stiffness and strength of various types of architectures including honeycomb, Voronoi, and cubic lattices.[74–77] In two-dimensional Voronoi honeycombs, introducing structural disorder (in terms of nonperiodic microstructure) weakened the structure at the apparent level and the Voronoi honeycombs resulted approximately 30% less strong than periodic, hexagonal honeycombs of the same density.[76] At the local level of single beams, the nonperiodic microstructure affected the strain distribution: higher strains were seen in a relatively small number of struts compared to periodic, hexagonal honeycombs.[76] In addition, in Voronoi honeycombs, the axial strains in the cell walls have been found to be approximately normally distributed.[78] In general, the redistribution of forces inside a cellular structure depends critically on the degree of randomness of the structure, with increasing randomness resulting in a broader distribution.[79] The effect of randomness is different in three-dimensional regular cubic lattices. In fact, these regular structures are highly ordered and, consequently, extremely sensitive to both strain localization and orientation effects.[80] Luxner and colleagues[75] showed that introducing some disorder had a positive mechanical outcome since it reduced the tendency of deformation localization (**Figure 6**) and it decreased the strong anisotropy of the cubic lattice. Interpreting these results for trabecular bone structures, one could assume that some disorder in the arrangement of trabeculae might be beneficial to prevent or retard catastrophic failure.[75] In addition to disorder, the role of defects on the local and the apparent mechanical properties of cellular solids has also been intensively analyzed with FE. In particular, different types of morphological imperfections such as struts waviness, struts misalignment, and missing struts, have been considered. Chen and coworkers[81,82] and performed systematic studies to investigate the role of different types of defects and imperfections on the apparent properties of two-dimensional cellular solids. The authors unraveled a link between the reduction in the mechanical properties and the switching in the main deformation mechanisms from stretching to bending induced by the defects. The largest reduction in the apparent yield of the models was caused by fractured struts whereas variation in the thickness of the beam had only second-order effects. Other authors have considered the load distribution around defects.[83,84] Ruffoni and coworkers,[84] for example, studied the relationship between the geometry of a point defect and the spatial distribution of the SED in an otherwise regular two-dimensional honeycomb. For hydrostatic loading, the SED was concentrated in the defect; conversely, uniaxial loading resulted in intricate distribution of the SED, with its highest values not in the defect but in its nearer environment. Sites of concentrated loading might be potential locations for failure initiation and thus, to understand the weakening of a structure they need to be investigated.

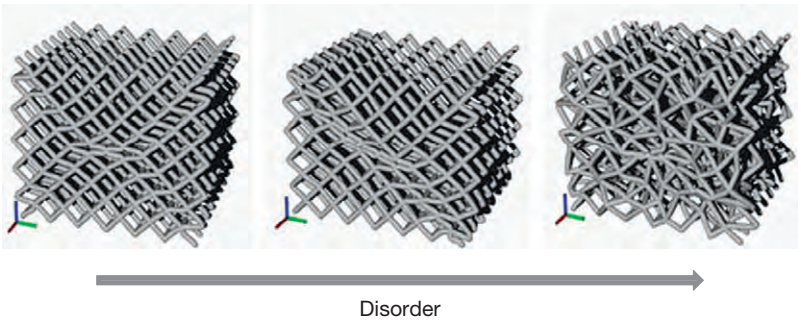

Figure 6 FE simulations of cubic lattices with increasing disorder (from left to right). The disorder is introduced by adding a random displacement to the original position of the vertices of the regular cubic lattice. Failure bands which represent highly localized deformations can be seen in the first structure; increasing the amount of disorder strengthens the structures by preventing the formation of localized failure regions. 3.307.3.1.2. Trabecular thinning versus trabecular loss

Trabecular architecture changes with age and bone is lost due to a reduction in the number of trabeculae as well as to thinning of trabeculae.[85] An important clinical issue connected with these changes is which of the two mechanisms (thinning vs. loss) causes the strongest reduction in bone strength for a similar amount of bone loss. Various computational studies on two- and three-dimensional cellular solids models have predicted trabecular loss as the worst scenario for the mechanical properties.[76,86] Guo and Kim[87] considered both rod-like and plate-like cellular architectures and, assuming an elasto-plastic material law, they were able to predict the behavior of both stiffness and strength following bone loss. Independently of the model microstructure (plate-like or rod-like), stiffness and strength were much more reduced when the reduction in BV/TV occurred through loss of trabeculae than through trabeculae thinning. In addition, the authors considered whether increasing the thickness of the remaining trabeculae after bone loss could recover the initial stiffness and strength of the system; that was not the case. Hence, to improve the clinical outcome of osteoporotic treatments it might be fundamental to start osteoporotic therapies at early stages, in order to preserve trabecular number (Tb.N) and connectivity.

3.307.3.1.3. Towards patient-specific stiffness and strength predictions

A recent study of van Lenthe *et al.*[88] has demonstrated the feasibility to apply cellular solids models to predict the mechanical behavior of trabecular bone specimens in a fast and accurate way. In order to generate a cellular solids model starting from high-resolution μCT images of trabecular bone, the first step is to decompose the trabecular network into its basic rod and plate elements. Slightly different procedures to obtain this decomposition have been presented.[89–91] In short, decomposition starts with a shape preserving skeletonization algorithm with a topological optimization procedure which is applied on a digital image of trabecular bone (**Figure 7(a)**). As a result, the bone architecture is reduced to a one-voxel thick skeleton. Subsequently a point classification algorithm which is able to say, for each point in the skeleton, whether it belonged to a rod or to a plate, is employed (**Figure 7(b)**). Eventually, according to this new classification, a final algorithm is utilized to expand the elements of the skeleton to their original size. This operation results in a spatially decomposed bone structure where rods and plates are labeled with a different color (**Figure 7(c)**). The structure can then be used to generate beam FE models. van Lenthe *et al.*[88] modeled each rod with one beam (circular cross-section) with length and thickness corresponding to the average morphometric values of the single element to be represented; for plates several crossing beams forming a shell-like structure were used (**Figure 7(d)**). In the study, the same μCT images were also directly converted into μFE and both models were solved with the same boundary conditions simulating uniaxial compression tests. Experimental compression tests were also performed to have gold standard measures for the apparent stiffness and strength of the specimens. The main advantage of the idealized approach is the reduction of the computational complexity of the models: the beam FE presented, with respect to high-resolution μFE, a reduction by two orders of magnitude of the number of nodes, which corresponded to 1000-fold reductions in CPUs time.[88] Despite the strong reduction in the complexity of the trabecular network, the 'coarse-grained' beam FE models introduced in that study were in excellent agreement with the results of both experimental and voxel-based FE models ($R^2 = 0.85$ and $R^2 = 0.97$, respectively; **Figure 7(e)**). Hence, the beam representation seems to be detailed enough to accurately estimate the overall mechanical properties and the deformation mechanisms of the samples.

3.307.3.2. μFE Modeling

As extensively explained throughout **Section 3.307.2**, μFE are based on high-resolution images obtained for instance with μCT or μMRI. Considering trabecular bone specimens, those images are three-dimensional virtual reconstructions with a resolution up to 10 μm. μFE have been widely used to investigate the mechanical properties of trabecular bone, with a special focus in linking mechanical behavior to microstructural characteristics. In this section, we will review the main modeling assumptions and the main findings of μFE modeling of trabecular bone.

3.307.3.2.1. Homogeneous versus heterogeneous tissue at the trabecular level

In most of the μFE studies on trabecular bone (likewise on whole bone, **Section 3.307.2**), trabecular tissue is normally considered homogeneous and isotropic and each element is

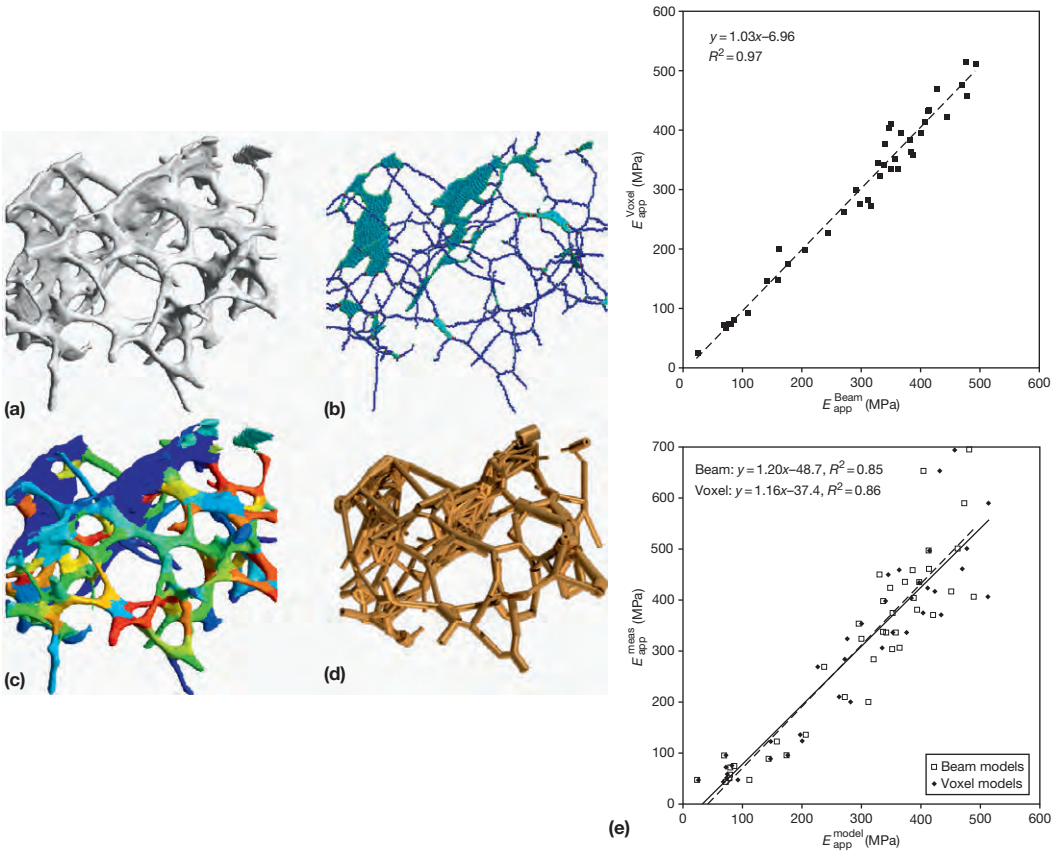

Figure 7 The procedure to generate a specimen-specific beam finite element model comprises various steps: (a) starting from a microcomputed tomography image of a trabecular bone specimen, (b) skeletonization and point classification are applied. Subsequently (c) an algorithm for multicolor dilation is used and (d) local values for thickness and volume of each decomposed trabecular element are then assigned to the beam model. Finally (e) the performance of the beam finite element model (in terms of stiffness) can be compared against predictions of high-resolution micro-finite element ($R^2 = 0.97$) and experimental results ($R^2 = 0.85$). Adapted from Van Lenthe, G. H.; Stauber, M.; Müller, R. *Bone* **2006**, *39*, 1182–1189, with permission.

given the same Young's modulus. This assumption is accurate enough for predicting the apparent elastic properties of trabecular bone specimen, as reported by several authors.[30,35,92,93] By comparing experimental versus μFE models is even possible to derive an apparent or effective modulus for the trabecular tissue. With such procedure different values for Young's modulus have been reported in the range 5–18 GPa. Most probably this wide range reflects natural biological variability (e.g., anatomical site, age) as well as differences in the experimental techniques, specimen size and element size.[16,46] Whereas for quantifying the elastic properties at the apparent level an effective tissue modulus works well, when considering the mechanical behavior of individual trabeculae this assumption might not be too accurate. In fact, trabecular tissue is quite heterogeneous and anisotropic; as a result of bone remodeling and mineralization, the trabeculae appear like a patchwork of different bone packets which have different mineral contents (**Figure 8**)[94,95] and different elastic moduli, as indicated by nanoindentation.[96] In addition, the distribution of the mineral content changes in osteoporotic patients (which have less mineral content and a strong heterogeneous distribution of the mineral) and after clinical antiresorptive therapies.[97] The effect of material inhomogeneity could be taken into account with μFE by assigning at each bone element a different tissue modulus; nevertheless, this procedure, especially at the trabecular level, is still quite controversial because of the following two issues. First, it is not clear how to correctly convert the gray levels of a μCT image into proper mineral contents. One adopted solution has been to consider gray values proportional to the local mineral content after a proper calibration with phantoms containing different known concentrations of hydroxyapatite.[98,99] Even if calibration procedures are implemented, the voxel values of μCT images are still somewhat influenced by image artifacts like beam hardening and they can only give qualitative information on mineral content.[100,101] In spite of these difficulties, the assessment of bone mineral content with μCT is a fascinating possibility and a lot of research is currently ongoing. The second uncertainty is the relationship between local mineral content and local elastic properties. Previous μFE studies have demonstrated that the nonuniform mineral distribution as well as the specific law used to correlate mineral content with Young's modulus can have a significant effect on the mechanical behavior computed with μFE.[102,103] Van der Linden *et al.*[103] considered trabecular specimens coming from human vertebrae and employed different relationships between mineral content

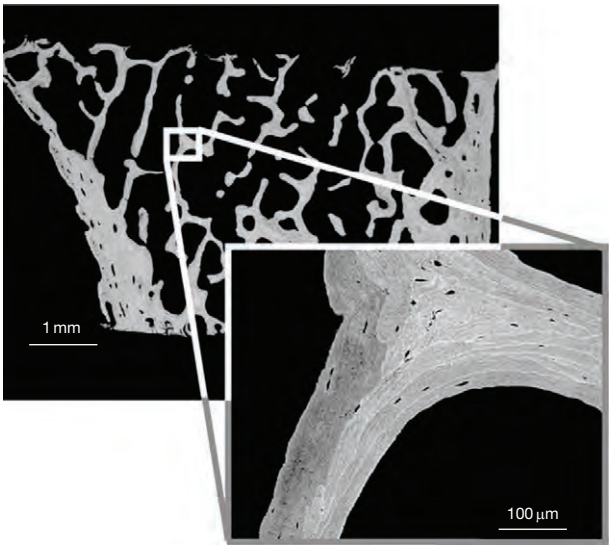

Figure 8 Section of a transiliac bone biopsy visualized with back-scattered electron imaging (BEI). The gray-level values are directly proportional to local mineral content. By increasing the resolution, the individual bone packets inside a trabecula can be seen. Each bone packet has different mineral content due to the processes of bone remodeling and mineralization. Dark gray represents young low mineralized bone and light gray means old high mineralized bone. and Young's modulus. For a linear relationship, the apparent stiffness of the specimens varied only slightly (up to 8%) compared to the uniform tissue model. Instead, with an exponential law, the apparent stiffness varied up to 20%. Results along the same line have been obtained considering trabecular samples coming from human mandibles: the incorporation of different mineralization values decreased the apparent elastic moduli to a maximum of 21% in comparison to the homogeneous models.[102] More insights into the correlation between mineral content and tissue stiffness has been obtained experimentally by combining nanoindentation[96] with accurate measures of local mineral content by means of back-scattered electron imaging (BEI).[104] In conclusion, µFE modeling provides excellent estimates of trabecular bone mechanical properties when considered at a scale where it behaves as a continuum. Whether it currently provides the same accuracy at the level of single trabeculae still remains to be established. For that purpose, more studies which combine µFE with accurate experimental measures of local mineral content and local tissue moduli are needed; it appears that the heterogeneous material distributions as seen in trabeculae could have a strong effect on the mechanism of deformation and failure especially for those trabeculae subjected to large deformations.

3.307.3.2.2. Failure properties

Although some work on bone failure characteristics with µFE has been performed on whole bone (or at least on large parts of entire bones, Section 3.307.2.4), the trabecular level – for obvious computational aspects – is still considered the preferred one for such types of investigations. Even at the trabecular level, only a few studies have incorporated nonlinear material properties in FE analysis in an attempt to better describe and understand bone failure.[16] No consensus has been reached as to what would be the best implementation of bone failure in µFE. This is not surprising because the precise failure mechanism and associated material properties (especially after yielding) of trabecular bone are still not well understood. One of the first attempts to add nonlinear material behavior to µFE analysis was done by Niebur and coworkers.[51] They proposed a bilinear constitutive model with asymmetric tissue yield strains in tension and compression, including a reduction of the tissue modulus by 95% after yield strains. The values of the yield strains could be obtained by a direct comparison with experimental testing and were 0.60% in tension and 1.01% in compression. The authors demonstrated that the proposed model, along with the assumption that yield properties were the same for all the considered specimens (trabecular samples coming from bovine tibias) was able to accurately describe the apparent yield in compression, tension, and shear. In addition to material nonlinearity, Stölken and Kinney[105] performed a computational study on a single trabecula and showed that local deformations could be very large. Therefore, also geometrical nonlinearity should be accounted for. Recently, more complex postyield behavior has also started to be characterized. Verhulp and colleagues,[106] for instance, introduced an iterative fitting procedure in order to determine the set of parameters to be used in µFE simulations to have the best agreement with experimental linear and failure results. In the study they considered both material and geometrical nonlinear behavior combined with µFE. It was found that accurate descriptions of the experimental compression tests were obtained by including a negative postyield modulus (compression softening) at the tissue level. Furthermore, variations in the postyield properties were less important than variations in the elastic and yield properties for the simulated apparent mechanical behavior.

3.307.3.2.3. Structural and mechanical anisotropy

µFE is a valuable tool to investigate the directional dependence of the mechanical properties of trabecular bone. It has been demonstrated that trabecular bone has an anisotropic behavior which is mainly governed by the orientation of the trabeculae[16]; hence, bone anisotropy has been mainly investigated at the trabecular level. The main advantage of µFE over more traditional experimental testing is that virtual mechanical tests can be run always on the same specimen in order to measure the apparent elastic properties along different directions. Using µFE it has been found that trabecular bone can be well described as an orthotropic material with nine independent parameters.[107] The orthotropic parameters can be determined by running only six FE simulations. Here, FE expands experimental techniques, because, accurate measurements of the orthotropic elastic constants of a given trabecular specimen with experimental mechanical testing are extremely difficult if not impossible. Mechanical anisotropy of trabecular bone is a manifestation of its structural anisotropy. Structural anisotropy has been characterized with the fabric tensor which is defined as a symmetric second-order tensor.[66] Various methods have been proposed to measure structural anisotropy and one of the most common is with the mean intercept length (MIL).[108]

The idea of the MIL method is to superimpose a linear grid with different orientations on a bone section; for each orientation, the mean length of the intersections between the grid and the bone–marrow interface is computed. A plot of the MIL as a function of the grid orientation can, in two dimensions, be fitted well by an ellipse and in three dimensions by an ellipsoid. The eigenvalues of the fabric tensor correspond to the principal axis of the ellipsoid and are used to describe bone structural anisotropy. μFE simulations has been employed to establish the relationships between the stiffness tensor and the fabric tensor in human cancellous bone samples.[66,109]

3.307.3.2.4. The role of structural indices

A main application of μFE modeling based on realistic trabecular geometries is the investigation of the relationship between mechanical properties and architectural features like BV/TV, anisotropy (fabric tensor), Tb.Th, Tb.N, trabecular separation (Tb.Sp), and connectivity. This topic is closely related to clinical research, in particular to the task of predicting in a robust manner bone fragility by looking at microarchitectural measures. One way to asses to which extent the use of architectural descriptors, in addition to BMD, improves the prediction of bone mechanical properties is to correlate the results of μFE calculations with geometrical measures based, for instance, on μCT images. Ulrich and coworkers[110] investigated more than 200 different cancellous bone samples taken from the iliac crest, lumbar spine, femoral head, and calcaneus and computed different geometrical parameters (BV/TV, Tb.Th, Tb.Sp, Tb.N, fabric tensor) as well as the mechanical competence of those samples (Young's moduli, shear moduli, and Poisson's ratios). The main finding of the study was that the prediction of mechanical properties increased from a value of 53% when considering only BV/TV (which is related to BMD) to 82% just by adding the anisotropy of the structure described by the fabric tensor. A maximum correlation of 92% was obtained with three parameters: BV/TV, Tb.Sp, and fabric tensor. Despite the promising evidence that including various architectural parameters (in addition to BMD) resulted in strong correlation with bone mechanical properties (stiffness), these results should be interpreted only in a statistical sense. They do not explain the real physical contribution of the microarchitecture to the mechanical behavior of bone. In fact, to understand how differences in bone microarchitecture influence bone stiffness and strength, insight into load transfer through the bone architecture is needed.[59] Additionally, it is not possible to find a general mathematical formulation that links structural indices and mechanics since the combinations of the structural parameters are strongly depended on anatomical sites.[111]

Considering connectivity, its role is still quite debated. Theoretical considerations based on cellular solids predict that connectivity strongly influences the main deformation modes. If a three-dimensional network has connectivity less than 12, its architecture is bending dominated and therefore quite soft. Conversely, if the connectivity is bigger than 12, the deformation mode becomes stretching dominated and hence the stiffness of the structure increases substantially.[2,112] In simple cellular solids the connectivity coincides with the coordination number, that is, the number of struts which meet at a node, whereas for more complex networks like trabecular bone, the definition of connectivity is more complicated. Intuitively connectivity describes the number of redundant trabeculae in the network, that is, the number of trabeculae that may be cut without increasing the numbers of separate parts in the bone structure.[113] Connectivity is a general topological property of a network and can be calculated through the Euler number. In a voxel-based image, the Euler number is computed by looking at the voxel filled with bone and combining the number of voxel corners, voxel edges, voxel faces, and voxel volumes inside a given volume of interest.[113] In addition, a correction for the artificially unconnected trabeculae that are generated when analyzing only a subregion of the entire trabecular network needs to be performed.[113] Interestingly, studies using μFE on human trabecular samples from various anatomical regions have reported no relationship between stiffness and connectivity.[114,115] One possible reason for this lack of correlation could be associated to the presence of both rod-like and plate-like structures inside the trabecular network. If during bone remodeling a plate is perforated, most probably the stiffness of the structure will decrease whereas the connectivity will increase as the fenestrated plate will be considered as a combination of new rods.[115] In addition, the high connectivity values of artificial structures are never present in trabecular bone. For example, in vertebral trabecular bone, the trabeculae are mainly oriented along the horizontal and the vertical direction which results in quite low connectivity values. Trabeculae that run diagonally though the vertebrae and hence that would substantially increase the connectivity are not observed.[2]

3.307.3.2.5. Mechanical behavior of single rods and plates

The relative amount of rods and plates in the trabecular network is another important determinant of the mechanical behavior of cancellous bone.[116,117] It is known that trabecular bone morphology is more plate-like for high volume fraction and more rod-like for low-volume fraction.[118] Additionally, with aging bone plates get perforated and therefore plate-like architectures tend to become more rod-like.[118] As reported in **Section 3.307.3.1**, various algorithms have been recently proposed to decompose the trabecular structure into basic rod and plate elements.[90,91] Such procedures, combined with newly developed local morphological descriptors for rods and plates, have been applied by Stauber and coworkers[117] to a cohort of 42 human vertebral trabecular bone samples to assess the role of local morphometry (i.e., the shape and form of each single bone element) in the measurement of bone architecture and its relative contribution to the mechanics of human vertebral bone. Specifically, the apparent Young's modulus of the trabecular specimens has been computed both with direct experimental compression testing and with μFE; the two methods correlated quite well ($R^2 = 0.85$). Furthermore, the authors proposed a multiple linear regression model based on local morphology which included mean trabecular spacing, mean slenderness of the rods, and the relative rod volume fraction and which was able to predict up to 90% of the variance of the computed apparent Young's moduli.[117] Liu and colleagues[89] have applied volumetric decomposition to better understand the influence of rods and plates on the anisotropic elastic properties of trabecular bone. The authors included bone specimens from femoral neck, tibia, and vertebral body. They reported significant differences in the relative arrangements of rods and plates: the majority of trabecular

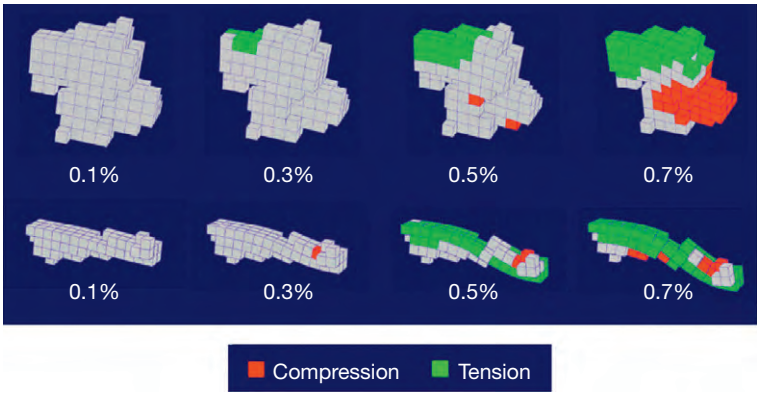

Figure 9 Qualitative visualization of failure in a plate (top) and a rod (bottom) during a simulated uniaxial compression test with microstructural finite element on a trabecular bone specimen. The plate and the rod had different orientations with respect to the main loading direction: the plate was oriented longitudinally whereas the rod was oriented transversally. The elements which failed in tension (colored greed) and compression (colored red) can be visualized for different values of the applied apparent strain. Adapted from Liu, X. S.; Bevill, G.; Keaveny, T. M.; Sajda, P.; Guo, X. E. *J. Biomech*. **2009**, *42*, 249–256, with permission.

plates were orientated along the principal direction of loading, whereas most of trabecular rods serve as transverse connections between longitudinal plates.[89] In a subsequent study, Liu and collaborators,[116] analyzed the micromechanical behavior of trabecular bone in terms of failure initiation and progression considering individual rod and plate elements. The novelty of the study resides in the combination of local trabecular decomposition with nonlinear μFE. The authors performed virtual compression tests on 15 human vertebral trabecular bone samples up to 1% apparent strain. The amount of failed trabecular plates and rods were recorded during loading and data were classified according to the trabecular orientation (Figure 9). Results indicated that trabecular rods tended to fail at the initiation of the compression (i.e., 0.1–0.2% apparent strain) whereas plates failed around the apparent yield point (i.e., 0.7% apparent strain). Interestingly, there was a strong correlation between the volume fraction of plates and the apparent yield strength whereas the volume fraction of rods was only poorly related with the yielding. Considering orientations, the weakest elements where most of the tissue failure was observed were longitudinal trabecular plates and transverse rods.

In conclusion, studies combining local decomposition in rods and plates with μFE seem quite promising to get a better picture of the role of architecture on deformations and failure in trabecular bone.

3.307.4. Microscale: Ultrastructural Features

At a length scale of about 1–3 μm bone ultrastructure becomes visible. In cortical bone the main ultrastructural features are the canal network and the osteocyte lacunae (Figure 10(a) and 10 (b)). Osteocyte lacunae are small holes inside the mineralized bone matrix containing a type of bone cell called osteocyte. Osteocytes are connected to each other and to the canal network through long processes located in small channels called canaliculi. These canaliculi have a diameter of about hundred nanometers. Bone canals are much bigger than osteocyte lacunae and they enclose blood vessels and nerves. The porosity of human cortical bone can vary quite a lot and values in the range from 5 to 38% have been measured using synchrotron radiation-based μCT (SR μCT).[119] The canal network gives the main contribution to cortical porosity and morphological descriptors of this intricate system, such as canal volume, canal diameter, canal length, and canal orientation, have been introduced.[120] In addition to canal network, the osteocyte lacunae have also been visualized and analyzed with respect to number and shape.[120,121] Those ultrastructural characteristics have been shown to influence the mechanical behavior of whole bones[122] as well as the initiation and propagations of cracks in the bone matrix.[123,124] In addition, osteocytes are believed to act as sensors which transform mechanical inputs into biological signals.[125] Hence, both for structural and biological aspects, it is of primary interest to characterize the mechanical environment around osteocyte lacunae as well as their microstructural response under loading.[126,127]

3.307.4.1. Osteocyte Lacunae

FE modeling can be employed to compute the stresses and strains around osteocyte lacunae. Recently, Bonivtch and colleagues[128] performed a parametric FE study of an idealized osteocyte lacuna modeled as an ellipsoid (Figure 10(c)). In addition to the lacuna geometry, the authors considered the role of canalicular diameters, perilacunar tissue modulus, and perilacunar tissue thickness. The main aim of the study was to compute the strain amplification factor (i.e., the ratio between the maximum strain around the lacuna and the applied strain) in the tissue due to the presence of the lacuna. Linear elastic FE analysis were performed and a deformation of 2000 microstrains was imposed; it is believed that this value might be close to the maximum physiological strain experienced in human long bones.[129] The maximum strain amplification factor predicted with the model was around 3. The presence of the canaliculi substantially contributed to increase the computed strains around the lacuna. Decreasing the perilacunar tissue modulus increased the

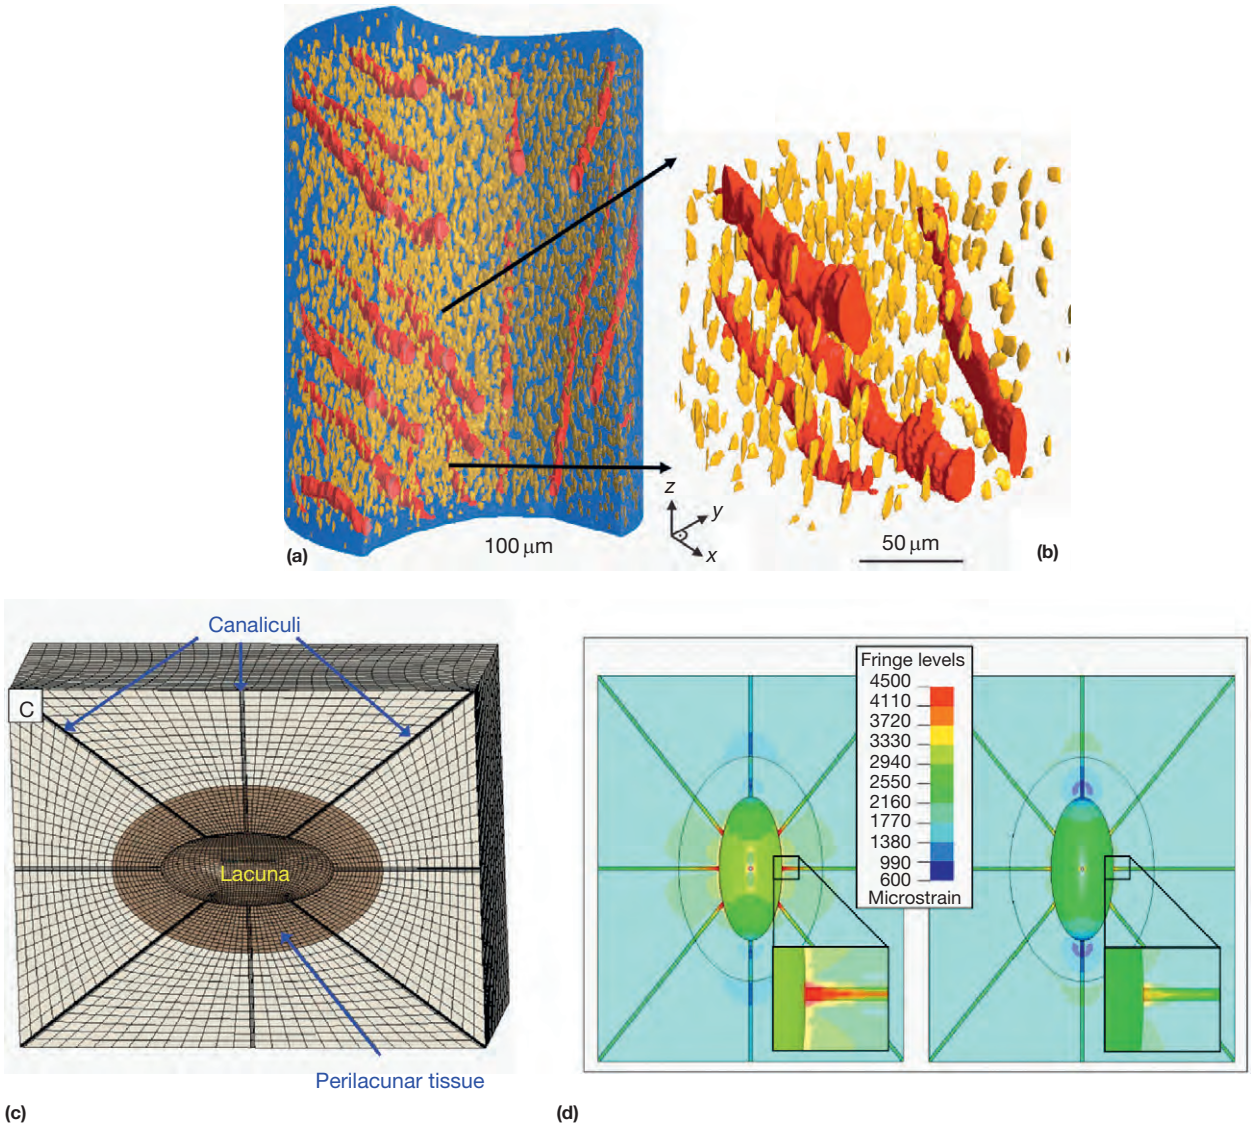

Figure 10 The ultrastractural features of cortical bone at a resolution of 700 nm measured with synchrotron radiation nanocomputed tomography. (a) Three-dimensional visualization of a cortical subregion in a mouse femur with the canal network (red) and osteocyte lacunae (yellow). (b) Close-up on the three-dimensional arrangement of lacunae and canals obtained by inverting the background voxel with the image voxel (negative imaging). (c) Finite element mesh for a region around an osteocyte lacuna including the lacuna, the perilacunar tissue, and the canaliculi. The tissue in close proximity to the lacuna (dark gray) is modeled with different material properties than the tissue further away from the lacuna (light gray). (d) Contour plots of the microstrains computed with FE simulations in the perilacunar region. Strain concentration is observed at the junction between lacuna and canaliculi. In addition, a low perilacunar modulus (left) causes higher strains than a high modulus (right). Adapted from Schneider, P.; Stauber, M.; Voide, R.; Stampanoni, M.; Donahue, L. R.; Müller, R. *J. Bone Miner. Res.* **2007**, *22*, 1557–1570; Bonivtch, A. R.; Bonewald, L. F.; Nicolella, D. P. *J. Biomech.* **2007**, *40*, 2199–2206, with permission.

maximum strain whereas the thickness of the perilacunar region had only a minor role (Figure 10(d)). Although the study contains quite strong assumptions like the idealized lacunar shape and the isotropic material properties (which, at this length scale, are obviously strongly anisotropic), the results clearly suggest that the application of macroscopic strains with magnitudes close to the *in vivo* values can produce quite high strain concentration around the osteocyte lacunae.[128] Hence, the hypothesized role of strain risers of these small holes inside bone tissue[130] can be quantified with FE simulations.

3.307.4.2. Canal Network

The role of cortical canals and of the lacunar canalicular network has been investigated mainly in connection with fluid flow and bone poroelasticity. It is assumed that the process of transducing external mechanical loads into internal stimuli at the level of osteocytes is mediated via fluid flow inside the canal and canalicular networks.[125] The main focus of the computational modeling in this area has been to compute flow-related parameters like pressure and velocity as a function of the applied external load. The canal network has been

in most of the cases modeled with idealized geometries. Reviewing those studies is outside the scope of this chapter. The reader interested in flow dynamic simulations in connection with bone ultrastructural features could consult the works of several investigators.[131–137] One possible way to include ultrastructure when assessing bone mechanical competence is with the so-called multilevel FE modeling.[138] Although the idea of a multiscale approach seems very promising,[28] the main limitation of such models is currently the strong idealization of the hierarchical levels, especially of bone ultrastructure. In fact, accurate three-dimensional reconstructions of bone ultrastructure require technologies which are not widely available, like synchrotron radiation-based nano-CT (SR nCT). In addition, the possible interactions between each hierarchical level are currently difficult to be assessed and modeled.

3.307.5. Nanoscale: Mineral and Collagen

In bone, at the material level, stiff mineral nanoparticles are embedded in a tough polymeric matrix. The matrix is mainly composed of type I collagen molecules, which self-assemble in a staggered fashion to form collagen fibrils.[2] The collagen matrix is stabilized by covalent cross-links between the collagen molecules; the amount of cross-linking changes during aging and metabolic bone diseases such as osteoporosis and it influences bone mechanical performance.[139,140] In addition to the organic matrix, bone contains nanocrystals of calcium phosphate which are periodically located along the collagen fibrils.[141] Also the physicochemical properties of mineral crystals are age-dependent and their changes can be correlated with impaired mechanical function of bone.[142] Hydroxyapatite is very stiff but brittle whereas collagen is two orders of magnitude softer but approximately three orders of magnitude tougher. Bone tissue at the nanoscale has a fibrillar nature: mineral and collagen are combined in the so-called mineralized collagen fibril. A simple mechanical model able to explain how to combine stiffness of the mineral and toughness of the matrix in bone at the nanoscale has been introduced by Jäger and Fratzl.[143] The model considers the mineralized collagen fibril and it is based on pure geometrical arguments. The main assumption is the staggered arrangement of stiff (mineral) elements embedded in a soft (protein) matrix. With this geometry, under applied tensile load, the mineral platelets carry tensile stresses while the main task of the protein layer is to transfer the load between adjacent mineral crystals by shear.[2,143,144]

3.307.5.1. Mechanics of the Mineral–Collagen Nanocomposite

The model introduced by Jäger and Fratzl for the mineralized collagen fibril[143] has been the starting point for subsequent investigations using FE simulations to assess bone properties at the nanoscale.[140,144–146] Siegmund and colleagues[140] investigated the specific role of the collagen matrix. In particular, different types of collagen cross-links were assumed and the deformation and failure of mineralized collagen fibrils were simulated. A composite material model for bone and mineral was developed and computer simulations were run for three different scenarios: without collagen cross-links, with only enzymatic cross-links, and with only nonenzymatic cross-links. The enzymatic cross-links were described by connecting the end terminal position of each collagen domain whereas the nonenzymatic cross-links, which have a more stochastic nature, were modeled by a random placement of cross-links at the interface between two collagen molecules. The study reported that the cross-links with the strongest influence on the mechanical behavior of the model were the nonenzymatic ones. From a mechanical point of view, at the nanolevel, these cross-links inhibited the sliding of the collagen and, therefore, increased the amount of load which was transferred to the mineral. This finding provides a micromechanical explanation on the negative influence of nonenzymatic collagen cross-links on bone toughness.[140] In a subsequent study, Dong and coworkers[145] implemented a two-dimensional probabilistic FE model based on mineralized collagen fibrils, to explore the propagation of microdamage at the tissue level. The model was composed of alternating layers of mineral and collagen and an initial defect was introduced in the form of a small hole in the mineral layer (**Figure 11(a)**). For the interface between mineral and collagen two situations were considered: a perfectly bonded interface and some degree of debonding in the vicinity of the defect. Material properties for mineral and collagen as well as geometrical dimensions were described in a statistical sense, that is, with random variables having a Gaussian distribution. A total of 200 different model realizations were simulated. The role of the mineral–collagen interface was pivotal for the failure propagation. For a perfectly bonded interface the most likely failure location was close to the defect (**Figure 11(b)**) whereas with some degree of interfacial debonding the failure location moved far away from the defect (**Figure 11(c)**), thus suggesting the formation of diffuse damage. Possible future refinements of the presented models might be the extension in the third dimension and the inclusion of more realistic material and geometrical properties for mineral and collagen.

3.307.6. Conclusions and Future Directions

The mechanical properties of bone depend on its hierarchical structure. In this chapter, we have discussed various FE applications that have increased our understanding of the relationship between bone structure and its mechanical function. Here, we have mainly focused on human bones. At the organ level we showed that the combination of microarchitectural bone imaging with FE is a powerful tool to improve strength assessment and individual fracture risk prediction. Whether the sophisticated engineering approaches presented in this chapter will find their way from research to the clinic is yet to be determined, but the high level of automation, the continuing increase in computational power and above all the improved predictive capacity over predictions based on bone mass, make clear that there is great potential in the clinical arena for *in vivo* FE simulations.[16] At the trabecular level, FEA has elucidated several mechanical aspects such as the role of trabeculae in defining the anisotropic mechanical behavior of bone and the relationship between structural indices and trabecular bone mechanical

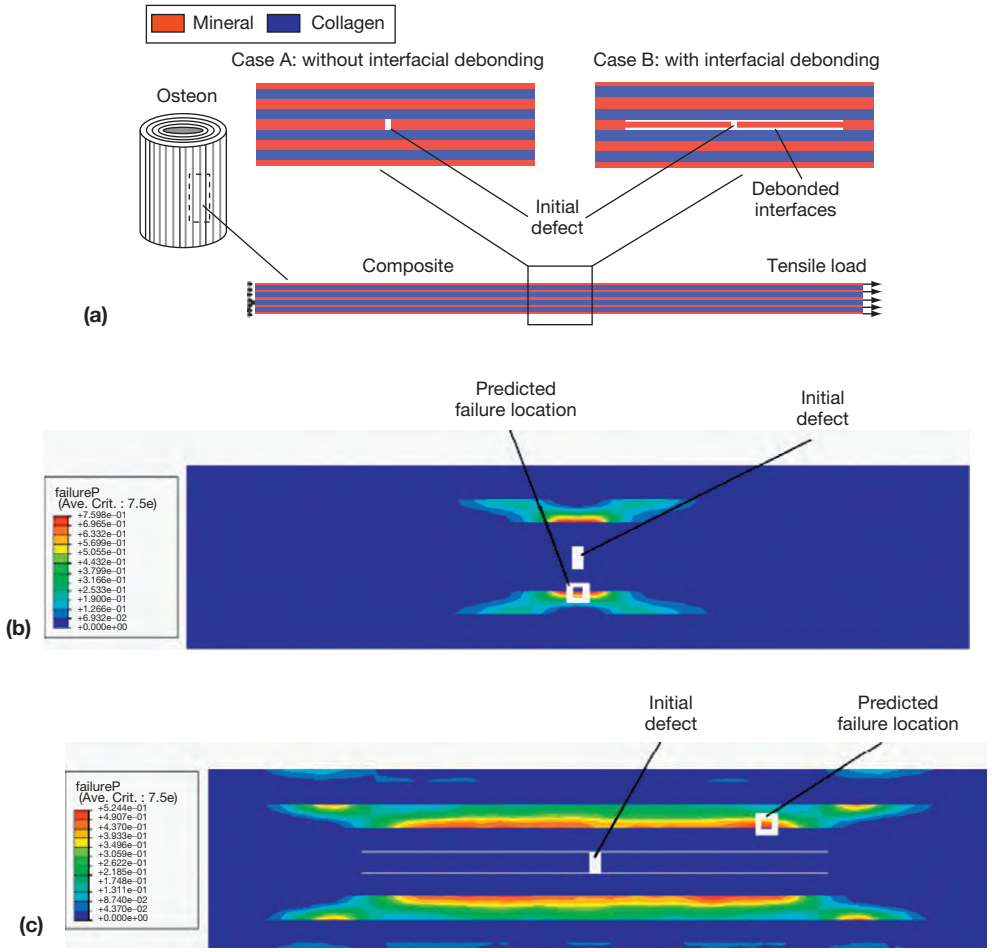

Figure 11 (a) Sketch of an idealized mineralized collagen fibril composed of alternating layers of mineral (red) and collagen (blue). An initial defect (white) is present in the mineral layer and two situations are condidered: (right) with and (left) withouth interfacial debonding at the collagen mineral interface. Contour plots of the failure distributions computed with FE analysis for (b) pefect bonding between mineral and collagen and (c) with some degree of debonding at the interface. In the first scenario, the most probable failure locations are very close to the defect; conversely, with interfacial debonding the failure is observed away from the defect. Adapted from Dong, X. N.; Guda, T.; Millwater, H. R.; Wang, X. *J. Biomech*. **2009**, *42*, 202–209, with permission.

properties. Future FE studies should aim to improve the failure prediction by considering, for example, the precise locations where failure will initiate and the modes of failure propagation. For that purpose, more accurate material models and constitutive laws for bone tissue have to be developed. Furthermore, a quantification of the contribution of individual architectural elements (in healthy and osteoporotic trabecular bone) to the strength of the trabecular structure would be beneficial, because it would provide further insights into which are the key elements to target in anti-osteoporosis therapy.

Experimental data at the microscale of bone has demonstrated that bone ultrastructure changes with age, with bone diseases or after drugs administration. Hence, ultrastructural features are nowadays considered important targets for the assessment of bone mechanical properties and pharmacological treatments.[121] Consequently, it can be expected that more FE studies which consider bone ultrastructure will be performed in the near future. One novel approach might be to perform FE simulations based on experimental measures of bone ultrastructure at the micrometer and submicrometer scale. One fascinating possibility might be to model the role of ultrastructural features on the formation and propagation of cracks inside bone tissue. However, for such models to work, information on the material behavior at the micro- and nanoscale would be needed. This knowledge might be provided by nanoscale FE where it might soon become feasible to investigate damage propagation in three dimensions at the level of the mineral–collagen nanocomposite.

In conclusion, FE analysis has been an indispensable computational tool in elucidating the relationship between bone structure and its mechanical function. It is expected to stay important considering the subject-specific analysis of bone strength based on subject-specific structural measures; an improved understanding of bone strength, fracture initiation, and progression could lead to more successful approaches in the prevention and treatment of age- and disease-related fractures. We expect that FE will become even more important in materials research considering the current trends in (bio)materials design, where the structure of biological materials is considered as a possible source of inspiration.

Glossary

Electrospinning A technique to stretch an electrically charged liquid into the form of a yarn.
Extracellular matrix The extracellular part of tissue that usually provides structural support to the cells in addition to performing various other important functions.
Glycosaminoglycans Long unbranched polysaccharides that maintain the function of collagen and elastin.
Micromechanics The analysis of composite or heterogeneous materials on the level of the individual constituents that constitute these materials.
Scaffold A temporary structure supporting materials and tissues in their synthesis.
Soft tissues Tissues that connect, support, or surround other structures and organs of the body, not being bone.

Abbreviations

AV	Aortic Valve
AVIC	Aortic valve interstitial cell
EC	Endothelial cell
ECM	Extracellular matrix
GAG	Glycosaminoglycans
HV	Heart valve
LV	Left ventricle
MTM	Maximum tangent modulus
MVAL	Mitral valve anterior leaflet
NAR	Nuclear aspect ratio
PEUU	Poly(ester urethane)urea
RVE	Representative volume element
RVFW	Right ventricular free wall
VEC	Valvular endothelial cells
VIC	Valve interstitial cell

3.308.1. Introduction

3.308.1.1. Background

Particular challenges are encountered in constitutive modeling for cardiac/cardiovascular tissues due to their complex mechanical behavior. For example, because of their oriented fibrous structures, they often exhibit pronounced mechanical anisotropy. In addition, they exhibit highly nonlinear stress–strain relationships, large deformations, viscoelasticity, and strong axial coupling. Taken as a whole, cardiac soft biological tissues defy simple material models. Mechanical investigations have usually been confined to uniaxial studies because of the difficulties in controlling two or even three-dimensional (3D) boundary conditions. However, due to anisotropy, uniaxial data cannot be used to extrapolate to the fully generalized 3D constitutive equations, even if multidimensional strain data from the uniaxial experiment is available. There have also been investigations using inflation of circular membranes, which under assumption of isotropy can provide the necessary experimental data. All tissues are anisotropic, however, and hence this method cannot be applied. Further, when attempting to determine material constants for complex material models, multiaxial testing methods that include complex testing protocols, which allow large variations in stress and strain states for full characterization, are required.[1] As with all soft biological tissues, multiaxial tests on cardiovascular structures are generally difficult to perform. Just a few of the experimental problems include small specimen sizes, structural and compositional heterogeneity, difficulty in gripping (without doing damage), dramatic effects of different gripping techniques (St. Venant-like effects), difficulty in precisely identifying material axes, difficulty in assuring constant forces along specimen edges, large specimen-to-specimen variability, and time-dependent changes due to biological degradation. In addition, the question of homogeneity of deformation within the specimen is paramount. These issues can often frustrate the application of even the most straightforward of attempts to develop a constitutive model. In addition to the above experimental issues, relating the observed mechanical response to tissue structure is perhaps more paramount than in other more traditional material applications, where the continuum scale is usually at most of the size of large polymer molecules. In contrast, cardiac tissues are comprised of a dense network of primarily myocytes, and collagen and elastin various fibers, which indicates a continuum scale at the fiber-scale (typically $\sim$1 μm). In addition, the fibers can undergo large rotations and exhibit nonlinear stress–strain behavior that can induce complex behaviors at the macrospecimen scale not easily accounted for in classic material models. Accounting for these behaviors in both experimental evaluation and formulation of appropriate constitutive models continues to be a challenge. The focus of this chapter is to review these problems and present solutions and future trends.

3.308.1.2. Structure–Function Relationships in Cardiovascular Tissues

The strength of any material, natural or synthetic, depends on the substances of which it is composed. Yet, despite a wide range of physiological function and variation in specific behavior, all soft connective tissues share the same principal constituents: collagen, elastin, muscle fibers, and glycosaminoglycans (GAGs). The unique properties of each tissue are a result of its distinctive structure, which is determined by the constituents present and their arrangement. Type I and Type III collagen form undulated fibers that provide support under tension whereas elastin, an aggregate fiber from microfibrils, provides elastic properties and the ability to undergo large extensions. In contrast to these fibrous components, GAGs are composed of long unbranched polysaccharides usually attached to a protein core to form proteoglycans, whose high negative charge makes GAGs hydrophilic. It is well known that collagen fibers can withstand high tensile forces, but have low torsional and flexural stiffness. Thus, the directions in which the fibers are oriented can be identified with the directions in which the tissue is able to withstand the greatest tensile stresses.[2]

Cardiovascular soft tissues, like all connective tissues, are complex composite materials comprised of insoluble fibers, microfibrils and a wide range of soluble proteins and glycoproteins. In particular, their extracellular matrix (ECM) provides specific mechanical and physiochemical properties, in addition to providing scaffolding for cell attachment and migration.[3] The most abundant proteins in the body and the predominant components of the ECM are members of the collagen family of proteins, which form the major structural elements of connective tissues.[3,4] Collagens are the major structural elements of most load-bearing connective tissues, where they contribute to mechanical stability as well as maintain their structural integrity. Many reviews exist that provide a detailed description of their structure,[5] and the interested reader is referred to these publications. Thus, the ability of collagen to transmit load and maintain the structural integrity of tissue is a consequence of the aggregation of collagen fibrils, which have a well-defined tensile function, into collagen fibers. It has been experimentally demonstrated that fibrils can have a wide range of diameters. The ultimate tensile strength of fibers is largely dictated by their diameter size. As a result, when tissue undergoes high tensile loading, the collagen fibers will have a larger cross-sectional area due to the large fibril diameters, allowing the tissue to maintain its integrity in the harsh loading environment.[6]

To provide an excellent example of a connective tissue that elucidates many of the key features of cardiovascular tissues, we present a brief background to tendon structure, formed primarily from dense networks of collagen fibers. When the tendon is placed between crossed polarizers and then viewed under a light microscope, an alternating dark and light banding appears.[7] This banding pattern is referred to as crimp, and can be found in all fibrillar collagens (i.e., collagen types I–III) of most mammalian tissues, with the exception of bone and articular cartilage.[8] Although collagen crimp is observed at the fiber level, Diamant and coworkers[7,8] determined that fiber crimp is a property of individual collagen fibrils. In spite of the ubiquitous nature of collagen crimp, the cause of crimping has yet to be determined. An early explanation for collagen crimp was that contraction of elastin fibers within the collagen structure induced crimp.[9] This theory was dispelled because rat tail tendon, which does not contain elastin, clearly demonstrates collagen crimp.[9] Some speculate that contraction of the mucopolysaccharide matrix, in which the fibrils are embedded, causes the fibrils to buckle.[9] Determination of the crimp

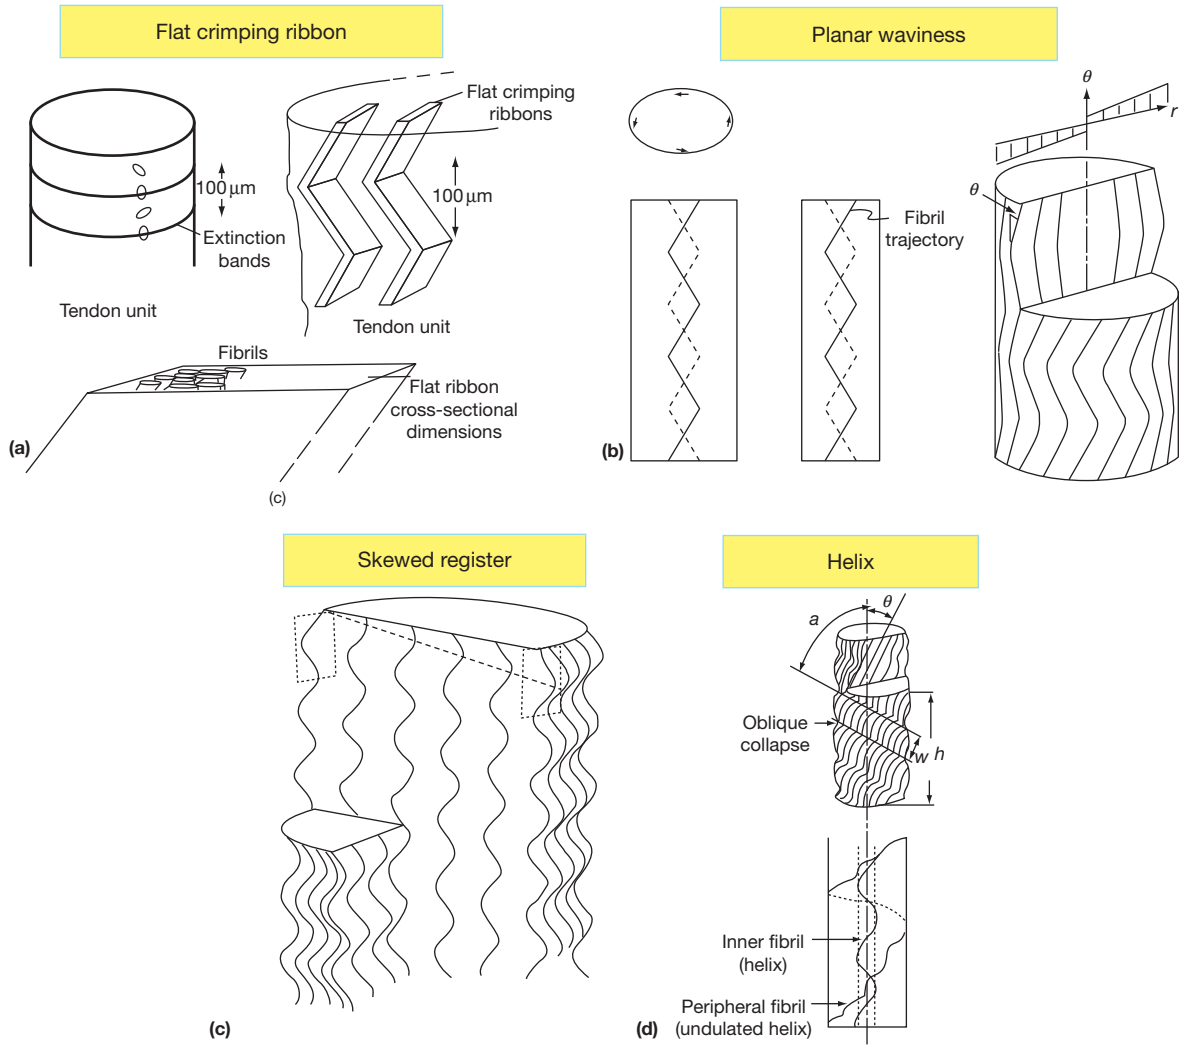

Figure 1 Proposed models for collagen crimp patterns. (a) Baer *et al.* proposed a flat crimping ribbon model. In this model, it is assumed that the fibrils have a ribbon-like cross-section that results in the flattened cylinder cross-section of the tendon unit, that is, fibers that give rise to the horizontally elongated tendon cross-section. (b) Kastelic *et al.* proposed that fibrils follow a wavy or zig-zag crimped course and are packed cylindrically. (c) Rowe *et al.* suggested the skewed register crimp model and stated that their findings did not support the cylindrical symmetry model of fibril packing. (d) Yahia *et al.* proposed that fibrils are helically organized around the fiber axis.

pattern, a result of fibril aggregation, is also not trivial and has led to various theories (Figure 1).[8]

Various models have been proposed for the crimp pattern found in tendons and ligaments. The models proposed are as follows: (1) a flat crimping ribbon model (Figure 1(a)),[10] (2) a planar waviness model (Figure 1(b)),[7,11–13] (3) a skewed register model (Figure 1(c)),[14] and (4) a helix model (Figure 1(d)).[15] The flat crimping ribbon model assumes that fibrils aggregate laterally to form a tendon unit, and the tendon units are bundled together with elastic fibers and fibroblasts, resulting in the macroscopic tendon. This model assumes that the fibrils have a ribbon-like cross-section that results in the flattened cylinder cross-section of the tendon unit, which gives rise to a horizontally elongated tendon cross-section. Polarizing microscopy has demonstrated that the crimped ribbons are all in phase, with their ribbon planes parallel throughout the tendon. It is to be noted that the flat crimped ribbons are thought to be responsible for the extinction bands that are evident under polarizing light. In the planar waviness model, fibrils are not straight and follow a wavy or zig-zag crimped course, and are packed cylindrically to form a collagen fiber.[11–13] Diamant *et al.*[7] claim that the fibril cross-sectional appears cylindrical and not like a flat ribbon, as was claimed by Baer *et al.*[16] Diamant *et al.* employed polarizing microscopy and demonstrated that collagen fibers of native tendons display a planar zig-zag morphology. Under polarizing light, collagen fibers gave rise to a periodic pattern of light and dark bands, which appeared and disappeared systematically as the crossed polarizers were rotated, or as the specimen was rotated about its longitudinal axis.[12] Small angle X-ray data presented by Gathercole and Keller supported this zig-zag morphology. Rowe *et al.* presented the skewed register crimp model and concluded that their findings did not support the cylindrical symmetry model of fibril packing. Instead, collagen

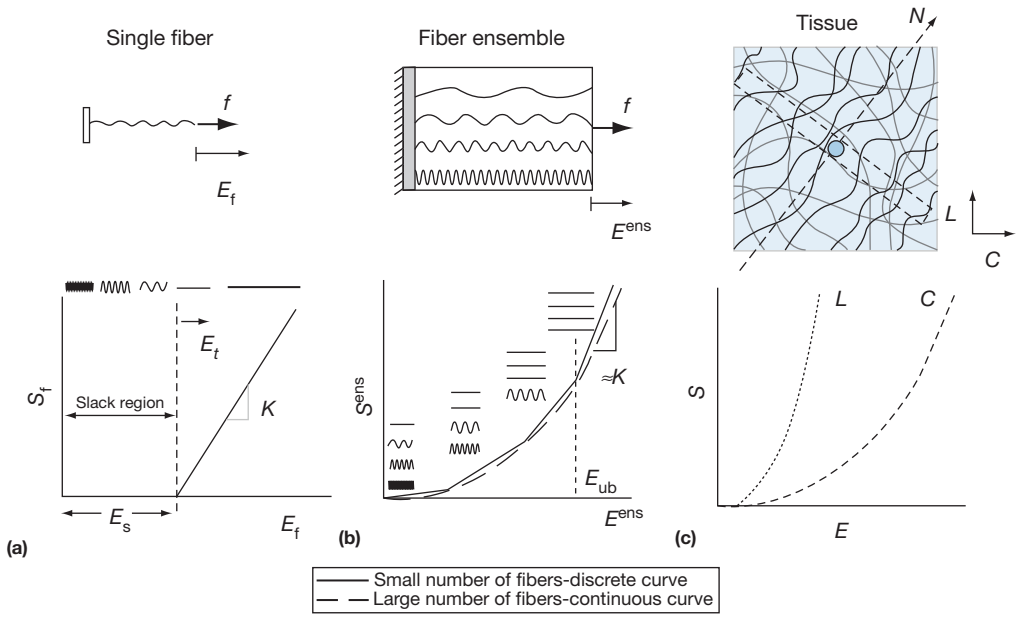

Figure 2 A general framework for collagenous soft tissue mechanical behavior, built from a single fiber. (a) The uniaxial loading of a crimped fiber, with the corresponding stress–strain curve, where *K* is the fiber modulus. (b) Uniaxial loading of an ensemble of fibers with the corresponding stress–strain curve, indicating how the recruitment of individual fibers results in a nonlinear stress–strain curve. (c) Scaling up to the tissue level produces an anisotropic mechanical behavior resulting from the specific distribution of fiber ensembles (see **Section 3.308.4** for term definitions).

fibrils appeared to aggregate side by side with flexibility in any direction in the register of wave patterns across the thickness of the fiber.[14] This configuration demonstrates that the peripheral fibrils are undulated helices while the central ones are normal helices.[15]

Not surprisingly, there is a strong correlation between fiber orientation and the functional requirements of tissues. Thus, collagen fiber orientation significantly affects the mechanical properties of a tissue. For example, when a tissue is loaded in only one direction *in vivo*, the collagen fibers of that tissue will orient in the direction of load, and the resulting mechanical properties will be anisotropic. However, if a tissue is loaded in all directions, the collagen fibers of that tissue will be oriented in all directions, and the tissue will possess an isotropic mechanical behavior. Thus, fiber direction is indicative of the dominant tensile stresses that a tissue undergoes, because fiber reorientation is the most efficient and selective way to optimize strength without increasing weight and metabolic cost, or "The least material is used in the most strategic locations to carry the greatest loads with the least strain."[6]

3.308.1.3. Nonlinearity of Soft Tissues

Mechanically, soft tissues exhibit a characteristic nonlinear stress–strain behavior. Following our focus on collagen, we note that this nonlinearity is a result of the particular structure of collagen fibers. Specifically, collagen fibers are crimped and transmit load only if stretched beyond the point where all the crimp has disappeared (**Figure 2(a)**). Once straightened, fibers are assumed to follow a linear elastic material model. Next, we extend this simple concept to a unidirectional ensemble of fibers, composed of fibers each of which has a separate degree of undulation (**Figure 2(b)**). Collagen fibers are recruited (straightened) with different amounts of strain due to the difference in their original degrees of crimping (**Figure 2(b)**), resulting in a nonlinear response. However, once all the collagen fibers are straightened, the stress–strain curve becomes linear. This linear elastic region is generally considered to be the threshold of reversibility. Next, to extend this to a complete tissue, we consider the tissue as a collection of fiber ensembles with varying orientation (**Figure 2(c)**). Tissues are composed of a large number of such ensembles with varying orientations. The angular distribution of these ensembles results in a unique and complex nonlinear bulk tissue response.

3.308.2. Heart Valve Tissues

3.308.2.1. Heart Valve Tissue Biomechanics

As our first example for cardiac tissues, we explore the valves of the heart, which are a remarkable example of highly developed structure and function.[17] For example, when open, the aortic valve (AV) allows for unobstructed outflow of blood from the ventricle during systole; with flow deceleration, it closes via Bernoulli effects, and the leaflet provides a complete closure to prevent valve regurgitation. All this is achieved through the unique and complex structure of the AV tissue, which consists of three layers (the fibrosa, spongiosa, and ventricularis), constructed principally of collagen, elastin, and GAGs.[18–23] The ventricularis layer faces the left ventricle and is composed primarily of collagen and elastin.[18–24] On the opposite face of the valve is the fibrosa layer. This layer faces the outflow and is composed predominantly of a dense network of type I collagen fibers, which exhibit macroscopic crimp and are aligned primarily in the circumferential direction.[19,23] The hydrophobic GAGs largely make up the central spongiosa,

resulting in a highly hydrated layer.[25–27] As its name implies, the ventricularis layer faces the left ventricular chamber and is composed of a dense network of collagen and elastin fibers. The spongiosa layer contains a high concentration of proteoglycans. The fibrosa layer is composed predominantly of a dense network of collagen fibers, and is thought to be the major stress-bearing layer. Interstitial cells (myofibroblasts) permeate the entire tissue structure, although they are generally more numerous in the spongiosa.

Further evidence of an adaptive structure is the unique structure of the commissure region, which approximately corresponds to the coaptation region. The coaptation region is not under any transvalvular pressure; it is loaded instead in a uniaxial-like manner due to the tethering forces generated at the attachment of the commissures to the aortic root. Unlike the biaxially loaded belly region, the uniaxial loading of the commissures would tend to make their structure more highly aligned, that is, more like a tendon. Like tendons, a highly aligned fiber network would have a very short transition region from low to high stiffness, as evidenced by rapid fiber uncrimping with stress. The highly aligned nature of the commissure region in the unloaded state and the more rapid realignment with transvalvular pressure in these regions are consistent with the pretransition strain level behavior of tendon-like materials. The results presented in **Section 3.308.1** suggest a complex structure-mechanical behavior and interactions in heart valve leaflets. It is useful to divide the study of the tissue-level biomechanics of heart valve (HV) leaflets into in-plane stretch and flexural deformation modes. These occur cyclically as the valve opens (flexure) and experiences surface shear stress from the local blood flow, followed by closure (flexure), then coaptation and full loading (tension). A detailed description of the three individual loading modes is presented in the following section.

3.308.2.2. Planar Biaxial Tensile Biomechanical Behavior of the Aortic Valve Leaflet

The mechanics of valvular tissues are complex: they exhibit a highly nonlinear stress–strain relationship; undergo large deformations; and express complex time-dependent behaviors that defy simple experiments and material models. Much of this behavior is a direct result of changes in their internal structure with strain, which involves both the straightening of highly crimped collagen fibers and rotation of these fibers toward the stretch axis. For valvular tissues, much of the previous work on the mechanical properties of the native and chemically treated aortic valve has relied on uniaxial mechanical testing.[23,28,29] These studies demonstrate that chemical fixation of intact valves, especially under pressure, alters the mechanical properties of the leaflets. Marked decreases in the extensibility are generally attributed to the 'locking' of the collagen fibers in the uncrimped state.[18,30] Tests on thin tissue strips, however, cannot mimic the heterogeneous multiaxial deformation fields, combined loading sequences, and native fiber kinematics found in the physiological environment. Mayne *et al.*[31] and Christie and Barratt-Boyes[32] have performed equibiaxial testing (i.e., equal levels of tension applied to each test axis), which overcomes many of the above limitations of uniaxial loading. However, derivation of a constitutive relationship solely from equibiaxial test data is limited due to multiple colinearities, which confound the ability to obtain reliable, unique model parameter values.[33]

The mechanical behavior and material parameters of tissues are determined through mechanical testing. Whole organ testing is more physiological, but the complex stress and strain boundary conditions on most organs, due to external loading by the surrounding organs or an irregular geometry, prevent an accurate investigation of isolated tissue response. For planar membrane or thin tissue sections, planar biaxial tests can be successfully used to investigate the mechanical behavior of various planar soft tissues[34–40] (**Figure 3**). Billiar and Sacks[34] generated the first complete biaxial mechanical data necessary for constitutive modeling of the aortic valve leaflet. Due to the small size and heterogeneous structure of the aortic valve leaflet, testing methods were developed and validated. Leaflet specimens were subjected to biaxial tests utilizing seven loading protocols to provide a range of loading states that encompass the physiological loading state (**Figure 4**). The leaflets demonstrated a complex, highly anisotropic mechanical behavior, including pronounced mechanical coupling between the circumferential and radial directions. Mechanical coupling between the axes produced negative strains along the circumferential direction and/or nonmonotonic stress–strain

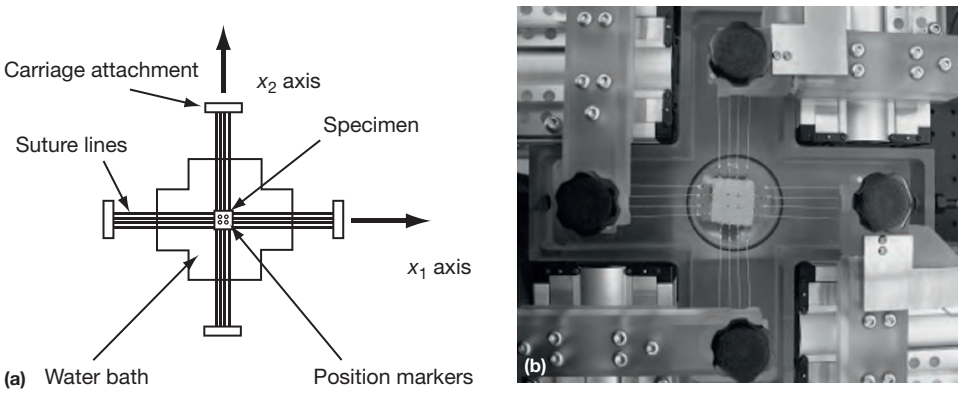

Figure 3 Schematic of a biaxial test (a) and photo of actual device (b). Note the use of four self-equilibrating suture lines to facilitate uniform loading along each of the specimen edges.

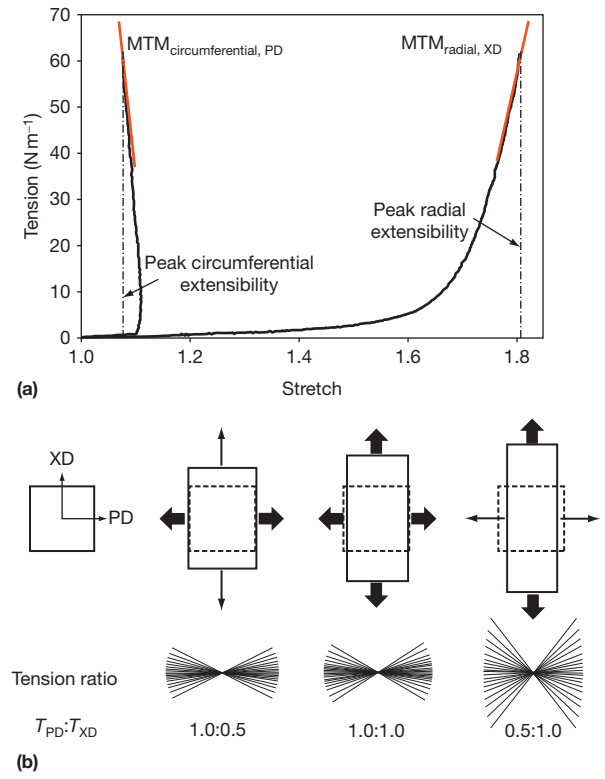

Figure 4 Application of traditional engineering metrics of material behavior is often inadequate as a descriptor of the complex behaviors observed in biological materials. (a) Load-bearing matrix-rich biological materials, such as native aortic valve leaflets, typically exhibit highly nonlinear and highly anisotropic tensile behaviors. (b) The extreme anisotropy and sharp transition from low to high stiffness is attributed to a coupled fiber recruitment process capable of exhibiting lateral contraction at high stress levels (circumferential shortening). As a consequence, the determination of traditional engineering indices of material behavior, such as tensile modulus, has little meaning (i.e., negative modulus). Adequate characterization of biological materials can necessitate more sophisticated methods to characterize their true mechanical behaviors.

behavior when subjected to equibiaxial tension, a behavior noted by Mayne *et al.*[31] but not explained. Moreover, Adamczyk and Vesely[41] measured AV leaflet strains *in situ* and found that negative strains can occur in the noncoronary leaflet.

In our laboratory and others,[31,42,43] biomechanical tissue analyses were conducted at quasistatic (strain rates of 4% per second to 12% per second) experimental conditions. However, we have shown that the deformations of heart valve leaflets can reach strain rates in excess of 300% per second. These findings have raised an important question: Are the quasistatic leaflet mechanical properties truly representative of their physiological behavior? The strain rate dependence of the mechanical properties of soft tissues has been extensively studied. Yet the literature indicates a wide range of findings, which are very much a function of the specific tissue composition and structure, as well as the specific testing methods utilized. Thus, the strain rate dependence of any one tissue needs to be properly investigated under realistic physiological loading states to model physiological functions. We explored, for the first time, the effects of strain rate (from quasistatic to physiologic) on the planar biaxial mechanical properties of the mitral valve anterior leaflet (MVAL).[44,45] A novel high-speed biaxial testing device capable of achieving strain rates was developed. Porcine MVAL specimens were loaded to physiological load levels with cycle periods of 15, 1, 0.5, 0.1, and 0.05 s. The resulting loading stress–strain responses were found to be remarkably independent of strain rate. The hysteresis, defined as the fraction of the membrane strain energy between the loading and unloading tension-areal stretch curves, was low (~12%) and did not vary with strain rate.

The underlying structural basis for this unique mechanical behavior is presently unknown. As collagen is the major structural component of the MVAL, we investigated the relation between collagen fibril kinematics (rotation and stretch) and tissue-level mechanical properties in the MVAL under biaxial loading using small angle X-ray scattering (SAXS).[46] A novel device was developed and utilized to perform simultaneous measurements of tissue-level forces and strain under a planar biaxial loading state. Collagen fibril D-period strain (ε_D) and the fibrillar angular distribution were measured under equibiaxial tension, creep, and stress relaxation to a peak tension of 90 N m^{-1}. The results indicated that, under equibiaxial tension, collagen fibril straining did not initiate until the end of the nonlinear region of the tissue-level stress– strain curve. At higher tissue tension levels, ε_D increased linearly with increasing tension. In creep tests, both tissue strain and ε_D remained constant, with no observable changes over the test length. These results suggest that valve leaflets can be modeled as 'functionally elastic' biological materials. In a follow-up study, we expanded these results to provide a more complete picture of the time-dependent mechanical properties of the MVAL. To accomplish this, biaxial stress relaxation and creep studies were performed on porcine MVAL specimens. Our primary finding was that while the MVAL leaflet exhibited significant stress relaxation, it exhibited negligible creep over the 3 h test. These results strengthened our assertion that the MVAL functionally behaves not as a linear or nonlinear viscoelastic material, but rather as an *anisotropic functionally elastic material*. These results appear to be largely unique in the soft tissue literature, suggesting as they do that valvular tissues are unique in their ability to withstand significant loading without time-dependent material effects.

3.308.2.3. Flexural Response of Native Valvular Tissues

During valve opening and closing, the leaflet is primarily deformed through flexure. While opening, the leaflet bends to straighten, and then curvature reverses as the leaflet conforms to the blood flow profile before reaching the full open position; during valve closing, the leaflet bends with the curve toward the ventricle as it approaches its morphologic closed state.[47] As GAGs largely make up the central spongiosa layer, it has been speculated that this layer serves to reduce the shear stresses resulting from the differential movement of the fibrosa and ventricularis during leaflet bending.[19,24,25,48–50] Further, it has been shown that larger strains in AVs compared to pulmonary valves are associated with the increase in collagen fiber rotation as well as crimp area.[51] Moreover, it has

been shown that the biaxial tensile biomechanical response of the AV is primarily from the collagenous fibrosa and ventricularis layers, with the response dominated by the fibrosa layer.[52] From these studies, it is hypothesized that under the quasistatic tensile loading, GAGs do not play a substantial role in the load-bearing mechanics as the biomechanical behavior is dominated by collagen and elastin. However, the role of GAGs in the time-dependent biomechanical behavior remains unclear.

We recently completed a study to determine GAGs' primary contribution to AV leaflet biomechanics utilizing enzymatic removal under planar tension and flexure: the two primary deformation modes experienced by the AV. Specimens were removed from the belly region of porcine AVs and subsequently treated with either an enzyme solution to remove the GAGs or a control (buffer with no enzyme) solution. Planar biaxial loading was conducted both on-axis and at 45° off-axis to induce maximum shear, with a separate group subjected to flexural testing. The results indicated that the removal of GAGs (1) did not affect extensional mechanical properties (either on- or 45° off-axis), including peak stretch, hysteresis, or creep, and (2) neither was the flexural effective modulus affected (**Figure 5(a)**); yet, the flexural hysteresis was markedly reduced from $35.96\% \pm 2.65\%$ to $25.00\% \pm 1.64\%$ ($p < 0.001$) in the control group as a result of GAG removal (**Figure 5(b)**). Collectively, these novel results suggest that GAGs do not play a role in the tensile properties of the valvular tissues, but rather may be important in providing a damping mechanism to reduce leaflet flutter. The results of this study support our hypothesis that GAGs do not play a measurable role in the tensile biomechanics of aortic valve tissues. Under extensional deformation and shear, collagen fibers rotate and straighten. GAGs interacting with the collagen fibers to contribute to the biomechanics under this loading state would induce viscous effects via fiber–matrix interactions, yet none were observed. In flexure, however, the biomechanical behavior is likely dominated by the crimped collagen fibers (not straightened ones) interacting with the GAGs. While it was noted that there were no bending direction effects in stiffness, it was observed that GAGs do play a significant role in the flexural hysteresis. These results suggest a damping role of GAGs in the aortic valve leaflet, reducing flutter during full systolic flow. This information can be utilized in the design and evaluation of novel engineered heart valves; minimizing valve flutter via enforcing hysteretic properties in flexure could assist in improving the long-term durability of these valve replacement options.

3.308.2.4. Micromechanics of Heart Valve Cells

The leaflets of all four HVs are sheathed by a single layer of valvular endothelial cells (VECs) that have been shown to be morphologically different from aortic endothelial cells (ECs).[53,54] Additionally, VECs are aligned with the collagen architecture of the valve, which is circumferentially oriented.[55] The VECs are believed to regulate vascular tone, inflammation, thrombosis, and remodeling, and their dysfunction has been linked with multiple disorders.[56] Within the proximal third of the leaflets, where they are innervated, there is believed to be a feedback mechanism between the VECs and the valve interstitial cells (VICs) wherein the nerves transmit information regarding released substances from the VECs.[57] Primarily, the release of cytokines has been shown to cause changes in interstitial cell structure and function.[58,59] VICs serve to maintain tissue structural integrity via protein synthesis and enzymatic degradation. Aortic valve interstitial cells (AVICs) are typically characterized as myofibroblasts; they exhibit phenotypic plasticity and may play an important role in valve pathophysiology. It has also been speculated that there exists some physical communication between the VECs and the VICs. However, to date no direct junctions have been observed between the two cell populations.[60]

While it is known that AVICs can respond to mechanical stimuli *in vitro*, the level of *in vivo* AVIC deformation and its relation to local collagen fiber reorientation during the cardiac cycle remain unknown. We have investigated the deformation of AVICs using porcine AV glutaraldehyde fixed under 0–90 mmHg transvalvular pressures. The resulting

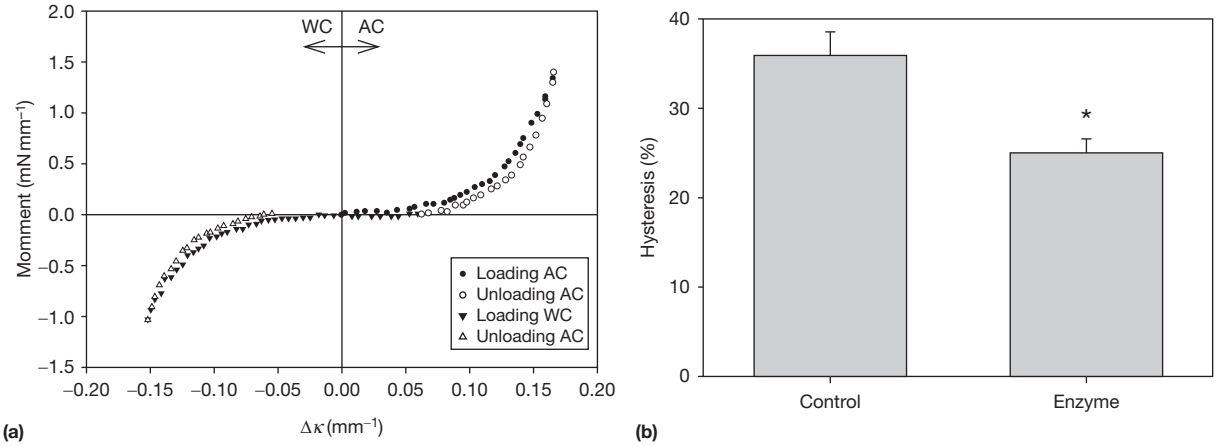

Figure 5 (a) Representative M versus $\Delta\kappa$ loading and unloading curve in both the WC and AC directions; the nonlinear sigmoidal response was present in the native, control, and enzyme treated groups. (b) Combined hysteresis in both directions exhibited a significant decrease from the control to the enzyme treated group ($p < 0.001$).

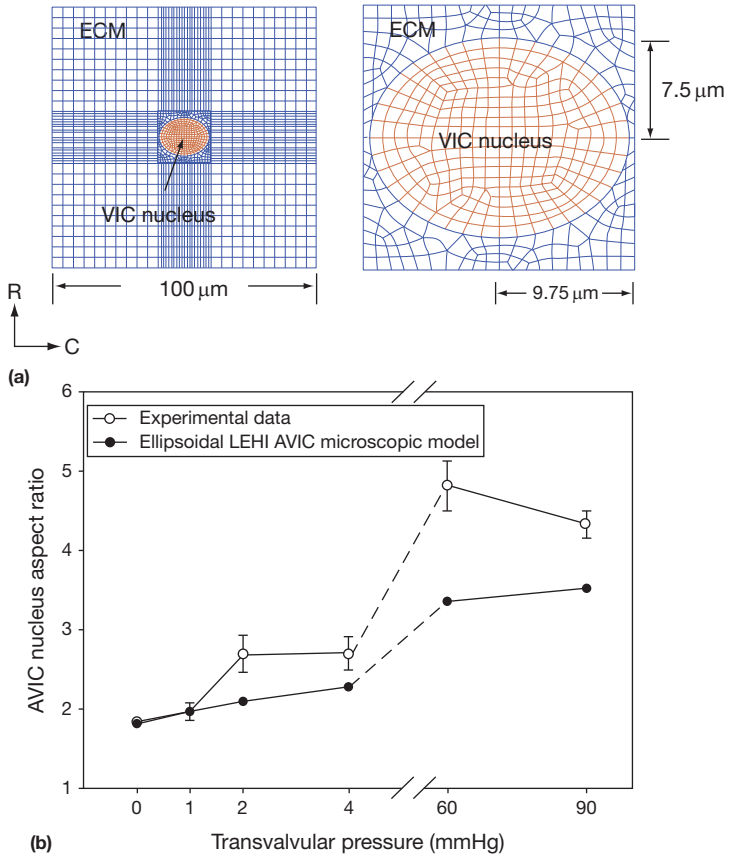

Figure 6 (a) The finite element mesh consisting of an AVIC nucleus within leaflet extracellular matrix, with the contributions of the cell membrane and cytoplasm being considered negligible. (b) A comparison of experimentally measured AVIC nuclear aspect ratio values with values predicted by the representative volume element (RVE) model plotted against the experimentally applied levels of transvalvular pressure (TVP). While the RVE model captured the overall trend, discrepancies with the experimental data increased at greater TVPs. This result indicated that significant compression of the AVICs was induced by local fiber compaction.

change in nuclear aspect ratio (NAR) was used as an index of overall cellular strain, and dependencies on spatial location and pressure loading levels quantified. A tissue-level finite element (FE) model of an AVIC embedded in the AV ECM was also used to explore the relation between AV tissue- and cellular-level deformations (Figure 6(a)). The results indicated large, consistent increases in AVIC NAR with transvalvular pressure (e.g., from a mean of 1.8 at 0 mmHg to a mean of 4.8 at 90 mmHg), as well as pronounced layer-specific dependencies. Associated changes in collagen fiber alignment indicated that little AVIC deformation occurs with the large amount of fiber straightening for pressures below ~1 mmHg, followed by substantial increases in AVIC NAR from 4 to 90 mmHg (Figure 6(a)). While the tissue-level FE model was able to capture the qualitative response, it also underpredicted the extent of AVIC deformation. This result suggested that additional micromechanical and fiber-compaction effects occur at high pressure levels. The results of this study form the basis for the understanding of transvalvular pressure-mediated mechanotransduction within the native AV and first-time quantitative data correlating AVIC nuclei deformation with AV tissue microstructure and deformation.

3.308.3. Myocardium

Myocardium, the muscle of the heart, has had a long history of biomechanical investigations, and wall stress is a major factor in heart function and physiology.[61] As for the previous mentioned tissues, essential to the understanding of the myocardial mechanical behavior is constitutive (stress–strain) relationship. Biaxial mechanical tests have been used to quantify the passive mechanical properties of left ventricle (LV) midwall myocardium, which have revealed its regionally dependent, anisotropic, and viscoelastic behavior.[62–68] In contrast, there is comparatively little data yet available on the mechanical properties of the right ventricle (RV) myocardium.

Our group has reported the passive biaxial mechanical properties of the right ventricle free wall (RVFW) myocardium as follows.[69,70] Hearts from five mongrel dogs (~20 kg), used in unrelated studies, were harvested using a chilled high-potassium cardioplegic solution. The sinus or conus region was first dissected from the RVFW. Any visible coronary vessels in the remaining RVFW myocardium were plugged with adhesive to minimize leakage of the cardioplegic solution from the excision boundaries during reinjection, which allowed for adequate perfusion of the remaining myocardium.

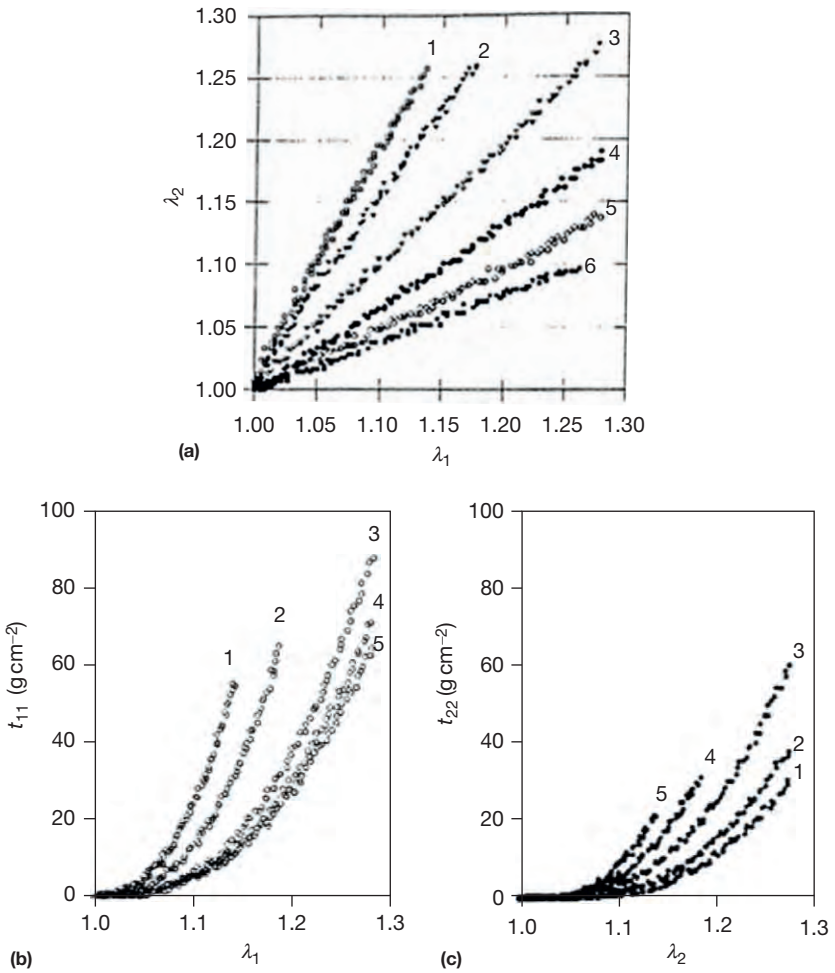

Figure 7 (a) Illustration of the six loading protocols used to characterize the passive RVFW myocardium mechanical properties. In each protocol, the ratio of the percentage elongation along each stretch axes was kept constant. The ratios used were 1:2, 1:1.5, 1:1, 1.5:1, 2:1, and 2.5:1, labeled as 1–6 on curves, respectively. (b, c) Typical stress–strain responses for the five loading protocols, with the labels on curves referring to the protocol numbers.

The remaining heart was placed in a chilled cardioplegic bath and reinjected with fresh chilled cardioplegic solution at 10–15 min intervals. A 2–3 mm sheet of fairly uniform thickness was prepared from the excised sections ~1 mm from the epicardial surface. After test completion, another specimen from the remaining RVFW region was similarly prepared and tested. All testing was performed in an oxygenated cardioplegic solution at room temperature within 3 h from the time of sacrifice. Specimens were preconditioned by performing ten cycles of equibiaxial stretch, with the load at either axes never exceeding 200 g. Immediately afterward, the unstressed specimen's optical target dimensions were recorded. This sequence was repeated until the optical target dimensions did not change by more than 3% from the prior measurement. Once stable optical target dimensions were obtained, the outer specimen dimensions were measured with a digital caliper. These dimensions were used as the references in all subsequent testing and analysis. The test protocol consisted of six tests in which the ratio of the percentage elongation along each stretch axes was kept constant (Figure 7(a)).

Both RVFW regions showed a greater stiffness in the fiber than the cross-fiber direction (Figure 7(b) and 7(c)). Both RVFW regions show a larger stiffness in the fiber than the cross-fiber direction. In general, we found that:

1. The overall qualitative response of the RVFW myocardium was similar to that of the LV myocardium. In both cases, the fiber direction was the direction of greater stiffness.
2. A greater degree of anisotropy was found for the RVFW myocardium compared to the LV midwall myocardium.
3. The conus region of the RVFW showed a greater degree of anisotropy compared to the sinus region.

Although qualitatively similar to the LV myocardium, the RVFW myocardium showed a consistently greater degree of anisotropy. Further, the RVFW showed clear regional differences in passive mechanical properties. The reasons for these differences are at present unknown, but they may be due to microstructural variations in the myocardium in different regions of the heart. Comparisons to other data for the LV is complicated by the different test protocols used. In earlier studies by Yin *et al.* cited above, similar degrees of varying anisotropy were

seen on the LV midwall myocardium. One may ask what mechanical advantages to the RVFW an increased level of anisotropy would bring. Like other biological structures, the heart is a paradigm of efficiency, and it is reasonable to expect that the observed differences satisfy the functional needs of their respective regions. A possible explanation is the close relation between the direction of maximum systolic deformation and mean fiber direction found in the RVFW.[71] It is possible that during systole the predominate stress component for each layer of the RVFW myocardium is in this same direction. A greater stiffness along this direction would tend to better support larger stresses. In the LV, no such similarity between the fiber direction and maximum deformation was found;[72] therefore, a less anisotropic property may be more mechanically advantageous in the LV. However, more studies of the stress distribution in the heart are required for a better understanding of the underlying causes of the differences in regional RV myocardial mechanical properties.

3.308.4. Constitutive Models of Soft Tissues

3.308.4.1. Introduction

Fung is considered the pioneer of phenomenological constitutive models for soft tissues, and many researchers have used variations of the so-called 'Fung-type' models for many different soft tissue applications.[37,73–76] Fung models are widely used because they are capable of capturing highly nonlinear mechanical behavior over a wide strain range. However, while Fung models and phenomenological models in general capture the general stress–strain behavior, they lack the ability to capture the underlying mechanisms contributing to tissue behavior, and the model parameters are not based on physiological phenomena. Structural models, on the other hand, are based on microstructural tissue features that are experimentally measurable and have the ability to relate tissue-level mechanical response to individual fibrillar constituent properties. Most soft tissues behave in a viscoelastic or related time-dependent manner. However, the mechanical behavior can be simplified by assuming a pseudoelastic behavior wherein the tissue is preconditioned and the stress–strain relation repeatable. The loading and unloading branches continue to be represented by a unique constitutive equation, but with differing parameter sets. We adopt this approach in the following section.

3.308.4.2. Stress and Strain Definitions

In the case of finite deformations, several different definitions of stress and strain are used. Let the vector $\mathbf{X}$ represent the position of a point P in the reference configuration, and $\mathbf{x}$ the position of that same material point in a deformed configuration. Then, the deformation gradient tensor $\mathbf{F}$ describes the transformation of the line segment $d\mathbf{X}$ to $d\mathbf{x}$ as $\mathbf{F} = \partial\mathbf{x}/\partial\mathbf{X}$. A change in an infinitesimal volume element (dV) from the reference to the deformed configuration is defined as $J = dV/dV_0 = \det\ \mathbf{F}$, which is equivalent to $J = \rho/\rho_0 = \det\ \mathbf{F}$ due to conservation of mass. Here, ρ is the tissue density in the current configuration and $\det\ \mathbf{F}$ is the determinant of $\mathbf{F}$. Because $\mathbf{F}$ contains rigid body motions, alternative measures of strains are defined that purely represent deformations giving rise to strain energy. The Right Cauchy-Green tensor $\mathbf{C}$, the Left Cauchy-Green tensor $\mathbf{B}$, and the Green–Lagrange or Green's strain tensor $\mathbf{E}$ are defined as

$$\begin{aligned}\mathbf{C} &= \mathbf{F}^T\mathbf{F}\\ \mathbf{B} &= \mathbf{F}\mathbf{F}^T\\ \mathbf{E} &= \frac{1}{2}(\mathbf{C}-\mathbf{I})\end{aligned} \quad [1]$$

where $\mathbf{I}$ is the identity tensor. Moving on to the most commonly used definitions of stress, the most natural definition is in the Cauchy sense, wherein the Cauchy stress tensor $\mathbf{t}$ is derived from the traction vectors acting on a body's surfaces and is defined in the deformed configuration. The first Piola–Kirchhoff stress tensor $\mathbf{P}$ is defined in the referential configuration. The second Piola–Kirchhoff stress tensor $\mathbf{S}$, while not having a simple physical meaning, represents a very useful stress measure. The following equations represent an overview of the relations between these stress tensors

$$\begin{aligned}\mathbf{P} &= J\mathbf{F}^{-1}\mathbf{t} = J\mathbf{t}\mathbf{F}^{-T}\\ \mathbf{S} &= J\mathbf{F}^{-1}\mathbf{t}\mathbf{F}^{-T}\\ \mathbf{P} &= \mathbf{F}\mathbf{S} = \mathbf{S}\mathbf{F}^T\\ \mathbf{S} &= \mathbf{F}^{-1}\mathbf{P} = \mathbf{P}\mathbf{F}^{-T}\end{aligned} \quad [2]$$

In the case of isothermal conditions (which is considered to be the case for biological tissues) and under the assumption of elastic behavior, we can define a scalar strain energy density function Ψ per unit undeformed volume. During an isothermal deformation, the strain energy is associated with the free energy per unit undeformed (reference) volume, and the strain energy is zero in the reference state. Under the assumption of hyperelasticity, we can then define

$$\mathbf{S} = \frac{\partial\Psi}{\partial\mathbf{E}} \quad [3]$$

so that $\mathbf{S}$ can be derived from Ψ. The goal for all constitutive modeling is thus to obtain the form and the parameter values for the scalar strain energy density function. A material with a constitutive relation of the form described by eqn [3] is called a hyperelastic material. In other words, the mechanical properties of a hyperelastic material are characterized completely by a scalar strain energy density function.

3.308.4.3. Phenomenological Hyperelastic Constitutive Models

Materials that keep the volume constant throughout a deformation are characterized by the incompressibility constraint $J = \det\ \mathbf{F} = 1$. For this class of materials, eqn [3] is expressed as

$$\mathbf{S} = 2\frac{\partial\Psi}{\partial\mathbf{C}} - p\mathbf{C}^{-1} = \frac{\partial\Psi}{\partial\mathbf{E}} - p\mathbf{C}^{-1} \quad [4]$$

where p is a Lagrange multiplier that is determined from the equations of motion and boundary conditions (kinematic constraints) and is usually associated with the hydrostatic pressure in a tissue. Note particularly that p does not generally have a direct physical interpretation, but under volume-changing deformations can only be interpreted as the hydrostatic pressure required to enforce incompressibility.[77] Under the assumption of pseudoelasticity, the strain energy function should technically be referred to as a pseudostrain-energy

function. Under the condition of plane stress (with $S_{13} = S_{23} = S_{33} = 0$) for planar biaxial deformation, the strain energy is dependent on the strain components E_{11}, E_{22}, E_{12}, E_{33}. Because of the incompressibility constraint, a reduced strain energy function can be defined as

$$\hat{\Psi}(E_{11}, E_{22}, E_{12}) = \Psi(E_{11}, E_{22}, E_{12}, E_{33}) \quad [5]$$

where the stress tensor components are

$$S_{11} = \frac{\partial \hat{\Psi}}{\partial E_{11}}$$
$$S_{22} = \frac{\partial \hat{\Psi}}{\partial E_{22}}$$
$$S_{12} = \frac{\partial \hat{\Psi}}{\partial E_{12}} - C_{12}C_{33}^2 \frac{\partial \Psi}{\partial E_{33}} \quad [6]$$

3.308.4.4. Fung and Coworkers

The first investigators to develop and utilize planar biaxial testing for soft biological tissues were Lanir and Fung, who, in 1974,[37,78] investigated the mechanical properties of rabbit skin. Briefly, a 3–6-cm square skin specimen was mounted in a trampoline-like fashion with up to 68 individual attachments distributed equally over the four specimen sides (17/side). As in the experiments by Rivlin and Saunders,[79] the tension on each line could be individually adjusted to ensure that a reasonably uniform stress was applied on each specimen side. Actuator motion was controlled utilizing a function generator. To avoid the effects of local stress concentrations of the suture attachments, bidirectional tissue strain was measured in a central region by monitoring the distance between pairs of lines separated by 5 mm along each axis using a video dimensional analyzers (VDAs).[80] Experimental results demonstrated that skin exhibited a nonlinear, orthotropic stress–strain response whose material axis depended on the specimen's anatomic orientation. While differences were observed between the loading and unloading curves due to hysteresis, the loading and unloading stress–strain responses were essentially independent of strain rate. It is important to note that these results *underscore the major phenomenon found in all subsequent biaxial mechanical investigations of soft tissues*.

Based on these experimental observations and data, Tong and Fung[81] used the above biaxial data to develop a constitutive model. Because of their insensitivity to strain rate, separate pseudostrain-energy functions could be developed for the loading and unloading phases of the stress–strain curve.[35] Thus, for the loading and unloading phases, the in-plane second Piola–Kirchhoff stresses are derived from a 2D strain energy function W

$$S_{ij} = \frac{\partial W}{\partial E_{ij}} \quad [7]$$

For this form of W (using their original notation), Tong and Fung observed from the experimental data that the stress–strain curves had a very shallow slope followed by an abrupt transition to a very high stiffness. For all practical purposes, the 'Fung' type model was developed

$$\rho_0 W = \frac{c}{2}(e^Q - 1) \quad [8]$$

where $Q = c_{ijkl}E_{ij}E_{kl}$. This is perhaps the most broadly used constitutive model to date for the biaxial response of soft biological tissues (as well as other loading states), including skin,[81] pericardium,[82] epicardium,[83] visceral pleura,[84] and myocardium. However, one of the difficulties in applying eqn [8] to biological tissue is the high amount of interspecimen variability, which in turn translates into wide variability in material parameter values. The sources of variability have been attributed to experimental noise or numerical instability of the fitting algorithms resulting from the nonlinearity. These problems can confound the ability to obtain a unique set of material constants either for a given specimen or for a class of biomaterials. Further, the residuals in nonlinear regression may not be normally distributed, disallowing conventional statistical analysis.

In their study of canine pericardium, Yin *et al.*[66] developed a statistical approach to assess the sources of the variability in material constants in describing biaxial stress–strain data and to account for them. Using experimental data for canine pericardium,[82] they determined a strain energy function (including exploration of the use of noninteger powers of the Green strain). They performed a residual analysis to determine if standard statistical methods could be used to assess the variability, and, if they were not, they used nonparameteric methods (boot strapping). The use of a five parameter exponential strain energy function found pericardial tissue to be strain-history dependent and anisotropic, which could not be attributed to either experimental noise or instability in the numerical algorithms.

Another form of the phenomenological constitutive equation is expressed in terms of a set of independent strain invariants of $\mathbf{C}$ or $\mathbf{B}$.[85] The first three (principal) invariants are defined in terms of principal stretches as

$$I_1 = tr\mathbf{C} = tr\mathbf{B} = \lambda_1^2 + \lambda_2^2 + \lambda_1^2$$
$$I_2 = \frac{1}{2}\left[(tr\mathbf{B})^2 - tr\mathbf{B}^2\right] = \lambda_1^2\lambda_2^2 + \lambda_1^2\lambda_3^2 + \lambda_2^2\lambda_3^2$$
$$I_3 = \det\mathbf{C} = \det\mathbf{B} = J^2 = \lambda_1^2\lambda_2^2\lambda_1^2 \quad [9]$$

Most biological tissues are characterized as anisotropic and can be viewed as being composed of an isotropic matrix material (i.e., ground substance) and one or more families of fibers responsible for the anisotropy, with the derivation of the constitutive relation based on the principle of *material symmetry*. This approach was initially proposed by Spencer[85,86] for elastomeric materials and is now being increasingly used.[87] The simplest representation of this is transverse isotropy, consisting of one family of fibers. The fiber direction in the reference configuration is defined by a unit vector $\mathbf{a}$, and its structural tensor is defined as $\mathbf{a}\otimes\mathbf{a}$. The pseudoinvariants of $\mathbf{C}$ and $\mathbf{a}$ are

$$I_4 = \mathbf{a}^T\mathbf{C}\mathbf{a} = \lambda_A^2$$
$$I_5 = \mathbf{a}^T\mathbf{C}^2\mathbf{a} \quad [10]$$

where λ_A is the fiber stretch in the direction of $\mathbf{a}$. Thus, for transversely isotropic materials, the strain energy is written as $\Psi = \Psi(I_1, I_2, I_3, I_4, I_5)$.

Humphrey *et al.* developed the following functional form for myocardium biaxial mechanical properties. In this approach, a subclass of transversely isotropic materials that are a function of two strain invariants were used[88]

$$W = W(I_1, I_4) \quad [11]$$

where W is the strain energy function, and I_1 and I_4 are the first and fourth strain invariants, respectively, with $I_4 = \alpha^2$ where α is the stretch ratio along the muscle fiber direction. This form allows the determination of the dependence of W_1 and W_α on I_1 and α directly from the experimentally obtained stress and deformation data[88]

$$2W_1 = \frac{\xi_4 \mathbf{t}_{11} - \xi_2 \mathbf{t}_{22}}{\xi_1 \xi_4 - \xi_2 \xi_3} \quad W_\alpha = \alpha \frac{\xi_1 \mathbf{t}_{22} - \xi_3 \mathbf{t}_{11}}{\xi_1 \xi_4 - \xi_2 \xi_3} \qquad [12]$$

where $W_1 = \partial W/\partial I_1$ and $W_\alpha = \partial W/\partial \alpha$, t_{ij} are the physical components of the Cauchy stress tensor, and

$$\begin{aligned}
\xi_1 &= \lambda_1^2 + \kappa_1^2 - \lambda_3^2 \\
\xi_2 &= \lambda_1^2 \cos^2(\theta) + 2\lambda_1\kappa_1 \cos(\theta)\sin(\theta) + \kappa_1^2 \sin^2(\theta) \\
\xi_3 &= \lambda_2^2 + \kappa_2^2 - \lambda_3^2 \\
\xi_4 &= \kappa_2^2 \cos^2(\theta) + 2\lambda_2\kappa_2 \cos(\theta)\sin(\theta) + \lambda_2^2 \sin^2(\theta) \\
\xi_5 &= \kappa_1\lambda_2 + \kappa_2\lambda_1 \\
\xi_6 &= \lambda_1\kappa_2 \cos^2(\theta) + (\lambda_1\lambda_2 + \kappa_1\kappa_2)\cos(\theta)\sin(\theta) + \kappa_1\lambda_2 \sin^2(\theta)
\end{aligned} \qquad [13]$$

where λ_i and κ_i are components of the deformation gradient tensor, and θ is the fiber angle with respect to the x_1 axis. Next, based on experimental plots of W_1 and W_α versus I_1 and α, they assumed the following functional form for $W(I_1, \alpha)$

$$W(I_1, \alpha) = \sum_{i=0}^{n} \sum_{j=0}^{m} c_{ij} (I_1 - 3)^i (\alpha - 1)^j \qquad [14]$$

where c_{ij} are material parameters. The interested reader is referred to[88] for details of the derivation. Based on the resulting response functions, as well as the theoretical restrictions on the values of c_{ij} (e.g., at zero strain $W(3, 1) = 0$, requiring $c_{00} = 0$), the following form for passive myocardium was derived

$$\begin{aligned}
W(I_1, \alpha) = {} & c_1(\alpha - 1) + c_2(\alpha - 1)^3 + c_3(I_1 - 3) \\
& + c_4(I_1 - 3)(\alpha - 1) + c_5(I_1 - 3)^2
\end{aligned} \qquad [15]$$

where c_i are the material constants. In obtaining the material constants, additional empirical inequalities were applied to set bounds on the values for c_i. The constant invariant tests used to derive eqn [15] require that the tissue specimen be subjected to simultaneous loading and unloading, which strictly violates pseudoelasticity.[35] Thus, data from only the loading portion of the equibiaxial strain and constant α tests were used to determine values for c_i. The data from constant I_1 tests were used to find only the functional form, and were hence excluded as the tissue experiences simultaneous loading and unloading during these tests. The resulting model was found to fit the biaxial data quite well, and was also found not to be overparameterized.[89] The results also emphasized the need for good data, including accurate measurement of the applied forces, original dimensions, and experimental deformations. Later, Sacks and Chuong[70] successfully applied eqn [15] to right ventricular myocardium, where the effects of a fiber splay were incorporated within the specimen. May-Newman and Yin[90] also applied a similar approach to the biaxial mechanical properties of the mitral valve. It is also interesting to note that the overall approach of using theoretically guided experiments is not restricted to the form of eqn [20], but it has also been successfully applied to the epicardium (a thin connective tissue layer surrounding the heart)[83] using the Fung model (eqn [8]) and constant E_{11} and E_{22} tests.

Clearly, the strength of the above approach is that it allows the derivation of the functional form of W to be based on direct evaluation of the experimental data. This avoids the limitations of the trial-and-error approach of earlier work, and is an elegant example of how theory and experiment can be successfully integrated. In principal, the approach can be applied to specimens where there is a nonzero distribution of fiber orientations. However, the author has found the model to be weakly dependent with respect to trans-mural layer orientations, potentially because of the transverse isotropy assumption (Sacks, unpublished data). More detailed, realistic interlayer models may need to be developed. Further, in order to determine the form of W, strict pseudoelasticity must be violated (i.e., the tissue must be subjected to simultaneous loading and unloading protocols). While the loading and unloading curves are qualitatively similar, differences do exist and may influence the sensitivity and final choice of the form. Moreover, one can extend this approach to two families of fibers, where the second fiber family is defined by the unit vector $\mathbf{b}$; additional strain invariants are defined as associated with this additional fiber family and the interaction between the two families. The invariants I_6–I_8 are defined as

$$\begin{aligned}
I_6 &= \mathbf{b}^T \mathbf{C} \mathbf{b} = \lambda_B^2 \\
I_7 &= \mathbf{b}^T \mathbf{C}^2 \mathbf{b} \\
I_8 &= \mathbf{a}^T \mathbf{C} \mathbf{b}
\end{aligned} \qquad [16]$$

Strain energy functions are often divided into an isotropic and an anisotropic part representing the isotropic matrix and the fibers, respectively, resulting in

$$\Psi = \Psi_{\text{iso}}(I_1, I_2) + \Psi_{\text{aniso}}(I_4, I_5, \ldots) \qquad [17]$$

when assuming incompressibility ($I_3 = 1$), which can be simplified to[87]

$$\Psi = \Psi_{\text{iso}}(I_1) + \Psi_{\text{aniso}}(I_4, I_6, \ldots) \qquad [18]$$

Different specific functional forms of Ψ_{iso} and Ψ_{aniso} have been proposed in the literature, where a neo-Hookean formulation is often used for Ψ_{iso}

$$\Psi_{\text{iso}} = \frac{C}{2}(I_1 - 3) \qquad [19]$$

For Ψ_{aniso}, many different phenomenological expressions have been proposed (e.g., Holzapfel *et al.*,[74] Holzapfel and Gasser,[87] Humphrey *et al.*,[88] Holzapfel,[91] Humphrey and Yin,[65] Natali *et al.*,[92] Yang *et al.*[93]). An interesting generalization of the invariant-based method has been presented by Ehret and coworkers.[94] They present a constitutive model for fiber-reinforced materials consisting of an arbitrary number of fibers, where each fiber is represented by its individual structural tensor and a weight factor.

3.308.4.5. Structural Constitutive Models for Multiphase Soft Tissues

The structural approach as introduced where each model parameter has physiological significance, allows for separate investigation of the contribution of each individual tissue component to the tissue's mechanical behavior, and will eventually provide the ability to elucidate changes as a result of

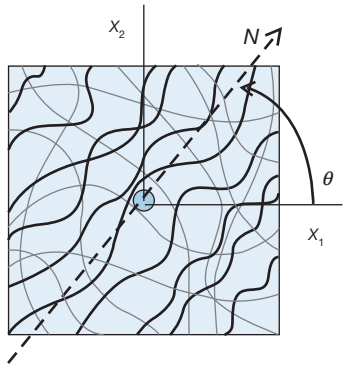

Figure 8 Schematic of the representative volume element. Fiber ensembles are an idealized group of fibers of varying undulation, aligned along the same angle θ, represented by the unit vector N.

pathological processes. The structural constitutive model described herein builds upon the theoretical work formally introduced by Lanir and coworkers[95–98] and extended by Sacks and coworkers,[1,99,100] in which the tissue-level response is related to the collective contribution of individual fiber ensembles. The term fiber ensemble refers to a collection of fibers sharing a common orientation. This modeling technique treats the fibrillar ECM component by homogenizing the fiber ensemble response. It is assumed that a representative volume element (RVE) can be identified that is large enough to represent the processes associated with the microstructure of the material in an average sense, yet sufficiently small compared to the characteristic length scale of the microstructure (Figure 8). The RVE is treated as a 3D continuum, and within the RVE, the following assumptions are made (see also Sacks[100]):

1. The tissue can be idealized as a network of fibers of varying types and structures, all embedded within a compliant ground matrix. The two fiber families considered in the current study are collagen and muscle.
2. Fiber–fiber and fiber–matrix interactions are ignored so that the net tissue response is the sum of the individual fiber responses.
3. Hydrostatic forces generated by the matrix are considered negligible compared to the fiber forces, and are handled by assuming that these components collectively induce an incompressible behavior at tissue level.
4. Contributions from nonload-bearing constituents are combined with the ground matrix.
5. Collagen fibers are intrinsically undulated (also called crimped) and gradually straighten with increased stretch. The load required to straighten the collagen fiber is considered negligible compared to the load transmitted by the stretched fiber. Once a fiber has been stretched to a straightened state, it will transmit load and be considered linear elastic.

The tissue-level strain energy density Ψ of the RVE is assumed to result from the contribution of muscle (M) and ECM, weighted by their respective volume fractions ϕ and is defined as

$$\Psi(\mathbf{E}) = \sum_i \phi_i \Psi(\mathbf{E}) = \phi_{\mathrm{ECM}} \Psi_{\mathrm{ECM}}(\mathbf{E}) + \phi_{\mathrm{M}} \Psi_{\mathrm{M}}(\mathbf{E}) \qquad [20]$$

If the tissue is considered to consist mostly of water (tissue density $= \sim 1\,\mathrm{g\,ml^{-1}}$), and if individual constituent densities are assumed to be equal, volume fractions can be approximated by mass fractions. Assuming a pseudoelastic, hyperelastic material response, the tissue-level second Piola–Kirchhoff stress $\mathbf{S}$ is derived from the strain energy as

$$\begin{aligned}\mathbf{S}(\mathbf{E}) &= \frac{\partial \Psi(\mathbf{E})}{\partial \mathbf{E}} - p\mathbf{C}^{-1} \\ &= \phi_{\mathrm{ECM}} \frac{\alpha \Psi_{\mathrm{ECM}}(\mathbf{E})}{\partial \mathbf{E}} + \phi_{\mathrm{M}} \frac{\partial \Psi_{\mathrm{M}}(\mathbf{E})}{\partial \mathbf{E}} - p\mathbf{C}^{-1}\end{aligned} \qquad [21]$$

where the Lagrange multiplier p accounts for the incompressible nature of the tissue.

A structurally based modeling approach for planar collagenous tissues is employed for the ECM strain energy function, where the contribution of individual fiber ensembles acting at independent orientations is summed over all orientations, using a statistical fiber orientation distribution function. Thus, it assumes the form

$$\begin{aligned}\Psi_{\mathrm{ecm}}(\mathbf{E}) &= \int_\theta R(\theta) \Psi_{\mathrm{col}}^{\mathrm{ens}}(\theta, \mathbf{E}) \mathrm{d}\theta \\ &= \int_\theta R(\theta) \Psi_{\mathrm{col}}^{\mathrm{ens}}(E^{\mathrm{ens}}(\theta)) \mathrm{d}\theta\end{aligned} \qquad [22]$$

where col stands for collagen, $R(\theta)$ is the fiber angular density function, $\Psi_{\mathrm{col}}^{\mathrm{ens}}$ is the strain energy associated with an individual collagen fiber ensemble (ens), and $E^{\mathrm{ens}} = \mathbf{N}^T \mathbf{E} \mathbf{N}$ is the uniaxial Green–Lagrange strain acting in the ensemble direction, defined by a unit vector parallel to the fiber axis in the reference configuration $\mathbf{N}$. The effective ensemble response has been modeled with a phenomenological expression[34,99,100] as well as with a formulation accounting for the recruitment process.[100]

The structural formulation for collagen fibers assumes that the fibers are crimped and transmit load only if stretched beyond the point where all the crimp has disappeared, that is, the slack stretch or strain. In the straightened condition, fibers are assumed to follow a linear elastic material model. In the case of straight fibers without slack, this implies $S_{\mathrm{f}} = \eta E_{\mathrm{t}}$ or $\Psi_{\mathrm{f}} = \frac{\eta}{2} E_{\mathrm{t}}^2$, where η is the fiber modulus and E_{t} is the true fiber strain. In the case of undulated fibers, E_{t} is related to the ensemble or fiber strain by $E_{\mathrm{t}} = \frac{E^{\mathrm{ens}} - E_{\mathrm{s}}}{1 + 2E_{\mathrm{s}}}$, where E_{s} is the fiber slack strain. In terms of E_{t}, the fiber stress–strain relation for an undulated fiber is

$$S_{\mathrm{f}} = \frac{\partial \Psi_{\mathrm{f}}}{\partial E_{\mathrm{f}}} = \frac{\partial E_{\mathrm{f}}}{\partial E_{\mathrm{t}}} \frac{\partial E_{\mathrm{t}}}{\partial E_{\mathrm{f}}} = \eta \frac{E_{\mathrm{f}} - E_{\mathrm{s}}}{1 + 2E_{\mathrm{s}}} \frac{1}{1 + 2E_{\mathrm{s}}} = \eta \frac{E_{\mathrm{f}} - E_{\mathrm{s}}}{(1 + 2E_{\mathrm{s}})^2} \qquad [23]$$

The ensuing fiber ensemble strain energy and stress–strain relation are then described as the sum of the individual fiber strain energies of the ensemble (Figure 8), weighted by the distribution of slack strains D, as

$$\begin{aligned}\Psi_{\mathrm{col}}^{\mathrm{ens}}(E^{\mathrm{ens}}) &= \int_0^{E^{\mathrm{ens}}} D(x) \Psi_{\mathrm{f}}(x) \mathrm{d}x = \frac{\eta}{2} \phi_{\mathrm{f}} \int_0^{E^{\mathrm{ens}}} D(x) \left[\frac{E^{\mathrm{ens}} - x}{1 + 2x} \right]^2 \mathrm{d}x \\ S_{\mathrm{col}}^{\mathrm{ens}}(E^{\mathrm{ens}}) &= \int_0^{E^{\mathrm{ens}}} D(x) S_{\mathrm{f}}(x) \mathrm{d}x = \eta \phi_{\mathrm{f}} \int_0^{E^{\mathrm{ens}}} D(x) \frac{E^{\mathrm{ens}} - x}{[1 + 2x]^2} \mathrm{d}x\end{aligned} \qquad [24]$$

Here, η is the collagen fiber modulus, ϕ_f the collagen fiber fraction, and $D(x)$ a recruitment function. For convenience, ϕ_f is often absorbed in the effective fiber modulus K

$$K = \phi_f \eta \quad [25]$$

Here, $D(x)$ describes the fraction of fibers realizing a fully straightened state at a given strain magnitude, which is effectively the distribution of slack strains $D(E_s)$. D is defined over $E_s \in [E_{lb}, E_{ub}]$, where E_{ub} is the upper bound strain defining an ensemble strain state where all fibers are straight, and E_{lb} the ensemble strain where recruitment begins (E_{lb} can be assumed to equal zero in many cases). Under equibiaxial strain conditions, E_{11} equals E_{22}, and zero shear is assumed ($E_{12} = 0$). Because of the fact that $D(x)$ is not directionally dependent, the fiber ensemble stress–strain relationship can be obtained directly from the experimental data using $S^{ens} = S_{11} + S_{22}$, and $E^{ens} = E_{11} = E_{22}$.[98,100] Hence, the parameters of the fiber ensemble model could be experimentally determined directly from an equibiaxial stretch protocol. Combining the above leads to a complete formulation for stress in the ECM component

$$\mathbf{S}(\mathbf{E}) = \eta\phi_f \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} R(\theta) \left\{ \int_0^{E^{ens}(\theta)} D(x) \frac{E^{ens}(\theta) - x}{[1+2x]^2} dx \right\} \mathbf{N} \otimes \mathbf{N} \, d\theta \quad [26]$$

The fiber distribution function R is represented by a β-distribution function with mean μ_R and standard deviation σ_R.

Forms and functions describing fiber recruitment, a process in which fibers in an individual ensemble engage into load transmission as they become fully straightened, have been presented in the literature.[100] The recruitment function $D(E_s)$ can be represented by different functions. The simplest relation is exponential in form:

$$D(E_s) = \frac{\left[\exp\left(a \frac{E_s}{E_{ub}}\right) - 1 + b \frac{E_s}{E_{ub}} \right]}{E_{ub}\left[\frac{b}{2} + \frac{(\exp(a) - 1)}{a} - 1\right]} \quad [27]$$

where the denominator is introduced to ensure $\int_0^{E_{ub}} D(x)dx = 1$. As an initial step, the recruitment function $D(E_s)$ is represented by means of a unimodal modified β-distribution with mean μ and standard deviation σ.[101] The β-distribution $B(\gamma)$ is defined on the interval $\gamma \in [0, 1]$, which is modified to be defined on the interval $[0, E_{ub}]$, with $\gamma = E_s/E_{ub}$, so that

$$D(E_s, \mu, \sigma) = \begin{cases} \dfrac{B(\gamma, s_1, s_2)}{E_{ub}} & 0 \le E_s \le E_{ub} \\ 0 & \text{otherwise} \end{cases} \quad [28]$$

where s_1 and s_2 are shape parameters computed from μ and σ using

$$s_1 = \frac{\mu^2 - \mu^3 - \mu\sigma^2}{\sigma^2}, \quad s_2 = s_1 \frac{1-\mu}{\mu} \quad [29]$$

the β-function is restricted to a unimodal shape with a lower bound of zero, and $s_1, s_2 > 1$ is enforced to prevent the upper bound going to infinity. Note, that for an unbound function $\mu, \sigma \in [0, 1]$.

Next, this model is extended by adopting a structurally guided form for the fiber ensemble strain energy. To take into account both levels of fiber uncoiling present in the bladder collagen fiber network, $D(E_s)$ is modified to the following bimodal distribution (with $j = 1$, 2, and γ a scaling factor):

$$D(E_s, \mu_j, \sigma_j, \gamma) = \gamma D_1 + (1-\gamma) D_2 \quad [30]$$

The parameters are bound in a similar manner, that is, the shape parameters are larger than 1 to enforce two distinguishable peaks, $\mu_1 < \mu_2$.

To estimate the fiber effective modulus, we note that if the tissue consisted of all straight fibers, the maximum tangent modulus (MTM) would equal K. At strain values $E^{ens} > E_{ub}$, all fibers are recruited, and MTM is determined using

$$\text{MTM} = \frac{\partial S^{ens}(E^{ens})}{\partial E^{ens}} \Big|_{E^{ens} \ge E_{ub}} = K \int_0^{E_{ub}} \frac{D(x)}{(1+2x)^2} dx \quad [31]$$

The greater the degree of slacked fibers in the tissue (either a longer slack length per fiber, or more slacked fibers), the lower is the MTM as compared to K. Hence, MTM provides a lower bound value for K, the integral on the right hand side of eqn [31] being lower than 1 because of the presence of fiber slack.

Experimentally, the E_{ub} is determined by finding the onset of constant stiffness from the S_{ens}-E_{ens} response curve, best determined from strain value, where the tangent modulus plateaus (**Figure 9(a)** and **9(b)**). To determine the ensemble model parameters K, μ, and σ, eqn [31] was fitted to the to S'–E' data using the Marquardt–Levenberg nonlinear least squares algorithm.[102] The posttransition tangent modulus value (equivalent to the MTM) was used as an initial estimate for the collagen fiber elastic modulus K. When applied to the native MVAL, mitral valve posterior leaflet (MVPL), and AV, the recruitment model was found to fit the data quite well, with an $r_2 \cong 0.99$. Aortic valve leaflet (AVL) was found to have the $E_{ub} = 0.3013 \pm 0.0323$, in comparison with MVAL (0.2692 ± 0.0487) and MVPL (0.2473 ± 0.01181). Moreover, the model predicted the very similar average K values for each valve leaflet type (mean ± s.e.m., $n = 6$ each): MVAL 123.443 ± 3.324 MPa, MVPL $= 124.114 \pm 7.830$ MPa, and AV $= 101.220 \pm 6.030$ MPa. It is interesting to note that these values are very similar to the 95.5 MPa measured using SAXS for the MVAL.[46] In addition to having greater structural realism, the recruitment model can perform better in stress overload situations. For example, both the exponential model and the recruitment model were fitted to the same equibiaxial strain data (**Figure 9(c)** and **9(d)**). We then simulated the trend beyond the used data range and examined the predicted trend with the ten real datum points. As anticipated, the exponential model predicted a continuous increase in tensile modulus with increased strain, whereas the fiber recruitment model provided accurately predicted the linear stress–strain relationship beyond the data range (**Figure 9(b)**). This result indicates the need for realistic constitutive models capable of prediction outside the range used to define the model, especially in situations where stress overloads need to be accurately predicted.

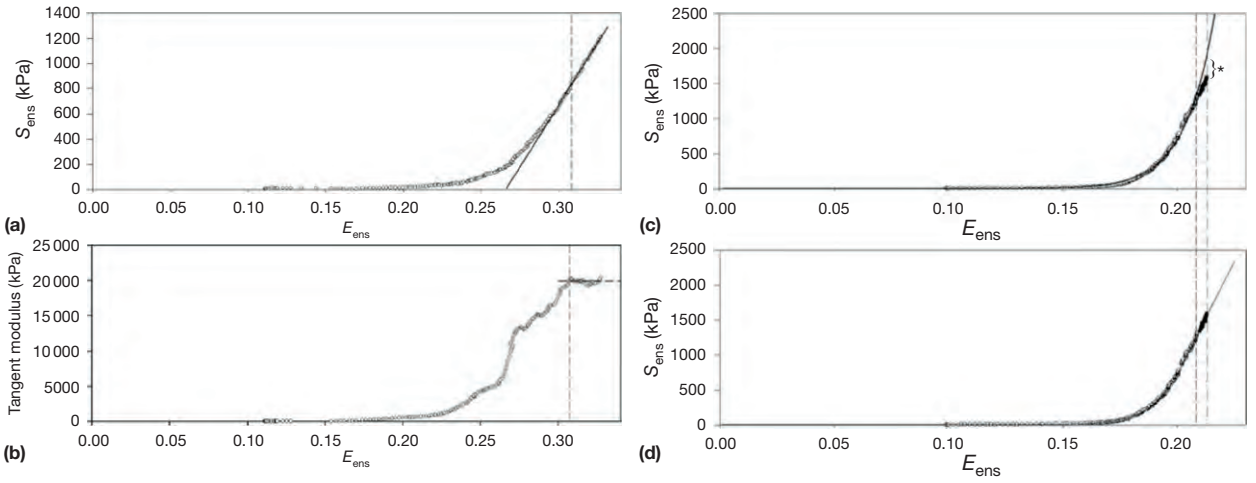

Figure 9 (a) A representative example of the effective fiber stress–strain curve of heart valve leaflets (MVAL), showing the characteristic long toe region, transitional region, and subsequent linear region. (b) Corresponding tangent modulus of the fiber stress–strain curve. Note the sharp rise of tangent modulus in the middle of the transitional region and the following plateau that shows a constant tensile modulus in the linear region. (c) The standard exponential model fitted to the data predicts a continuous increase of stiffness beyond the used data range, whereas the fiber recruitment model correctly predicts a linear stress–strain relationship beyond the used data range.

3.308.5. Emulating Native Tissue Mechanical Behavior in Engineered Tissues

3.308.5.1. Introduction

Surgical replacement of cardiac tissues using engineered tissue/regenerative medicine approaches has become a major research focus in the field of biomaterials and biomechanics. For example, in pediatric applications, growth of the replacement valve is essential to eliminate the need for reoperations as the patient grows. The ultimate heart valve replacement characterized as a nonobstructive, nonthrombogenic living tissue valve substitute that lasts the lifetime of the patient, provides ongoing remodeling and repair of cumulative injury, and potentially grows with the recipient is an important goal.[103] Such a valve would be particularly useful in the treatment of the ~20 000 children with congenital heart disease born in the United States each year and especially those with valvular disease. In this population, the anticoagulation required with mechanical valves is particularly dangerous and tissue valve substitutes undergo accelerated calcification. Thus, a fundamental problem inherent in the use of existing mechanical and biological prostheses in the pediatric population is their failure to grow, repair, and remodel. Engineered tissue approaches have the potential to address these and related tissues.[103]

However, engineered tissue approaches in cardiac tissue engineering ultimately have to function mechanically at the tissue and organ levels. As shown earlier in the text, collagenous soft tissues exhibit a wide array of unique mechanical behaviors, which can be probed by a variety of testing modes (tension, shear, bending, torsion, etc.). Practically speaking, the application of traditional engineering metrics of material behavior to soft biological materials can be not only difficult but also potentially unsuitable. When characterizing material performance, it is important to consider the functional relevance of a chosen method of mechanical testing and its interpretation relating to tissue function. For instance, valvular tissue stiffness with the highly anisotropic and nonlinear behavior of the tissues as discussed in the preceding sections cannot be adequately described by singular indices of material behavior. This is apparent in the circumferential response of valvular tissues under biaxial loading, where specimen contraction is observed at high stress states rendering the calculation of a MTM erroneous (Figure 4). The basis for this coupled, anisotropic response between material directions is the result of a reorganization of the fiber constituents (i.e., structural anisotropy). While helpful in providing potentially comparable metrics of tissue behavior, tabulated values, which appear in contemporary literature, can be misleading and belie the complex mechanical responses characteristically observed in soft load-bearing tissues. While the matching of metrics related to tensile strength (i.e., ultimate tensile stress and ultimate percent elongation) or tensile modulus has merit when applied appropriately, this approach gives little indication of the full material response during loading. Again, in the case of valvular tissues, if one was to simply match peak stress–strain values without considering the native material loading response, it would likely lead to inadequate coaptation or closing of the heart valve and result in poor function. Native cardiac tissues often exhibit highly specific, complex mechanical behaviors necessitating more sophisticated and thorough methods of characterization. This is also true for scaffolds and engineered constructs, as discussed in the following sections.

3.308.5.2. Electrospun Scaffolds

Elastomeric scaffolds fabricated by electrospinning natural polymers, synthetic polymers, or polymer blends have received widespread attention, largely due to their ability to produce biocompatible polymer constructs that exhibit many soft tissue-like mechanical behaviors.[104–106] Electrospinning is a highly versatile process capable of creating a wide array of material behaviors through the alteration of production

parameters or polymer choice. As such, it is necessary to assess these mechanical behaviors in a systematic manner. For practical reasons, uniaxial tensile testing is often employed to obtain basic material properties such as the elastic modulus, strain at the onset of yielding, and ultimate tensile strength.[107–113] From the systematic mechanical evaluation conducted by Courtney *et al.*, several scaffolds were manufactured with varying degrees of structural anisotropy or fiber alignment, which was controlled by altering the rotational velocity of the collection mandrel. Increase in rotational velocity results in an increase in fiber alignment,[105,114–116] and this was experimentally measured from scanning electron microscopy (SEM) micrographs via an image analysis algorithm.

The controlled structural anisotropy produced during manufacturing directly led to more nonlinear, anisotropic material responses. These structural properties form a complex 3D scaffold with tunable tissue-level mechanical behavior that can be remarkably similar to the gross biaxial mechanical response of the native pulmonary valve leaflet.[104] It has also been shown that the tensile response of some musculoskeletal tissues, namely, knee meniscus and annulus fibrosis tissues, can be emulated well by electrospun scaffolds.[105,117] Much of the work found in the recent literature has focused on the structural and mechanical characterization of electrospun materials with limited effort made in the development of modeling frameworks to further assess our understanding of electrospun material behavior. Nerurkar *et al.* have adapted a homogenization modeling approach originally presented by Yin and Elliot to compare predicted mechanical behaviors of electrospun poly-ε-caprolatone and the inner and outer lamella of native annulus fibrosus tissue. Structure-based modeling attempts originally developed for dense collagenous planar tissues have proven quite successful in capturing the mechanical behavior of electrospun scaffolds under biaxial modes of deformation.[104] It was noted that the model predicted a higher degree of fiber orientation than measured experimentally. This is attributed to structural characteristics of the polymer fibers measured in the image analysis algorithm but not accounted for in the model formulation.

In order to improve upon these initial modeling efforts and gain a better appreciation of how these materials function across multiple length scales, work was recently undertaken by Stella *et al.* to quantify additional structural characteristics. The electrospun scaffolds investigated in this study exhibited complex, hierarchical architectures spanning multiple length scales.[118] As a result, understanding the mechanisms by which these materials deform and behave under various loading conditions was not a simple task. Fiber tortuosity, diameter, and fiber orientation distributions were all quantified as the electrospun specimen underwent planar biaxial modes of deformation. In addition, the deformation behavior of the scaffold was investigated across multiple scales by defining three characteristic lengths (micro (1–2 μm), meso (40–50 μm), and macro (1–3 mm)). Fiber tortuosity, a measure of how much a fiber deviated from being straight in the unloaded scaffold, was observed to be dependent on mandrel velocity during both production and orientation. As the scaffold underwent planar biaxial modes of deformation, fiber tortuosity was eliminated and substantial fiber rotational kinematics was observed, contributing to an intricate fiber recruitment process.[119] Electrospun constructs were observed to follow gross affine fiber transformations and can be described in a manner similar to collagenous scaffolds.[120] Interestingly, some fibers were observed to rotate or change their direction of orientation during deformation, while as a population, no net change was measured. This is likely an additional manifestation of the local heterogeneity that exists at the microscale. With increased specimen deformation, a monotonic decrease in poly(ester urethane)urea (PEUU) fiber diameter was measured for all specimens. Furthermore, it was observed that the neighboring fibers were well attached where they overlapped or intersected, impeding translation of fibers with respect to one another; but this did not appear to inhibit rotational fiber kinematics about these points of intersection. Johnson *et al.*[121] presented a similar hypothesis for reduced fiber mobility in electrospun polymers exhibiting 'point bonding.' In short, polymer sintering was utilized on electrospun poly (ε-caprolatone) scaffolds to invoke definite point bonds between fibers. Scale-dependent variations in deformation were observed and these were attributed to the complex, spatially variant structure that results from the electrospinning process. These heterogeneous variations occur at the microscale that a cell might experience. The overall strain behavior tends to become increasingly more homogenous as the scale of interest approaches the tissue level.

The unique coupled matrix–cell deformation response of electrospun scaffolds integrated with cells was also recently investigated (**Figure 10**).[119] The scaffolds exhibited microfiber morphologies and kinematics that were shown to directly influence local cellular deformations. For instance, in the unstrained configuration, the electrospun fibers exhibited a tortuous architecture that transitioned to a web-like network of straight, interconnected fibers at high levels of strain. The deformations of the microintegrated cells were found to be primarily mediated primarily by this phenomenon. The cell-integrated constructs underwent fully recoverable large deformations akin to many native tissues. Initially, the integrated cells exhibited a rapid increase in NAR as the fibers straightened and tortuosity was reduced. Once the PEUU fibers became straightened and the architecture transitioned to an interconnected web-like structure, changes in NAR were observed to remain constant. Microintegrated cell deformation was mediated by the local reduction of tortuosity or straightening of the PEUU fibers. Thus, cell–scaffold interactions can be subtle and can bring about unique deformation behaviors. These results indicate that it may be possible to successfully emulate gross native tissue behavior without exactly replicating their highly complex microarchitectures. Attempts to delineate the individual contributions of structural fiber characteristics such as tortuosity and fiber kinematics to the construct's mechanical behavior would be quite cumbersome and might better lend itself to the development of a numerical framework to explore this unique, interrelated phenomenon.

3.308.5.3. Modeling Scaffold Structure–Function Relationships

Elucidation of the mechanical behavior of native biological materials is further confounded by tissue-specific, highly specialized multiscale constituent arrangements, which dictate their unique mechanical functions. While the

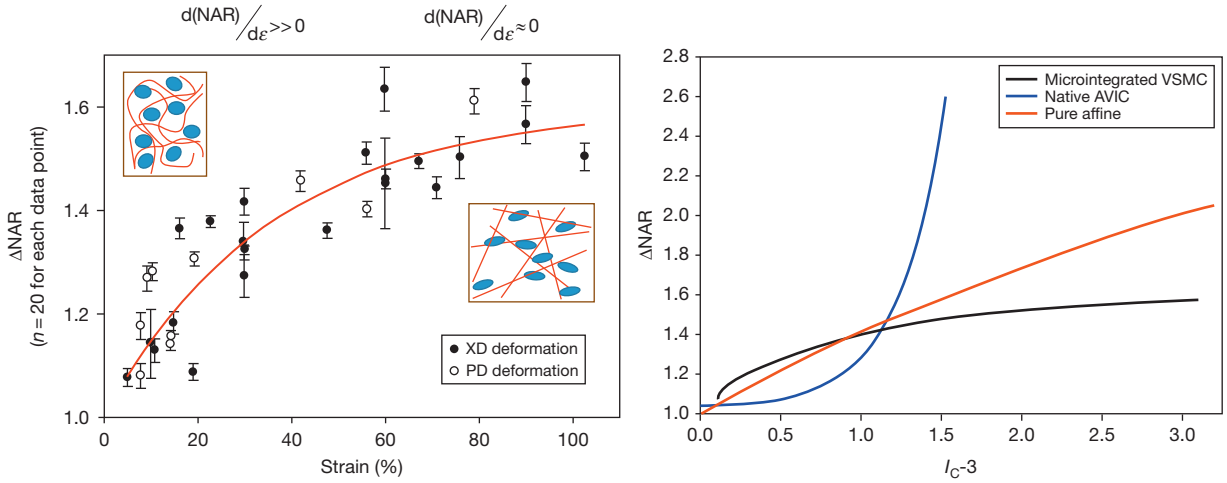

Figure 10 Strain-induced changes in electrospun polyester microarchitecture and resulting nuclei deformation. A composite of all nuclear aspect ratio measurements (mean ± s.e.m.) demonstrated a rapid increase to 60% strain, after which a plateau was observed with further strain increases, indicating that nuclei deformations are dominated by local fiber straightening. A composite cell–scaffold deformation response (bottom) is provided for native porcine aortic valve leaflet, cell-integrated electrospun poly(ester urethane)urea, and a theoretical purely affine cell deformation response to macroscopic strain.

development of new materials continues to be the focus of ongoing research, achievement of material behavior that is functionally comparable to native tissue is currently limited. Despite advancements made in recent years, there continue to be a multitude of unanswered fundamental questions, which inhibit the production of truly functional tissue surrogates. While more thorough methods for the characterization of native and engineered biological tissues are necessary, the answers to many fundamental biological or structural questions cannot be ascertained through experimental testing alone. By combining well-posed theoretical frameworks with experimentally derived observations, it is possible to elucidate the complex interrelated mechanisms presented by nature. Modeling approaches can serve as valuable tools not only to simplify and test our understanding of complex biological systems but also to guide future hypothesis-based investigations. Correspondingly, methods to restore, maintain, or improve tissue or whole organ function must incorporate a thorough understanding of the intricate multiscale hierarchical arrangements typically found in nature. Engineering sustainable solutions concerned only with tissue or organ-level function disregards the multifaceted, coordinated function of these tissue structures and their constituents, which are in turn a result of cellular or subcellular processes that reach down to the molecular scale of protein interactions and gene transcription. Surely, one model cannot incorporate this large range in scales with our current understanding of biological processes. Rather, a hierarchy of models and approaches is necessary to connect the established continuum-level relationships (i.e., phenomenological,[91,122–125] structural[64,87,97,98,100,126–128]) with underpinning cell and subcellular events. From a modeling point of view, a vital aspect of these models consists of the difficult task of seamlessly coupling various length scales.

For materials with regular, repeating structures, unit cell-based modeling approaches can successfully relate microstructural responses to global material behavior. Stylianopoulos and coworkers[129–131] have developed such a model for the mechanical behavior of collagen fiber networks. Briefly, the unit cell, the representative unit of the continuum that encompasses the periodicity of the microstructural parameters, contains an idealized fiber mesh generated in-silico. A group of unit cells are then perturbed in a defined manner (i.e., uniaxial tension) and a force balance within each unit cell results in a volume-averaged macroscopic response. In related work, Zahalak *et al.*[132] and Marquez *et al.*[133,134] have developed constitutive relations to relate individual cellular contributions to macroscopic material response in an effort to elucidate active and passive cell deformation responses and material properties. The fundamental unit of this model comprised cells, idealized as contractile rods, within a compliant matrix. Both constituents were parametrically assigned linear elastic, isotropic material properties. Because of these assumptions, the predictive capabilities are limited as biologic materials typically exhibit nonlinear viscoelastic behaviors. However, they did show that the strain experience by the cell can be related to macroscopic strain via a scalar valued strain factor and that reasonable approximations of cell stiffness can be determined from measured tissue properties. One shortcoming of the unit cell approach is that it neglects the structural heterogeneity seen in biological tissues and the incorporation of increased structural complexity is penalized by significant computational demands. Moreover, native dense collagenous tissues are long fiber composites with fiber lengths up to the millimeter scale while the characteristic length scale of this model is much shorter as defined by unit cell dimensions.

Additionally, efforts spent on assessing appropriate material specific RVE size have been insufficient. Morphology descriptors produced through image analysis such as material porosity, fiber density, fiber alignment distribution, fiber connectivity distribution, and fiber diameter strongly depend on the material architecture at micromeso level. This can be

demonstrated by studying the evolution of these parameters over regions of interest of increasing sizes and/or repeating the image analysis over analogous regions differing in location. Morphology feature fluctuations and location dependency gradually cease as the analyzed region of interest approaches an appropriate RVE size. A direct implication is that an image analysis technique remains incomplete if it does not identify an appropriate RVE for the variable of interest. RVE size in random composites can be derived by statistically, numerically, or empirically studying the stabilization of the analyzed variable over RVEs of increasing sizes.[135,136] Thus, the importance of identifying the appropriate RVE size is twofold. First, in terms of material characterization, it contributes to the development of reliable tools to assess scaffold manufacturing process repeatability and second, in terms of mechanical modeling, the analysis performed at the RVE can provide physically meaningful data. In particular, structural deterministic models depend greatly on rigorously defined material structural descriptions. This need, where the model capability relies prevalently on the accuracy of the network topology, has been extensively highlighted in the recent literature.[129–131,137,138]

Furthermore, microarchitectural data extraction accuracy is not only crucial but also fundamental in stochastic representations of engineered scaffolds for the minimization of the gap between the real and the simulated structure. The potential of a structural deterministic approach in elucidating the inherently multiscale nature of native and engineered soft tissue response seems to justify its apparent complexity.[129–131,138] An alternative path for deterministic modeling is the reproduction of the entire scaffold area or volume without duplicating the RVE. The main benefits of this alternative solution are that the implicit error introduced by the multiscale approach is removed and the information at the meso level is preserved. For instance, tortuosity measurements of a collagen fiber can be performed in a heart valve leaflet under loaded and unloaded configurations, which would otherwise be neglected in the multiscale approach where the fibers cannot cross element boundaries. However, these expected benefits are counterbalanced by a significant increase in computational cost.

The modeling strategies outlined above also have potential use for the rational design of future scaffold morphologies at the macro (tissue-engineered construct size, shape, etc.) and microlevel (fiber connectivity, fiber density, fiber alignment, etc.). This has the potential to profoundly impact the fields of tissue engineering and mechanobiology, whereby empirically driven experimentation can be augmented or replaced with more rational design approaches. Relating macroscopic kinematic events to the cell environment and understanding the cellular responses to these cues are critical to the production of engineered tissue surrogates. It has been shown that mechanical cues modulate many cellular processes and the ability to understand and predict the events leading to healthy tissue accretion or adaptive repair/growth can guide mechanical training regimes to produce robust tissue formation. Efficacious repair or replacement of abnormal or lost tissue relies on our ability to reproducibly control cellular responses to exogenous cues.

Clearly, a better understanding of the effects of cardiac-engineered tissue scaffold architecture on cell morphology, metabolism, phenotypic expression, and prediction of material mechanical behavior have recently begun to receive increased attention. A novel image-based analysis approach has been

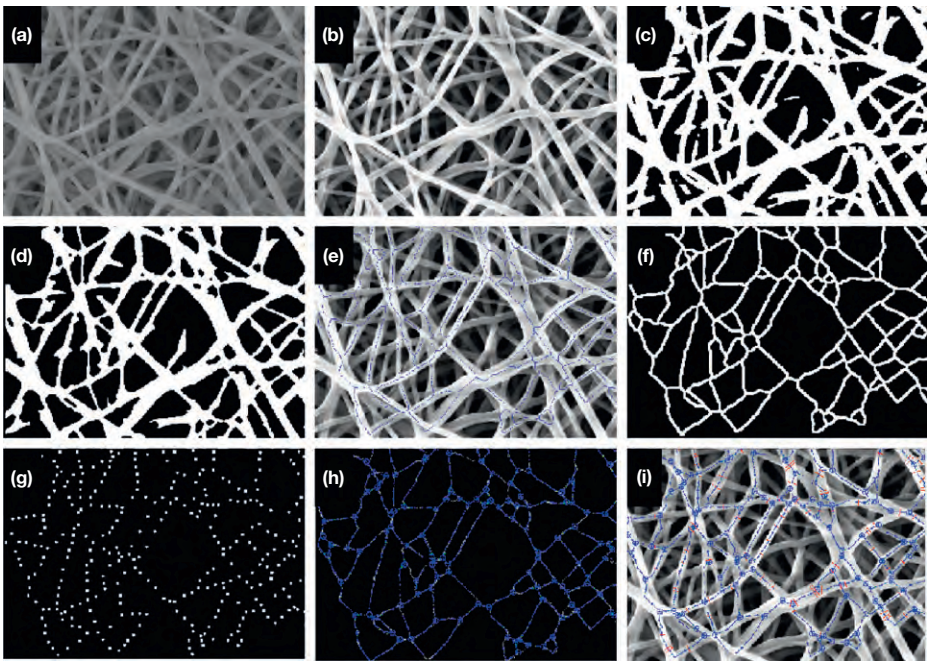

Figure 11 (a) Starting scanning electron microscopy image. (b) Image histogram equalization followed by 3 by 3 median filtering. (c) Local thresholding through Otsu method. (d) Thinning, smoothing, and removal of isolated pixel areas through a cascade of different morphological operators. (e) Skeletonization. (f, g) Binary filters for Delaunay network refinement. recently developed to automatically characterize engineered tissue fiber network topology.[139] Microarchitectural features that fully defined fiber network topology, including fiber orientation, connectivity, intersection spatial density, and diameter (Figure 11), were detected and quantified. Algorithm performance was tested using SEM images of electrospun PEUU (ES-PEUU) scaffolds. SEM images of rabbit mesenchymal stem cell (MSC) seeded collagen gel scaffolds and decellularized rat carotid arteries were also analyzed to further evaluate the ability of the algorithm to capture fiber network morphology regardless of the scaffold type and the evaluated size scale. The image analysis procedure was validated qualitatively and quantitatively, comparing fiber network topology manually detected by human operators ($n = 5$) with that automatically detected by the algorithm. Correlation values between manually detected and algorithm-detected results for the fiber angle distribution and for the fiber connectivity distribution were 0.86 and 0.93, respectively. Algorithm-detected fiber intersections and fiber diameter values were comparable (within the mean $\pm$ standard deviation) with those detected by human operators. This automated approach identifies and quantifies fiber network morphology as demonstrated for three relevant scaffold types and provides a means to (1) guarantee objectivity, (2) significantly reduce analysis time, and (3) potentiate broader analysis of scaffold architecture effects on cell behavior and tissue development both *in vitro* and *in vivo*.

Abbreviations

CFD	Computational fluid dynamics
CFL	Courant–Friedrichs–Lewy
CT	Computed tomography
CV	Control volume
DNS	Direct numerical simulation
DVI	Digital volumetric imaging
ECM	Extracellular matrix
FCC	Face-centered cubic
FEM	Finite element method
LB	Lattice-Boltzmann
MRI	Magnetic resonance imaging
MRM	Magnetic resonance microscopy
PBT	Polybutylene terephthalate
PDLLA	Poly D,L-lactic acid
PEG	Polyethylene glycol
PEGT	Polyethylene glycol terephthalate
PEOT	Polyethylene oxide terephthalate
PGA	Polyglycolic acid
PLA	Polylactic acid
PLAGA	Polylactic-*co*-glycolic acid
REV	Representative elementary volume
RHS	Right-hand side

Symbols

a	Average radius of the fiber (m)
a_p	Specific area of the particle (m^2)
$\mathbf{A}$	Discretized convective operator
$A_{\beta e}$	Area of entrances and exits of the averaging volume
$A_{\beta\sigma}$	Area between the fluid and solid phases
$\mathbf{b}$	Closure vector for pressure deviation
$\mathbf{B}_G$	Discretized gradient operator
$\mathbf{B}$	Second-order closure tensor for velocity deviation
c	Artificial compressibility factor
C_F	Forchheimer coefficient
c_g	Intrinsic average concentrations of glucose ($mol\,m^{-3}$)
C_i	Concentration of species i ($mol\,m^{-3}$)
C_l	Intrinsic average concentrations of lactate ($mol\,m^{-3}$)
C_o	Intrinsic average concentrations of oxygen ($mol\,m^{-3}$)
d_p	Average diameter of the fibers (m)
d_{pore}	Pore diameter (m)

$\mathbf{d}$	Alternate closure vector for pressure deviation
$\mathbf{D}$	Alternate second-order closure tensor for velocity deviation
$\mathbf{D}_{\mathrm{eff}}$	Effective diffusivity tensor of each species ($m^2\,s^{-1}$)
$\mathbf{D}_i$	Diffusion coefficient of species i ($m^2\,s^{-1}$)
$\mathcal{D}_{i\beta}$	Diffusivity of species i in the culture medium ($m^2\,s^{-1}$)
E_0	Surface concentration of the transporter proteins ($mol\,m^{-2}$)
$\mathbf{F}$	Forchheimer correction tensor
$\mathbf{F}_b$, $\mathbf{f}$	Body force vector (N)
$\mathbf{g}$	Velocity imposed at the boundaries of the averaging volume ($m\,s^{-1}$)
G	Hydraulic conductivity
$\mathbf{I}$	Identity tensor
$\mathbf{J}_{\mathrm{conv}}$	Convective flux of species ($mol\,m^{-2}\,s^{-1}$)
$\mathbf{J}_{\mathrm{diff}}$	Diffusive flux of species ($mol\,m^{-2}\,s^{-1}$)
$\mathbf{J}_{\mathrm{total}}$	Total flux of species ($mol\,m^{-2}\,s^{-1}$)
k_d	Death coefficient due to apoptosis
k_g	Homogenous cell growth rate coefficient
k_k	Carman–Kozeny constant
K	Isotropic permeability value ($m^2\,s^{-1}$)
K_0 and K_1	Modified Bessel functions of the second kind of orders 0 and 1
$K_{\parallel}$	Permeability parallel to the flow direction ($m^2\,s^{-1}$)
$K_{\perp}$	Permeability perpendicular to the flow direction ($m^2\,s^{-1}$)
K_c	Modified Contois saturation constant
K_{eq}	Equilibrium constant
K_m	Michaelis–Menten constant ($mol\,m^{-3}$)
K_{pr}	Product susceptibility constant
$\mathbf{K}$	Permeability tensor ($m^2\,s^{-1}$)
$\mathbf{K}_{\mathrm{visc}}$	Discretized viscous operator
$\mathbf{l}$	Computational lattice vector
L	Length scale (m)
L_f	Average length of the fibers (m)
l_β	Characteristic length scale of the liquid phase (average pore size) (m)
l_σ	Characteristic length scale of the solid phase (scaffold matrix and cells) (m)
m_s	Maintenance coefficient
$\mathbf{M}$	Discretized mass matrix
$\mathbf{n}$	Outward pointing unit normal vector
$\mathbf{n}_{\beta\sigma}$	Normal vector at the scaffold matrix–fluid interface
p	Fluid pressure ($N\,m^{-2}$)
$\hat{p}$	Variation of pressure
$\tilde{p}$	Pressure deviation about the intrinsic averaged pressure
r	Radius of the averaging volume (m)
$\dot{R}$	Production/consumption rate of species ($mol\,m^{-3}\,s^{-1}$)
Re	Reynolds number
S	Surface area (m^2)
t	Time (s)
$\mathbf{T}$	Traction vector
$\mathbf{u}$	Fluid velocity vector ($m\,s^{-1}$)
$\tilde{\mathbf{u}}$	Velocity deviation about the intrinsic averaged velocity ($m\,s^{-1}$)
$\hat{\mathbf{u}}$	Variation of velocity vector
V	Volume (m^3)
V_{max}	Half-maximal rate of species consumption ($mol\,m^{-3}\,s^{-1}$)
Y_{XS}	Yield of cells per unit oxygen
α_2, α_3, α_4, α_5	Transport kinetic parameters
γ, γ_1	Adjustable parameters
ε_s	Volume fraction of the scaffold matrix
ε_β	Volume fraction of the fluid or porosity
ε_σ	Volume fraction of the cells
θ	Weight for the time-stepping scheme
κ_i	Relative measure of the importance of intercellular diffusivity
λ	Tortuosity of the porous medium
μ	Newtonian viscosity ($N\,s\,m^{-2}$)
μ_{max}	Maximal cell specific growth rate (s^{-1})
ρ	Fluid density ($kg\,m^{-3}$)
ρ_{cd}	Cell density within scaffold
ρ_{cell}	Specific cell density (m^{-3})
ϕ	Volume fraction of the scaffold
ψ	Generic variable
Ψ_{fibers}	Mass flow rates at the porous fibers
Ψ_{inlet}	Mass flow rates at the inlet pipe (s^{-1})
Ψ_{outet}	Mass flow rates at the outlet pipe

3.309.1. Introduction

This chapter reviews the mathematical and computational models used to predict the transport processes involving biomaterials. Transport processes involve both fluid momentum transfer and mass transfer of species. This review will be restricted to isothermal processes and consequently heat transport will not be discussed. The intention here is to provide bioengineers with references to important state-of-the-art models that can be employed to accurately predict transport processes in biotechnological applications of recent interest. While the models described are general in nature, specific focus is given to the area of tissue engineering involving porous scaffolds exposed to dynamic flow conditions such as those that prevail in many modern-day bioreactors.

Tissue engineering is the application of principles and methods of engineering and life sciences toward the development of biological substitutes to restore, maintain, or improve physiological functions. Engineered tissues are very useful in basic biological studies, pharmacological and toxicological screens, and as replacement tissues for clinical applications. Most cells require cues from a three-dimensional (3D) environment to form relevant physiological tissue structures in vitro. Traditionally developed 2D surfaces have been shown to be insufficient to reproduce the true morphology and functionalities of cells compared to 3D cultures and

associated 3D tissue-like structures. The 3D matrix affects the mass transfer of solutes, growth factors, and enzymes thereby establishing proper tissue-scale solute concentration gradients, as well as local pericellular gradients. Also, morphogenetic and remodeling events that occur over larger-length scales may be modeled only using the 3D cell culture environments.[1,2] For 3D cell culture employed in tissue engineering, porous 3D scaffolds are extensively used to manipulate cell function and guide new tissue formation.[3] The formation of cohesive, organized, and functional 3D tissues in a 3D matrix (scaffold) is an exceedingly complex event.[4] An important requirement for such scaffolds is that they should balance mechanical function and mass transport to aid biological delivery and tissue regeneration.[5]

A suitable environment for the proliferation and differentiation of cells seeded within a porous scaffold is afforded by a dynamic bioreactor. Many such bioreactors that aim at reproducing the physiological environment (including biochemical and mechanical functions) specific to the tissue to be regenerated have been developed over the past several years. Some of the common types of bioreactors widely employed in tissue engineering include spinner flasks,[6] rotating wall vessels,[7–15] perfusion culture bioreactors,[16] and more recently, the wavy-walled reactors.[17] A review of several types of bioreactors is reported in Freed *et al.*[18] In general, improved cell viability, proliferation, and extracellular matrix production have been demonstrated in such bioreactors relative to static controls. While the chemical and mechanical properties of many of the scaffold materials employed in these bioreactors are well characterized, the prevailing fluid dynamics and mass transport of species inside the complex microenvironment of the scaffolds are not so well understood.[19] It is well known that an important factor for the growth of cells is the mass transfer of species such as oxygen, and nutrients such as glucose. Supplying the cells seeded within the support scaffold with sufficient nutrients and oxygen requires a knowledge of transport phenomena of these species.[20] Cells relying only upon the diffusion of nutrients inside the porous scaffold such as that would occur in static cultures produce thinner tissues.[21] Also, diffusion-limited growth of cells is often confined to the outer parts of the porous scaffolds while the central core becomes necrotic due to the nonavailability of nutrients.[22]

Transport of oxygen and nutrients can be improved by using dynamic bioreactors that enhance mass transfer of species through convection. The transport processes in such bioreactors usually occur on multiple scales, namely, the microscopic scales of the individual cell and the scaffold to the macroscopic scale of the bioreactors.[23] Therefore, to correctly characterize and evaluate the mass transfer processes, an understanding of these processes occurring at both the micro and macro levels is required. A large number of experimental and computational methods have been developed for biotechnological studies involving cell culture in bioreactors. Many of these studies have focused mainly on the characterization of macroscale flows and some involving solid and porous microcarriers.[11–15,24] However, detailed models of the complex transport processes occurring at the pore scale (microscopic scale) within a porous 3D scaffold are few in number largely due to the complexity presented by the scaffold architecture. Optimization of such scaffold architectures requires a detailed evaluation of design parameters such as the distribution of local shear stress, local concentration of the solutes, and material–cell interactions within these scaffolds in order to obtain the most appropriate conditions of growth for various cell types.[25] Experimental quantification of the dynamics of flow and mass transfer within the microscale environment of the 3D scaffold is usually very difficult and time-consuming. However, these aspects may be understood and evaluated employing mathematical models and numerical methods such as computational fluid dynamics (CFD). In this chapter, we present some of the important and useful mathematical models for characterizing the transport of species through 3D porous scaffolds through which there is flow of a cell culture medium (in contrast to pure static cultures). In particular, a perfusion culture system is picked as the representative bioreactor. The perfusion culture system represents an important class of bioreactors that enable efficient and uniform seeding of scaffolds of various compositions, architectures, and porosities through direct perfusion of a cell suspension through the pores of a 3D scaffold.[26] A schematic of a perfusion culture system is shown in **Figure 1**. A known flow rate or fluid velocity is prescribed at the inlet. Fluid flows through the porous scaffold and exits through the outlet. The objectives are to characterize the flow dynamics and transport of species within such a scaffold.
