Chapter 234 :: Immunobiologicals, Cytokines, and Growth Factors in Dermatology

:: Stephen K. Richardson & Joel M. Gelfand

IMMUNOBIOLOGICALS, CYTOKINES, AND GROWTH FACTORS AT A GLANCE

- Immunobiologicals are drugs, defined as compounds engineered from living organisms that induce or alter immune responses by interacting with specific biologic targets.
- Used to treat conditions with immune abnormalities.
- Those used to treat cutaneous disease include recombinant cytokines and growth factors, monoclonal antibodies, and fusion proteins.
- Targeting the immune system with biologics may result in an increased risk of infections and malignancies.

Immunobiologicals are compounds synthesized in living organisms that exhibit immune modulatory properties. They consist of recombinant cytokines, growth factors, antibody-based agents, and fusion proteins. Those with dermatologic indications are discussed in this chapter and are listed in Table 234-1. Fig. 234-1 illustrates the molecular targets of these compounds. Fig. 234-2 depicts the cellular events that mediate cutaneous inflammation and identifies the molecular interactions affected by specific immunobiological agents.

RECOMBINANT CYTOKINES AND GROWTH FACTORS

Cytokines are low-molecular-weight polypeptides that exhibit paracrine and/or autocrine activity in the mediation of immune responses. They may act as growth factors by inducing the proliferation of specific immune cell populations. A particular cytokine may also influence the production of other cytokines and the behavior of cellular populations that express its receptor. Over the past two decades, recombinant cytokines have proven to be invaluable for the treatment of conditions in which immunologic aberrations exist or among which some clinical benefit might be derived from augmentation or suppression of the host immune response.

RECOMBINANT INTERFERONS

(See also Chapters 231 and 235)

TABLE 234-1
Immunobiologicals, Cytokines, and Growth Factors

	Action	Dosing for Dermatologic Indications
Recombinant interferons		
Interferon-α and Interferon-γ	▪ Enhances cell-mediated cytotoxicity against viral disease and malignancy via promotion of MHC expression and suppression of Th2 cytokine production	▪ Variable
Recombinant Interleukins and growth factors		
Interleukin 2	▪ Maintains helper T-cell populations ▪ Enhances natural killer cell cytotoxicity and lymphokine activated cell activity	▪ Variable
Interleukin 1 receptor antagonist	▪ Blocks the interaction between IL1 and its receptor ▪ Suppresses IL1 mediated inflammatory responses (e.g., leukocyte recruitment, osteoclast activation)	▪ Variable
Granulocyte-macrophage colony-stimulating factor	▪ Promotes the proliferation and differentiation of myeloid precursors	▪ Variable
Platelet-derived growth factor	▪ Promotes wound healing via angiogenic activity and proliferative effects on fibroblasts and smooth muscle cells	▪ Daily application of gel to affected site
Antibody-based therapeutics		
Anti-TNF-α	▪ Infliximab: chimeric monoclonal antibody; neutralizes both membrane-bound and soluble TNF-α ▪ Adalimumab: human monoclonal antibody; neutralizes both membrane-bound and soluble TNF-α	▪ 5-mg/kg IV at week 0, 2, and 6, then q8wk 80-mg SC followed by 40-mg SC 1 week later, then 40-mg SC qow ▪ 80 mg SC followed by 40 mg SC 1 week later, then 40 mg SC qow
Anti-IL12/IL23	▪ Ustekinumab: human monoclonal antibody; inhibits IL-12 and IL-23 mediated inflammatory processes	▪ Patients <100 kg: 45-mg SC followed by same dose at week 4, and q12wk thereafter (▪ Patients >100 kg: receive 90 mg)
Anti-LFA-1	▪ Efalizumab: humanized monoclonal antibody; interferes with lymphocyte activation, cytotoxicity, and trafficking to the skin; *withdrawn from US market in 2009 because of PML*	▪ 0.7-mg/kg SC followed by 1 mg/kg qwk
Anti-CD20	▪ Rituximab: chimeric monoclonal antibody; promotes a reduction in $CD20^+$ cells (B-cells)	▪ Variable
Fusion proteins		
Alefacept	▪ Human IgG1 Fc region fused to LFA-3 extracellular domain; interferes with T-cell activation by blocking the interaction between LFA-3 and CD2	▪ 15 mg IM qwk for 12 weeks
Etanercept	▪ Human IgG1 Fc region fused to TNF type II receptor domain; neutralizes soluble TNF-α	▪ 50-mg SC biw for 12 weeks, then 50-mg SC qwk
Denileukin Diftitox	▪ Diphtheria-toxin component fused to IL2; promotes apoptosis of T-cells expressing the high affinity IL2 receptor, CD25	▪ Variable

INTERFERON-α. IFN-α is a Type I interferon produced by plasmacytoid dendritic cells. It enhances cell-mediated cytotoxicity against viral disease and malignancy by increasing MHC I expression by antigen-presenting cells, stimulating NK cell activity, promoting the development of Th1 cells, and suppressing the production of Th2 cytokines.[1,2]

Recombinant IFN-α may be administered as a subcutaneous or intramuscular injection and has been utilized for a broad range of dermatologic conditions that include cutaneous T-cell lymphoma, melanoma, nonmelanoma skin cancer, Kaposi sarcoma, Behcet disease, hemangiomas, condyloma acuminatum, verruca vulgaris, and keloids.[3] A pegylated form (containing polyethylene

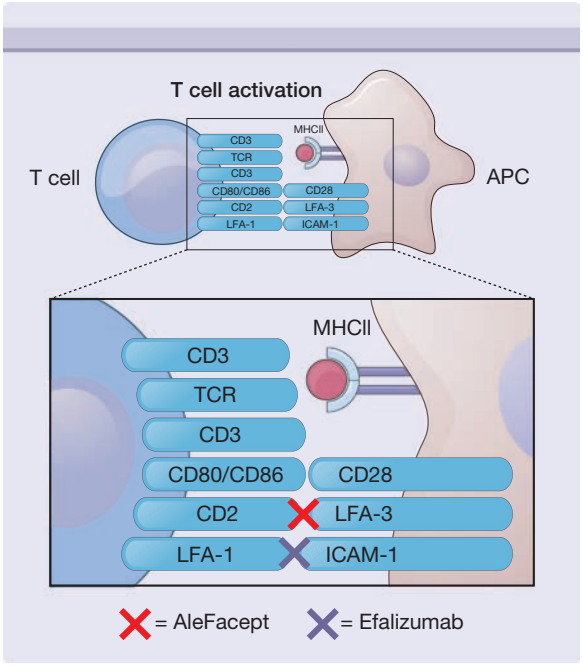

Figure 234-1 Immunobiologicals may modify immune responses via inhibition of T-cell activation. Efalizumab blocks interactions between leukocyte function-associated antigen 1 (LFA-1) and intercellular adhesion molecule 1 (ICAM-1), whereas alefacept interferes with interactions between CD2 and LFA-3. MHC II = major histocompatibility complex II; TCR = T–cell receptor.

glycol) of this compound is currently available which has a longer half-life and increased patient tolerability.[2] Prior to the availability of pegylated IFN-α, treatment was typically administered 3×/week with dosing dependent upon the condition being treated and patient response to therapy. Pegylated IFN-α may be administered once weekly with a steady state plasma level achieved within 5–9 weeks.[4]

There is extensive experience using IFN-α for the treatment of cutaneous T-cell lymphoma (CTCL). Objective clinical responses have been noted among 50%–75% of CTCL (Stage Ia–IVa) patients treated with different IFN-α dosing regimens.[5] Typically, it is administered subcutaneously at a starting dose of 1.5–3.0 million units three times per week. When combined with other immunodulatory therapies, high clinical responses have been achieved among patients with Sézary syndrome.[6]

The most common side effect associated with IFN-α therapy is "flu-like" symptoms characterized by fever, sweats, chills, myalgias, and arthralgias. These symptoms typically resolve over the first ten days of therapy and can be managed with acetaminophen. Patients may also experience injection site reactions. Other associated side effects include fatigue, depression, weight loss, photosensitivity, peripheral neuropathy, psychosis, hypothyroidism, and sexual dysfunction.[2,7] Laboratory abnormalities include elevated hepatic transaminases and leukopenia. Liver function tests and a complete blood count should be evaluated every 1 to 2 weeks upon initiation of therapy, or with any increase in dosing.[2]

IFN-α is contraindicated for use in patients with a known hypersensitivity to the drug or any of its components. Relative contraindications include a history of cardiovascular disease, renal disease, hepatic disease, central nervous system disorders, and/or preexisting mental illness. IFN-α is a pregnancy category C medication with unknown safety during lactation. Multiple case reports have suggested that IFN-α may induce, exacerbate, or unmask autoimmune disorders including immune-mediated thyroid disease, anemia, thrombocytopenia, sarcoidosis, and connective tissue disorders. IFN-α should be used with caution among patients with $CD8^+$ CTCL, as multiple cases of disease progression have been reported in this setting.[8–10] This finding may be explained by the inherent ability of Th1 cytokines to augment $CD8^+$ T-cell activity.

INTERFERON-γ. IFN-γ is a cytokine produced by Th1 lymphocytes. Similar to IFN-α, it enhances cell-mediated cytotoxicity and suppresses Th2 cytokine production. IFN-γ has also been shown to enhance MHC 2 expression and interleukin 12 (IL12) production by antigen-presenting cells. In the dermatologic setting, it is reported to exhibit clinical efficacy in the management of chronic granulomatous disease and CTCL.

Children with chronic granulomatous disease treated with IFN-γ exhibited a significant reduction in the frequency of infections and associated hospitalizations.[11] This has been attributed to its ability to partially correct defects in oxidative metabolism and promote superoxide release, thus enhancing phagocytes' ability to combat infection.[12]

Studies regarding the use of IFN-γ in the treatment of CTCL are limited. Partial clinical responses have been reported among patients treated with IFN-γ during all stages of disease.[13] This has been attributed, in part, to its ability to suppress the production of Th2 cytokines by malignant cells.[14] Thus, IFN-γ offers an alternative therapeutic option for patients who may not tolerate or respond to IFN-α therapy secondary to the formation of neutralizing antibodies, cognitive dysfunction and/or fatigue—which are more frequently associated with IFN-α therapy.[15]

IFN-γ is administered via intravenous, intramuscular, and subcutaneous routes. The recommended dosing for children with chronic granulomatous disease is 50 μg/m^2 three times a week for life.[16] We have utilized IFN-γ doses ranging from 50–100 μg three times a week for the treatment of adult CTCL patients.[2]

Adverse effects associated with IFN-γ are similar to those reported for IFN-α and include flulike symptoms, elevated hepatic transaminases, leukopenia, and thrombocytopenia. IFN-γ is a pregnancy category C medication with unknown safety during lactation. Its contraindications are similar to those reported for FN-α.

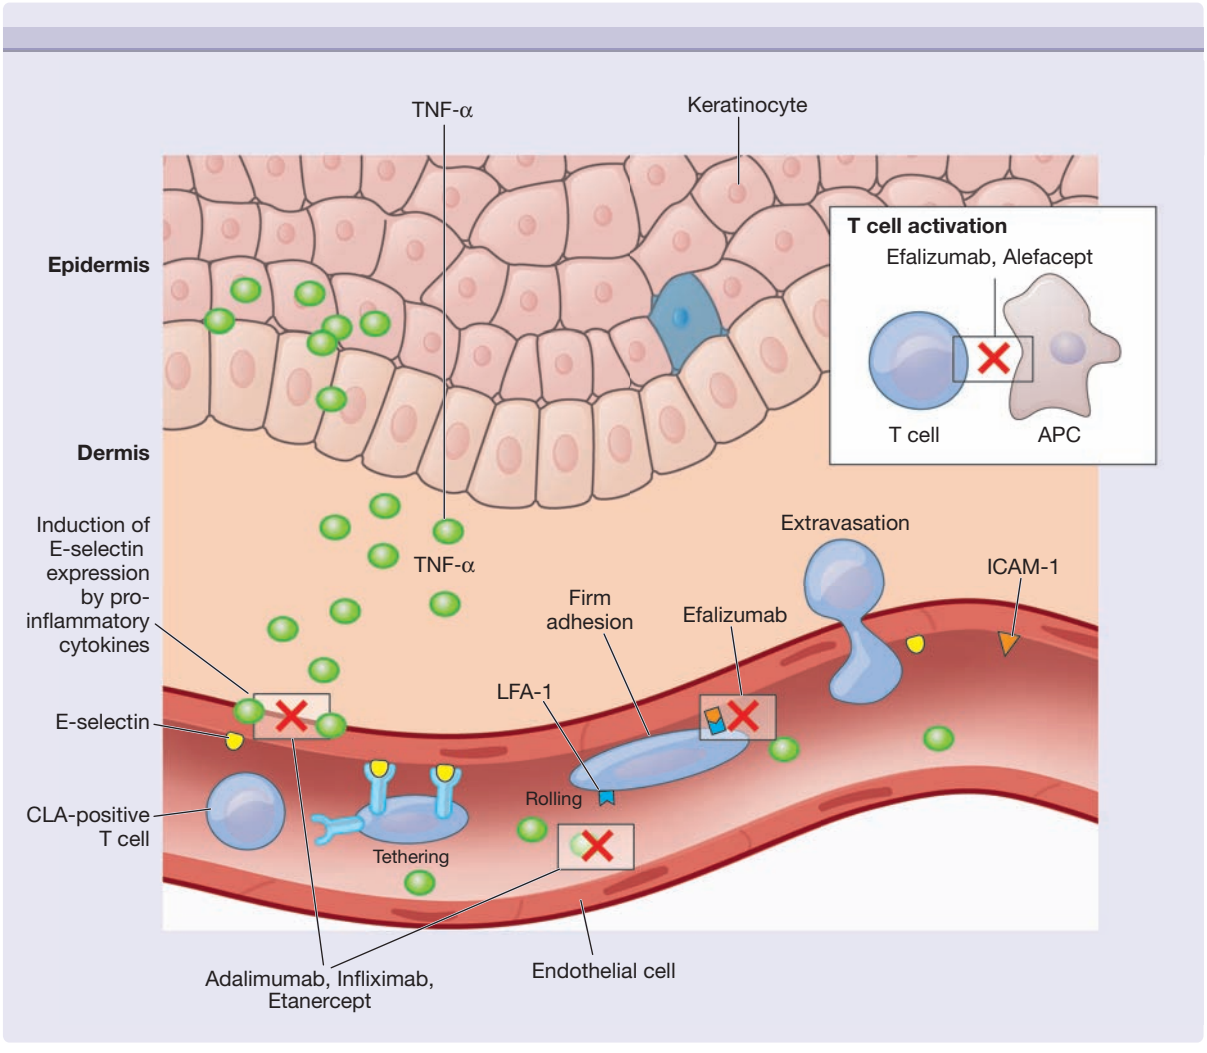

Figure 234-2 Cutaneous inflammation results in the production of inflammatory cytokines that induce keratinocyte proliferation and increase expression of molecules such as E-selectin. Immunobiologicals may interfere with immune cell trafficking by binding to specific cell surface receptors, deplete target cell populations through direct binding to cell surface proteins, suppress cytokine activity through the action of cytokine targeting compounds, and alter immune responses via the activity of recombinant cytokines with inhibitory or proinflammatory properties. The cellular interactions and cytokines targeted by several of the immunobiological agents discussed in this chapter are depicted. CLA = cutaneous lymphocyte-associated antigen; ICAM-1 = intercellular adhesion molecule 1; LFA-1 = leukocyte function-associated antigen 1; TNF-α = tumor necrosis factor-α.

RECOMBINANT INTERLEUKINS AND GROWTH FACTORS

INTERLEUKIN 2. Interleukin 2 (IL2) is a Th1 cytokine with antitumor activity produced by $CD4^+$ lymphocytes in response to activation by antigen-presenting cells. IL2 has been shown to promote the proliferation and maintenance of helper T-cell populations. In addition, it has been shown to enhance both natural killer cell cytotoxicity and lymphokine-activated cell activity.[17] In the dermatologic setting, recombinant human IL2 has been used for the treatment of melanoma.

Several studies have reported durable clinical responses among melanoma patients treated with IL2 therapy. This finding led to the FDA approval of this medication for the treatment of patients with metastatic disease. In early studies, high dose intravenous IL2 therapy (600,000–720,000 IU/kg) led to a 15% to 20% overall response among melanoma patients, with 4% to 6% achieving a complete clinical response.[18–20] Unfortunately, prolonged responses are only achieved by a minority of patients. Over the past two decades, IL2 has been combined with other treatment modalities in an attempt to enhance clinical response rates and overall survival among melanoma patients.[21]

Adverse effects associated with infused IL2 include fever, chills, hypotension, thrombocytopenia, vascular leak syndrome, pulmonary edema, cardiac arrhythmias, renal compromise, and exfoliative erythroderma.[2,3] IL2

is contraindicated for use in patients with a known hypersensitivity to the drug or any of its components. It is also contraindicated for patients with a history of an abnormal thallium stress test, abnormal pulmonary function tests, or organ allograft transplantation. IL2 is a pregnancy category C medication with unknown safety during lactation.

INTERLEUKIN 1 RECEPTOR ANTAGONIST.

Interleukin 1 (IL1) is a proinflammatory cytokine produced by monocytes/macrophages that are involved in the recruitment of leukocytes to inflamed tissue, the generation of acute phase reactants, activation of osteoclast activity, induction of collagenase production by chondrocytes, and fever induction. In combination with other inflammatory cytokines, IL1 has been implicated in the pathogenesis of conditions that include rheumatoid arthritis and neonatal-onset multisystem inflammatory disease (NOMID).

The potentially damaging effects of prolonged IL1-α and/or IL1-β exposure are normally balanced by a naturally produced interleukin-1 receptor antagonist (IL1ra), which counters the effects of excessive IL1 exposure. If this protective mechanism is overcome, tissue damage may ensue. Anakinra is a recombinant IL1ra that was approved by the Food and Drugs Administration (FDA) in 2001 for the treatment of moderate-to-severe rheumatoid arthritis among adult patients who failed to respond to other antirheumatic drugs. It binds to the IL1 Type 1 receptor and competitively inhibits IL1 binding. The interaction between anakinra and the IL1 receptor does not activate the IL1 receptor accessory protein, thus no signal transduction cascade ensues.

Aside from adult rheumatoid arthritis, anakinra has been reported to exhibit clinical efficacy in the management of other inflammatory conditions, including Still disease, polyarticular juvenile rheumatoid arthritis, Muckle-Wells syndrome, and NOMID. This is a chronic inflammatory condition which presents during early childhood with a constellation of clinical findings that include an urticarial cutaneous eruption, central nervous system abnormalities, and bone deformities. A recent study to address the efficacy of anakinra in the management of NOMID reported a rapid clinical response to daily injections (1–2 mg/kg) with all patients achieving marked clearing of their cutaneous disease.[22] A small study to address the long-term safety and efficacy of anakinra among NOMID patients reported sustained clinical improvement for 26–42 months (the duration of follow-up) with no adverse events aside from mild injection-site reactions.[23]

Clinical trials have suggested a small increased risk for infection among anakinra treated patients. Thus, treatment should not be initiated among patients with an active infection. The use of this drug in combination with TNF-inhibitor therapy should be avoided. Anakinra is contraindicated among patients with known allergies to *Escherichia coli*-derived proteins. The most common side effect associated with treatment is injection site reaction.

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR.

Granulocyte-macrophage colony-stimulating factor (GM-CSF) is a growth factor that induces the proliferation of myeloid precursors and is involved in the proliferation, differentiation, and migration of dendritic cells.[24] In the dermatologic setting, GM-CSF has been reported to exhibit efficacy as a wound-healing agent by promoting the proliferation of keratinocytes in the setting of ulcerated, diseased skin.[25,26] It has also been utilized as an antitumor agent in the treatment of melanoma and CTCL.

Regression of in-transit melanoma and cutaneous metastases have been reported with the administration of intralesional recombinant GM-CSF.[27,28] A phase II trial in which GM-CSF was administered to postsurgical, clinically disease-free, stage III or IV melanoma patients reported enhanced survival among treated patients compared to matched historical controls.[29] It has also been used as an adjuvant in combination with other treatment modalities for the treatment of melanoma.[30,31]

GM-CSF has been shown to induce the differentiation and proliferation of antigen-presenting cells,[32] and may contribute toward disease improvement in CTCL through its ability to replete antigen-presenting cell populations, which are reduced in Sézary syndrome patients. Recombinant human GM-CSF has been used as adjuvant therapy in the treatment of patients with Sézary syndrome. Clinical improvement was reported in a patient treated with an aerosolized form of the medicine.[33] Recombinant human GM-CSF dosing for the treatment of dermatologic disease has not been standardized. GM-CSF was used in combination with other immune modulating therapies for the treatment of Sézary syndrome leading to enhanced clinical responses in a non-placebo controlled study.[6] Associated side effects include fatigue, myalgia, injection site reactions, and generalized cutaneous reactions. GM-CSF is contraindicated for use in patients with a known hypersensitivity to the drug or any of its components. Administration of this drug concurrently with chemotherapy is not recommended, as some combinations may increase myelosuppression. GM-CSF is a pregnancy category C medication with unknown safety during lactation.

RECOMBINANT HUMAN PLATELET-DERIVED GROWTH FACTOR.

(see also Chapter 235) Platelet-derived growth factor (PDGF) is a peptide produced by platelets, macrophages, neutrophils, and smooth muscle cells that has proven to be of clinical benefit for the management of chronic wounds. It consists of two polypeptide chains (A and B) that form dimers linked by disulfide bonds. The PDGF-BB homodimer has been shown to promote granulation tissue formation, wound angiogenesis, re-epithelialization, and the proliferation of fibroblasts and smooth muscle cells in the cutaneous microenvironment. It is currently the only growth factor approved by the FDA for the treatment of diabetic foot ulcers.

Several randomized control studies have reported the efficacy of PDGF-BB for the treatment of pressure

ulcers and lower extremity ulcers in diabetic patients. A phase III study reported significant efficacy of PDGF-BB in the time required to achieve complete wound closure for the treatment of chronic diabetic neuropathic ulcers of the lower extremities.[34] This multicenter, double-blind, placebo-controlled study reported a 43% increase in the incidence of wound closure, and a 32% reduction in the time required to achieve complete wound closure compared to patients receiving a placebo gel. When combined with good wound care, daily application of PDGF has been found to substantially improve time to healing of chronic diabetic neuropathic foot ulcers.[35]

PDGF-BB (100 μg/g) is distributed as a topical gel that should be applied daily and refrigerated when not in use. Studies addressing the safety of recombinant human PDGF-BB found no increased risk for cardiovascular, respiratory, musculoskeletal, or central nervous system disorders among patients with lower extremity diabetic neuropathic ulcers treated with topical PDGF-BB compared to patients treated with placebo or general ulcer care.[36] Patients receiving PDGF-BB therapy did not develop neutralizing antibodies to the drug, nor did they exhibit an increase in mortality relative to placebo. Cutaneous eruptions have been reported but are uncommon. Recombinant PDGF-BB is contraindicated for use in patients with a known hypersensitivity to the drug or any of its components. It also should not be applied to sites affected by cutaneous neoplastic disease. PDGF-BB is a pregnancy Category C medication with unknown safety during lactation. In 2008, a black box warning was added to the safety labeling of this drug as it was associated with an increase in cancer mortality among patients treated with three or more tubes (15 g/tube) of the gel.

ANTIBODY-BASED THERAPEUTICS

Advances in immunobiology have led to our ability to synthesize antibodies that target specific cytokines and cell surface receptors. By utilizing them to interrupt specific signaling cascades, we have been able to manipulate immune responses through the activation or suppression of pathways mediating inflammation, tolerance, and antitumor immunity. The structural nature of a recombinant antibody can be determined by the suffix associated with its name [*-ximab*: chimeric monoclonal antibody (a hybrid antibody consisting of human and murine antibody components), *-zumab*: humanized monoclonal antibody, *-umab*: human monoclonal antibody, *-cept*: antibody fusion protein that mimics immunoglobulin].

ANTIBODIES AGAINST CYTOKINES

(See Chapter 11)

ANTITUMOR NECROSIS FACTOR. Antitumor necrosis factor-α (anti-TNF-α) is a cytokine that has been linked to the pathogenesis of psoriasis and other inflammatory conditions including psoriatic arthritis, rheumatoid arthritis, and inflammatory bowel disease. It is produced by multiple cell types in the skin (keratinocytes, Langerhans cells, and dermal mast cells),[37] which are believed to contribute to the pathogenesis of inflammatory dermatoses (see Fig. 234-2). TNF triggers its effects by binding to its p55 and p75 receptors expressed primarily on the surface of keratinocytes, neutrophils, endothelial cells, and fibroblasts. In combination with other proinflammatory cytokines, it is believed to be involved in the recruitment of immune cells to the cutaneous microenvironment.[38] TNF may also contribute to both the inhibition of keratinocyte apoptosis and the induction of keratinocyte proliferation in psoriasis.[39,40]

Psoriasis is a chronic inflammatory condition of the skin that affects over 2% of the adult population.[41] Elevated levels of TNF-α have been detected in the cutaneous lesions of psoriasis patients.[42] Murine studies support a role for TNF-α in the activation and proliferation of lymphocytes, which induce psoriatic lesions.[43] Elevated TNF-α levels have also been reported in patient serum and has been shown to correlate with disease activity.[44,45]

Three biologics, which inhibit TNF-α are approved for psoriasis: (1) infliximab, (2) adalimumab, and (3) etanercept. Infliximab and adalimumab are antibody-based therapeutics, whereas, etanercept is a fusion protein. Although all three drugs inhibit TNF-α, they are structurally different and have unique pharmacodynamic and pharmacokinetic profiles. Given their shared molecular target, certain of their properties will be discussed together as a "class" for comparative purposes in this section. Etanercept will be reviewed in more detail in the Section "Fusion Proteins."

Infliximab and adalimumab bind to both soluble and membrane-bound TNF, whereas etanercept binds primarily to soluble TNF.[46] Infliximab and adalimumab also have a greater propensity to induce lymphocyte apoptosis compared to etanercept, as they can lyse cells with membrane-bound TNF through complement activation and/or antibody-dependent, cell-mediated cytotoxicity.[47] Given its inability to effectively associate with membrane-bound TNF, etanercept is incapable of activating complement-mediated apoptotic pathways. In terms of pharmacokinetics, the subcutaneous administration of adalimumab and etanercept yields smooth and uniform concentration time profiles at steady state, whereas the intravenous dosing of infliximab results in very high peak-to-trough ratios.[48] Infliximab binds TNF quickly and irreversibly, whereas etanercept sheds about 50% of soluble TNF within 10 minutes of binding.[47] The pharmacodynamic, pharmacokinetic, and structural differences between TNF inhibitors may result in differing safety and efficacy profiles. While infliximab appears to be more efficacious than etanercept in the management of autoimmune granulomatous diseases such as Crohn disease, sarcoidosis, and granulomatosis with polyangiitis (Wegener's); its use[47] has been associated with a higher risk of granulomatous infections.[49]

Indications. Etancercept, infliximab, and adalimumab are FDA approved for the treatment of

moderate/severe plaque-stage psoriasis and psoriatic arthritis. Additionally, etanercept is FDA approved for rheumatoid arthritis, ankylosing spondylitis, and juvenile rheumatoid arthritis; infliximab is approved for rheumatoid arthritis, Crohn disease, ulcerative colitis, and ankylosing spondylitis; and adalimumab is approved for rheumatoid arthritis, juvenile idiopathic arthritis, ankylosing spondylitis, and Crohn disease. Other TNF inhibitors, without dermatologic indications, have also been approved by the FDA and include golimumab (for the treatment of rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis) and certolizumab pegol (for the treatment of Crohn disease and rheumatoid arthritis).

Case reports and small case series suggest potential efficacy of TNF-α inhibitors for the management of numerous inflammatory dermatologic conditions that include apthous stomatitis, Behcet disease, cicatricial pemphigoid, dermatomyositis, eosinophilic fasciitis, hidradenitis suppurativa (HS), multicentric reticulohistiocytosis, necrobiosis lipoidica diabeticorum, pityriasis rubra pilaris, pyoderma gangrenosum, sarcoidosis, scleroderma, Sneddon-Wilkinson syndrome, and SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteitis) syndrome.[50] A phase 2, randomized, placebo-controlled trial conducted at a single institution reported a higher response rate among HS patients treated with infliximab (5 mg/kg on weeks 0, 2, and 6) compared to placebo. More specifically, a greater percentage of infliximab-treated patients achieved a >50% reduction in baseline HS Severity Index (HSSI) score at week 8 compared to placebo.[51] In addition, 60% of infliximab-treated patients achieved a 25% to 50% reduction in HSSI compared to 6% of placebo.

Initiating Therapy and Monitoring. TNF inhibitors have been the most extensively studied class of biologics and therefore they have detailed and relatively robust safety data compared to other biologics. TNF inhibitors are immunosuppressive, and therefore, patients should be carefully screened for signs and symptoms of malignancy and infection prior to initiating therapy as well as during the course of treatment. Product labeling and published guidelines recommend screening for latent tuberculosis infection with a tuberculin skin test prior to initiating therapy with etanercept, infliximab, and adalimumab.[52] A whole blood test, such as QuantiFERON-TB gold or T-SPOT. TB assay, is an alternative screening method that offers higher specificity and comparable sensitivity to the traditional tuberculin skin test. It is particularly useful among BCG-vaccinated individuals who are more likely to exhibit a false-positive PPD reaction. TNF inhibitors should be used with caution in patients with a history of congestive heart failure—infliximab at doses >5 mg/kg is contraindicated in patients with moderate-to-severe congestive heart failure.

Infliximab may be associated with liver function test abnormalities, which, in rare cases, have led to hepatic failure. Additionally, TNF inhibitors have been associated with reactivation of hepatitis B in patients who are chronic carriers. Some of these cases have been fatal; therefore, one should consider monitoring liver function tests during TNF therapy and screening at-risk patients for hepatitis B. Small cases series suggest that TNF inhibitors can be used safely in patients with Hepatitis B when lamivudine is given concurrently. Larger studies, however, will be necessary to further substantiate these findings.[53] No exacerbation of liver disease has been reported among hepatitis C-positive patients receiving TNF inhibitor therapy. In fact, it has been suggested that TNF inhibitor therapy may contribute toward improving clinical outcomes among this patient population given their potential to suppress TNF-induced hepatic inflammation and fibrosis.[54,55] A recent multicenter study addressing the efficacy of etanercept in the treatment of alcoholic hepatitis reported increased mortality among patients with moderate-to-severe disease after 6 months of therapy; thus, the use of TNF inhibitors in this setting should be avoided if possible.[56]

Risks, Precautions, and Complications

Infection. TNF inhibitors are associated with serious infections including pneumonia, sepsis, tuberculosis, histoplasmosis, coccidioidomycosis, and other invasive fungal infections, thus accounting for the black box warning for infection. Product labeling also indicates that for patients who have resided in regions where histoplasmosis and coccidioidomycosis are endemic, the risks and benefits of TNF inhibitor therapy should be carefully considered. A recent meta-analysis of rheumatoid arthritis patients treated with infliximab or adalimumab in randomized controlled trials suggested that use of these agents result in one excess serious infection for every 59 patients treated for a period of 3–12 months.[57] Use of etanercept with anakinra has been associated with an increased risk of serious infections, and therefore, it is recommended that anakinra not be used concurrently with any TNF inhibitor. One prospective study reported an increased incidence of herpes zoster among rheumatoid arthritis patients treated with anti-TNF monoclonal antibodies (adalimumab, infliximab) compared to conventional disease-modifying antirheumatic drugs (DMARDs).[58] A meta-analysis addressing the risk of serious infections (infection requiring antibiotic treatment and/or hospitalization) among rheumatoid arthritis patients treated with adalimumab and infliximab reported a significantly increased risk for such infections compared to placebo.[57] Another meta-analysis addressing the risk of serious infections among RA patients treated with adalimumab, etanercept, or infliximab, with and without adjustment for exposure, reported no increased risk of serious infection at manufacturer recommended doses, however, there was a two-fold increased risk of serious infection among patients treated with higher doses (two to three times the recommended dose).[59]

Malignancy. A black box warning for malignancy was added to the product labeling of TNF inhibitors after cases of lymphoma and other malignancies were reported among adult and pediatric patients.

A meta-analysis [data from 9 randomized controlled trials (RCTs)] of 3,493 RA patients treated with adalimumab or infliximab demonstrated an increased risk of solid organ malignancies.[57] This increased risk proved to be dose dependent. Nonmelanoma skin cancers accounted for the majority of reported malignancies followed by lymphoma in this study. Infliximab has been associated with aggressive hepatosplenic T-cell lymphomas in postmarketing surveillance of patients with Crohn disease treated with concomitant azathioprine or 6-mercaptopurine. Additionally, aggressive cutaneous T-cell lymphomas have been reported in patients receiving TNF inhibitors.[60] A meta-analysis integrating data from 18 randomized control trials, involving 8,808 RA subjects, reported no increased risk for lymphoma, nonmelanoma skin cancer, and melanoma among patients treated with adalimumab, etanercept, and infliximab.[59]

A comprehensive review of the literature addressing the risk of lymphoma among patients receiving biologic therapy suggests the use of such agents to be safe with respect to lymphoma risk among those treated for a limited time (up to 4 years).[61] A meta-analysis addressing the risk of malignancies among rheumatoid arthritis patients reported a higher point estimate of malignancy among etanercept-treated patients compared to placebo, however, the results were not statistically significant.[62] Current data are insufficient to definitively rule out an increased risk of lymphoma, or causal relationship between biologic therapies and lymphoma. The largest observational study to date suggests a slightly higher risk of lymphoma associated with adalimumab and infliximab compared to etanercept in the French population.[63]

It remains unclear whether the excess risk of lymphoma reported in observational studies is due to the TNF inhibitor or the severity of the underlying disease (e.g., rheumatoid arthritis), which itself may portend a greater risk of lymphoma. Psoriasis patients may also have an increased risk of lymphoma, independent of biologic therapy and therefore additional studies will be necessary to determine if long-term exposure to biologics impacts lymphoma risk in psoriasis patients.[64]

Neurological Events. TNF inhibitors have been associated with rare cases of new onset demyelinating disease and with exacerbation of clinical and radiologic findings in patients with a history of demyelinating disease (e.g., multiple sclerosis).

Autoimmunity. TNF inhibitors may be associated with the development of antinuclear antibodies and antidouble-stranded DNA antibodies compared to placebo, the clinical significance of which is unknown. Rarely, TNF inhibitors have been associated with lupus-like syndromes and vasculitis.

Immunizations. TNF inhibitors may lower the titer response to immunizations; however, the clinical significance of this observation is unknown. Most patients with psoriatic arthritis receiving etanercept were able to mount effective B-cell immune responses to pneumococcal polysaccharide vaccine. Live vaccines should not be used in patients taking TNF inhibitors.

Hematologic Events. Rare cases of serious hematologic events have been associated with TNF inhibitors.

Other Events. Cases of worsening congestive heart failure, in addition to new onset cases, have been reported. Psoriasiform eruptions, both pustular and plaque-like, have also been reported among patients treated with TNF inhibitors. The onset of this paradoxical reaction may occur anywhere from one month to several years after initiation of therapy. The majority of cases have been reported among RA patients and have been primarily pustular in nature.[65,66] Discontinuation of the medication and initiation of oral immunosuppressants (methotrexate, cyclosporine, prednisone) +/− topical steroid therapy has led to clinical improvement/resolution of the lesions.

Pregnancy and Lactation. TNF inhibitors are pregnancy category-B medications with unknown safety during lactation.

INFLIXIMAB. Infliximab is a 149-kDa monoclonal chimeric antibody that consists of a murine antigen-binding region with specificity for human TNF-α fused to a human IgG1 constant region. A phase III, double-blind, placebo-controlled trial in patients with psoriasis reported that 80% of patients treated with infliximab (5 mg/kg) achieved a PASI 75 at week 10, whereas, at week 50, 61% of patients achieved a PASI 75.[67] This decrease in response over time has been reported in other clinical settings as well. When utilized as a monotherapy for Crohn disease, a shorter duration of response and higher risk for infusion reactions has been attributed to the formation of antibodies against infliximab.[68]

By nature of its chimeric structure, infliximab may be targeted by the host immune system if the murine portion of its structure is identified as foreign.[69] Neutralizing antibodies generated against infliximab have also been reported among patients treated for rheumatoid arthritis and psoriasis.[67,70] Strategies to decrease the formation of neutralizing antibodies include use of concomitant immunosuppressive medications (e.g., methotrexate), and regular (as opposed to intermittent) dosing of the drug. Infliximab is also associated with the development of ANA and antidouble-stranded DNA antibodies, the clinical significance of which is unknown. (See Section "Anti-TNF-α" for greater detail on indications, initiating, and monitoring therapy, risks, precautions, and complications.)

Infliximab is administered intravenously as a 5-mg/kg dose over 2–3 hours on weeks 0, 2, 6, and every 8 weeks thereafter. Infliximab has a serum half-life of ~9 days. Through its ability to neutralize both membrane-bound and soluble TNF-α, infliximab is believed to decrease cutaneous inflammation and promote keratinocyte differentiation in psoriatic plaques. In-vitro studies also suggest that infliximab may promote disease improvement through an ability to induce apoptosis of lesional keratinocytes.[71]

Although infliximab has demonstrated marked clearing of psoriasis, several recent reports have

suggested the potential for infliximab to induce or exacerbate psoriatic disease via unknown mechanisms.[72]

ADALIMUMAB. Adalimumab is a fully human 148-kDa monoclonal antibody against TNF-α. Similar to infliximab, it inhibits TNF-α signaling by binding to both soluble and membrane-bound forms. Adalimumab is administered as a subcutaneous injection with a serum half-life of 10–20 days. Psoriasis patients receive an 80-mg dose at week 0, followed by a 40-mg dose 1 week later and then every other week thereafter.

The short- and long-term efficacy of adalimumab has been evaluated among 1,212 patients with moderate-to-severe chronic plaque psoriasis in a phase III randomized, double-blind, placebo controlled trial.[73] After 16 weeks of treatment, 71% of adalimumab-treated patients achieved a PASI 75 compared to 7% of placebo. At week 33, adalimuab-treated patients who had achieved a PASI 75 were rerandomized 1:1 to continue receiving adalimumab or placebo through week 52. Among these patients, 5% of those who continued to receive adalimumab experienced a loss of adequate response (i.e., a <50% improvement in PASI response relative to baseline) compared to 28% of patients who were rerandomized to placebo. These findings, in combination with the results of the open-label extension study of this trial, support the notion that continuous therapy may be necessary to achieve sustained clinical responses among patients.[73] A randomized trial comparing the efficacy and safety of adalimumab to methotrexate reported the superior efficacy of adalimumab after 16-weeks of therapy.[74] More specifically, 80% of the adalimumab group achieved PASI 75 compared to 36% and 19% of the methotrexate and placebo groups, respectively. Two severe adverse events were reported in each treatment group.

Antibody formation against adalimumab has also been reported. One study addressing the clinical implications of this phenomenon found that psoriasis patients with low serum adalimumab trough concentrations, secondary to antibody formation, were more likely to exhibit a lack or loss of response to treatment compared to patients with higher trough concentrations.[75] Injection site reactions occur with adalimumab, however, they are generally mild and self-limited. (See Section "Anti-TNF-α" for greater detail on indications, initiating, and monitoring therapy, risks, precautions, and complications.)

ANTI-INTERLEUKIN 12 /INTERLEUKIN 23. Ustekinumab is a human IgG1k monoclonal antibody that is FDA approved for the treatment of moderate-to-severe plaque psoriasis. Ustekinumab targets the p40 subunit of IL12 and interleukin 23 (IL23). These cytokines are involved in the activation of natural killer cells and the differentiation of naive $CD4^+$ T-cells into Th1 and Th17 effector cells. Upon activation, Th17 cells secrete multiple cytokines, including interleukin 17 (IL17) and interleukin 22 (IL22). IL22 has been shown to contribute to the epithelial dysregulation and abnormal proliferation of keratinocytes characteristic of psoriasis and has been strongly implicated in its pathogenesis. High levels of p40 mRNA have been detected in psoriatic plaques; whereas, a notable reduction in its expression has been reported in clinically improved lesions after treatment.[76]

Several studies have addressed the efficacy and safety of ustekinumab for the treatment of patients with moderate-to-severe psoriasis. A phase III, double-blind, placebo-controlled trial found that 66.7% of patients receiving ustekinumab 45 mg (at weeks 0, 4, and every 12 weeks thereafter) achieved a PASI 75 by week 12, compared to 75.7% of patients receiving ustekinumab 90 mg, and 3.7% placebo.[77] A study comparing ustekinumab to the TNF inhibitor etanercept among patients with moderate-to-severe psoriasis reported superior efficacy of ustekinumab at a dose of 45 or 90 mg (at weeks 0 and 4) compared to etanercept at a dose of 50 mg twice weekly over a 12 week period.[78] A PASI 75 was achieved by 73.8% and 67.5% of ustekinumab treated patients at doses of 45 mg and 90 mg, respectively, compared to the etanercept treatment group, among whom 56.8% achieved a PASI 75 at week 12 ($p \leq 0.01$). A higher incidence of injection site reactions was reported among the etanercept treatment group; otherwise, the proportion of adverse events was comparable between the two treatment groups.

Indications. Ustekinumab was approved by the FDA in 2009 for the treatment of adult patients with moderate-to-severe plaque psoriasis who are candidates for systemic and/or phototherapy.

Initiating Therapy and Monitoring. Ustekinumab should only be administered by a healthcare provider. Dosing of the medication is weight based. Patients under 100 kg receive an initial 45-mg SC dose, which is repeated 4 weeks later. Subsequent dosing is administered every 12 weeks. Patients weighing over 100 kg receive a 90-mg dose with the same aforementioned dosing schedule. The serum half-life for ustekinumab has been reported to range from 14.9 +/− 4.6 days to 45.6 +/− 80.2 days according to the package insert. Ustekinumab is a pregnancy category-B medication with unknown safety during lactation.

Risks, Precautions, and Complications. The most commonly reported adverse events associated with ustekinumab were nasopharyngitis, upper respiratory tract infections, headache, and fatigue. Injection site reactions have also been reported but are less common.

Given its immunosuppressive properties, ustekinumab may increase one's risk for infection and certain cancers. Studies among patients with an inherited deficiency of IL12/IL23 have shown an increased risk for viral and bacterial infections (*Salmonella* and mycobacterial).[79–81] Thus, prospective patients should be screened for tuberculosis prior to initiating therapy. Ustekinumab should not be administered to patients with active or latent tuberculosis until they have undergone treatment. The BCG vaccine should be avoided for at least one year before, during, or after treatment with ustekinumab.

One case of reversible posterior leukoencephalopathy syndrome (RPLS) was reported among patients

treated with ustekinumab during its clinical development. RPLS is a noninfectious syndrome characterized by headache, visual changes, seizures, and confusion. It has multiple ascribed etiologies including hypertension, electrolyte abnormalities, and a reaction to medications. Patients should be monitored for RPLS symptoms during the course of therapy. Live vaccines are contraindicated during treatment. The safety and efficacy of ustekinumab beyond 2 years of therapy remains undetermined. Large long-term studies of ustekinumab will be necessary in order to define the risk of cancer and serious infections with this novel agent.

ANTIBODIES AGAINST CELL SURFACE RECEPTORS

EFALIZUMAB. Efalizumab is a recombinant humanized monoclonal IgG1 antibody against the α-subunit of the leukocyte function-associated antigen 1 [LFA-1, CD11a (Fig. 234-1)]. LFA-1 is a member of the β-2 integrin family and is involved in lymphocyte activation, enhanced cytotoxic T-cell function, and the trafficking of lymphocytes to the skin (see Fig. 234-2). In both short- and long-term studies, efalizumab has exhibited efficacy in the treatment of patients with moderate-to-severe psoriasis. Efalizumab was withdrawn from the United States market in April 2009 after three cases of progressive multifocal leukonencephalopathy (PML) were reported among patients receiving the drug. PML is a rare, life-threatening infection that is most prevalent among immunosuppressed individuals. It is caused by the JC virus, a typically harmless virus among immunocompetent individuals.

RITUXIMAB. Rituximab is a humanized chimeric monoclonal antibody against CD20, a cell surface protein expressed by mature and pre-B cells. It has been shown to induce the depletion of B-cells in vivo. CD20 expression is lost during the differentiation of B-cells to plasma cells. Aside from playing a crucial role in antibody production, B-cells may also serve as antigen presenting cells and have been shown to provide costimulatory signals, which promote $CD4^+$ T-cell expansion and effector cell function.[82]

Rituximab is FDA approved for the treatment of patients with moderate-to-severe rheumatoid arthritis and for the treatment of relapsed or chemorefractory (low-grade or follicular) $CD20^+$ non-Hodgkin B-cell lymphomas and has been shown to transiently reduce the population of $CD20^+$ cells in the circulation.[83] This effect is achieved by its ability to enhance antibody and complement-mediated cytotoxicity, and promote the apoptosis of malignant $CD20^+$ cells.[84] Aside from its role in the treatment of lymphoma and rheumatoid arthritis, rituximab has been increasingly used off-label for the management of other autoimmune diseases. More specifically, reports have suggested its efficacy for the treatment of paraneoplastic and refractory pemphigus, autoimmune hemolytic anemia, granulomatosis with polyangiitis (Wegener's) hypocomplementemic urticarial vasculitis, systemic lupus erythematosus (SLE), cutaneous B-cell lymphoma, chronic graft-versus-host disease, and epidermolysis bullosa acquisita.

Caution, however, should be taken before initiating therapy with rituximab for off-label use. Two cases of PML were reported to the FDA in 2006 involving patients who received rituximab for the treatment of SLE.[85] Recent reports have also noted marked progression of Kaposi sarcoma among patients treated for autoimmune hemolytic anemia and Castleman disease.[86,87]

In a case series of patients receiving rituximab for autoimmune bullous disorders (pemphigus vulgaris, bullous pemphigoid, and mucous membrane pemphigus), severe adverse reactions were noted in three of seven patients.[88] These reactions, which consisted of serious infections, enteropathy, and pulmonary embolism, were believed to be associated with concurrent high-dose adjuvant immunosuppression and underlying malignancy among the affected individuals. In a study involving 11 patients with refractory pemphigus vulgaris treated with rituximab and intravenous immune globulin, no infections or other clinically significant adverse effects were noted.[89] Additionally, no severe adverse effects were reported in case series and open-label studies among patients treated with intralesional and/or intravenous rituximab for cutaneous B-cell lymphoma and dermatomyositis.[90] A study addressing the safety of rituximab for the treatment of diffuse cutaneous systemic sclerosis (among 15 patients) reported mild infusion reactions (affecting 46% of patients), urinary tract infection and a dental abscess affecting a single patient, and one case of prostate cancer at six month follow-up.[91]

Indications. Rituximab is FDA approved for the treatment of $CD20^+$ non-Hodgkin's B-cell lymphomas and moderate-to-severe rheumatoid arthritis.

Initiating Therapy and Monitoring. No specific dosing regimen has been established for the off-label use of this medicine in the dermatologic setting. Rituximab is usually administered at a standard dose of 375-mg/m^2 body surface area at weekly intervals. Premedication with acetaminophen and antihistamines should be considered to decrease the risk for infusion reactions. Monitoring of blood cell counts and serum antibody levels may be pursued every 2–3 months while on therapy. A rapid depletion of $CD20^+$ B-cells occurs after treatment and may last from 2–6 months before recovery. Live vaccines should not be administered to patients prior to and during therapy.

Rituximab is a pregnancy category C medication with unknown safety during lactation.

Risks, Precautions, and Complications. Reported adverse effects associated with rituximab therapy include fatal infusion reactions, vasculitis, hepatitis B reactivation, tumor lysis syndrome, renal toxicity, severe mucocutaneous reactions, cardiac arrhythmias/angina and bowel obstruction/perforation. Cases of PML have been reported among patients

with lymphoid malignancies and SLE treated with rituximab.[92]

FUSION PROTEINS

ALEFACEPT

Alefacept is a bioengineered protein consisting of the human IgG1 antibody Fc region fused to the first extracellular domain of human lymphocyte function-associated antigen-3 (LFA-3). LFA-3 is a member of the immunoglobulin superfamily and is expressed on the surface of antigen presenting cells (see Fig. 231-2). It normally binds to CD2 which is preferentially expressed on the surface of effector/memory T-cells, an interaction that plays an important role in the activation of T-cells in response to antigen. Alefacept is believed to prevent the activation of T-cells by blocking this interaction (see Fig. 231-1).[93] In addition, it may induce the apoptosis of memory T-cells via binding of its IgG1 portion to the CD16 receptor of natural killer cells.[94]

INDICATIONS. Alefacept was the first biologic agent FDA approved for the treatment of psoriasis in 2003. Studies have evaluated the efficacy of both intravenous and intramuscular dosing (7.5-mg IV qwk and 15-mg IM qwk), however, only the IM form is commercially available at this time. A randomized, placebo-controlled phase III trial of adult patients with chronic plaque psoriasis involving at least 10% body surface area was performed to address the efficacy and safety of alefacept therapy (15-mg IM qwk) for 12 weeks.[95] PASI 75 responses were achieved by 21% of treated patients. Among this group, 71% maintained at least a PASI 50 in the 12-week follow-up period. No opportunistic infections or disease rebound was noted during this time.

Reports of off-label use of alefacept in the treatment of other inflammatory dermatoses such as graft versus host disease, lichen planus and alopecia areata have been published.[96,97] A randomized, double-blind , placebo-controlled study found alefacept to be ineffective for the treatment of patients with severe alopecia areata.[98] Alefacept has shown promise in the treatment of psoriatic arthritis as a monotherapy and in combination with methotrexate.[99,100]

INITIATING THERAPY AND MONITORING. Alefacept is contraindicated in patients with HIV infection and should not be used in patients with a $CD4^+$ T lymphocyte count that is below normal. On the basis of published studies and manufacturer recommendations, alefacept treatment is typically initiated as a 15-mg intramuscular dose administered on a weekly basis for 12 weeks, followed by a 12-week period of nontreatment observation. The serum half-life of alefacept is approximately 12 days. Improved efficacy may be achieved by increasing the initial treatment course to 16 weeks.[101] Phase III clinical trials have shown increased efficacy of alefacept after successive courses of treatment (up to five courses) with no observed compromise in safety or tolerability.[102,103]

Upon initiation of therapy, CD4 and CD8 T-cell counts should be monitored every 2 weeks and treatment should be withheld if the CD4 count drops below 250 cells/μL; counts should then be monitored weekly. If the CD4 count remains below 250 for over 4 weeks, treatment should be discontinued. In general, alefacept should not be initiated in patients with low CD4 counts or an active infection within 2 weeks of therapy. Treatment of patients with a history of a prior malignancy should be pursued with caution.

Alefacept is a pregnancy category B medication with unknown safety during lactation.

RISKS, PRECAUTIONS, AND COMPLICATIONS. Alefacept is well tolerated with a limited side effect profile. Pooled data from randomized controlled trials revealed a low incidence of malignancy among treated patients, which was similar to untreated patients. Abnormalities in liver function tests were more frequent compared to placebo, and serious liver reactions have been reported in postmarketing studies. No correlation between $CD4^+$T-cell counts and infection has been reported. $CD4^+$ T-cell mediated antibody titer responses to external antigens appear to remain intact after treatment.[104] Large, long-term follow up studies will be necessary to determine if the immunosuppressive properties of alefacept increase the risk of serious infections and malignancies.

ETANCERCEPT

Etanercept is a fusion protein consisting of the human TNF type II receptor linked to a human IgG1 Fc region, already briefly discussed with the anti-TNF agents. It blocks the effects of TNF-α by binding to it in the circulation, thus preventing it from associating with its cell surface receptor. In a double-blind, placebo-controlled study, 49% of psoriatic patients treated with high-dose etanercept (50 mg twice weekly) for 12 weeks achieved at least a PASI 75, whereas only 4% of patients in the placebo group attained this result.[105] Continued clinical improvement was noted in the subsequent weeks with 59% of high-dose etanercept-treated patients achieving PASI 75.

In a study addressing the efficacy of etanercept for the treatment of children and adolescent patients with moderate-to-severe plaque psoriasis, patients were randomly assigned to a double-blind trial of weekly subcutaneous etanercept (0.8 mg/kg to a maximum of 50 mg) or placebo.[106] After 12 weeks, 57% of patients receiving etanercept achieved a PASI 75 compared to 11% of placebo ($p<0.001$). Over the following 24 weeks, both groups received open-label etanercept. Four serious adverse events were reported (three infections and one ovarian cyst removal). Overall, etanercept may offer a relatively safe and efficacious treatment option for pediatric patients with advanced plaque psoriasis.

For adults, etancercept is initiated at a dose of 50-mg SC 2×/week for 12 weeks, then reduced to 50-mg qwk (or 25-mg SC twice weekly). The median time to relapse

after discontinuation of therapy after 6 months is estimated at 70–91 days.[107] The serum half life of etanercept is between 4 and 25 hours. Injection site reactions may occur with etanercept; however, they are generally mild and self-limited. (See Section "Anti-TNF-α" for greater detail on indications, initiating and monitoring therapy, risks, precautions, and complications.)

DENILEUKIN DIFTITOX

Denileukin diftitox (DAB389-IL2) is a ligand-toxin fusion protein consisting of a fragment of diphtheria toxinfused to interleukin-2 (IL2). DAB389-IL2 is believed to associate with malignant cells expressing the high-affinity IL2 receptor. Upon binding to the receptor, it is internalized within endosomes, where its ADP-ribosyltransferase region is cleaved and translocated into the cytoplasm. In the cytoplasm, it interrupts protein synthesis, eventually leading to apoptosis of the affected cell.

CD25 represents the α-chain of the IL2 receptor. It serves both as a marker for activated T-cells, as well as for a unique population of $CD4^+$ T-cells that express the transcription factor, FoxP3, called regulatory T-cells ($CD4^+CD25^+FoxP3^+$). Naturally occurring regulatory T-cells exhibit immunosuppressive properties and have been shown to play an important role in the induction of immune tolerance. Murine melanoma models indicate a role for regulatory T-cells in suppressing antitumor immunity.[108] In addition, the in-vivo use of anti-CD25 specific antibody was shown to deplete regulatory T-cell populations and enhance tumor regression in the murine system.[109] Because of its ability to deplete $CD25^+$ T-cells, DAB389-IL2 may contribute to antitumor immunity by eliminating regulatory T-cells in addition to malignant cells that express the CD25 component of the IL2 receptor.

A recent study examining the ability of DAB389-IL2 to eliminate regulatory T lymphocytes among human patients with metastatic melanoma revealed neither any significant change in Foxp3 levels nor objective clinical response among treated patients.[110] Studies of other human malignancies in which large populations of regulatory T cells were present exhibited a notable reduction in circulating regulatory T-cells and enhanced effector T-cell activation in response to DAB389-IL2.[111] Thus, the ability of DAB389-IL2 to eliminate regulatory T cells and enhance antitumor immunity in human malignancies requires further study. In addition, its effects on $CD25^+$ nonregulatory effector T-cells, which also play an important role in antitumor immunity, is under investigation.

In a phase III double-blind, placebo-controlled study, patients with advanced or refractory cutaneous T-cell lymphoma were randomized to receive DAB389-IL2 by infusion at doses of 9μg/kg/day or 18μg/kg/day.[112] All patients had failed at least one prior therapy (the median number of prior therapies was five) and were shown to have at least 20% CD25 expression among tumor cells in the skin. Treatment was administered for 5 consecutive days and was repeated every 3 weeks for up to eight treatment cycles. Intent to treat analysis revealed a 30% clinical response rate among all treated patients, characterized by a 50% reduction in tumor burden. Ten percent of patients achieved a complete clinical response characterized by no evidence of cutaneous disease. The majority of patients exhibited a clinical response within the first three treatment cycles. The durability of response was higher among complete responders with a median of 9 months. The median duration of response among partial responders was 4 months. No statistically significant difference in response was noted between the two dosing groups. Another study reported a direct correlation between CD25 expression by lesional skin in CTCL patients and response to DAB289-IL2. More specifically, 78.5% of patients with high CD25 expression, which correlated with advanced CTCL, exhibited a clinical response to DAB289-IL2, in comparison to only 20% of patients with low-to-undetectable CD25 expression.[113]

DAB389-IL2 is FDA approved for the treatment of cutaneous T-cell lymphoma in which the malignant cell population expresses the CD25 receptor. Studies have reported clinical efficacy with the use of DAB289-IL2 in the treatment of patients with moderate-to-severe plaque psoriasis; however, it is not approved for this indication.[114,115]

INITIATING THERAPY AND MONITORING.

DAB389-IL2 is administered intravenously over at least 15 minutes. Doses at 9 μg/kg/day and 18 μg/kg/day have been utilized for the treatment of cutaneous T-cell lymphoma.

DAB389-IL2 is a pregnancy category C medication with unknown safety during lactation.

RISKS, PRECAUTIONS, AND COMPLICATIONS.

Infusion-reactions represent the most common adverse effect associated with DAB389-IL2 treatment and may be characterized by fever, hypotension, arthralgias, dyspnea, rash, and chest/back tightness. DAB389-IL2 has also been associated with flu-like symptoms, a reversible transaminitis, vascular leak syndrome, and a morbilliform cutaneous eruption. DAB389-IL2 is contraindicated among patients with a known hypersensitivity to any of its components.

CONCLUSION

In this chapter, we have discussed a number of biologic agents currently available for the management of dermatologic disease. Large, prospective, long-term, follow-up studies will be necessary to fully discern the safety of these agents. As we have discussed, targeting of the immune system with biologics may result in an increased risk for serious infections and malignancies. The emergence of PML among patients treated with efalizumab, 5 years after its approval, highlights the need for ongoing pharmacovigilance of novel therapeutic agents.

Immunobiologics require complex and expensive manufacturing processes, which may ultimately limit their utilization. Because these drugs generally exhibit reduced efficacy over time, long-term disease control remains a challenge for many patients. As we further characterize the immunopathogenesis of cutaneous disease, new potential targets may be identified, thus improving our ability to manage conditions that may otherwise be poorly responsive to current therapeutic modalities.

Chapter 235 :: Antiangiogenic Agents

:: Ricardo L. Berrios, Michael Y. Bonner, Jonathan Hofmekler, & Jack L. Arbiser

ANTIANGIOGENIC AGENTS AT A GLANCE

- "Direct" antiangiogenic agents act directly on untransformed endothelial cells to prevent proliferation, migration, and survival.
- "Indirect" antiangiogenic agents inhibit tumor-produced oncogene proteins that promote a proangiogenic state.
- Antiangiogenic agents are a promising class of drugs because they are effective against slow-growing tumors.

In 1971, Judah Folkman published a landmark paper hypothesizing that all tumor growth is dependent on angiogenesis and that inhibitors of angiogenesis could be used to treat cancers.[1] The ensuing years have proven him correct and have seen the development of new agents that, either alone or in adjunct, have shown promise not only in oncology but in a variety of dermatologic conditions as well.

Antiangiogenic drugs can be classified as either "direct" or "indirect," the former acting directly on untransformed endothelial cells to prevent proliferation, migration, or survival, a process that normally occurs upon stimulation by proangiogenic molecules; and the latter by inhibition of tumor-produced oncogenic protein products that promote proangiogenic states. Angiogenesis inhibitors as a drug class provide a unique approach to cancer treatment because they are also effective against slow-growing tumors, while traditional therapies, such as chemotherapy and radiation, work best on rapidly dividing cells. In the future, the switch to an angiogenic phenotype may be able to be blocked in clinically undetectable cancers, thus preventing disease progression using therapies directed, in part, by angiogenesis biomarkers.[2,3] Current applications of these agents center on oncologic and ophthalmologic diseases but dermatologic indications are also promising.

Figure 235-1 shows the key points of action of some of the antiangiogenic drugs discussed in this chapter in normal skin, inflammatory conditions, precancerous lesions, and malignancy.

INTERFERON-α 2B (INTRON A)

(See also Chapters 231 and 234)

Interferon-α (IFN-α) made history in 1988 as the first antiangiogenic therapy used in humans, for the successful treatment of pulmonary hemangiomatosis in a pediatric patient. IFN-α 2b is a synthetic cytokine made from the bacterium *Escherichia coli* transformed with recombinant DNA, and has similar actions to its natural endogenous counterpart, IFN-α, a type I IFN produced naturally by the immune system.

MECHANISM OF ACTION

The IFNs act through the Janus kinase-signal transducers and activators of transcription (Jak-STAT) pathway. IFN-α, which is both a direct and indirect antiangiogenic agent, was first observed to impair capillary endothelial cell migration. Its properties as an indirect antiangiogenic agent include the ability to decrease tumor cell production of basic fibroblast growth factor (bFGF), which may explain its success in treating hemangiomata.[3] IFN-α has well-known antiviral activity and antitumor activity, which may be mediated in part by upregulating major histocompatibility complex class I antigen expression, activating natural killer cells, controlling progression through cell cycle checkpoints, and activating apoptosis.

INDICATIONS

Interferon-α 2B is currently indicated for the treatment of chronic hepatitis B (which may be chemopreventive against hepatocellular carcinoma), chronic hepatitis C, acquired immunodeficiency syndrome (AIDS)-associated Kaposi sarcoma, and condylomata acuminata. It is also indicated in the following malignancies: malignant melanoma (adjuvant to surgical therapy in patients at high risk of systemic recurrence; must be administered within 56 days postoperatively), hairy cell leukemia, and follicular lymphoma.[4] Off-label uses in dermatology include cutaneous T-cell lymphoma (CTCL, mycosis fungoides) and basal and squamous cell skin cancer. It has also been used in the treatment of infantile hemangiomas along with corticosteroids or in the event of corticosteroid resistance; however, given rising concerns over the risk of spastic diplegia (especially in children under 1 year of age), its utility in this setting has been somewhat tempered.[5]

CONTRAINDICATIONS

(See Box 235-1)

PHARMACOKINETICS

IFN-α 2b comes as a powder that, upon reconstitution, should be used immediately but may be stored up to

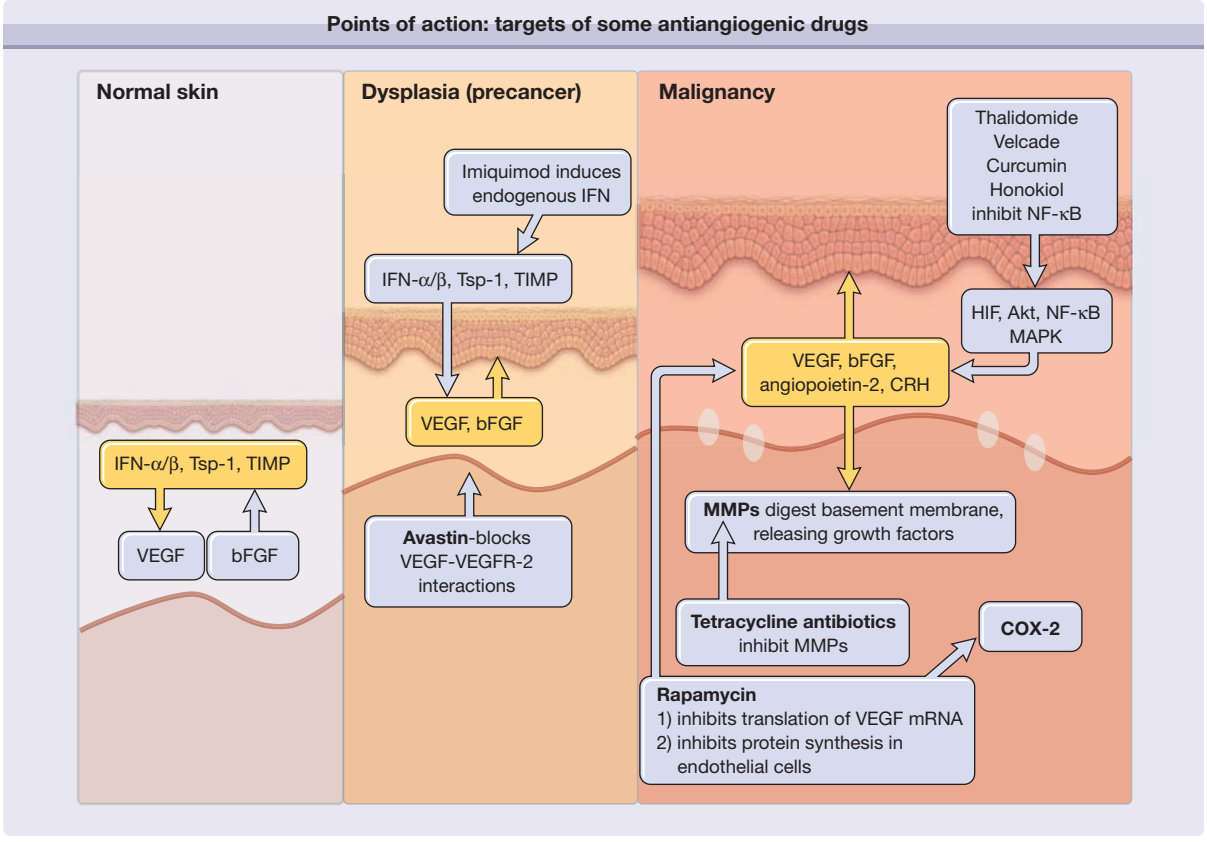

Figure 235-1 Schematic depiction of the key points of action of some of the antiangiogenic drugs discussed in this chapter in normal skin, precancerous lesions, and malignancy. bFGF = basic fibroblast growth factor; COX-2 = cyclooxygenase 2; CRH = corticotropin-releasing hormone; HIF = histoplasma inhibitory factor; IFN = interferon; MAPK = mitogen-activated protein kinase; MMP = matrix metalloproteinase; mRNA = messenger RNA; NF-κB = nuclear factor κB; TIMP = tissue inhibitor of metalloproteinases; Tsp-1 = thrombospondin 1; VEGF = vascular endothelial growth factor; VEGFR-2 = vascular endothelial growth factor receptor 2.

24 hours at 2°C–8°C (36°F–46°F). It can be given by subcutaneous (SC), intramuscular (IM), intravenous (IV), or intralesional routes. Its half-life is 3–12 hours when given SC or IM and 30 minutes when given IV. The drug is likely metabolized by the kidneys. Polyethylene glycol IFN-α 2b has a 10-fold increase in the half life, decreased toxicity, and increased compliance.[4,6] For dosing, see Table 235-1.

BOX 235-1 CONTRAINDICATIONS TO INTERFERON-α

- Hypersensitivity to IFN-α or any drug components
- Combination IFN-α and ribavirin therapy in pregnancy or in males whose female partners are pregnant
- Autoimmune hepatitis
- Personal history of a hemoglobinopathy (e.g. sickle cell disease, thalassemia major)
- Renal insufficiency (creatinine clearance <50 mL/minutes)

COMPLICATIONS[4]

(See Box 235-2)

RISKS AND PRECAUTIONS[4]

- Pregnancy category: C
- Pediatrics

The safety and efficacy in children has not established for any indications other than chronic hepatitis B and C.

BEVACIZUMAB (AVASTIN)

MECHANISM OF ACTION

Bevacizumab is a recombinant, humanized, immunoglobulin G1 monoclonal antibody against vascular endothelial growth factor (VEGF). VEGF is a growth factor that promotes angiogenesis by supporting endothelial cell replication and survival as well as vascular permeability. This potent proangiogenic molecule is

TABLE 235-1
Interferon-α 2B Dosing[4]

Disease	Dose
Malignant melanoma high-dose regimen	Induction: 20 million IU/m^2 IV infusion over 20 minutes, 5 consecutive days/week for 4 weeks Maintenance: 10 million IU/m^2 SC three times/week for 48 weeks
Malignant melanoma adjuvant low-dose regimen (in clinical trials)	Maintenance: 3 million U SC three times/week for 1 year
Acquired immunodeficiency syndrome-related Kaposi sarcoma	30 million IU/m^2 SC or IM three times/week until disease progression or maximal response has been achieved after 16 weeks
Condylomata acuminata	1 million IU per lesion (maximum of five lesions per course) three times/week on alternate days for 3 weeks. May administer additional courses at 12–16-week intervals
Hemangiomas	3 million U/m^2/day for at least 6 months.[7]

upregulated in a majority of human tumors and serves to alter tumor vasculature.

Binding of bevacizumab to VEGF is direct and specific. The antibody also competitively binds VEGF receptor 1 (VEGFR-1) and VEGFR-2, preventing VEGF from binding to its receptors and initiating the signaling cascade. It has also been shown to reduce and normalize tumor vascularity.[8]

BOX 235-2 COMPLICATIONS OF INTERFERON-α

- Flu-like symptoms (headache, fatigue, fever, chills, tachycardia, myalgia, and anorexia)
- Depression (new-onset depression or worsening of pre-existing depression; patients should be monitored during therapy for severe depression, and therapy should be discontinued if necessary)[4]
- Sarcoidosis (observed in combination IFN-α-ribavirin therapy)
- Spastic diplegia (a form of cerebral palsy that is a neuromuscular condition characterized by hypertonia and spasticity in the muscles of the lower extremities; Little disease)[5]
- Gastrointestinal perforation with associated intra-abdominal abscess or fistula formation

BOX 235-3 COMPLICATIONS OF BEVACIZUMAB

- Wound dehiscence (Incisions should be healed completely before treatment initiation; drug should be held for at least 28 days prior to elective surgery)
- Serious hemorrhagic events including hemoptysis, gastrointestinal bleeding, central nervous systems (CNS) hemorrhage, epistaxis, vaginal bleeding, and pulmonary hemorrhage. Use in patients with active hemorrhage or recent history of hemoptysis is not advised.
- Arterial thromboembolic events including cerebral infarction, transient ischemic attacks, myocardial infarction, angina, and others.
- Reversible posterior leukoencephalopathy syndrome (RPLS), a neurological disorder characterized by headache, seizure, lethargy, confusion, blindness and other visual or neurologic disturbances, that is diagnosed and confirmed by magnetic resonance imaging (MRI)
- Hypertension (monitoring every two to three weeks during course of treatment is advised)
- Proteinuria
- Infusion reactions

INDICATIONS

Bevacizumab was the first antiangiogenesis drug approved by the US Food and Drug Administration (FDA) in February 2004 for the first-line treatment of metastatic colorectal carcinoma when given in combination with intravenous 5-fluorouracil-based chemotherapy but also has indications for nonsmall cell lung cancer, metastatic human epithelial growth factor-2-negative breast cancer, glioblastoma, and metastatic renal cell carcinoma.[9] Bevacizumab, in combination with either other antiangiogenic agents or chemotherapy, is currently being investigated in metastatic melanoma, hemangioendothelioma, and angiosarcoma. Other than a history of hypersensitivity, no known contraindications to bevacizumab therapy exist.[9]

COMPLICATIONS[9]

(See Box 235-3)

CETUXIMAB (ERBITUX)

MECHANISM OF ACTIONS

Cetuximab is a chimeric, human-murine monoclonal antibody against the epithelial growth factor receptor (EGFR), and, as such, competitively inhibits the

BOX 235-4 COMPLICATIONS OF CETIXUMAB THERAPY

- Serious infusion reactions
- Acneiform neutrophilic folliculitis—appearance correlates with clinical response
- Pruritus
- Electrolyte disturbances
- Abdominal pain and upset
- Infections associated with neutropenia

BOX 235-5 COMPLICATIONS OF PANITUMUMAB

- Severe dermatologic toxicities (dermatitis acneiform, pruritus, erythema, rash, skin exfoliation, paronychia, dry skin, skin fissures)
- Photosensitivity
- Pulmonary fibrosis
- Electrolyte disturbances
- Infusion reactions

binding of epithelial growth factor (EGF), transforming growth factor (TGF), and other associated ligands. Downstream signaling blockade results in myriad of antitumor properties including decreased proliferation, cellular motility, and invasive potential via downregulation of signaling molecules such as basic fibroblast growth factor (bFGF, a product of keratinocytes) and interleukin 8 (IL-8).[14,15] Angiogenesis is also inhibited through decreased EGFR-mediated VEGF expression.

INDICATIONS

Cetuximab is currently indicated for the treatment of metastatic colorectal carcinoma and squamous cell carcinoma of the head and neck, either alone or in combination with radiation or chemotherapy.[16] Additionally, its use in squamous cell carcinoma of the skin is currently under investigation. Given the demonstrated role of bFGF in melanoma, cetuximab may also play an eventual role in its treatment. Other than a history of hypersensitivity, there are no known contraindications.

COMPLICATIONS[16]

(See Box 235-4)

PANITUMUMAB (VECTIBIX)

MECHANISM OF ACTION

Panitumumab is an entirely human monoclonal antibody directed against EGFR. Like cetuximab, it blocks ligand interactions associated with the EGFR (EGF, TGF) and downstream signaling molecule like VEGF, bFGF, and IL-8; however, because panitumumab is not chimeric, the hypothesized benefit is better overall efficacy and immunologic tolerance.[17]

INDICATIONS

Panitumumab is currently indicated for progressing, metastatic colorectal carcinoma in combination with or as a single agent following chemotherapy.[18] No known dermatologic uses or investigations into potential uses exist at this time, but, given its similarity to cetuximab, possible investigations into panitumumab's utility in cutaneous squamous cell carcinoma and melanoma is warranted. Other than a history of hypersensitivity, there are no known contraindications.

COMPLICATIONS[18]

(See Box 235-5)

In 1965, Sheskin prescribed thalidomide for psychosis in one of his patients and accidentally discovered that thalidomide effectively treated his/her erythema nodosum leprosum (ENL). The FDA approved thalidomide in 1998 for the treatment of ENL and currently classifies it as an orphan drug.

As interest in thalidomide's ability to treat a wide variety of refractory diseases grows, a promising class of drugs named ImiDs® or immunomodulatory thalidomide analogues has come under development and investigation. One member of this new class of drugs, lenalidomide (CC-5013, Revlimid), has been approved for the treatment of multiple myeloma, myelodysplastic syndromes, and chronic lymphocytic leukemia. However, phase III clinical studies of lenalidomide for the treatment of metastatic melanoma did not show a significant effect.[28]

MECHANISM OF ACTION

Thalidomide exhibits a wide range of effects in vitro and in vivo. Its mechanisms of action are still unclear, but, exhibiting antineoplastic, immunomodulatory, and antiangiogenic properties, thalidomide downregulates the expression of VEGF, bFGF, and possibly tumor necrosis factor-α (TNF-α), IFN-α, insulin-like growth factor-1 (IGF-1), nuclear factor-κB (NF-κB), IL-6, and IL-12.[29,30] Its antiangiogenic properties may be the basis for its antineoplastic activity, but its myriad of other effects likely accounts for its teratogenicity.[31] Apart from its hypnosedative properties, thalidomide's eventual effects on the immune system result in a reduction in helper T-cell:suppressor T-cell ratio and decreased leukocyte chemotaxis and monocyte phagocytosis.[32] Additionally, human keratinocytes demonstrate increased migration and proliferation when exposed to thalidomide.[33]

INDICATIONS

Thalidomide is currently approved and considered first-line therapy for the acute treatment of the cutaneous manifestations of moderate-to-severe erythema nodosum leprosum (ENL) as well as maintenance therapy for prevention and suppression of the cutaneous manifestations of ENL recurrence. In combination with dexamethasone, it is also approved for the treatment of newly diagnosed multiple myeloma.[34] Off-label uses include Kaposi sarcoma, hemangioendotheliomas, severe aphthous stomatitis (especially in patients with AIDS), psoriasis, and a variety of other dermatologic conditions.[30]

CONTRAINDICATIONS

(See Box 235-6)

INITIATING THERAPY

Thalidomide therapy should be reserved for patients with debilitating, serious diseases that have proven refractory to other therapies. The manufacturer of thalidomide has developed a restricted distribution program called System for Thalidomide Education and Prescribing Safety (S.T.E.P.S.®), which requires both prescribers and dispensing pharmacists to be registered, and it is mandatory for patients to be informed about the program, adhere to its requirements, and demonstrate in writing an understanding of these warnings. Female patients of childbearing potential (defined by the program as sexually mature women who have not undergone a hysterectomy or who have not been postmenopausal for at least 24 consecutive months) must have a negative pregnancy test (with a β-human chorionic gonadotropin sensitivity of at least 50 milliunits/mL) within 24 hours of treatment initiation. Patients must use reliable contraception (two effective methods unless using the abstinence method) for a period of at least 1 month before initiating therapy and must continue this practice during and for 1 month after therapy is completed. Male patients are required to use latex condoms, even in patients who have had a vasectomy.[34]

MONITORING THERAPY

S.T.E.P.S.® requires patient monitoring during therapy. Strict guidelines for pregnancy testing are outlined for males and females of childbearing potential to prevent possible fetal damage. If, during the course of therapy, a patient becomes pregnant, the drug should be stopped immediately and the exposure reported to the FDA and the manufacturer (Celgene; Summit, New Jersey, USA). Patients should then see an obstetrician/gynecologist with experience in reproductive toxicity.[34]

BOX 235-6 CONTRAINDICATIONS OF THALIDOMIDE THERAPY

- Pregnancy class: X
- Hypersensitivity to the drug or its components

BOX 235-7 RISKS AND PRECAUTIONS OF THALIDOMIDE THERAPY

- Hypersensitivity
- Bradycardia
- Stevens-Johnson syndrome and toxic epidermal necrolysis
- Seizures
- Pregnancy category: X

RISKS AND PRECAUTIONS[34]

(See Box 235-7)

COMPLICATIONS

(See Box 235-8)

SIROLIMUS (RAPAMUNE)

(See also Chapter 233)

MECHANISM OF ACTION

Isolated from the bacterium *Streptomyces hygroscopicus*, sirolimus is a macrocyclic lactone antibiotic with immunosuppressant, antifungal, and antineoplastic properties. After forming a complex with FK binding protein-12 (FKB-12), sirolimus acts by inhibiting the interaction of the mammalian target of rapamycin (mTOR) with its substrates; mTOR is a serine-threonine protein kinase activated by several growth factors whose downstream targets affect cell cycle control and angiogenesis in normal and neoplastic cells.[49] Sirolimus has been shown to decrease levels of hypoxia inducible factor-1α (HIF-1α), significantly inhibit VEGF-mediated vascular endothelial cell stimulation, bFGF-induced angiogenesis, and T-cell activation and proliferation.[50] Via suppression of mTOR complex 2, it also inhibits Akt activation.[51] Of the drugs used in the solid organ transplant setting including cyclosporine and tacrolimus, rapamycin has the greatest antiangiogenic activity. To that effect, it may be useful for the prevention of squamous cell carcinoma and lymphoma in the immmunosuppressed, transplant population.

INDICATIONS

Rapamycin is currently approved for prophylaxis against renal transplant rejection, as well as an agent in drug-eluting cardiac stents to prevent restenosis

BOX 235-8 COMPLICATIONS OF THALIDOMIDE THERAPY

- Teratogenicity
  - Thalidomide's embryopathy is well documented. Thalidomide is pregnancy category X, and patients selected for therapy must follow strict contraceptive measures as directed by the program. Thalidomide-induced defects in limb formation may be due to bFGF inhibition, as bFGF has been shown to induce embryologic limb formation.[35]
- Peripheral neuropathy
  - Thalidomide is neurotoxic and may result in a sensory, symmetrical distal polyneuropathy, which may later evolve to include motor symptoms as well. Neurotoxicity can be permanent. Incidence of peripheral neuropathy in patients receiving thalidomide ranges from 0.5%–25.0%. Patients with preexisting peripheral neuropathy should not begin treatment. Baseline nerve conduction studies should be obtained before treatment initiation along with monthly monitoring during the first three months decreasing to 6-month intervals thereafter during treatment. A 40% decrease in nerve conduction necessitates treatment discontinuation.[34]
- Neutropenia
  - Because of the risk of neutropenia, baseline measurements should be obtained (with a white blood cell count with differential) then monitored regularly during the treatment course. Treatment should not be initiated in patients with an absolute neutrophil count (ANC) of less than 750/mm^3.[3,34]
- Other side effects
  - Other side effects include drowsiness, orthostatic hypotension, rash, fever, and increases in human immunodeficiency virus (HIV) viral loads.[34,36]

after coronary artery angioplasty.[52] Off- label uses in dermatology include the treatment of psoriasis, Kaposi sarcoma, tuberous sclerosis, angiofibromatosis, and lymphangioleiomyomatosis.[53–57] There are also case reports of its efficacy in nephrogenic systemic fibrosis (NSF), scleroderma, and dermatomyositis.[58–60] On-going clinical trials are looking into the utility of sirolimus in the prevention of nonmelanoma skin cancer in patients following kidney transplant, that of topical sirolimus in basal cell nevus syndrome (Gorlin-Goltz syndrome), and in combination with pulse dye laser in port wine stain. Other than a history of hypersensitivity to it or other rapamycin derivatives, there are no known contraindications.

COMPLICATIONS

(See Box 235-9)

BOX 235-9 COMPLICATIONS OF SIROLIMUS

- Systemic toxicities
  - Complications that may occur include headache, thrombocytopenia, arthralgia, interstitial pneumonitis, and hypercholesterolemia.[52]
- Cutaneous toxicities
  - Cutaneous side effects of therapy include angioedema, leukocytoclastic vasculitis, xerosis, and aphthous ulceration, which all resolve with discontinuation of therapy.[52,61]
- Increased susceptibility to infections and malignancies[52]

BORTEZOMIB (VELCADE)

MECHANISM OF ACTION

Bortezomib is the first proteasome inhibitor to gain FDA approval. This novel class of drugs acts by impairing the ability of the proteasome to degrade a variety of ubiquitinated proteins. Proteasome inhibitors may promote a proapoptotic state by preventing the degradation of tumor-suppressor proteins, such as p53 and inhibitors of NF-κB. NF-κB upregulates the transcription of genes involved in neoplastic progression including VEGF.[67] Bortezomib also acts directly to inhibit chemotaxis, capillary formation, and transcriptions of VEGF, IL-6, IGF-1, ang-1, and ang-2.[68] Because it has been shown to correlate with NF-κB activity, chemoresistance might also be lessened in the presence of bortezomib.

INDICATIONS

Bortezomib is currently indicated for the treatment of recurrent or refractory multiple myeloma and mantle cell lymphoma.[68] Investigational applications include CTCL, squamous cell carcinoma, and metastatic melanoma.[69]

CONTRAINDICATIONS

- Hypersensitivity to bortezomib, boron, or mannitol[70]

COMPLICATIONS[70]

- Hypotension
- Peripheral neuropathy and RPLS
- ARDS
- Blood dyscracias (neutropenia, thrombocytopenia)
- Fatigue, malaise, and weakness
- CYP3A4 drug metabolism interactions

CORTICOSTEROIDS

(See Chapter 224)

The role of corticosteroids in angiogenesis is a bit of a mixed picture, with neutral, anti-, and proangiogenic effects having been observed in various cases. In the setting of uveal melanoma, El Filali et al demonstrated no significant differences in levels of VEGF, PDGF, or TSP-1 in in-vitro models treated with triamcinolone acetate.[71] In vivo and in vitro models of prostate cancer have shown potentiation of antiangiogenesis by docetaxel when concurrently exposed to dexamethasone as measured by levels of VEGF, IL-8, and chemokine ligand-1 (CXCL-1).[72] Contrastingly, sequential deliveries of dexamethasone followed by VEGF showed an increase in vascularity in a biosensor-model implant into murine subcutaneous fat.[73] Whatever the ultimate mechanism and role, the clinical utility of steroids as anti-inflammatory and antiangiogenic is readily apparent.

BECAPLERMIN (REGRANEX)

(See also Chapter 234)

Chronic wounds have become increasingly prevalent in recent years with the rise in incidence of diabetes and the increasingly aging population. Treatment of these wounds is particularly challenging because normal wound-healing processes have been disrupted.

MECHANISM OF ACTION

Becaplermin [recombinant human platelet-derived growth factor (rhPDGF) BB] is the first FDA-approved angiogenesis-stimulating therapy. Endogenous PDGF is chemotactic for several cell types necessary for wound healing, and is also a mitogen for fibroblasts, the source for extracellular matrix components like glycosaminoglycans and fibronectin. Thus, PDGF is an important factor in the formation of granulation tissue.

INDICATIONS

Becaplermin gel is currently indicated for the treatment of lower extremity, diabetic, neuropathic ulcers. The ulcers must be adequately vascularized and reach at least the subcutaneous tissue.[74,75] Off-label uses include the application of becaplermin to ulcerated hemangiomata, surgical wounds, grafts, and flaps.[77,78,79]

CONTRAINDICATIONS

Becaplermin gel is contraindicated in patients with known cancer in the treatment area or a history of hypersensitivity.[75]

BOX 235-10 RISKS AND PRECAUTIONS OF BECAPLERMIN THERAPY

- Because becaplermin gel is nonsterile, it should not be applied to wounds closed by primary intention.
- An increased rate of mortality due to malignancy has been observed in patients treated with 3 or more tubes of becaplermin gel, and caution should be used in patients with a known history of malingnacy.
- Pregnancy category: C
- The safety and efficacy of becaplermin has not been evaluated in children less than 16 years of age.

DOSING REGIMEN

Becaplermin gel should be applied topically once daily with the dose depending on the size of the lesion; generally, every square inch of ulcer requires 2/3 or 1⅓ inches of gel from a 15-g or 2-g tube, respectively. After application, the area should be covered with a saline-moistened dressing then left in place for approximately 12 hours. The dose should be recalculated every 1–2 weeks to ensure accurate dosing as the wound changes size. Becaplermin gel should be used along with proper ulcer care.[75]

MONITORING THERAPY

If there is less than a 30% decrease in size after 10 weeks or if the wound has not completely healed after 20 weeks of treatment, the treatment plan should be reevaluated.[75]

RISKS AND PRECAUTIONS[75]

(See Box 235-10)

Complications of Becaplermin therapy are rash, hypersensitivity reaction (most often to the paraben or *m*-cresol components) and ulcer-related complications (incidence was similar in becaplermin vs. placebo groups).[75]

Chapter 236 :: Drug Interactions

:: Stephen E. Wolverton

INTRODUCTION

The topic of drug interactions is strikingly complex and rapidly evolving. Even experts in this area of pharmacology must rely on print and electronic resources pertaining to drug interactions on a regular basis. With these facts in mind, this chapter focuses on a wide variety of principles, with selected drug interactions utilized to illustrate these principles, as opposed to providing extensive lists of potential drug interactions. Furthermore, there will be an attempt to provide a stratification of risk, putting the greatest emphasis on the drug interactions with the greatest risk to individual patients.

DEFINITIONS

The most basic definition of a drug interaction is when two drugs are being administered simultaneously in a patient, and one drug alters the other's serum/tissue levels or mechanism of action. The drug interaction can affect the *efficacy* or increase the likelihood of *adverse effects* from one or both drugs. Furthermore, a drug interaction can occur without clinically evident alteration of efficacy or adverse effects. In contrast, drug interactions which induce either a loss of drug efficacy or new adverse effects are known as *adverse drug interactions*. The topic of drugs interactions is important to physicians in all aspects of medicine regardless if the clinician (a) prescribes the drug "responsible" for a given drug interaction, or (b) the drug previously prescribed by this same clinician is the "victim" of a drug prescribed by another clinician.

PRINT AND ELECTRONIC RESOURCES

In reviewing this chapter, the reader is encouraged to strive for a "recognition recall" level of memory; no one can possibly master and retain all important drug interactions. Through learning key principles that assist in attaining the broadest possible understanding of the multitudes of potential drug interactions, a clinician may best be able to interpret and react to new clinician situations involving potential drug interactions. One should always attempt make things "make sense" using the general principles that follow. It is always acceptable to (1) call a drug information pharmacist, (2) call or e-mail an expert in drug interactions, or (3) look up possible interactions in various print and electronic resources. Selected resources for drug interactions are listed in Table 236-1.

P-GLYCOPROTEIN

The topic of *P*-glycoprotein and the role in drug interactions has been relatively recently documented. *P*-glycoprotein is most common at important points of entry into body or important body structures (gastrointestinal tract, blood brain barrier) as a means to ensure protection against various "toxins". *P*-glycoprotein is important for a number of drugs with highly variable absorption, such as digoxin and cyclosporine. Although the topic is not discussed further in this chapter, the interested reader can find additional information in a review by Shapiro and Shear.[1]

PHARMACOKINETIC AND PHARMACODYNAMIC DRUG INTERACTIONS

DEFINITIONS

All drug interactions can be divided into either *pharmacokinetic* or *pharmacodynamic* interactions, which is true

TABLE 236-2
Pharmacokinetic (PK) Steps Pertaining to Drug Metabolism and Interactions

PK Step	Primary Interactions	Examples
Absorption	Loss of efficacy	Divalent cations and tetracyclines or fluoroquinolones ↑ gastric pH (antacids) and itraconazole or ketoconazole
Distribution	Toxicity	NSAIDs and methotrexate Sulfonamides and methotrexate
Metabolism	Loss of efficacy *and* toxicity	Examples in eTable 236-3.1 in online edition and Tables 236-7 through 236-10
Excretion	Toxicity	Sulfonamides and methotrexate Digoxin and cyclosporine

↑ = increase; NSAIDs = nonsteroidal anti-inflammatory drugs.

regardless of whether they are an *adverse* drug interaction or an interaction without loss of drug efficacy or the onset of new toxicity.[2] Conceptually pharmacokinetics deal with "what the body does to the drug", while pharmacodynamics deals with "what the drug does to the body". In the most basic sense, these definitions relate to the normal pharmacology of a given drugs therapeutic effects, as well as in the clinical setting of drug interactions.

VARIOUS SUBTYPES OF PHARMACOKINETIC DRUG INTERACTIONS

Pharmacokinetic drug interactions are much more common than pharmacodynamic drug interactions. This category of interactions results from alterations in a drug's serum and/or tissue levels. The ADME model (see Sections "Various Subtypes of Pharmacodynamic Interactions" and "Subtypes of Metabolic Drug Interactions") of studying pharmacokinetics pertains to this category of interactions. The steps from entry of the drug into the body until excretion of the drug and/or its metabolites includes (1) *a*bsorption, (2) *d*istribution, (3) *m*etabolism, and (4) *e*xcretion. The importance of each of these steps is detailed elsewhere.[2] Examples of drug interactions involving each of these steps are included in Table 236-2.

VARIOUS SUBTYPES OF PHARMACODYNAMIC INTERACTIONS

Pharmacodynamic drug interactions are much less common than pharmacokinetic drug interactions. This category of interactions deals with alterations in the mechanism of either the desired pharmacologic effect or mechanism for an adverse effect. The drug levels are not of central importance in this category of interactions. The two primary subtypes of interactions include (1) agonist—similar "polarity" of the pharmacologic effects for the two interacting drugs, and (2) antagonist—opposite "polarity" of the pharmacologic effects for the two interacting drugs. Both agonist and antagonist interactions can produce either a positive (improved therapeutic response) or negative (toxicity) biologic response. Selected examples to illustrate this innately confusing terminology are listed in Table 236-3. Conceptually the various aspects of drug pharmacodynamics occur between the "distribution" and "metabolism" steps of the pharmacokinetics sequence. An exception to this principle would be for any prodrug that requires metabolic conversion to the active drug form to generate a pharmacologic response. Two examples would be the conversion of valacyclovir (prodrug) to acyclovir (corresponding active drug) and of famciclovir (prodrug) to penciclovir (corresponding active drug).

TABLE 236-3
Pharmacodynamic Categories of Drug Interactions

Category	Examples	Comments
Agonist interaction—same "polarity" of mechanism		
Positive pharmacologic effect	Prednisone and azathioprine	"Steroid-sparing" effects
Negative pharmacologic effect	Hydroxychloroquine and chloroquine	↑ risk of retinopathy
Antagonist interaction—opposite "polarity" of mechanism		
Positive pharmacologic effect	Methotrexate and folic acid	↓ methotrexate adverse effects
Negative pharmacologic effect	β-blockers[a] and epinephrine[b]	Unopposed α-adrenergic effects, ↑↑ blood pressure

[a]Noncardioselective β-blockers.
[b]Epinephrine at very high doses if very high volumes of lidocaine with epinephrine are utilized during a procedure (very rare).
↑ = increase; ↓ = decrease; ↑↑ = large increase.

SUBTYPES OF METABOLIC DRUG INTERACTIONS

The four steps of the "ADME" model for drug pharmacokinetics all have potential drug interactions, with either loss of efficacy or toxicity. By far the greatest number of important drug interactions occurs at the "metabolism" step. Drugs need to be relatively lipophilic to the entire body and travel to the site(s) of intended pharmacologic effect. Subsequently drugs must be converted to relatively hydrophilic metabolites to be excreted in bile or urine. Only a small fraction of drugs are excreted in their active form.

The body has two categories of drug metabolizing enzymes to accomplish the biotransformation of a relatively lipophilic drug form to a more hydrophilic form in order to facilitate renal or biliary excretion. These categories are phase I and phase II metabolic enzymes. It is important to note that these phases do not necessarily occur in a set sequence from phase I to phase II. Phase I enzymes are primarily cytochrome P-450 (CYP) mixed function oxidative enzymes which typically create a somewhat more polar site of attachment for the subsequent phase II (conjugation) enzymes. Examples of the phase I and phase II enzymes which are of greatest importance to drug interactions are listed in eTable 236-3.1 and eTable 236-3.2 in online edition. Several of these enzymes have polymorphisms of importance to explaining the spectrum of risk between various patients in various ethnic groups.[3]

ISOFORMS OF CYP OF GREATEST IMPORTANCE TO DRUG INTERACTIONS

The importance of cytochrome P-450 (CYP) 3A4 and CYP 2D6 lies in the fact that these isoforms metabolize about 50% and 20%–25% of all drugs, respectively. Due to some overlap of drug substrates that are metabolized by both CYP isoforms, roughly two-thirds of all drugs are metabolized by at least one of these two pathways. Other CYP isoforms of greatest potential importance to drug interactions include CYP 2C9, CYP 2C19, CYP 1A2, and CYP 2E1.

DRUG SUBSTRATES, INHIBITORS, AND INDUCERS

DRUG SUBSTRATES

A substrate is basically a drug in the process of being metabolized to a more water-soluble form (metabolite) to enable excretion. A substrate may "travel" down one or more than one metabolic pathway, including possibly more than one CYP isoform. The metabolic pathway may be either a CYP isoform, a non-CYP pathway (phase II), or both. Furthermore, a substrate may also be an inhibitor or inducer of the drug's metabolic pathway. An example would be cyclosporine, which is both a substrate and inhibitor of CYP 3A4.

Warfarin has both an *S*-enantiomer ("super" warfarin—more potent) and *R*-enantiomer (less potent). The *S*-enantiomer is metabolized predominantly by CYP 2C9, while CYP 3A4 and CYP 1A2 metabolize the *R*-enantiomer. Drug interactions involving the *S*-enantiomer are overall more important because of (a) the greater "potency" of the *S*-enantiomer, and (b) the fact that it is metabolized only by one pathway (thus, no alternative metabolic pathways), should a CYP 2C9 enzyme inhibitor be utilized in the same patient.

Substrates of greatest interest for three of the most important CYP isoforms are listed in Table 236-4. References listed in Table 236-1 can be consulted for more comprehensive lists of CYP isoforms and pertinent drug substrates.

SUBSTRATES WHICH ARE NARROW THERAPEUTIC INDEX DRUGS

A given drug's "therapeutic index" is merely the ratio of the drug dose producing the desired therapeutic response versus the drug dose producing toxicity. A drug with a "narrow" therapeutic index would represent drugs for which the ratio is relatively close to the number "1" regardless of which is the numerator and denominator. Several examples of relatively narrow therapeutic index drugs are listed in Table 236-5.

ENZYME INHIBITORS

An enzyme "inhibitor" is a drug that slows/decreases the rate of metabolism of another drug substrate. Visualizing this process in a traffic analogy, the inhibitor blocks the flow of traffic (drug metabolism) on a shared road (CYP isoform or a phase II metabolic pathway). Drug interactions involving enzyme inhibitors are characterized by three generalizations. The net result is (1) immediate, (2) resultant increased substrate drug levels, and (3) resultant drug toxicity. In these interactions, the risk of toxicity is greatest with narrow therapeutic index drugs such as methotrexate, cyclosporine, and warfarin. In addition, drug substrates with just a single metabolic pathway are at greater risk for toxicity than similar drugs with more than one metabolic pathway. In the above traffic analogy, conceptually the backed up traffic can be diverted to an alternative highway if the substrate can be metabolized by another metabolic pathway (CYP isoform or phase II conjugation enzyme).

Two of the strongest inhibitors of CYP 3A4 are erythromycin (macrolide antibiotic) and ketoconazole (azole antifungal agent). In each of these drug groups, there are alternatives that have little or no inhibitory effect on the CYP isoform involved in the potential drug interaction of interest. Examples of variations of enzyme inhibition within a drug group are listed for inhibitors of CYP 3A4, CYP 2D6, and CYP 2C9 in eTable 236-5.1 in online edition.

TABLE 236-4
Some Important Substrates for Several Important CYP Isoforms

CYP 3A4 Substrates	CYP 2D6 Substrates	CYP 2C9 Substrates
Antibacterial agents	Analgesics	Antibacterial agents
Erythromycin	Codeine	Sulfonamides
Rifampin	Meperidine	Anticoagulants
Anticoagulants	Morphine	*S*-warfarin enantiomer
R-warfarin enantiomer	Antidysrhythmics	Anticonvulsants
Antidysrhythmics	Encainide	Phenytoin
Amiodarone	Flecainide	Valproic acid
Digoxin	Mexelitine	NSAIDs
Lidocaine	Propafenone	Diclofenac
Calcium channel blockers—all	β-Blockers	Ibuprofen
H_1 antihistamines[a]	Metoprolol	Piroxicam
Fexofenadine	Propranolol	Statins
Loratadine	SSRI antidepressants	Fluvastatin
Statins	Fluoxetine	Rosuvastatin
Atorvastatin	Paroxetine	
Lovastatin	Tricyclic antidepressants	
Simvastatin	Amitriptyline	
Hormonal contraceptives	Clomipramine	
Immunosuppressive agents	Desipramine	
Cyclosporine	Doxepin	
Tacrolimus		

[a]Terfenadine and astemizole are 3A4 substrates—have been taken off the market in the United States.
Note: This table is intended to give important examples and is far from comprehensive; for more complete information, consult database of Dr. David Flockhart at Indiana University Department of Medicine (see Table 236-1).
Adapted from Shapiro LE, Shear NH: Drug interactions. In: *Comprehensive Dermatologic Drug Therapy*, 2nd edition, edited by SE Wolverton. London, Elsevier, 2007, p. 949–975

ENZYME INDUCERS

An enzyme "inducer" is a drug that speeds up the metabolism of a drug substrate. The inducer facilitates traffic on the "highway" (metabolic pathway) for drug metabolism. The generalizations involving enzyme inducers result in (1) delayed effects, (2) lowered drug levels, and (3) loss of drug efficacy. Drug interactions involving enzyme induction are delayed somewhat (typically up to a week or more) because they require synthesis of new protein (most notably a synthesis of a given CYP isoform). Conceptually from a traffic analogy standpoint, this synthesis would equate to creating a new lane that once opened would facilitate more rapid and efficient transport of vehicles (drug substrates).

Most CYP enzyme inducers affect more than one CYP isoform. Some of the strongest enzyme inducers include rifampin and the aromatic anticonvulsants phenytoin, phenobarbital, and carbamazepine. Griseofulvin is also

TABLE 236-5
Selected Narrow Therapeutic Index Drugs

Category	Drug Name	CYP Isoform	Most Important Acute Toxicities
Anticoagulants	Warfarin	2C9, 3A4, 1A2	Hemorrhage (thrombosis if warfarin effect inhibited)
Antidepressants	Doxepin[a]	2D6	Excessive sedation, tachyarrhythmias
Bronchodilators	Theophylline	1A2	Central nervous system toxicity
Immunosuppressive agents	Cyclosporine Methotrexate	3A4 None[b]	Renal toxicity, hypertension, hyperlipidemia Pancytopenia, liver toxicity
Inotropic agents	Digoxin	3A4	Cardiac tachyarrhythmias, atrioventricular block

[a]Overall doxepin is the "safest" drug on this list; however, in the presence of strong CYP 2D6 inhibitors, CNS and cardiac toxicity is an important issue.
[b]As opposed to CYP inhibition with other drugs above, the greatest risk of methotrexate toxicity is with concomitant use of drugs such as trimethoprim (dihydrofolate reductase inhibitor) and sulfamethoxazole (dihydropteroate synthetase inhibitor), which also inhibit enzymes important to folate metabolism.

TABLE 236-6
Clinical Scenarios in Which Enzyme Inducers Lead to Loss of Efficacy

Substrate	Enzyme Inducer	CYP Isoform	Clinical Result
Warfarin	Rifampin[a]	3A4	Thrombosis if significant loss of anticoagulant effect
Hormonal contraceptives	Rifampin[a] Griseofulvin	3A4 3A4	Possible unintended pregnancy Possible unintended pregnancy
Cyclosporine, tacrolimus	Rifampin[a]	3A4	Loss of organ transplanted (graft)

CYP = cytochrome P-450
[a]Given that enzyme induction generally takes a week or more to reach clinical significance, a 7–10 day course of rifampin (as commonly prescribed for community-acquired MRSA may fall short of the time period for maximal risk; however, appropriate caution (ideally avoid coprescribing) is required in these clinical settings.
Note: The drugs listed in this table are drugs that are commonly prescribed by dermatologists; the aromatic anticonvulsants—carbamazepine, phenobarbital, and phenytoin, and several other drugs are also important enzyme inducers.

an enzyme inducer, albeit a relatively weak inducer. Some clinical scenarios pertinent to dermatology of enzyme induction of significant importance are listed in Table 236-6.

GENETIC POLYMORPHISMS[3]

The term "polymorphism" as it pertains to drug metabolism merely represents a mutation in a phase I or phase II enzyme that results in clinical importance differences of enzyme activity compared to normal. Conceptually "variability" results in a unimodal distribution (a single bell-shaped curve), whereas a genetic polymorphism creates a bimodal distribution (at least two bell-shaped curves) when putting enzyme activity on a graph. Clinically significant polymorphisms involving drug metabolizing enzymes most notably include both phase I enzymes (CYP 2D6 and CYP 2C9) and phase II enzymes (*N*-acetyl transferase 2 and thiopurine methyltransferase). These polymorphisms can result in (1) drug interactions, (2) altered metabolism of a drug used as monotherapy, (3) cutaneous drug reactions or (4) systemic drug interactions. Table 236-7 summarizes examples of the clinical outcomes in these three categories from the above four drug metabolic enzyme polymorphisms.

CLINICAL SCENARIOS

VARYING RISK OF INDIVIDUAL DRUG INTERACTIONS

Not all drug interactions are "adverse" drug interactions; these pharmacokinetic and pharmacodynamic interactions do not result in an adequate change in drug levels or mechanisms of action to have clinical importance. Furthermore, only a small percentage of drug interactions have a life-threatening potential. At the conclusion of the chapter, twelve of the most potentially serious drug interactions pertinent to dermatology are highlighted. In between these two extremes is where the majority of drug interactions exist. In these clinical settings, the clinician has a great deal of flexibility concerning therapeutic choices. From these three categories, one can derive one additional traffic analogy:

TABLE 236-7
Clinical Relevance of Drug Metabolism Enzyme Polymorphisms

Polymorphism	Specific Drug	Drug Interaction	Monotherapy Result	Drug Reaction
Phase I enzymes				
CYP 2D6	Doxepin	Paroxetine, fluoxetine (↑ severity in IM, PM)	Toxicity (sedation) PM Loss of efficacy EM, URM	*None*
CYP 2C9	Warfarin	Fluconazole	Toxicity (hemorrhage) PM Loss efficacy (thrombosis) URM	*None*
Phase II enzymes				
N-acetyl transferase-2	Isoniazid	*None*	*None*	Drug-induced lupus erythematosus
Thiopurine methyltransferase	Azathioprine	Allopurinol (↑ risk in IM, PM)	Toxicity (pancytopenia) IM, PM Loss of efficacy EM	*None*

↑ = increase; CYP = cytochrome P-450; URM = ultrarapid metabolizer; EM = extensive metabolizer; IM = intermediate metabolizer; PM = poor metabolizer.

- Adverse drug interactions with life-threatening potential (*red* light)—do *not* proceed (e.g., fluconazole and warfarin; the clinician must choose an alternative antifungal agent such as itraconazole or terbinafine).
- Adverse drug interactions of clinical importance, but not life threatening (*yellow* light)—proceed with caution [see examples in Section "Therapeutic Options with "Proceed with Caution" (Yellow Light) Clinical Scenario"].
- Other drug interactions of no clinical risk due to minor effect of "interaction" on drug levels or mechanisms of action (*green* light)—can proceed with the drug combination and can reassure the patient.

THERAPEUTIC OPTIONS WITH "PROCEED WITH CAUTION" (YELLOW LIGHT) CLINICAL SCENARIO

Typically, there is substantial latitude concerning these clinical scenarios. The clinician may choose to avoid the drug combination altogether if there are suitable drug alternatives or if the disease being treated presents minimal risk to the patient. Alternatively, the clinician may choose one or several of the following options: (1) lower the drug dose—azathioprine and allopurinol, for which a 75% reduction of azathioprine dose is recommended, (2) monitor closely from a clinical standpoint—doxepin and an SSRI antidepressant such as paroxetine or fluoxetine, following the level of sedation closely, and/or (3) appropriate laboratory testing—can order an AM doxepin serum levels when the drug is administered with CYP 2D6 inhibitors such as paroxetine or fluoxetine. Concerning the doxepin/SSRI interaction described above, the clinician may choose to use an SSRI antidepressant alternative that does not inhibit the CYP 2D6 pathway (e.g., citalopram, escitalopram, or sertraline). From a proactive standpoint, baseline genetic testing of either the CYP 2D6 and CYP 2C19 polymorphisms are readily available. This genetic testing may determine in advance the rate of metabolism by the specific CYP isoform in that individual. Possibilities with genetic testing include the following (listed in descending order from the most rapid to the slowest rate of drug metabolism):

- Ultrarapid metabolizer (URM)—uncommon, may involve gene "duplication".
- Extensive metabolizer (EM)—most common subset, homozygous for the "wild type" (full metabolic activity) gene.
- Intermediate metabolizer (IM)—relatively frequent, heterozygous for the "wild type" gene.
- Poor metabolizer (PM)—also uncommon, homozygous for the gene mutation (low/absent metabolic activity).

Some additional examples of the "proceed with caution" scenarios illustrating these therapeutic options are listed in Table 236-8.

TABLE 236-8
Options with "Proceed with Caution" Type of Drug Interactions

Clinical Option[a]	Examples
Clinical Scenario: want to prescribe doxepin for pruritus in patient on either paroxetine or fluoxetine	
Clinical monitoring	Watch closely for sedation
Laboratory monitoring	Order an AM doxepin level
Lower drug dose	Dose doxepin very conservatively
Alternative drugs to prescribe	Have primary physician switch to an alternative SSRI antidepressant or a nonselective reuptake inhibitor antidepressant *or* could prescribe hydroxyzine, cetirizine, etc.
Baseline genetic testing	Could order base CYP 2D6 genotype testing to see if patient a poor metabolizer
Clinical Scenario: want to prescribe erythromycin for acne to a patient on simvastatin	
Clinical monitoring	Could monitor for muscle pain or weakness (by itself, never an option)
Laboratory monitoring	Monitor muscle enzymes (CPK, aldolase)
Lower drug dose	Lower dose of either erythromycin or simvastatin
Alternative drugs to prescribe	Azithromycin, a suitable macrolide *or* prescribe an alternative antibiotic group; also request primary physician to consider fluvastatin, rosuvastatin, pravastatin
Clinical Scenario: want to prescribe itraconazole for extensive tinea corporis to a patient on warfarin[b]	
Clinical monitoring	Could monitor for bruising/hemorrhage elsewhere (by itself, never a viable option)
Laboratory monitoring	Follow INR values very closely
Lower drug dose	Lower dose of either the itraconazole or warfarin (through primary physician)
Alternative drugs to prescribe	Terbinafine and topical antifungals are primary alternatives

[a]In each clinical scenario, more than one option may be undertaken simultaneously.
[b]With patients on warfarin, for whom clinicians wish to give fluconazole these "proceed with caution" options are not pertinent; fluconazole and warfarin is a "red light" scenario in which coprescribing these drugs must be totally avoided.

TABLE 236-9
A Dozen Critical Drug Interactions

Number	Specific Toxicity	Category		CYP	Substrates	Precipitant Drugs
1.	Torsades de pointes	PK	Tox	3A4	Terfenadine, astemizole, cisapride	Erythromycin, ketoconazole, itraconazole
2.	Pancytopenia	PK	Tox	—	Methotrexate	Trimethoprim/sulfamethoxazole
3.	Agranulocytosis	PK	Tox	—	Azathioprine	Allopurinol
4.	Hemorrhage	PK	Tox	2C9	Warfarin	Fluconazole
5.	Thrombosis/embolism	PK	LOE	3A4	Warfarin	Rifampin, Rifabutin
6.	Sedation	PK	Tox	2D6	Doxepin	Fluoxetine, paroxetine
7.	Sedation	PD	Tox	—	Doxepin	H_1 antihistamines – sedating
8.	Renal failure/rhabdomyolysis	PK	Tox	3A4	Cerivastatin	Gemfibrozil (and other 3A4 inhibitors)
9.	Renal toxicity	PK	Tox	3A4	Cyclosporine	Erythromycin, clarithromycin, ketoconazole, itraconazole
10.	Renal toxicity	PD	Tox	—	Cyclosporine	Gentamicin (and other potentially renal toxic drugs)
11.	Liver toxicity	PD	Tox	—	Methotrexate	Acitretin (previously etretinate)
12.	Loss of transplanted organ	PK	LOE	3A4	Cyclosporine	Rifampin, rifabutin

CYP = cytochrome P-450; PK = pharmacokinetic; PD = pharmacodynamic; Tox = toxicity; LOE = loss of efficacy.
Note: These critical drug interactions are listed roughly in descending order of risk.

LESSONS TO BE LEARNED FROM DRUGS TAKEN OFF THE MARKET

There are some important lessons to be learned from drugs interactions that produced life-threatening risk, which led to several drugs being taken off the market. Two issues are worth highlighting concerning the drug interactions, which led to drug removal. In both cases, a known CYP enzyme inhibitor (CYP 3A4 inhibitors) was commonly coprescribed with a CYP 3A4 drug substrate with a narrow therapeutic index. Secondly, in each case, the US Food and Drug Administration published warnings in the form of "Dear Doctor" letters (subsequently known as "Dear Health Care Professional" letters) that in retrospect did not bring about an adequate change of clinician prescribing habits to warrant drug continuation. Several of the potentially life-threatening drug interactions leading to drug withdrawal include the following:

- H_1 antihistamines terfenadine and astemizole—a form of ventricular tachycardia (torsades de pointes) seen with (strong CYP 3A4 inhibitors erythromycin or ketoconazole commonly coprescribed with these drugs).
- HMG CoA reductase inhibitor cerivastatin (a "statin")—rhabdomyolysis (a strong CYP 3A4 inhibitor gemfibrozil commonly coprescribed with this drug).

CONCLUSION: A DOZEN DRUG INTERACTIONS OF IMPORTANCE TO PRACTICING DERMATOLOGISTS

There are numerous potential drug interactions for the clinician to consider. When trying to pick a starting point to understand adverse drug interactions, it is logical to start with the most potentially serious drug interactions. With this principle in mind, I have compiled a list of a dozen drug interactions which are potentially serious, and thus, of great importance to practicing dermatologists and other clinicians utilizing these drugs (Table 236-9).

With proper awareness of drugs for which potential interactions need to be considered and regular usage of drug interaction databases, clinicians can reduce the incidence of adverse drug interactions. Patient education is likewise essential to minimizing this risk. In the vast majority of cases, a less risky therapeutic alternative is typically available if the print/electronic resources indicate a potential drug interaction. Finally, when in doubt, do not prescribe the drug or drugs in question until a definitive answer on the safety of coprescribing the medications in question can be answered.

SECTION 38

Physical Treatments

Chapter 237 :: Phototherapy

:: Jennifer A. Cafardi, Brian P. Pollack, & Craig A. Elmets

PHOTOTHERAPY AT A GLANCE

- Phototherapeutic devices have varying properties with respect to depth of UV penetration into the skin, effects on cells and molecules, potency, side effects and diseases in which they are most effective.
- In use today are narrowband and broadband UVB, UVA as part of psoralen photochemotherapy (PUVA), UVA1 and targeted phototherapy (excimer lasers and nonlaser monochromatic excimer light sources).
- Narrowband UVB is currently preferred to treat psoriasis, other inflammatory skin diseases, and vitiligo.
- Psoralen-UVA photochemotherapy (PUVA) combines oral or topical psoralen compounds with UVA light sources. Its main uses are treatment of cutaneous T-cell lymphoma, vitiligo, and psoriasis that is resistant to narrowband UVB.
- UVA1 phototherapy is particularly effective for sclerotic skin diseases such as localized scleroderma, acute flares of atopic dermatitis and urticaria pigmentosa.
- Targeted phototherapy allowing relatively high UV doses to be delivered to diseased skin while sparing normal skin.

Diseases amenable to phototherapy include psoriasis, atopic dermatitis, cutaneous T-cell lymphoma, vitiligo, localized and systemic scleroderma, pruritus, photodermatoses, lichen planus, pityriasis lichenoides, urticaria pigmentosa and granuloma annulare.

Phototherapy is the use of ultraviolet radiation or visible light for therapeutic purposes. Its beneficial effects in vitiligo were first recognized thousands of years ago in India and Egypt, and its activity is now well established for a variety of other dermatologic conditions. The enduring appeal of phototherapy is based on its relative safety coupled with an ongoing interest in its molecular and biological effects. The manufacture of light sources that emit selective wavelengths of radiant energy, identification of photosensitizers with unique photochemical properties, and the development of novel methods for the delivery of light to cutaneous and noncutaneous surfaces have all contributed to its expanded use for dermatologic and nondermatologic conditions. Aside from lasers, high output incoherent light sources, and visible light sources employed for photodynamic therapy, the main phototherapic devices that are in use today are broadband UVB (BB-UVB), narrowband UVB (NB-UVB), UVA1, and UVA for psoralen photochemotherapy (PUVA). Ideally, devices used for therapeutic ultraviolet radiation (UVR) should do so in a safe, efficient and cost-effective manner. Understanding the basic principles of these devices is important for dermatologists and other providers utilizing phototherapy for the management of dermatologic diseases.[1–2]

MECHANISMS OF PHOTOTHERAPY

The different wavelengths of ultraviolet radiation used for phototherapy each have distinct photochemical and photobiologic properties, which include differences in depth of penetration and the range of molecules in the skin with which they interact. As a consequence, each form of phototherapy has unique properties with respect to potency, side effects, and diseases in which they are effective.

Most UVB radiation (290–320 nm) is absorbed by the epidermis and superficial dermis.[3] This form of radiant energy produces many different types of DNA damage[4]; however, pyrimidine dimers and 6,4 pyrimidine-pyrimidone photoproducts are thought to be particularly important for both its efficacy and its toxicity. UVB also causes photochemical changes in *trans*-urocanic acid, converting it to the *cis*-form of the molecule. Urocanic acid is a breakdown product

of histidine and is present in large amounts in the stratum corneum. Originally considered to be a natural photoprotectant, there is now a substantial evidence that *cis*-urocanic acid is a mediator of the UVB-induced immunosuppression.[5] A third direct target of UVB radiation is the amino acid tryptophan. UVB converts tryptophan into 6-formylindolo[3,2-*b*]carbazole (FICZ), which binds to the intracellular arylhydrocarbon hydroxylase (Ah) receptor, initiating a series of events that culminates in activation of signal transduction pathways. One such pathway results in expression of cyclooxygenase-2, an enzyme required for synthesis of prostaglandin E_2.[6] Finally, there is evidence that UVB exposure leads to the generation of reactive oxygen intermediates, which has downstream effects such as DNA damage in the form of 8-oxo-deoxyguanosine, lipid peroxidation, activation of signal transduction pathways and stimulation of cytokine production.[7]

In contrast to UVB radiation, which has a relatively superficial depth of penetration, UVA radiation (320–400 nm) can reach the mid- or lower dermis.[3] It is therefore more effective than UVB for skin diseases in which the cutaneous pathology lies deeper than the superficial dermis. Like UVB, UVA radiation can produce pyrimidine dimers in DNA, but, on a per photon basis, it is much less effective at doing so.[8] In most situations, the major biological effects of UVA radiation are due to the generation of reactive oxygen intermediates.[9] Following UVA exposure, reactive oxygen intermediates are formed in mitochondrial enzyme complexes during oxidative phosphorylation. Although the skin contains antioxidants, reactive oxygen intermediates formed during phototherapy exceed the amount that can be neutralized by endogenous photoprotective activities. UVA-induced oxidants are capable of harming DNA, lipids, structural and nonstructural proteins and organelles such as mitochondria. The generation of oxidants following UV exposure has been implicated in photoaging of the skin and skin cancer.

In psoralen photochemotherapy, psoralen photosensitizers are activated by UVA radiation, and the depth of penetration of PUVA is the mid-dermis. The major photochemical effect of psoralen photochemotherapy is damage to DNA. The changes in DNA differ from those of UVB and UVA without psoralens.[10] Psoralens used for photochemotherapy have two double bonds that can absorb UVA radiation. When administered to an individual, these compounds intercalate with DNA. Following UVA exposure, they form a single adduct with DNA and then become a bifunctional adduct, cross-linking the DNA strands in the double helix when a second photon is absorbed. There is also some evidence that photochemotherapy augments the production of reactive oxygen intermediates such as singlet oxygen. This effect has been implicated in induction of the cyclooxygenase enzyme and activation of arachidonic acid pathways.[11]

EFFECTS ON THE IMMUNE SYSTEM

(See also Chapter 90)

The photoimmunological effects of phototherapy are thought to provide an explanation, at least in part, for its efficacy in cutaneous diseases in which T-cell hyperactivity predominates (e.g., psoriasis, atopic dermatitis, lichen planus). Under normal circumstances, both effector and regulatory T-cells are generated, with the overall intensity of the immune response dependent on the relative proportion of effector and regulatory T-cells populations that are present. UVB exposure inhibits activation of effector T-cells, whereas it leaves formation regulatory T-cells unaltered.[12] As a result, the equilibrium of effector and regulatory T-cells is biased toward a diminished cell-mediated immune response. This perturbation in the balance of effector and regulatory T-cells reflects disruption of the activities of dendritic cells within the skin, the major function of which is to present antigen to T-lymphocytes. This is due to direct effects of UVB on dendritic cells and indirectly through the production of IL-10 and prostaglandin E_2, both of which have been shown to diminish the capacity of dendritic cells to present antigen to effector T-cells and to suppress T-cell responses.[13] Increased levels of IL-10 have been found after UVB, UVA1, and PUVA exposure. PGE_2 production occurs through UVB effects on keratinocytes[14–16]; UVB is an inductive stimulus for cyclooxygenase-2, which is important for PGE_2 production. Other immunosuppressive soluble mediators that have been reported to be increased following UVB exposure including agonists of the platelet-activating factor receptor,[17] MSH, and calcitonin gene-related peptide.[18]

PUVA has effects that are similar to UVB with respect to antigen presenting cells within the skin, the balance between effector and regulatory T-cells, and the production of soluble immunosuppressive mediators.[12] There is limited information on the effect of UVA1 on antigen presenting cells and on effector and regulatory T-cells.

In addition to its actions on cutaneous antigen presenting cells, phototherapy causes cell death by apoptosis in T-cells present in cutaneous lymphoid infiltrates. This has been demonstrated for UVA1 phototherapy in the lymphocytic infiltrate in atopic dermatitis,[19] and for narrowband UVB in psoriasis.[20]

Another immunological effect of phototherapy is on expression of ICAM-1 (CD54) and other adhesion molecules. ICAM-1 is not normally present on epidermal keratinocytes, but can be induced in a variety of inflammatory skin conditions. It facilitates T-cell binding to keratinocytes, through its interaction with LFA-1 that is present on T-cells. UVB, UVA1, and PUVA have all been shown to interfere with keratinocyte expression of ICAM-1, and this effect of phototherapy may therefore contribute to its efficacy in diseases, which have increased keratinocyte ICAM-1 expression.[12]

EFFECTS ON MAST CELLS

Both UVA1 and PUVA have deleterious effects on mast cells, although the mechanisms of action differ.[21–22] PUVA is not cytotoxic for mast cells, and because of this the reduction in mast cell concentrations in the dermis of PUVA-treated skin is relatively small. However, it does stabilize mast cell membranes and in so

doing limits the release of histamine and other mediators when these cells are stimulated to degranulate.[22] In contrast, chronic therapy with UVA1 results in apoptosis of mast cells with a marked reduction in their concentrations in the dermis, which can last for several months.[20] Both PUVA and UVA1 have been employed to treat selective mast cell–mediated diseases.

EFFECTS ON COLLAGEN

One of the downstream effects of UVA-induced generation of reactive oxygen intermediates is activation of matrix metalloproteinase-1 (MMP-1),[23–24] the major biologic activity of which is degradation of collagen. UVA radiation also increases the production of IL-1 and IL-6, which are stimuli for MMPs.[25] PUVA has also been shown to increase MMPs.[26] These effects of UVA1 and PUVA on MMP-1 and collagen degradation provide the rationale for its use in sclerotic skin diseases.

EFFECTS ON THE EPIDERMIS (KERATINOCYTES)

UVB, PUVA, and UVA all cause acanthosis of the epidermis and thickening of the stratum corneum.[27] This effect accentuates light scattering and increases its absorption by the upper levels of the epidermis. As a consequence, phototherapy treatment doses must be progressively increased so that an equivalent number of photons can reach the lower levels of the epidermis and dermis where therapeutic targets lie. On the other hand, this attribute of phototherapy has been exploited for the management of chronic photosensitivity disorders because this "hardens" the skin, permitting individuals afflicted with these disorders to tolerate greater amounts of sun exposure.

EFFECTS ON MELANOCYTES

Exposure to ultraviolet radiation is also known to stimulate melanogenesis,[28] which is at least in part a consequence of DNA damage and/or its repair.[29–32] Experimental studies have shown that treatment of melanocytes with DNA repair enzymes increases the melanin content of melanocytes,[33] and application of small fragments of thymidine dinucleotides to guinea pig skin produces a tanning response.[30–32] The stimulatory effects on melanogenesis increase the tolerance of patients with some photosensitivity disorders to ambient sun exposure, but also decrease the efficacy of phototherapy unless the doses of ultraviolet radiation are gradually increased.

Narrowband UVB and PUVA are also employed to repopulate vitiliginous skin with melanocytes. The mechanism by which phototherapy stimulates repigmentation of vitiliginous skin is incompletely understood, but may involve stimulation of hair follicle melanocyte proliferation and migration.[34] Cytokines and other inflammatory mediators released from other cells, such as keratinocytes, are thought to stimulate inactive melanocytes in the outer root sheath of hair follicles to proliferate, mature, and migrate to repopulate the interfollicular epidermis.[35]

PHOTOTHERAPY APPARATUSES

In the ideal situation, the wavelengths that are most effective for the treatment (i.e., the action spectrum) for every dermatologic condition would be known and there would be a device capable of delivering those wavelengths specifically to lesional skin. For some skin diseases such as psoriasis, great strides have been made toward this ideal and targeted therapy using devices such as excimer lasers[36] and nonlaser devices known as monochromatic excimer light (MEL) devices[37] that can deliver wavelengths of UVR at or close to those that are most effective at clearing psoriatic plaques have been evaluated and are being used clinically. Unfortunately, for most dermatologic conditions this information is unknown. However, the increased availability of improved phototherapy devices and novel treatment approaches are providing new options for patients and clinicians. In addition, as more studies are conducted utilizing phototherapy devices, a better understanding of how best to use older technologies is being obtained.

BASIC PRINCIPLES OF PHOTOTHERAPY DEVICES AND TYPES OF LAMPS

Phototherapy devices generate light by the conversion of electrical energy into electromagnetic energy. Filters and fluorophores are used to modify the output such that the desired wavelengths are emitted. There are several types of lamps (or bulbs) used to generate therapeutic UVR. These include incandescent lamps, arc lamps, and fluorescent lamps.

Incandescent lamps generate UVR by passing an electric current through a thin tungsten filament, which, in turn, generates heat and light. Because much of the electrical energy is converted to heat, these lamps are relatively inefficient light sources and have relatively short life spans. By sealing the tungsten filament in a quartz envelope that contains a halogen (bromine or iodine), the filament can be made to emit more energetic photons without reducing the longevity of the bulb. These lamps are called quartz halogen lamps and can emit wavelengths within the UV, visible, and IR ranges. In clinical dermatology, these lamps are employed primarily for situations such as phototesting and photodynamic therapy that require visible light.

Arc or gas discharge lamps were the first effective artificial sources of UVR. Arc lamps take advantage of the fact that when a high voltage is passed across two electrodes in the presence of a gas, the electrons of the gas atoms become excited. The *arc* of an arc lamp refers to the electric arc generated when the gas is ionized (ionized gas is also known as *plasma*) by a high electric current. When the gas electrons return to their ground state, light is emitted. The type of gas incorporated into the lamp determines the wavelengths

that are emitted (i.e., spectral output). The output of arc lamps can be modulated by altering the gas pressure within the bulb such that at high pressures, the peak wavelength output broadens. High-pressure arc lamps typically contain mercury or xenon gas whereas low-pressure arc lamps utilize fluorescent material. In addition to altering the gas pressure to modify the spectral output of arc discharge lamps, the addition of metal halides broadens the output spectrum such that it becomes nearly continuous across the UV spectrum. For example, when mercury arc lamps are operated at high pressures, they have output emission peaks (so called mercury lines) seen at 297, 302, 313, 334, and 365 nm. In contrast, if a metal halide is added to the mercury, the output between these peaks is increased and is thus more continuous. The use of optical filters can then further refine the output of these lamps such that only the desired wavelengths are emitted. The advantage of metal halide lamps is the high output, which allows for shorter treatment times. However, they are more costly and more difficult to operate than fluorescent lamps. One example of a metal halide lamp currently in clinical use is the UVA1 light source.

Fluorescent lamps are the most commonly used sources of therapeutic UV light. These lamps take advantage of the fact that chemicals called *phosphors* (a specific type of chromophore also called a *fluorophore*) absorb and then reemit light. The light that is reemitted is of lower energy (and thus longer wavelength) than the inciting light. Using this principle, the UVC irradiation (that peaks at 254 nm) generated from a low-pressure mercury lamp can be converted to the longer UVB and UVA wavelengths of light that are desirable for phototherapy. The final output of a fluorescent lamp is dictated by the specific phosphor of the bulb. An important advance in photodermatology came with the development of a modified fluorescent lamp that emits largely at 311 nm.[38] Broadband UVB and UVA light sources used for PUVA are other examples of fluorescent lamps.

Because different forms of phototherapy are used to treat different diseases, it is important and practical to divide devices based upon wavelength. Devices to deliver broadband UVB (BB-UVB), 311-nm narrowband UVB (NB-UVB), UVA (for use in psoralen photochemotherapy), and UVA1 (340–400 nm) are available in the United States and in most other countries. In addition to differing by spectral output, phototherapy devices range in the surface area that they are designed to treat (whole body, localized regions, or only lesional skin). Devices used for large body surface areas resemble booths (which patients enter for each treatment). These devices come in a variety of styles from round cylinders to folding units that can be unfolded for treatments and then collapsed while not in use. Devices have been developed to treat more limited areas (such as the palms and soles) and as such they are substantially smaller in size. Finally, targeted therapy utilizes devices that can deliver therapeutic ultraviolet radiation only to lesional skin and range in size from small handheld units to devices with a handheld wand attached to a larger UVR-generating component.

BROADBAND UVB AND NARROWBAND UVB

Originally used for psoriasis therapy, artificial sources of broadband UVB (BB-UVB) have been used therapeutically since the early twentieth century. In particular, UVB combined with the topical application of coal tar (as developed initially by William Goeckerman) was a mainstay of psoriasis treatment for many decades.[39] More recently, with the development and availability of narrowband UVB, some dermatologists have concluded that BB-UVB is obsolete.[40] However, BB-UVB is still widely used in the United States for a variety of conditions including psoriasis, atopic dermatitis, prurigo nodularis, and uremic pruritus.[36] In addition, some patients who are unable to tolerate NB-UVB will respond to BB-UVB.[36]

The most commonly employed devices that deliver BB-UVB utilize fluorescent lamps. These devices emit UVR over a broad spectral range. Approximately, two-thirds of the output is in the UVB range and the rest is primarily in the UVA. However, because wavelengths within the UVB have nearly much more energy than wavelengths within the UVA, the UVA emitted contributes little to the therapeutic efficacy, assuming the patient is not taking a photosensitizing medication. BB-UVB and NB-UVB have been specifically designed to limit output below <290 nm (i.e., in the UVC range).

The wavelengths that most efficiently clear psoriasis are approximately 313 nm.[41] In contrast, wavelengths less than 300 nm are the most efficient at causing erythema and nonmelanoma skin cancer. Based on this knowledge, light sources, termed narrowband UVB (NB-UVB), have been produced.[38] These light sources emit only wavelengths between 308 and 313 nm, and have largely supplanted BB-UVB UV radiation sources for phototherapy. Although originally used to treat psoriasis, they have now been used to treat a number of other inflammatory skin diseases as well.

The initial starting dose of both broadband and narrowband UVB is determined in one of two ways (Tables 237-1 and 237-2). In the first, the minimal erythema dose (MED) is determined by exposing 6 one cm^2 areas of skin on the inner aspect of the forearm or lower back to gradually increasing amounts of UV radiation from the same device that will be used for phototherapy. Twenty-four hours later, the UV exposed areas of skin are examined and the smallest UV dose that results in uniform erythema over the entire area, considered the MED, and phototherapy is initiated at 50% to 70% of that amount. Alternatively, the initial dose of phototherapy is established based empirically on Fitzpatrick skin phototype[42] (see Tables 237-1 and 237-2). Subsequent exposures are given 2–5 times per week and the dose is increased at each treatment, assuming the patient has not developed an erythema response. If an erythema response has occurred, then, depending on its severity, the dose is either reduced or the treatment is delayed (see Tables 237-1 and 237-2). The maximum NB-UVB dose that should be administered is 2,000–5,000 mJ/cm^2 depending on the photoreactive skin type. If patients miss treatments, dosage

TABLE 237-1
Narrowband UVB Phototherapy[a]

I. MED-based
  A. MED determination
    Expose 1-cm^2 areas on the lower back or inner aspect of the forearm to 200, 400, 600, 800, 1,000, 1,200 mJ/cm^2; read at 24 h
  B. Initial exposure: 50%–70% of MED
  C. Subsequent exposures: 2–5 times per week
    Increase UV dose by 10%–20% with each treatment
II. Fitzpatrick skin phototype–based
  Initial exposure based on Fitzpatrick skin phototype; subsequent exposures as above

modifications should be made to avoid burns (see Table 237-5).

PUVA

Psoralen-UVA photochemotherapy (known by the acronym PUVA) combines the oral ingestion or topical application of psoralens with exposure to UVR in the UVA range. Although psoralens and sunlight had been employed for thousands of years for the treatment of vitiligo, it was not until 1947 that PUVA in its modern form was described, initially for the treatment of vitiligo, and subsequently for the treatment of psoriasis.[43]

Three forms of psoralen are used in photochemotherapy regimens: 8-methoxypsoralen (8-MOP), 5-methoxypsoralen (5-MOP), and 4,5′,8-trimethylpsoralen (TMP). In the United States, only 8-methoxypsoralen is available. There are two oral formulations of 8-MOP, a micronized form which is typically given at a dose of 0.6 mg/kg 120 minutes prior to UVA exposure or a dissolved form which is given at a dose of 0.4–0.6 mg/kg 90 minutes before UVA exposure. The dissolved preparation is absorbed faster and yields higher and more reproducible serum levels and is therefore more commonly employed as a part of PUVA phototherapy regimens.

The most common sources of radiation for PUVA therapy are UVA fluorescent lamps, which have a maximum emission at 352 nm, near the absorption maximum for psoralens. For oral PUVA therapy, UVA radiation is usually initiated at a dose that corresponds to the 50%–70% of the minimum phototoxic dose (MPD) or according to the Fitzpatrick skin phototype (Table 237-3). The MPD is determined by having the patient take the dose of the oral psoralen to be used for the photochemotherapy treatment and exposing 6 one-cm^2 areas of skin to gradually increasing doses of UVA. The MPD is evaluated 72 hours after UVA exposure and is the lowest amount of UVA that produces a uniform erythema over the entire area. In the United States, it is more common to initiate therapy based on the Fitzpatrick skin phototype (see Table 237-3). Treatments are usually given 2–4 times per week, avoiding consecutive days. The amount of UVA that is to be given is increased with each treatment. UVA dose

modifications are made if an erythema response develops or treatments are missed (see Table 237-3).

Delivery of psoralens in bathwater is popular in some areas of the world because it provides a uniform drug distribution over the skin surface, is associated with very low psoralen plasma levels, and rapid elimination of free psoralens from the skin. This form of psoralen delivery circumvents gastrointestinal side effects and possible phototoxic hazards to the eyes associated with the oral form. Skin psoralen levels are highly reproducible, and photosensitivity lasts no more than two hours. Bath-PUVA consists of 15–20 minutes of whole-body immersion in solutions of 1-mg 8-MOP per liter of body temperature bathwater (Table 237-4). 5-MOP and trimethylpsoralen are also employed for bath PUVA. Irradiation is performed immediately after bathing, as photosensitivity decreases rapidly. Bath PUVA is started at 30% of the MPD. Treatments are typically given twice weekly. Guidelines for bath, local immersion, and other topical PUVA forms have been published by the British Photodermatology Group.[44] A cost-effectiveness analysis of data collected across four centers in Scotland revealed that courses of both bath PUVA and other topical PUVA were consistently more expensive than oral PUVA.[44] This is related predominantly to the increased nursing time required, although the cost of topical preparations also tends to be greater than oral preparations.

More recently, cream PUVA has been developed, which can be used to treat local and more widespread disease. Thirty minutes following the application of a psoralen-containing cream, patients are exposed to UVA irradiation.

AVOIDANCE AND MANAGEMENTS OF BURNS

Sunburn-like reactions are the most common short-term adverse effect of phototherapy. UVB burns usually peak at 12–24 hours, and PUVA burns at 24–48 or even 72 hours, with more severe burns peaking later than mild ones. Severe burns over a large portion of

TABLE 237-5
Modification of Phototherapy Dose for Erythema or Missed Sessions[a]

No erythema	Increase by 25%
Erythema with no pain	No increase
Erythema with pain	Hold treatment until symptoms subside
Erythema with pain and blistering	Hold treatment until symptoms subside and then reduce dose by 50% from last dose
Modification of phototherapy dose for missed treatments:	
<1 week	No increase in dose
1–2 weeks	Decrease dose by 50% (BB-UVB) or 25% (NB-UVB or PUVA)
2–3 weeks	Decrease dose by 75% (BB-UVB) or 50% (NB-UVB PUVA)
>3 weeks	Restart at initial exposure dose

[a]Modified from Refs. 1, 330, and 331.

the skin surface produce systemic toxicity with fever and malaise in addition to pain. Severe PUVA burns, which extend well into the dermis, can lead to epidermal sloughing and are an indication for admission to a burn-care hospital facility. To avoid exacerbating a still developing PUVA burn, it is recommended that PUVA treatments not be given on consecutive days. Table 237-5 specifies the UVB or UVA dose adjustments in the event of a burn reaction during phototherapy. A burn reported by the patient at the next visit, even if no longer visible, should be managed in the same manner as a still-visible reaction. Burns over limited body areas, such as just the face or breasts, can be managed by local application of an appropriate sunscreen before or part way through subsequent treatments, especially if the area is not affected by the disease being treated. However, care must be taken to consistently protect the same area(s) in order to avoid a sudden full treatment to previously shielded skin.

Repeated UV-irradiated skin develops tolerance to subsequent exposures, allowing and indeed mandating progressively larger doses for optimal therapeutic effect. However, this tolerance is rapidly lost when exposures cease, requiring downward adjustments of dose after as little as 1 week (Table 237-5) to avoid burns.

UVA1. Because of its longer wavelength, UVA1 phototherapy (340–400 nm) is able to penetrate more deeply into the skin than UVB or shorter range UVA called UVA2 (i.e., 320–340 nm). The first report describing a device capable of emitting UVA1 occurred in 1981.[45] It was not until 1992 when the therapeutic benefit of UVA1 was demonstrated for atopic dermatitis that greater interest in the therapeutic properties of UVA1 occurred.[46–47] Initially, one obstacle to the widespread use of the initial UVA1 devices was the intense heat that they generated. Newer UVA1 phototherapy units incorporating a specialized filtering and cooling system that removes nearly all wavelengths above 530 nm have largely eliminated this problem. Though not widely available in the United States, these light sources are useful for the management of a variety of dermatological conditions for which other forms of phototherapy are not helpful.[48–49]

UVA1 is administered 3–5 times per week. There have been several studies, which have attempted to establish the optimal amount of UVA1 to administer at each treatment session.[50–54] Three dosing regimens have been used: (1) low dose (10–30 J/cm^2), (2) medium dose (40–70 J/cm^2), and (3) high dose (130 J/cm^2).[50–54] Although several comparison studies have been performed, at this point, there is no consensus as to which dose is best. In general, patients are started at 20–30 J/cm^2 and increased to the full dose within 3–5 treatments.[55] The risk of burns is far less than with UVB or PUVA therapy.

TARGETED PHOTOTHERAPY

Unlike the previously described phototherapy devices that expose both lesional and uninvolved skin to UVR, targeted phototherapy delivers therapeutic doses of UVR only to lesional skin. Targeted phototherapy has also been called focused phototherapy, concentrated phototherapy, and microphototherapy. Several devices are available to deliver targeted phototherapy including both monochromatic (one wavelength) and polychromatic systems. There are several advantages to targeted phototherapy. These devices spare normal skin, thereby allowing higher fluences to be delivered to diseased skin while decreasing the risk of acute and chronic side effects to normal skin. Targeted therapy can be used on treatment-resistant lesions and on difficult anatomic locations (such as the scalp, chin, and nails). The handheld nature of a targeted phototherapy device may be easier for young children than receiving treatments in a phototherapy booth, which can be large and intimidating. The limitations of targeted phototherapy are device expense and the fact that it may not be practical for patients with more than 10% to 20% of body surface area involved to receive treatments in this manner. The preventive action of phototherapy on uninvolved but at-risk skin is also lost. Targeted phototherapy devices include excimer lasers and nonlaser devices known as monochromatic excimer light (MEL) devices.[37] Both types of devices have been used to deliver targeted therapy to treat specific lesions of diseases such as psoriasis and vitiligo.[36–37] While both types deliver monochromatic UVB irradiation (most commonly at 308 nm), they differ in several respects. Lasers typically deliver UVR to a smaller area but are capable of emitting higher amounts of radiation over a shorter period of time. In contrast, MEL devices deliver monochromatic irradiation to a larger area but with a lower power density. There are also several devices that emit polychromatic UVA or UVB (BB- or NB-UVB)

to targeted areas. These devices typically utilize fiberoptic systems coupled with UVB generating sources. These devices have spot sizes from 1–3 cm. In addition, they have multiple delivery programs and automatic calibration, which makes treatment with predetermined dosages possible. These devices are smaller, less expensive, and have less maintenance problems than lasers.[56–57] Treatment protocols with targeted phototherapy vary depending on the type of device that is employed.

SAFETY OF PHOTOTHERAPY

Safety principles are common to most phototherapy devices. Equipment should be checked on a regular basis by the clinical staff or the manufacturer's engineer, since bulb output may change over time, and internal dosimetry components may fail. While phototherapy is usually delivered without incident, the risk of overtreatment is real, although the exact incidence of adverse events attributable to phototherapy is unknown and varies depending on the device. Importantly, with the exception of PUVA therapy for which formal long-term follow-up studies established an increased risk of lentigines, squamous cell carcinoma and melanoma, other forms of phototherapy appear to be remarkably safe.[36,58] Newer therapies such as narrowband UVB and UVA1 appear to be relatively safe especially compared to nonphototherapeutic options for the same diseases, but await longer follow-up.

UVB

Repeated exposure of the skin to UV irradiation does result in cumulative actinic damage regardless of the source. With respect to nonmelanoma skin cancer, most studies have shown that there is little risk beyond that associated with habitual sun exposure with either BB-UVB or NB-UVB phototherapy.[59–60] Greater than 300 treatments BB-UVB is associated with a modest but significant increase in SCC and BCC.[61] However, the carcinogenic risk of a single PUVA treatment is about seven times greater than a single UVB treatment.[62] As a result of its safety profile and efficacy, NB-UVB has emerged as a leading therapy for a number of skin diseases. Several studies have also shown that long-term exposure to BB-UVB combined with topical tar preparations is not associated with an increased risk of SCC.[63]

PUVA

ACUTE SIDE EFFECTS. The side effects of PUVA include drug intolerance reactions as well as the combined action of psoralens plus UVA radiation. Oral 8-MOP may cause nausea (10% of patients) and vomiting, and this occasionally necessitates discontinuation of treatment. These side effects are more common with liquid preparations rather than with crystalline preparations, probably because of higher psoralen serum levels. The nausea may be minimized or avoided by instructing the patient to take 8-MOP with milk, food, or ginger (e.g., ginger cookies, ginger ale, ginger supplements)[64] or to divide the dose into two portions, taken approximately one-half hour apart. Other reported effects include nervousness, insomnia, and depression. With 5-MOP, nausea is rare, even with doses up to 1.8 mg/kg body weight.

Following exposure to UVA, approximately 10% of patients undergoing PUVA therapy will experience pruritus. In most cases, this can be alleviated by bland emollients. Some patients with severe pruritus may require systemic treatment. A stinging pain may rarely occur, and the mechanism for this is unknown. The symptoms are usually unresponsive to antihistamines, and, in most instances, subside when the treatment is discontinued.

Mild and often transient focal erythema after PUVA therapy occurs frequently. Any area showing erythema with tenderness or blistering should be shielded during subsequent UVA exposures until the erythema has resolved. As noted above, erythema appearing within 24 hours may signal a potentially severe phototoxic reaction, and may worsen progressively over the next 24 hours, since peak erythema with PUVA characteristically occurs at least 48 hours after the treatment. In that situation, patients should be protected from further UVA exposures and sunlight, and should be monitored closely until the erythema has resolved.

Very rare side effects of PUVA include polymorphous light eruption-like rashes, acne-like eruptions, subungual hemorrhages caused by phototoxic reactions of the nail beds, onycholysis of the nails, and occasionally hypertrichosis of the face. These disappear when treatment is discontinued. Analysis of laboratory data in several large studies revealed no significant abnormal findings in patients receiving PUVA over prolonged periods of time.[65–67]

Chronic Actinic Damage. Chronic exposure to PUVA may result in skin changes that resemble photoaging, and which is aggravated by chronic natural sun exposure. PUVA lentigines are small brown macules with irregular borders and uneven pigmentation[68] and are histologically characterized by proliferation of large melanocytes.[69] In contrast to solar lentigines, melanocytes in PUVA lentigines often display an increased size of melanosomes, clustering and binucleation with nuclear hyperchromatism, and cellular pleomorphism. T1799A B-type Raf (BRAF) mutations have been found to be present in PUVA lentigines,[70] but the full significance of this is not yet understood, as both cutaneous malignant melanoma and benign melanocytic nevi often have BRAF mutations.[71–74] The presence of these lesions is directly related to the number of PUVA treatments and total UVA dose that has been administered. The absence of PUVA lentigines serves as a useful indicator of a lower risk of PUVA malignancy.[75]

Carcinogenesis. Cutaneous malignancies are the major concern of long-term and repeated PUVA treatments. The risk of nonmelanoma skin cancer and possibly malignant melanoma increases in a dose-dependent

manner. In laboratory animals, 8-MOP and 5-MOP have unequivocally induced skin cancer at levels of drug and UVA irradiation comparable to those used in PUVA therapy.[76] Cancer development is thought to stem from both DNA damage and down-regulation of the immune system. The PUVA Follow-up Study, which evaluated 1,380 patients who began PUVA treatment for psoriasis in 1975 and 1976 has documented major health events in these individuals in a prospective manner. Overall, patients who were treated with at least 337 PUVA treatments exhibited a 100-fold increased risk of SCC compared to that expected from population incidence rates.[77] Moreover, almost 4% of patients with SCC developed metastases, most commonly originating in the genital area. There is uncertainty about PUVA being the sole factor as many of the patients in the long-term follow-up studies also had significant exposure to sunlight and to treatments with carcinogenic potential, including arsenic, UVB, and methotrexate. The risk of developing SCC with PUVA may be further potentiated by the use of cyclosporine and, for this reason, cyclosporine is contraindicated in individuals who have been treated with PUVA.[78] Oral retinoids used concurrently with PUVA, on the other hand, reduce the risk of SCC.[79]

Individuals treated with PUVA are at increased risk of cutaneous malignancies of the genitalia, and this has led to standard protection of the genitalia during phototherapy.[80] The risk is dose-dependent, with a 90-fold increased risk of genital tumors among patients exposed to high doses of PUVA compared with that expected in the general population. Men treated with high-dose exposures to both PUVA and topical tar/UVB have the greatest risk of genital tumors.[80–81] There is currently no standardized regimen for genital shielding. There are pouches for genital shielding that are commercially available, but the cost and availability may be prohibitive. Factors influencing the effectiveness of UV irradiation protection include fiber composition, porosity (intrinsic to which is number of layers, weave type, and thread count), mass, and color.[82–83] Commonly used protective agents include surgical masks, paper towels, blue surgical towels, and underwear. The efficacy of these materials has been studied, and surgical masks were found to provide insufficient protection against UV irradiation most likely due to increased porosity (looser weave) and decreased mass.[84]

The relationship between PUVA and melanoma has also been examined in detail. The PUVA Follow-Up Study has provided evidence that individuals with at least 250 treatments and at least 15 years from the first PUVA treatment were at increased risk of developing melanoma.[85] Patients who developed a phototoxic reaction more easily were at higher risk for melanoma than those with darker skin.[86] As a result of those studies, a personal or family history of melanoma or a history of greater than 200 PUVA treatments is considered to be a relative contraindication to further PUVA therapy.[86]

In patients employing PUVA therapy in combination with methotrexate for at least 36 months, the incidence of lymphoma was more than 7 times higher than that of cohort members earlier in the study who had not taken methotrexate.[87]

Ophthalmologic Effects. UVA is absorbed in the lens and in the presence of UVA, psoralens can bind protein, DNA, and RNA. Because the lens never sheds its cells, protein-bound 8-methoxypsoralen accumulates in the lens, increasing the risk of irreversible opacification.[88] There have been reports of various ocular problems in patients on PUVA including cataracts, 89–90 conjunctival hyperemia,[91] and decreased lacrimation.[91]

A 25-year prospective study[92] sought to evaluate the effect of PUVA on the eyes. Participants were instructed to use UVA-blocking eyewear when outside or looking outside through window glass during daylight for a minimum of 12 hours, although current labeling calls for 24 hour protection. This study found no relationship between increasing numbers of PUVA sessions and visual impairment or cataracts, and demonstrates that increasing exposure to PUVA does not increase cataract risk among middle-aged and older persons using eye protection as practiced by this cohort.[92] Other smaller studies have also found no increase in cataract formation or visual impairment.[93–96]

UVA1

UVA1 phototherapy is generally well tolerated.[52–53] Reported side effects include intense tanning, erythema, pruritus, urticaria, tenderness, a burning sensation, polymorphous light eruption, eczema herpeticum and bacterial superinfection.[48–49,54] However, because UVA1 phototherapy has only been available since the 1990s, the long-term effects are still under investigation.

SPECIAL CONSIDERATIONS

HIV. The safety of phototherapy and photochemotherapy in HIV-positive patients has been debated. Ultraviolet radiation may activate HIV by the induction of NF-κB,[97–99] and UVB therapy increases *HIV-1* gene expression in the skin.[100–102] However, BB-UVB phototherapy does not appear to affect plasma HIV levels nor does it have an effect on CD4 counts.[101,103–104] In general, phototherapy is thought to be safe for HIV patients.[105] A consensus statement published by the American Academy of Dermatology in 2010 concluded that for moderate-to-severe psoriasis in HIV-positive patients, phototherapy and antiretrovirals are the recommended first-line therapeutic agents.[106]

CHILDREN. NB-UVB is now preferred to PUVA in children for most skin conditions, because of concern about PUVA side effects including phototoxicity, carcinogenicity, photoaging, and the potential development of cataracts.

MISCELLANEOUS. Patients who have had arsenic exposure are at increased risk for cutaneous

malignancies and should avoid phototherapy. Transplant patients have a much higher risk of skin cancer compared to the general population and, in that patient population there is a relative contraindication to phototherapy. Photosensitizing medications should theoretically be avoided during phototherapy treatment, although in practice many patients uneventfully receive phototherapy while taking tetracycline, hydrochlorothiazide, or other photosensitizing drugs. There are anecdotal reports of an association between chronic use of voriconazole and the development of aggressive cutaneous malignancies including melanoma.[107–110]

DISEASES AMENABLE TO PHOTOTHERAPY

(Table 237-5)

Responses of the diseases listed in eTable 237-6 are discussed in detail online. See also Chapter 238.

:: Herbert Hönigsmann, Rolf-Markus Szeimies, & Robert Knobler

PHOTOCHEMOTHERAPY AND PHOTODYNAMIC THERAPY AT A GLANCE

- Photochemotherapy [psoralen and ultraviolet A light (PUVA)] has been successfully used for more than 30 years. Its effectiveness has profoundly influenced dermatologic therapy in general, providing treatment for a number of diverse disorders besides psoriasis and vitiligo.
- PUVA can be combined with topical treatments and with some systemic agents (retinoids, methotrexate, and, perhaps, biologics) to enhance efficacy and to reduce the number of exposures.
- The most important adverse effects of oral PUVA consist of an increased risk of squamous cell carcinoma and a possible risk of melanoma. No such increased risk was found so far with bath-PUVA.
- Extracorporeal photochemotherapy (ECP) was introduced in the 1980s for the palliative treatment of erythrodermic cutaneous T-cell lymphoma.
- ECP appears to have a major impact in the treatment of graft-versus-host disease after allogeneic bone marrow transplantation where it allows progressive reduction or even discontinuation of the concomitant immunosuppressive therapy without an increase in graft-versus-host disease activity. Several other indications are under investigation.
- No serious side effects have been reported with ECP.
- Photodynamic therapy (PDT) for skin tumors started with the introduction of topical photosensitization by a porphyrin precursor (5-aminolevulinic acid) that would avoid generalized light sensitivity over many weeks.
- Current experience with PDT of epithelial cancers and precancerous conditions suggests that actinic keratoses, Bowen disease, superficial and nodular basal cell carcinomas, and early squamous cell carcinomas can be treated curatively.
- The only significant side effect of topical PDT is a stinging pain during and shortly after irradiation. PDT has neither mutagenic nor carcinogenic potential.

PHOTOCHEMOTHERAPY

Photochemotherapy with psoralens combines the use of oral or topical psoralens (P) and ultraviolet A radiation (UVA), termed *PUVA*. Psoralens are phototoxic compounds that enter cells and then absorb photons to produce photochemical reactions that alter the function of cellular constituents.[1] This interaction results in a beneficial therapeutic effect after repeated controlled phototoxic reactions. Psoralens can be administered orally or applied topically to the skin in the form of solutions, creams, or baths. This therapy is currently used in the treatment of several common and uncommon skin diseases.

HISTORICAL BACKGROUND

In the 1970s, it was shown that orally administered 8-methoxypsoralen (8-MOP) and subsequent irradiation with artificial UVA was a highly effective treatment for psoriasis.[2,3] Psoralen baths (soaking in a dilute psoralen solution) and subsequent UVA exposure (bath-PUVA), which originated in Scandinavia,[4] is also being used in many European institutions. The effectiveness of all variants of PUVA has been widely confirmed and has profoundly influenced dermatologic therapy, in general, providing treatment for numerous disorders in addition to psoriasis (Table 238-1). A major advance in phototherapy was the development of fluorescent bulbs that emitted narrowband UVB radiation at 311–313 nm in the mid-1980s. This narrow spectrum is slightly inferior in clearing psoriasis or mycosis fungoides. However, due to the fact that it is easier to perform and possibly safer than PUVA, it is now more frequently used in many phototherapy centers. Narrowband UVB phototherapy is also beneficial for a variety of other dermatoses that were previously treated with PUVA. Nevertheless PUVA has still remained the mainstay for recalcitrant diseases.

TABLE 238-1
Phototherapy-Responsive Diseases

Therapy of Disease	Prevention of Disease Symptoms
■ Psoriasis	■ Polymorphous light eruption
■ Palmoplantar pustulosis	■ Hydroa vacciniforme[a]
■ Mycosis fungoides (stages IA, IB)	■ Solar urticaria
■ Vitiligo	■ Erythropoietic protoporphyria[a]
■ Atopic dermatitis	■ Chronic actinic dermatitis[a]
■ Generalized lichen planus	
■ Urticaria pigmentosa	
■ Cutaneous graft-versus-host disease	
■ Generalized granuloma annulare	
■ Pityriasis lichenoides*	
■ Lymphomatoid papulosis[a]	
■ Pityriasis rubra pilaris[a]	
■ Localized scleroderma[a]	

[a]Experience limited to small number of patients.

PRINCIPLES OF PHOTOCHEMOTHERAPY

The rationale for PUVA therapy is to induce remissions of skin diseases by repeated, controlled phototoxic reactions. These reactions occur only when psoralens are photoactivated by UVA. Due to the penetration characteristics of UVA, absorption of photons is confined to the skin. However, there is also some evidence that PUVA may exert systemic effects through circulating lymphocytes affected while transiting through the skin. Clinically, PUVA-induced phototoxic reactions are characterized by a delayed sunburn-like erythema and inflammation.

PSORALENS. Three psoralens are used in PUVA therapy. Methoxsalen or 8-methoxysporalen (8-MOP), obtained from the seeds of a plant called *Ammi majus*, is most widely used and the only psoralen available in the United States. Bergapten or 5-methoxypsoralen (5-MOP) and trioxsalen or 4,5′,8-trimethylpsoralen (TMP) are available in Europe and elsewhere.

Psoralen Photochemistry.[5–7] Psoralens intercalate between apposing DNA base pairs in the double helix in the absence of UV radiation. Absorption of photons in the UVA range results in the formation of a 3,4- or 4,5-cyclobutane addition product (adduct) with pyrimidine bases of native DNA. In the first step of this photochemical reaction, a monofunctional adduct with thymine or cytosine is formed. Some psoralens, including 8-MOP, TMP, and 5-MOP, can absorb a second photon, and this reaction leads to the formation of a bifunctional adduct with a 5,6 double bond of the pyrimidine base of the opposite strand, thus producing an interstrand cross-link of the double helix (Fig. 238-1). This intercalation of psoralens with epidermal DNA suppresses both DNA synthesis and cell division, and it was originally assumed that this was the therapeutic mechanism in psoriasis. However, cross-linking does not appear to be a prerequisite for the therapeutic effect,[7] and successful PUVA treatment of other skin diseases is unlikely to be directly caused by this molecular reaction; psoralens also react with RNA, proteins, and other cellular components, and indirectly modify proteins and lipids via singlet oxygen-mediated reactions or by generating free radicals.[7] Perhaps these mechanisms contribute to the effects of PUVA in diseases that are not hyperproliferative in nature.

The formation of mono- and bifunctional photoadducts in DNA results in the immediate inhibition of DNA synthesis. The interstrand cross-links are believed to be largely responsible for eliciting skin photosensitization reactions of linear psoralens such as 8-MOP. Excessive production of these cyclobutane adducts causes cell death. Mutation and skin carcinogenesis also result from photoconjugation of psoralens to DNA because the cells surviving this DNA damage tend to repair it through an error-prone repair process.[7]

In type II reactions (see Chapter 90), reactive oxygen species ($^1O_2$, O_2, or OH) induce the oxidation of cellular lipoprotein membrane lipids and destruction of membrane-bound cytochrome P450. The membrane-damaging events activate the arachidonic acid metabolism pathway, which results in an increase of secondary oxidation products that contribute to the increased synthesis of eicosanoids. Furthermore, the reactive oxygen species can directly damage DNA by generating DNA strand breaks.[7]

Mechanisms of Photochemotherapy. Hypotheses about the mechanism of action in psoriasis are based on the known photoconjugation of psoralens to DNA with subsequent suppression of mitosis, DNA synthesis, and cell proliferation, expected to revert increased cell proliferation rates in psoriasis to normal. However, PUVA also alters the expression of cytokines and cytokine receptors, downregulates certain lymphocyte and antigen-presenting cell functions, influences adhesion molecule expression, and diminishes Langerhans cell numbers within the epidermis. In addition, PUVA affects immune effector cells such as lymphocytes or polymorphonuclear leukocytes. Because there is evidence that psoriasis is caused primarily by the action of blood-derived immunocytes, it is reasonable to speculate that PUVA therapy may act by affecting immune function through a direct phototoxic effect on lymphocytes in skin infiltrates. This is consistent with the observation that several other disorders that are not hyperproliferative in nature but immunomediated also respond well to PUVA. PUVA can revert pathologically altered patterns of keratinocyte differentiation and reduce the number of proliferating epidermal cells. Infiltrating lymphocytes are strongly suppressed by PUVA, with variable effects on different T-cell subsets. Lymphocytes are far more likely to undergo apoptosis than keratinocytes[8] in

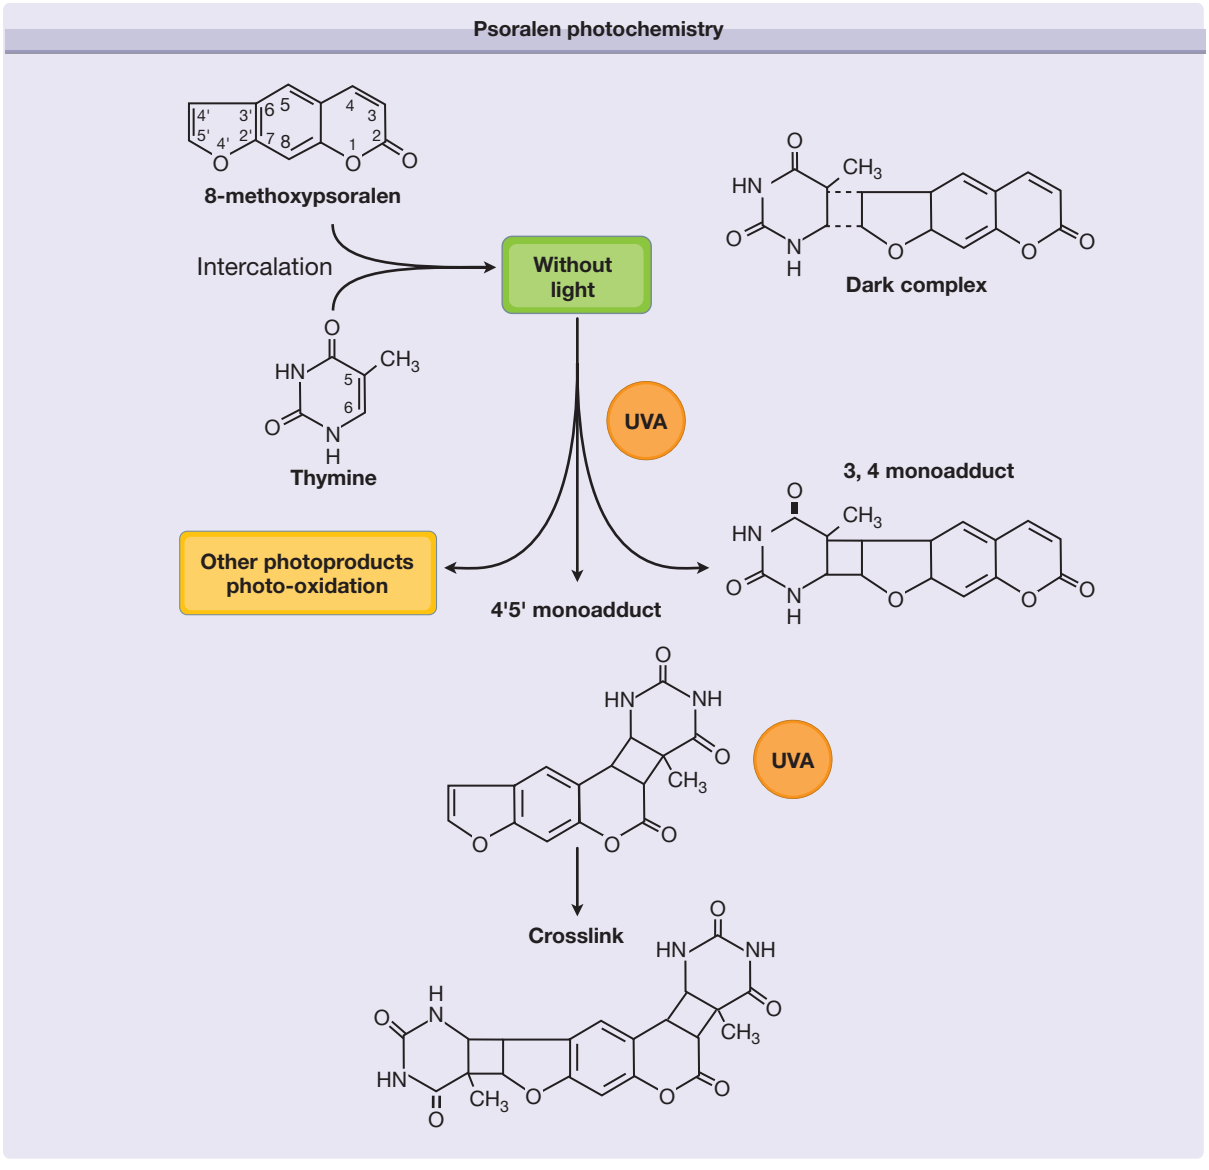

Figure 238-1 Psoralen photochemistry. Psoralens intercalate between apposing DNA base pairs forming a "dark complex." Absorption of ultraviolet A (UVA) photons leads to a 3,4- or 4,5-cyclobutane monoadduct with pyrimidine bases of native DNA. The absorption of a second photon results in a bifunctional adduct producing an interstrand cross-link of the double helix.

response to PUVA, which may explain the high efficacy in cutaneous T-cell lymphoma (CTCL), as well as in inflammatory skin diseases including psoriasis that is now recognized to be in part T-cell mediated as well as hyperproliferative. Although much is known about pathways and mechanisms of psoralen photosensitization, the interactions and relative contributions to the clearing of a specific disease are not well understood.

Psoralens also stimulate melanogenesis. This involves the photoconjugation of psoralens to DNA in melanocytes, mitosis, and subsequent proliferation of melanocytes, an increased formation and melanization of melanosomes, an increased transfer of melanosomes to keratinocytes, and activation and increased synthesis of tyrosine mediated in part by stimulation of cAMP activity.

Pharmacokinetics. The important steps between the ingestion of a psoralen and its arrival at the site of action include absorption, first-pass effect, blood transportation, and tissue distribution. The absorption rate of a psoralen from the gut depends mainly on the physical characteristics of the preparation and the fat content of the concomitant food intake. Liquid preparations of 8-MOP and 5-MOP give higher and earlier peak serum levels than do crystalline formulations. In addition, peak serum levels are achieved by liquid preparations after a relatively reproducible time interval in all subjects, whereas wide time variability occurs with crystalline formulations. Before reaching the skin via the circulation, psoralens are metabolized during passage through the liver. Plasma levels of 8-MOP administered orally at different doses show a

strong nonlinearity, indicating a saturable first-pass effect. The unpredictable pharmacokinetic behavior is probably due to inter- and intraindividual variations of intestinal absorption, first-pass effect, blood distribution in the body, metabolism, and elimination of the drug.

Within the same individual, serum levels of 8-MOP correspond fairly well with skin reactivity, the peak of skin phototoxicity coinciding with peak serum levels. However, phototoxic responses to PUVA show large interindividual variations. Hence, measurement of serum psoralens is a research tool and not used to monitor clinical therapy.

The pharmacokinetics of 8-MOP after topical treatment depend on the method of application. 8-MOP topically applied as a 0.15% emulsion or solution leads to plasma levels comparable to those found with oral treatment if large areas of the body are treated. In contrast, plasma levels after bath-PUVA treatment of almost the total body surface are very low. Bathwater-delivered psoralens are readily absorbed in the skin but are promptly eliminated without cutaneous accumulation.[8]

Ultraviolet A Radiation. UVA sources commonly used for PUVA therapy are fluorescent lamps or high-pressure metalhalide lamps. The typical fluorescent PUVA lamp has an emission peak at 352 nm and emits approximately 0.5% in the UVB range. UVA doses are given in Joules per centimeter^2, usually measured with a photometer with a maximum sensitivity at 350–360 nm. Although the action spectrum of antipsoriatic activity and phototoxic erythema peaks at 335 nm, longer wavelengths have proved equally effective for clearing psoriasis if delivered in an adequate dose to obtain an equal erythemogenic response.[9]

Photosensitivity Effects of Photochemotherapy. PUVA treatment produces an inflammatory response that manifests as delayed phototoxic erythema, proportional to the dose of both drug and UVA as well as to the individual's sensitivity to phototoxic reactions. 8-MOP dose changes within individuals, over a narrow but clinically relevant range, appears to significantly alter the threshold for PUVA erythema, but not the rate of increase in erythema intensity with increasing UVA dose.[10] Importantly, the time course of PUVA erythema differs from sunburn or UVB erythema that appears after 4–6 hours and peaks 12–24 hours after exposure. PUVA erythema does not appear before 24–36 hours and peaks at 72–96 hours, or even later. Hence, daily PUVA treatments can result in unexpected severe delayed cumulative phototoxicity. PUVA erythema has a shallower dose-response curve than UVB erythema (by a factor of approximately 2) and this difference is maintained even at the point of maximum erythema.[11] Severe PUVA reactions may lead to blistering and to superficial skin necrosis. Overdoses of UVA are frequently followed by swelling, intense pruritus, and, sometimes, by a stinging sensation in the affected skin area, possibly as a consequence of damage of superficial nerve endings. Erythema is at present the only available parameter that allows an assessment of the magnitude of the PUVA reaction; thus, it represents an important criterion for dose adjustments.[9]

Pigmentation is the second important effect of PUVA. It may develop without clinically evident erythema, especially when oral 5-MOP or TMP is used; this is particularly important in the treatment of vitiligo and for the preventive therapy of certain photodermatoses. In unaffected skin, PUVA pigmentation is maximal approximately 7 days after a PUVA exposure and may last from several weeks to months. As with sun-induced pigmentation, the individual's ability to tan is genetically determined, but the dose-response curve is much steeper. A few PUVA exposures result in a much deeper tan than that produced by multiple exposures to solar radiation.

TREATMENT PROTOCOLS

Topical Treatment. Application of 8-MOP in creams, ointments, or lotions followed by UVA irradiation is effective in clearing psoriasis but has several disadvantages. The nonuniform distribution on the skin surface induces unpredictable phototoxic erythema reactions and irregular patches of cosmetically unacceptable hyperpigmentation. Furthermore, if numerous lesions are present, the application is laborious and time consuming, and the treatment does not prevent the development of new active lesions in previously unaffected, untreated areas. Therefore, topical PUVA with psoralen creams, ointments, or lotions is now used only for limited plaque psoriasis and for palmoplantar disease.

Bath Photochemotherapy. The use of bathwater delivery of psoralens provides for a uniform drug distribution over the skin surface, very low psoralen plasma levels, and rapid elimination of free psoralens from the skin. Bathwater delivery of 8-MOP circumvents gastrointestinal side effects and possible phototoxic hazards to the eyes because there is no systemic photosensitization. Skin psoralen levels are highly reproducible, and photosensitivity lasts no more than 2 hours. The higher incidence of unwanted burn reactions can be prevented by a lower starting dose [50% of the minimal phototoxic dose (MPD)] and a more cautious dosimetry in the initial treatment phase. A major drawback in many treatment facilities is the requirement for a bathtub. Originally, bath-PUVA was performed with TMP, but 8-MOP and 5-MOP are now being used as well. Bath-PUVA consists of 15–20 minutes of whole-body immersion in solutions of 0.5- to 5.0-mg 8-MOP per liter of bathwater. Irradiation needs to be performed immediately, as photosensitivity decreases rather rapidly. TMP is more phototoxic after topical application and is used at lower concentrations than 8-MOP. Minimal phototoxicity dose (MPD) determination for bath-PUVA must take into account that the phototoxic threshold declines during the early treatment phase,[8] in contrast to oral PUVA. Guidelines for bath, local immersion, and other topical PUVA forms have been published by the British

Photodermatology Group and are based, where possible, on the results of controlled studies, or otherwise on consensus.[12]

Oral Treatment. In oral PUVA, 8-MOP is administered orally (0.6–0.8 mg/kg body weight) 1–3 hours before exposure, depending on the absorption characteristics of the particular drug brand. Liquid drug preparations are absorbed faster and yield higher and more reproducible serum levels than microcrystalline forms. For 5-MOP, the usual dosage is 1.2- to 1.8-mg/kg body weight.

The initial UVA doses are determined by either the patient's skin type[13–15] or by MPD testing.[9] The MPD is defined as the minimal dose of UVA that produces a barely perceptible, but well-defined, erythema when template areas of the skin are exposed to increasing doses of UVA. Erythema readings are performed 72 hours after testing, at which time the psoralen phototoxicity reaction usually reaches its peak. The MPD test should be performed on previously nonexposed skin (e.g., buttocks). Although the MPD test is more time-consuming than phototyping, it allows for more accurate and higher UVA doses during initial treatment. Table 238-2 shows recommendations for dosimetry in bath and oral PUVA.

Repeated exposures are required to clear PUVA-responsive diseases, with gradual dose increments as pigmentation develops. Lower doses quite frequently result in failure of treatment except in those diseases in which induction of pigmentation is the desired objective. In most dermatoses amenable to PUVA, the frequency of treatments is reduced after satisfactory clearing of disease, and the last UVA dose is used as a maintenance dose, if maintenance treatment is planned. The duration of this maintenance phase and the frequency of treatments depend on the particular disease being treated and its propensity to relapse.

INDICATIONS FOR PHOTOCHEMOTHERAPY

PHOTOCHEMOTHERAPY FOR PSORIASIS.

Basically all types of psoriasis respond to PUVA (Figs. 238-2 and 238-3), although the management of erythrodermic or generalized pustular psoriasis is more difficult.[8] The effectiveness of oral PUVA in inducing and maintaining remission of psoriasis has been widely documented and confirmed by large-scale clinical trials (see Figs. 238-2 and 238-3).

Administration. Three studies have compared bathwater delivery of 8-MOP with oral administration.[8] In two reports, initial doses were determined by skin typing, and treatments were given two to three times weekly. Dose increments were instituted with every treatment in one study, whereas smaller increments were given every third treatment in the other. In the third report, patients were treated according to the standard European regimen for oral PUVA, which is still in use (treatments four times weekly with an intermission on Wednesdays until clearing). This showed the lowest incidence of treatment failures and overdose phenomena, despite the potential burn risk of back-to-back PUVA treatments. Compared with oral 8-MOP, bath-PUVA showed equal clearing rates with fewer exposures.[8] The greater therapeutic efficacy could be because of a higher penetration of psoralens through the abnormal stratum corneum overlying psoriatic plaques, as compared with healthy perilesional skin where phototoxicity is monitored during the therapy. The incidences of erythema and pruritus were similar or lower compared with oral therapy. Systemic intolerance, such as nausea and vomiting, were not observed.

Oral 5-MOP–PUVA represents an alternative to oral 8-MOP–PUVA. Psoriatic lesions are cleared with a

TABLE 238-2
Recommended Treatment Schedule for Photochemotherapy[a]

Determination of MPD	Reading	After 96–120 hours (Bath-PUVA) After 72–96 hours (Oral PUVA)
Start of treatment	First therapeutic dose	30% of MPD (bath-PUVA) 50%–70% of MPD (oral PUVA)
Treatments two to four times weekly	No erythema, good response No erythema, no response Minimal erythema Persistent asymptomatic erythema Painful erythema (with or without blistering)	Increase once weekly by 30% Increase by 30% per session No increase No increase No treatment until symptoms subside
Resumption of treatment after missed sessions	After resolution of symptoms	Reduction of last dose by 50%; next increase by 10%

MPD = minimal phototoxic dose; PUVA = psoralen and ultraviolet A light.
[a]Exact practices vary between the U.S. and Europe and among practitioners in specific locales, based on historical teaching and individual experiences. See also Chapter 237.

Figure 238-2 Twenty-three-year-old patient with generalized psoriasis (seborrheic type). **A.** Before photochemotherapy treatment. **B.** After treatment. (From Wolff K et al: Photochemotherapie bei Psoriasis. Klinische Erfahrungen bei 152 Patienten. *Dtsch Med Wochenschr* **100**:2471, 1975 with permission.)

comparable number of treatments, but at the expense of significantly higher cumulative UVA doses. This difference may be due to the lower phototoxicity potential of 5-MOP and of its higher tanning activity. However, 5-MOP–PUVA therapy is not associated with nausea and vomiting and has a lower incidence of pruritus and severe phototoxic erythema.[8]

On complete clearing, patients are often assigned to maintenance therapy, during which the frequency of treatments is gradually reduced. The purpose of maintenance therapy is to achieve longer remission. Maintenance therapy in the original European regimen consisted of 1 month of twice-weekly treatments, with the last UVA dose used for clearing, followed by

Figure 238-3 Twenty-three-year-old patient with generalized psoriasis (plaque-type). **A.** Before photochemotherapy treatment. **B.** After treatment. (From Wolff K, Hönigsmann H: Clinical aspects of photochemotherapy. *Pharmacol Ther* **12**:381, 1981 with permission.)

Figure 238-4 Eighteen-year-old patient with pustular psoriasis (von Zumbusch type). **A.** Before photochemotherapy treatment. **B.** After treatment. (From Hönigsmann H et al: Photochemotherapy for pustular psoriasis (von Zumbusch). *Br J Dermatol* **97**:119, 1977, with permission.)

another month of once-weekly exposures. According to other recommendations,[16] maintenance treatment should be considered only on rapid relapses, because patients with a stable remission may be overtreated, and long-term risks of PUVA are related to the total cumulative phototoxic doses. In one recent left-right comparison study with psoriatics, PUVA maintenance treatment over 2 months did not increase the length of remission.[17] Thus, maintenance treatment should be given only in selected cases.

Erythrodermic and generalized pustular psoriasis (von Zumbusch type) respond to PUVA (Fig. 238-4), but the time required to induce remission is considerably longer, more treatments are needed, and higher failure rates are reported, compared with plaque or guttate varieties. Pustular eruptions of palms and soles are quite recalcitrant to treatment, regardless of whether they are true localized pustular psoriasis, nonpsoriatic palmoplantar pustulosis or pustular psoriasis, or pustular eczema. Oral PUVA alone can produce a slow but definite remission in many cases, but a considerable number of patients require adjunctive therapy for clearing. As mentioned above, the combination with topically applied 8-MOP can be beneficial, but bath-PUVA appears to be also quite effective in such cases.

PUVA alone can produce definite remissions in many patients with psoriasis, but a considerable number require additional therapies for clearing. Such combination therapy improves efficacy and may reduce side effects.

Combination Treatments

Topical Combinations. Topical adjuvant therapies with glucocorticoids, anthralin, and tar preparations, and, more recently, with calcipotriol and tazarotene, have yielded good results. However, adjunctive topical therapy is unacceptable to some patients.

Methotrexate. A combination of PUVA and methotrexate can reduce the duration of treatment, number of exposures, and total UVA dose and is also effective in clearing patients unresponsive to PUVA or UVB alone.[18] This combination appears to be safe if used during the clearing phase only. However, if used for long-term treatment, PUVA and methotrexate may act synergistically in the development of skin cancers.[19]

Cyclosporine. Cyclosporine plus PUVA dramatically enhances skin carcinogenesis. This is in keeping with the observation of a greatly increased risk of cutaneous squamous cell carcinomas in patients with solid organ transplants maintained on this immunosuppressant. Thus, this combination should be definitely discouraged.[8,20–22]

Retinoids. The therapeutic efficacy of PUVA therapy is dramatically increased by daily oral retinoid (etretinate, acitretin, isotretinoin; 1 mg/kg) administration beginning 5–10 days before the initiation of PUVA, and continued throughout the clearing phase. This so called *RePUVA* characteristically reduces the number of exposures by one-third and the total cumulative UVA dose by more than one-half. RePUVA also often clears "poor responders" who are not brought into complete remission by PUVA alone.[23]

The mechanism of the synergistic action of retinoids and PUVA is unknown, but may be a result of the accelerated desquamation that optimizes the optical properties of the skin and reduction of the inflammatory

infiltrate. As an additional theoretic benefit, etretinate and other retinoids may protect against long-term carcinogenic effects of PUVA. In one study, patients with psoriasis treated with PUVA in combination with systemic retinoids showed a reduced risk of squamous cell carcinoma but not a significantly altered incidence of basal cell carcinoma (BCC).[24] Although retinoid toxicity is generally not a concern because the administration is limited to the clearing phase, the potential teratogenicity of retinoids represents a serious concern for women of childbearing age. In these patients, the use of isotretinoin is advisable because contraception is necessary for only 1 month after discontinuation of therapy, in contrast to etretinate and acitretin, which require 2 years of contraception because of their slower elimination.[8]

Biologics. The mechanism of action of biologic agents suggests that there may be additive effects in treating psoriasis with PUVA, but this remains to be further defined in clinical trials.[25,26] Presently, there are no long-term studies evaluating the safety and efficacy of the combination of any biologics with PUVA.

PUVA FOR CUTANEOUS T-CELL LYMPHOMA (CTCL, MYCOSIS FUNGOIDES).

Since the first promising results with PUVA in CTCL in 1976,[27] numerous investigators from the United States and Europe have confirmed the efficacy of PUVA for CTCL.[28] Treatment schedules and dosimetry are essentially the same as for psoriasis. The treatment consists of a clearing phase (Fig. 238-5), a maintenance phase consisting of two exposures per week for 1 month and one exposure per week for another month, and a follow-up phase without therapy. Remission should be confirmed by histologic examination of previously involved skin sites. After therapy is discontinued, the patient is monitored monthly and later bimonthly. If a relapse occurs, the patient is again subjected to a full PUVA course. Some investigators advocate permanent maintenance treatment consisting of treatments once monthly or every other month. However, the course of CTCL varies considerably from patient to patient, and clinical experience suggests that patients benefit most from individualized treatment schedules.[8]

Relapses often respond as well as the initial lesions when PUVA is resumed. Clinical remissions appear to be directly related to phototoxic destruction of the malignant lymphocytes that infiltrate the skin. Thus, complete clearing may be induced when the cells are confined to the epidermis and superficial dermis, the depth of effective UVA penetration into the skin.

Present knowledge indicates that PUVA is an excellent treatment option that may induce long-lasting disease-free intervals in CTCL if used in the early stages of the disease.[28] In later stages, PUVA may reduce the tumor cell burden and thus may act synergistically with other treatment. It improves quality of life and may prolong survival when used in combination with more aggressive treatment modalities. Prolonged remissions were observed with combinations of PUVA with retinoids, bexarotene,[29,30] or interferon-α 2a.[31–33]

Patients with tumor-stage CTCL exhibit a high rate of early recurrences and, therefore, require indefinite maintenance treatment. PUVA causes complete tumor resolution only when used in combination with local x-ray treatment and/or systemic chemotherapy. Most follow-up studies have demonstrated that the great majority of patients with early disease can be kept in remission with or without maintenance therapy for several years, but tumor-stage patients (IIB) usually experience multiple recurrences despite aggressive

Figure 238-5 Forty-six-year-old patient with cutaneous T-cell lymphoma (mycosis fungoides) stage IB. **A.** Before photochemotherapy treatment. **B.** After treatment (clearing phase).

combination therapies and eventually die within a few years.[28] Currently, no therapeutic regimen is known to alter the disease course of CTCL. Psoralen UV-A is an effective treatment for MF, inducing long-term remissions and perhaps in some cases disease "cure." Thirty percent to 50% of patients remain disease free for 10 years, but late relapses occur.[34]

Successful treatment of erythrodermic CTCL (Sézary syndrome) has been reported with extracorporeal PUVA (photopheresis) [see Section "Extracorporeal Photochemotherapy (Photopheresis)"]. Possible long-term hazards related to frequent PUVA treatments are better justified for patients with CTCL, compared with patients with benign conditions.

PHOTOTHERAPY FOR ATOPIC DERMATITIS. Many patients with atopic eczema can benefit from PUVA therapy.[35] The treatment guidelines are the same as for psoriasis. However, the condition is more difficult to treat, and quite often a higher number of treatments are required to clear the eczema. There is a high and early recurrence rate, requiring frequent maintenance exposures. However, in a recent study, PUVA provided a better short- and long-term response than medium-dose UVA1 in patients with severe atopic eczema.[36] A combination of PUVA with topical glucocorticoids appears to be superior to PUVA alone in maintaining remissions. Because the average patient is young, long-term maintenance therapy is problematic; and combination of PUVA with topical immune modulators (tacrolimus, pimecrolimus), although effective, cannot be recommended until more data are available. The mechanism of action of PUVA in atopic eczema is unclear; current concepts support an alteration of lymphocytes in the dermal infiltrate.

PHOTOTHERAPY FOR LICHEN PLANUS. In generalized lichen planus, PUVA can provide an effective alternative to systemic glucocorticoid treatment, although it appears to be more resistant to PUVA than psoriasis when treated according to a similar schedule. More exposures and higher cumulative UVA doses are required for clearing, and not all patients respond satisfactorily. An exacerbation during PUVA treatment has been reported in a few patients. In patients who clear, relapses respond equally well when PUVA is resumed. Bath-PUVA can also clear lichen planus, and combined PUVA-etretinate regimen may be considered.[37]

PHOTOCHEMOTHERAPY FOR CUTANEOUS MASTOCYTOSIS. In cutaneous mastocytosis (urticaria pigmentosa), PUVA leads to a temporary involution of skin lesions[38] probably due to chronic degranulation of the mast cells. The treatment results in loss of Darier sign, relief of itching, and flattening and even complete disappearance of cutaneous papules and macules. Surprisingly, even systemic symptoms such as histamine-induced migraine and flushing improve gradually as treatment is continued.[38] In most patients, the manifestations of the disease recur several months after discontinuation of PUVA, but the recurrences respond as well as the original lesions.

Because treatment of cutaneous mastocytosis has been unrewarding with other modalities, the use of PUVA, although not curative, seems to be warranted in patients when the disease is causing severe distress.

PHOTOTHERAPY FOR MISCELLANEOUS DERMATOSES. Both acute and chronic pityriasis lichenoides[37] respond to PUVA, and favorable results have been reported for lymphomatoid papulosis.[39] However, the experience with these conditions is limited to a few anecdotal cases. In pityriasis rubra pilaris, the results are quite inconsistent. Some cases seem to respond well, others may flare, and some require combination treatment with retinoid or methotrexate therapy. Generalized granuloma annulare has been reported to clear completely, but long-term maintenance treatment was required to maintain remissions.[40] Regrowth of hair was noted in alopecia areata with either topical or systemic PUVA exposures localized to the alopecia areas. Follow-up studies of larger patient groups concluded that PUVA is generally not an effective treatment for alopecia areata.[41] The experience of the present authors has also not been encouraging. Localized scleroderma and panscleroticmorphea have been successfully treated with bath-PUVA and oral PUVA.[42,43]

PHOTOCHEMOTHERAPY FOR CHRONIC GRAFT-VERSUS-HOST DISEASE. Acute and chronic cutaneous graft-versus-host disease (GVHD) has become indications of increasing importance. Because of the clinical and histologic similarities of idiopathic lichen planus and lichenoid GVHD, PUVA treatment was evaluated for the latter.[44] PUVA cleared or improved this lichen planus-like eruption in patients who had not responded to conventional immunosuppressive therapy alone. PUVA can also improve acute GVHD,[45] although results of PUVA treatment for scleroderma-like variants of cutaneous GVHD are controversial. According to our own experience, the more circumscribed, localized forms appear to respond to PUVA with softening of the fibrotic, sclerotic connective tissue, but more widespread, disseminated lesions hardly respond.

Improvement of mucosal erosions followed by healing, observed during treatment of chronic lichenoid GVHD with PUVA, suggests that PUVA may exert both local and systemic effects, but this is not proven. There is no improvement of GVHD of other organs, such as the liver. The therapeutic regimen used for the treatment of chronic GVHD is basically the same as for psoriasis. UVA doses should not be increased too aggressively, to avoid erythema and possible (re)activation of GVHD. In general, increase of the UVA dosage by 0.5 J/cm^2 at maximum after every second to fourth exposure is recommended. Patients are exposed to UVA radiation three to four times weekly. After clearing of skin lesions, the frequency of exposures is reduced.

Because there appears to be an overall increased risk of secondary malignancies for all bone marrow/peripheral stem cell recipients, patients should be examined on a regular basis for the development of cutaneous malignancies, independent of whether they have been treated with PUVA.

PHOTOCHEMOTHERAPY FOR VITILIGO. Vitiligo was the first disease treated with an ancient form of psoralen PUVA in India and Egypt. PUVA in its modern form stimulates melanogenesis, melanocyte proliferation, and migration, and *can* reconstitute the normal skin color in *many* vitiligo patients *although the actual response rate has still not been defined*. However, it is less used now since narrowband UVB phototherapy has been shown to be effective and possibly safer alternative for repigmentation of this condition (see later).

To induce maximal repigmentation, patients need long-term therapy with 100–200 exposures given twice or thrice weekly. Approximately 70% of patients respond after 12–24 months (Fig. 238-6), defined as the development of perifollicular macules of repigmentation. If there is no response after 6 months or approximately 50 treatments (as defined as perifollicular macules of repigmentation), PUVA should be terminated. If treatment is discontinued, this newly acquired repigmentation may be lost. The permanency of PUVA-induced repigmentation in vitiligo is poorly documented. Some investigators have reported continuing pigment loss following PUVA, while others have reported the repigmentation to be long lasting.[46]

Patient selection appears to be particularly important in vitiligo treatment. Lips, distal dorsal hands, tips of fingers and toes, areas of bony prominences, palms, soles, and nipples are very refractory to treatment, and patients with involvement limited to these areas should be excluded. Segmental vitiligo tends to show a variable response. Because of the different response in different body areas, total repigmentation is only rarely achieved, and some 30% of patients do not respond at all despite many months of therapy. Duration of the disease before PUVA therapy does not affect response rate.[46] It should be mentioned here that in a recent trial of nonsegmental vitiligo, narrowband-UVB therapy resulted in a better color match than oral PUVA.[47]

Figure 238-6 Twelve-year-old patient with generalized vitiligo of 4 years' duration. **A** and **C.** During the initial phases of photochemotherapy treatment. **B** and **D.** One month after treatment (8-methoxypsoralen + artificial ultraviolet A) with thrice-weekly exposures for 10 months.

The mechanisms by which PUVA induces repigmentation in vitiligo skin are speculative. However, PUVA's known effect on a number of immunologic reactions suggests a suppression of the autoimmune stimulus for melanocyte destruction.

PHOTOCHEMOTHERAPY AS PREVENTION FOR PHOTODERMATOSES. Tolerance to sunlight can be induced in several photodermatoses by PUVA therapy.[48] In polymorphous light eruption, the most common photodermatosis, PUVA is the most effective preventive treatment.[49] In approximately 70% of patients with this condition, a 3- to 4-week PUVA course of two to three treatments per week suffices to suppress the disease on subsequent exposure to sunlight such as a holiday trip or the arrival of summer. The initial exposure and dose increments during therapy should be performed according to the guidelines outlined for psoriasis. PUVA has the advantage of a rapid and intense pigment induction at relatively low UVA doses that usually remain well below the threshold doses for eliciting the rash. Approximately 10% of patients develop typical lesions during the initial phase of PUVA, but these usually disappear when treatment is continued. The authors' treatment schedule consists of three to four treatments per week for 3–4 weeks in early spring. PUVA protects only temporarily, but subsequent sun exposures usually maintain protection and many patients remain protected for 2–3 months even after their pigmentation has faded.

The mechanism by which phototherapy induces tolerance to sunlight is not clear. Hyperpigmentation and thickening of the stratum corneum may be important factors, but other mechanisms, such as modulations of cutaneous immune function, may also be involved.[49]

There is also some experience with PUVA prophylaxis of other photodermatoses. In solar urticaria, PUVA therapy appears to be the most effective preventive treatment available and is certainly better than antihistamines. Tolerance to sunlight can be increased 10-fold or more after a single treatment course.[50] The suppressive effect may last throughout the summer if the patients have regular sunlight exposures, which seems to be necessary to maintain tolerance. Problems may arise during the first PUVA exposures, because, in some patients, the urticaria threshold dose is very low. In these cases, careful conditioning by stepwise UVA irradiation of single quadrants of the body surface a few hours before each PUVA treatment has proved useful. Treatments with PUVA are then given during the refractory period of presumed mast cell degranulation.

Successful PUVA therapy has also been reported in occasional cases of chronic actinic dermatitis and hydroa vacciniforme. Limited experience in patients with erythropoietic protoporphyria indicates that, with a very cautious approach and in combination with β-carotene, PUVA may increase light tolerance considerably.[51,52]

Extended treatment is usually not required in polymorphous light eruption but may be necessary in solar urticaria and chronic actinic dermatitis. There exist no ready-to-use schedules for these latter conditions, and PUVA is usually just one part of the management.[51]

PHOTOCHEMOTHERAPY IN HUMAN IMMUNODEFICIENCY VIRUS-INFECTED PATIENTS. The use of phototherapy and PUVA in human immunodeficiency virus (HIV)-infected patients with skin diseases is controversial. Both therapies can induce systemic immune suppression and may modify the immune status of the patient in a way that would worsen HIV disease.[53] Both UV radiation and psoralen photosensitization activate the HIV promoter, which could boost viral gene transcription and, eventually, virus production,[54] although available data and theoretic considerations indicate that UVB is more likely to be a hazard than PUVA in an HIV-infected population.[55,56] Nevertheless, oral PUVA treatment of psoriasis does not detectably accelerate progression of HIV disease or increase PUVA side effects, and hence PUVA is not considered contraindicated for HIV-positive patients with responsive skin diseases.[57]

SIDE EFFECTS AND TOXICITY OF PHOTOCHEMOTHERAPY

(Table 238-3)

ACUTE SIDE EFFECTS. The side effects of PUVA include drug intolerance reactions as well as side effects of the combined action of psoralens plus UVA radiation. Oral 8-MOP (0.6–0.8 mg/kg) has a high incidence of nausea (30% of patients) and vomiting (10% of patients), and this may occasionally require discontinuation of the treatment. The mechanism of this adverse effect is unknown. These side effects are more common with liquid preparations than with crystalline preparations, probably because of higher psoralen serum levels. With 5-MOP, nausea occurs rarely, even with doses of up to 1.8 mg/kg body weight.

Undesired acute effects of the combined action of psoralens and UVA include unexpectedly severe delayed erythema reactions. Severe burns with blistering can occur and may rarely require hospitalization. When large areas of skin are affected, systemic symptoms of excess phototoxicity, such as fever and general malaise, may occur. Nonsteroidal anti-inflammatory drugs and topical and systemic corticosteroids may be required to alleviate the symptoms but have to be given early. Some patients experience persistent pruritus during PUVA treatment, particularly after slight UVA overdosage, and, in rare cases, a stinging pain may develop in circumscribed areas. The mechanism is unknown although a phototoxicity reaction affecting cutaneous nerves is postulated, and the symptoms are unresponsive to antihistamines. These complaints usually subside on continuation of treatment. Overdosage phenomena occur mostly in body areas not usually exposed to natural sunlight. Cautious dosimetry can minimize these side effects. The danger of overdosage is much less with 5-MOP than with 8-MOP.

Very rare side effects of PUVA include polymorphous light eruption-like rashes, acne-like eruptions, subungual hemorrhages caused by phototoxic reactions in the nail beds, and occasional hypertrichosis of the face. These disappear when treatment is

TABLE 238-3
Side Effects and Toxicity of Photochemotherapy

Acute Side Effects	
Drug intolerance	Nausea, vomiting with oral MOP, but not with 5-MOP.
UVA overdosage	Can range from an increased delayed erythema reaction to severe burns with blistering. When large areas of skin are affected, systemic symptoms of excess phototoxicity, such as fever and general malaise, can occur.
Pruritus	Some patients experience persistent pruritus during photochemotherapy (PUVA) treatment, particularly after slight UVA overdosage.
Laboratory data	No significant abnormal findings in patients receiving PUVA over prolonged periods of time.
Potential Long-Term Risks	
Chronic actinic damage	Chronic exposure to PUVA may produce changes in the skin that resemble photoaging. PUVA lentigines and generalized PUVA lentiginosis result from repeated and prolonged treatment and are commonly associated with high cumulative doses of UVA and a large number of treatments. So far, no increased risk of cutaneous melanoma associated with these lentigines has been recorded.
Carcinogenesis	The risk of squamous cell carcinoma, but not of basal cell carcinoma, is significantly increased in comparison with matched controls, and the magnitude of the increase appears to be dose-dependent. There is still uncertainty about PUVA being the sole factor—many of the affected patients had previous exposure to excessive sunlight and to treatments with carcinogenic potential, including arsenic, UVB, cyclosporine, and antimetabolite therapy. No increased risk was found so far with bath-PUVA.
Melanoma	Stern et al. reported from patients enrolled in the PUVA Follow-up Study (16-Center Study [69]) that, beginning 15 years after first exposure to PUVA, an increased risk of melanoma was observed. This risk was greater in patients exposed to high doses of PUVA and appeared to be increasing with the passage of time. The conclusions of this study have been questioned, and the authors now agree that the observed risk of melanoma does not represent an absolute contraindication to PUVA or that PUVA therapy should be abandoned. Rather, the risks of both melanoma and squamous cell carcinoma in PUVA should be weighed against the substantial efficacy of PUVA and the risks of other therapies.
Ophthalmologic effects	Several studies have shown no indication that psoralen-induced cataracts occur in patients undergoing long-term photochemotherapy, even in patients who neglected eye protection.

MOP = 8-methoxypsoralen; PUVA = psoralen and ultraviolet A light.

discontinued. Single case reports note exacerbation of systemic lupus erythematosus and bullous pemphigoid during PUVA.

LABORATORY DATA. Analysis of laboratory data in several large-scale studies showed no significant abnormal findings in patients receiving PUVA over prolonged periods of time.[13,14,58] Serial laboratory examinations performed over a period of several years have not revealed any substantial evidence for impairment of hepatic function. Liver biopsies after 1 year of therapy did not reveal hepatotoxicity.[59] No evidence exists suggesting impairment of renal function.[13] Several large-scale studies have negated a suggested relation between PUVA therapy and the occurrence of antinuclear antibodies.[60]

POTENTIAL LONG-TERM RISKS OF PHOTOCHEMOTHERAPY

Chronic Actinic Damage. Repeated photodamage to the skin can be expected to result in cumulative injury regardless of whether it is induced by sunlight, artificial UV radiation, or PUVA. Chronic exposure to PUVA may produce changes that resemble photoaging and that may compound the injury induced by sunlight.

PUVA lentigines and generalized PUVA lentiginosis result from repeated and prolonged treatment and are commonly associated with high cumulative doses of UVA and a large number of treatments.[14] The lentigines exhibit irregular borders and uneven pigmentation. No increased risk of cutaneous melanoma has been associated with these lentigines, but the cosmetic effect may be quite disturbing.

Carcinogenesis. Cutaneous carcinogenicity is the major concern for long-term PUVA treatment associated with high cumulative UVA doses. PUVA is a photocarcinogen (see Chapter 112). In laboratory animals, 8-MOP and 5-MOP have been unequivocally shown to induce skin cancer at levels of drug and UVA irradiation comparable to those used in PUVA therapy.[61,62] This risk is related to DNA damage, but PUVA-induced down-regulation of immune responses may play an additional role. This risk has to be assessed against the potential therapeutic benefit.

Long-term follow-up PUVA studies are confounded by the fact that patients, particularly those with severe psoriasis, are likely to have been exposed previously to

other carcinogenic treatments, such as ionizing radiation, UVB therapy, methotrexate, tar, or arsenic, and accurate exposure data are often lacking.

In PUVA patients, the risk of squamous cell carcinoma, but not of BCC, is significantly increased in comparison with matched controls and the magnitude of the increase appears to be dose dependent.[19,62] However, there is uncertainty about PUVA being the sole factor—many of the affected patients had previous exposure to excessive sunlight and to treatments with carcinogenic potential, including arsenic, UVB, and antimetabolite therapy.[63] Particularly, high levels of UVB exposure appear to increase the risk of nonmelanoma skin cancer in PUVA-treated patients.[64] An increased risk of any skin cancer with oral PUVA has not been shown in the non-Caucasian population.[65] According to one study, the genitalia in men previously treated with tar and UVB appeared to be particularly susceptible to PUVA carcinogenesis,[66] but in a separate population the risk seemed not to be increased if only PUVA was used.[67] In a retrospective study from France comprising 5,400 patients treated with PUVA between 1978 and 1998, no case of genital skin cancer was found, despite the fact that the genital area had not been protected.[68] This makes it unlikely that genital shielding is absolutely necessary.

Carcinogenicity of 5-MOP–UVA therapy in PUVA-treated patients is not documented, but 5-MOP has shown mutagenicity similar to 8-MOP in model systems.

Stern et al reported that of the cohort of 1,380 patients enrolled in the so-called *16 Center PUVA Follow-up Study,* 23 patients have developed 26 invasive or in-situ cutaneous melanomas over a period of roughly 25 years. Beginning 15 years after first exposure to PUVA, this constituted an increased risk of melanoma.[69,70] This risk was greater in patients exposed to high doses of PUVA and appeared to increase with the passage of time. Still, the authors conclude that the observed risk of melanoma does not represent an absolute contraindication to PUVA. Rather, the risks of both melanoma and squamous cell carcinoma in PUVA should be weighed against the substantial efficacy of PUVA and the risks of other therapies.[70,71] As well, no increased risk of melanoma has been observed so far in any large-scale study from Europe; and several other US studies did not show an increased risk of melanoma in patients treated with PUVA[72,73] Of note, PUVA's long-term risks have been subject to much greater scrutiny than the risks of other therapies advocated for severe psoriasis, such as methotrexate and, particularly, immunosuppressive therapies such as cyclosporine. These latter therapies greatly increase cancer risk in populations less likely to have substantial exposures to other known cutaneous carcinogens such as UVB than are patients with severe psoriasis. Early detection through careful, long-term follow-up and education of PUVA patients may reduce the long-term morbidity and mortality associated with this therapy, as can low cumulative dosage regimens.[74]

Studies of 944 Swedish and Finnish patients[75] and 158 Finnish patients[76] with psoriasis showing no association between cutaneous cancer and TMP or 8-MOP bath-PUVA, respectively, are also reassuring. Mathematic model studies indicate that the observed risk of squamous cell carcinoma is much higher with PUVA than with UVB,[77] but the carcinogenic risk of narrowband UVB in comparison with PUVA is unknown, and it will be crucial to monitor its long-term effects in psoriatics.

Ophthalmologic Effects. Data from animal studies indicate a risk of premature cataract formation due to PUVA, but clinical evaluation suggests no increase in lens opacities, even in patients who neglect careful eye protection during long-term PUVA.[78,79]

PATIENT SELECTION AND CONTRAINDICATIONS

In view of the potential short-term and long-term hazards of PUVA, the assignment of patients should be based on consideration of the risks and the benefit for the individual patient. If only a short-term course of therapy is planned, as, for example, in prevention of photodermatoses, the benefit very probably outweighs the risk. In the treatment of a malignant condition such as CTCL, long-term risks may be discounted because other treatment options bear even greater long-term risks. The major concerns relate to long-term treatment of psoriasis, by far the most common indication for PUVA. Careful patient selection is mandatory, bearing in mind that long-term risks of alternative therapies may simply be less well documented rather than less. Guidelines have been published.[15]

PUVA is not recommended during pregnancy, and women should be advised to use contraceptive measures while on PUVA. This precaution is only for reasons of absolute safety as there is no evidence that 8-MOP alone is teratogenic, and UVA does not penetrate through the abdominal and uterine walls. Further, a retrospective study in 256 deliveries among the cohort of the 16-Center PUVA Follow-Up Study revealed no birth defects.[80] However, it has to be emphasized that RePUVA bears the risk of retinoid teratogenicity.

Severe impairment of hepatic and renal functions is usually considered a contraindication to PUVA because metabolism and excretion of psoralens may be inadequate. PUVA is also contraindicated in patients with known light-aggravated or light-induced diseases such as lupus erythematosus, porphyria (but, as mentioned earlier, light tolerance can be induced by PUVA in erythropoietic protoporphyria), and xeroderma pigmentosum. Pemphigus vulgaris and bullous pemphigoid may be exacerbated by PUVA. Patients with chronic actinic damage and a history of skin cancers may be at higher risk for the development of new cancers. Previous arsenic intake and previous treatment with ionizing radiation also seem to increase the risk of nonmelanoma skin cancers. Immunosuppressed patients should probably not receive PUVA, although this is not yet clearly defined. As outlined earlier, PUVA can be used in HIV-positive patients. Cataracts and aphakia are not contraindications if adequate eye protection is employed.

CONCLUSIONS AND PERSPECTIVES

PUVA is a highly effective treatment for several dermatologic diseases. Although there exists comprehensive clinical experience documenting PUVA's short-term safety when used according to standardized methods, potential long-term sequelae are still being studied. Thus, treatment decisions should take into account whether other equally effective forms of therapy that carry a lower risk are available. Risk-versus-benefit varies with the disease being treated.

Severe widespread psoriasis is a devastating disease that may impair professional, social, and private life. After more than three decades of experience with PUVA for the treatment of psoriasis, it is evident that this therapy offers innumerable patients the chance to resume a normal life. For disabling psoriasis, the choice of therapies lies not between risk and safety but among modalities (methotrexate, cyclosporine, UVB, and biologics), none of which is absolutely safe.[71]

EXTRACORPOREAL PHOTOCHEMOTHERAPY (PHOTOPHERESIS)

Extracorporeal PUVA (ECP) was introduced in the 1980s for the palliative treatment of erythrodermic CTCL,[81] a disorder characterized by circulating malignant lymphocytes. Its efficacy was subsequently confirmed by several clinical trials and approved in 1988 by the US Food and Drug Administration for this indication. At the International Consensus Conference on Staging and Treatment Recommendations for CTCL in 1994[82] and at the European Organization for Research and Treatment of Cancer Consensus Recommendations in 2006,[83] ECP was recommended as the first line of treatment for patients with erythrodermic CTCL.

Attempts to better characterize those CTCL patients likely to respond to ECP revealed a significant association between response and CD4:CD8 ratio. Patients with a ratio less than 10 are more likely to respond than patients with a ratio greater than 10. There is also a marginally significant association between response and lactic acid dehydrogenase (LDH) level, with patients whose LDH is not elevated at the start of treatment responding better than patients with an elevated LDH.[84]

Besides CTCL, ECP also plays an important role in the treatment of chronic GVHD after allogeneic bone marrow transplantation with excellent response rates. ECP has also been used in uncontrolled studies in several other autoimmune diseases including systemic sclerosis, acute allograft rejection among cardiac, lung, and renal transplant recipients[85–87] and Crohn disease, with some success.

TREATMENT METHOD

ECP originally involved the oral administration of 8-MOP followed by phlebotomy at the time of peak photosensitization passage of blood fractions from one arm vein through a photopheresis machine and back. A discontinuous flow cell separator harvests peripheral blood mononuclear cells (PBMCs) in a buffy coat collection and returns the red cell fraction to the patient without further treatment. The collection of PBMC is then exposed to 2.0 J/cm^2 of UVA using a photopheresis device that ensures exposure of individual PBMC in a thin film to the light source and then reinfused into the patient. More recently, 8-MOP is administered directly to the heparinized plasma and buffy coat fraction as it flows through a UVA exposure system, thereby avoiding 8-MOP-induced nausea and unintended phototoxicity with subsequent incidental sun exposure.[88] This treatment is customarily repeated on 2 successive days at 2- to 4-week intervals.

MECHANISM OF ACTION

The mode of action of ECP remains unknown. The PUVA exposures likely induce apoptosis of circulating malignant lymphocytes. However, it has also been shown that infusion of autologous haptenated cells in which apoptosis had been initiated by 8-MOP/UVA induces immunologic tolerance. This tolerance is likely due primarily to regulatory T cells because transfer can be achieved in an animal model. Induction of regulatory T cells could also explain why ECP exerts a beneficial effect in a wide variety of immune-mediated diseases and why generalized immunosuppression does not occur with ECP.[89,90]

SIDE EFFECTS

No serious side effects have been reported with ECP. With oral ingestion of 8-MOP, transient nausea is not uncommon (as in oral PUVA therapy) and, rarely, episodes of hypotension and vasovagal reflex due to volume shifts during treatments have been noted. However, these events usually do not interfere with the treatment.

TREATMENT RESULTS

CUTANEOUS T-CELL LYMPHOMA. Erythrodermic CTCL (Sézary syndrome) was the first disease for which ECP was evaluated. A response occurs in up to 75% of the patients, with complete remissions in up to 25%. In Sézary syndrome patients who do not sufficiently respond to ECP alone, ongoing studies are evaluating possible synergistic effects with other treatments such as interferon-α, methotrexate, bexarotene, and total-skin electron-beam therapy.[91–94]

GRAFT-VERSUS-HOST DISEASE AND ALLOGRAFT REJECTION. ECP appears to have a major impact in the treatment of GVHD after allogeneic bone marrow transplantation.[95,96] In patients with either acute or chronic GVHD, ECP allows reduction or even discontinuation of immunosuppressive therapy without an increase in GVHD activity. More

TABLE 238-4
Indications for Photopheresis (As Seen by Regulatory Agencies in 2006)

Sufficient evidence available	
Erythrodermic cutaneous T-cell lymphoma	Chronic graft-versus-host disease
Acute graft-versus-host disease	Organ transplant rejection
Experimental and investigational	
Scleroderma	Nephrogenic fibrosing dermopathy
Bullous dermatoses	Lichen planus
Crohn disease	Multiple sclerosis

than 450 patients with chronic (even steroid refractory cases), GVHD treated with ECP have been reported, with mean response rates of 63% (range 29%–100%). Responses were highest for those patients with cutaneous or mucous membrane involvement. Positive results have also been published for acute GVHD.[87,97] ECP is especially useful for patients affected by GVHD resistant to conventional treatment.

As mentioned above, ECP is effective in the treatment of acute allograft rejection among lung, cardiac, and renal transplant recipients. ECP is effective for patients resistant to conventional treatments, particularly if started early. Benefit is obtained without the complications typically encountered with immunosuppressive regimens used to control organ rejection.[98,99] Table 238-4 shows indications for photopheresis as currently approved by regulatory agencies.

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) aims to destroy the desired target selectively thereby minimizing damage to normal tissue. The photodynamic reaction consists of the excitation of photosensitizers (usually porphyrins) by visible light in the presence of oxygen, resulting in the generation of reactive oxygen species, particularly singlet oxygen. These reactive oxygen species mediate cellular and vascular effects, depending on the tissue localization of the photosensitizer, and results in a direct or indirect cytotoxic effect on the target cells.[100] In dermatology, PDT has been used effectively for precancerous and malignant conditions such as actinic keratosis, BCC, Bowen disease, and superficial squamous cell carcinoma, as well as for inflammatory and infectious dermatoses such as localized scleroderma, acne vulgaris, and leishmaniasis. A relatively new approach is the treatment of ageing skin with PDT (photochemorejuvenation).

PRINCIPLES OF PHOTODYNAMIC THERAPY

PHOTOSENSITIZERS. The ideal photosensitizer for PDT in dermatology should meet the following criteria: (1) chemical purity, (2) high singlet-oxygen quantum yield, (3) significant light absorption at wavelengths that penetrate the skin sufficiently deeply, (4) high tissue selectivity, and (5) efficacy after topical application.

Porfimer sodium (Photofrin), a systemically administered mixture of several hematoporphyrin derivative (HpD) ethers and esters, has a low selectivity for skin tumors and leads to long-lasting photosensitivity; consequently, it is far from ideal for dermatologic use. In contrast, 5-aminolevulinic acid (ALA), an intermediate in heme biosynthesis or its methyl ester (MAL) leads to synthesis of photosensitizing protoporphyrin IX in the target tissue.[101] In this case, the concentration of the photosensitizer depends on the metabolic status of the diseased tissue with photosensitization greatest in precancerous or malignant tissue. ALA in combination with the blue light and MAL in combination with red light are approved by the US Food and Drug Administration for the treatment of actinic keratoses. In Europe, New Zealand, Australia, and South America, MAL has also been registered for superficial and nodular BCCs, and Bowen disease.

Most photosensitizers generate singlet oxygen with a quantum yield between 5% and 20%. A high quantum yield means that less sensitizer is required in the target tissue to induce sufficient PDT effects. The light absorption maxima of the current sensitizers are in the visible range (400–700 nm). In this range, light penetration in tissue is only up to 3 mm, limiting PDT to superficial tumors unless interstitial light propagation is used. A high selectivity for sensitizer accumulation in target tissue is necessary to avoid damage to surrounding normal tissue, and this is particularly important when larger areas are treated (e.g., actinic keratoses). ALA and MAL show reasonably high selectivity after topical application, with the ratio of porphyrin induction in skin tumors to the surrounding tissue higher than 10:1,[102] likely due to a combination of enhanced ALA-MAL penetration through an abnormal stratum corneum and altered metabolism and accumulation within the premalignant or malignant cells.

LIGHT SOURCES AND DOSIMETRY. Light penetration into skin increases with longer wavelengths up to 1,100 nm. Although porphyrins absorb maximally in the Soret band (400–410 nm, blue light), there are minor absorption peaks at longer visible light wavelengths. To increase depth of penetration while matching the absorption maxima of porphyrin photosensitizers, wavelengths around 630 nm are often used. Lasers are effective but they are quite expensive, require regular maintenance, and have a small treatment aperture. Hence, simpler incoherent light sources represent a valuable alternative. Fluorescent lamps or light-emitting diodes with appropriate red or blue light emission are commercially available and designed for treatment of large surface areas. Also, intense pulsed light sources are used for dermatologic PDT. Dosimetry depends on the photosensitizer and light source used, as well as on the condition to be treated. For PDT of epithelial cancer, photosensitization must be sufficient to induce necrosis or apoptosis. With current incoherent light sources (lamps, light-emitting diodes),

the treatment duration, apart from of ALA-MAL incubation time, is approximately 10–15 minutes. For treating inflammatory dermatoses, significantly lower doses suffice because the goal appears not to be cell death but rather sublethal damage or modulation of cellular functions.

MECHANISM OF ACTION. PDT-induced effects are mediated by photo-oxidative reactions. During irradiation, the photosensitizer absorbs light (energy) and is converted to an excited (triplet) state. The energy can then be transferred to molecular oxygen (type II photo-oxidative reaction), resulting in the generation of reactive oxygen species, mainly singlet oxygen. The biologic effects can be divided into primary cellular and secondary vascular damage. With HpD, early visible damage consists of cell membrane defects as a consequence of lipid peroxidation with consequent cell lysis. Depending on the intracellular localization of the photosensitizers, damage to subcellular structures, such as mitochondria, lysosomes, or endoplasmic reticulum, also occurs, whereas DNA is not a primary target. These direct effects probably play a key role in topical PDT, whereas vascular effects after systemic administration of photosensitizers appear to be the decisive event. These effects consist of vasoconstriction, blood stasis, and thrombosis of tumor vessels leading to tumor ischemia and subsequent necrosis.[103]

PHOTODYNAMIC THERAPY IN DERMATOLOGY

Table 238-5 lists current applications for PDT described in the literature. In contrast to other organs, the skin can be sensitized by either intravenous, topical, or intralesional routes of administration of the photosensitizer.

TABLE 238-5
Current Indications for Photodynamic Therapy

Oncologic	Nononcologic (All Off-Label Uses)

[b]Approved in the European Union, Austarila–New Zealand, and Brazil.

SYSTEMIC PHOTODYNAMIC THERAPY. PDT after systemic administration of HpD and porfimer sodium has been used for both skin cancers and inflammatory dermatoses. Standard therapeutic procedures do not yet exist.

Systemic Photodynamic Therapy for Oncologic Indications.

Systemic PDT with porfimer sodium for Bowen disease is very effective,[104] but invasive squamous cell carcinomas respond less well, with recurrence rates of up to 50% within 6 months. Systemic PDT for BCCs, first used in 1981,[105] has been reported by Oseroff and coworkers[106] to give initial complete responses in 92.2% of 77 patients with sporadic BCC or nevoid BCC syndrome.[106] In these patients, the 5-year recurrence rate was 15%.

Benzoporphyrin-derivative monoacid ring A (verteporfin), registered for the ophthalmologic indication of age-related macular degeneration, is also under investigation for PDT of BCC and offers a duration of cutaneous photosensitization of less than 72 hours, significantly shorter than that of porfimer sodium.[107]

Systemic Photodynamic Therapy for Nononcologic Indications.

The use of PDT with HpD was reported for the treatment of psoriasis as early as 1937; better results were reported using red light instead of UVA,[108] and systemic PDT with verteporfin was also investigated in a phase I study of 15 patients in whom clinical severity scores for psoriatic plaques improved after five weekly treatments.[109]

TOPICAL PHOTODYNAMIC THERAPY. Small hydrophilic molecules like ALA or MAL penetrate well into the skin, particularly if the stratum corneum is abnormal, as is the case in some epidermal tumors.[101] In addition, epidermal cells and the pilosebaceous unit synthesize porphyrins to a much greater extent than fibroblasts, myocytes, or endothelial cells[102]; epithelial tumors generally synthesize much higher amounts of protoporphyrin IX than the surrounding tissue and can therefore be destroyed without equivalent damage to healthy skin (Fig. 238-7).[101,110] Topical ALA-MAL-induced photosensitivity thus preferentially affects the target area. Systemic porphyrin induction is not observed after topical application.[111] The only significant side effect of topical ALA-MAL PDT is a stinging pain during and shortly after irradiation, proportional to the intensity of the phototoxicity reaction.

Topical Photodynamic Therapy for Oncologic Indications.[112–118]

The experience with treatment of epithelial cancers and precancerous conditions with PDT to date suggests that actinic keratoses,[112,113] Bowen disease (Fig. 238-8),[114] superficial and nodular BCCs,[115–117] and SCCs (tumor thickness less than 2 mm) are suitable for topical ALA/MAL-PDT. For this purpose, both photosensitizers are applied topically for variable incubation periods, with or without occlusion, followed by visible light exposure.

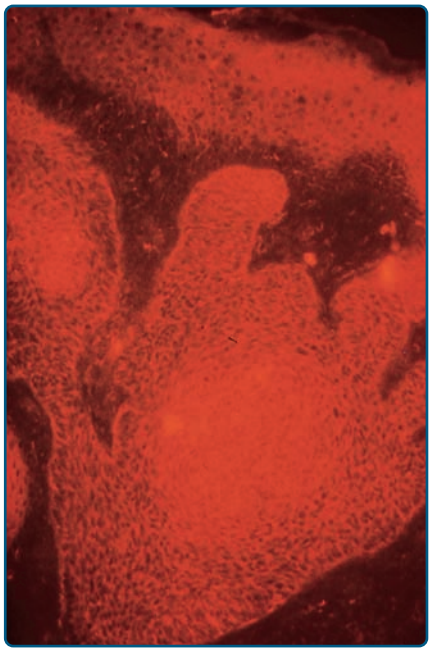

Figure 238-7 Endogenous porphyrin fluorescence after topical application of 20% aminolevulinic acid formulation to a solid basal cell carcinoma. Twelve hours after aminolevulinic acid application, there was strong fluorescence of the tumor-bearing areas, and weak-to-no fluorescence of the surrounding dermis. Also visible is fluorescence in the overlying epidermis. (From Szeimies RM, Sassy T, Landthaler M: Penetration potency of topical applied & alpha-aminolevulinic acid for photodynamic therapy of basal cell carcinoma. *Photochem Photobiol* **59**:73, 1994.)

Actinic keratoses have been studied most extensively and respond to PDT as readily as to local cryotherapy or to broad area 5-fluorouracil (see Chapter 220) or imiquimod therapy (see Chapter 221) administered over weeks to months. Topical application of a 20% ALA solution for 14–18 hours followed by irradiation with blue light (417 nm) for 1,000 seconds (10 J/cm^2) clears more than 80% of actinic keratoses after 1–6 months,[113] and 90% complete clearance at 1 and 5 months was observed after one full face treatment using a 1- to 3-hour incubation period.[113,114] However, cutaneous metastases of malignant melanoma, pigmented BCC, and sclerodermiform variants of BCC respond poorly to ALA-PDT, probably because of insufficient porphyrin synthesis and/or penetration of light within the lesions.[110] Treatment efficacy is enhanced by repeated treatment sessions.[117]

In superficial and nodular BCCs, two randomized phase-III studies have been reported so far comparing MAL-PDT with either surgery or cryotherapy. After an observation period of 60 months, MAL-PDT for superficial BCC showed a similar recurrence rate as cryotherapy (22% versus 20%). In nodular BCC, MAL-PDT was compared with simple excision; recurrence rates after 60 months were 14% and 4%, respectively. In both studies, the cosmetic outcome was considered superior for the PDT-treated groups.[115,116] Indeed, these and other reports[117] suggest that a major theoretic benefit of ALA/MAL-PDT is elimination of skin cancers without scarring, as well as prevention of such lesions in high-risk patients treated periodically with broad area PDT.

Figure 238-8 Bowen disease. **A.** Lesion located on the right lower leg. **B.** Twelve months after topical aminolevulinic acid-photodynamic therapy [10% aminolevulinic acid ointment, application for 4 hours, irradiation with argon-pumped dye laser (175 mW/cm^2; 180 J/cm^2)], clinically and histologically, there were no signs of tumor residue.

CTCL (mycosis fungoides) also responded in eight single case reports to ALA-MAL PDT after several treatment sessions. Controlled investigations are currently not available, and, as with PUVA treatment of single lesions, this treatment would not be expected to prevent the appearance of new lesions in other areas.[118]

Topical Photodynamic Therapy for Non-Oncologic Indications.[119–135] Few data are available regarding the treatment of inflammatory and proliferative skin conditions. These include psoriasis, localized scleroderma, human papilloma virus (HPV)-associated conditions, leishmaniasis, acne, and rosacea.

ALA/MAL-PDT is also effective for acne and rosacea, although optimal protocols have not been developed. In two separate studies,[128,129] 22 patients with mild-to-moderate acne on the back received 20% ALA cream under occlusion for 3 hours. The areas were then exposed to broadband (550–700 nm) or laser light (635 nm) using various protocols. The authors observed a significant reduction in inflammatory acne lesion counts compared with baseline that persisted at least 20 weeks in some patients.[128] One study found a reduction in sebaceous gland size and sebum secretion, as well as reduced fluorescence attributable to *Propionibacterium acne*,[128] although the other did not.[129]

PDT with ALA has also been demonstrated to enhance the treatment of photodamaged skin with a variety of lasers and light sources. Improvement of global appearance, fine lines, tactile skin roughness, mottled hyperpigmentation, and telangiectasias has been described.[132–135] Mode of action is based on the degradation of altered collagen and elastotic material and the formation of newly synthetized collagen directly underneath the epidermis.[136,137]

PERSPECTIVES

The efficacy of PDT in the treatment of superficial neoplastic skin lesion, particularly actinic keratoses, Bowen disease, and superficial BCCs, has been sufficiently documented. PDT may also find a place in the treatment of selected patients with inflammatory dermatoses. Nonetheless, the limitations of both systemic and topical PDT have to be kept in mind. Crucial issues are the depth of the penetration of light, as well as of the sensitizer, into the skin, and inability to ensure complete eradication of malignancy by histologic criteria.

Chapter 239 :: Lasers and Flashlamps in Dermatology

:: Michael Landthaler, Wolfgang Bäumler, & Ulrich Hohenleutner

LASERS AND FLASHLAMPS AT A GLANCE

- Lasers are the most precise and selective surgical tools in existence.
- Nonscarring treatment of vascular lesions, pigmented lesions, tattoos, and hair follicles relies on a process called *selective photothermolysis*. For each of the aforementioned broad indications, there are lesion variants that are highly responsive to laser therapy, lesions that are occasionally responsive, and lesions for which laser treatment is contraindicated.
- Pulse duration strongly influences safety and efficacy, and, in general, should be approximately equal to the thermal relaxation (cooling) time of specific targets in a given patient.
- Port-wine stains are congenital neurovascular lesions best treated in early childhood that respond well, but rarely completely, to laser treatment.
- Laser treatment is useful for treatment of ulcerated infant hemangiomas.
- Fractional resurfacing is a technique in which thousands of laser microbeams per square centimeter are used to stimulate epidermal and dermal remodeling. It is a less invasive treatment for photoaging than is ablative laser resurfacing.
- Use of any laser or flashlamp (intense pulsed light) for hair removal poses a severe risk of eye injury when used near the eye. Other risks include fires, inhalation of the vaporized tissue plume, electrocution, and a host of side effects such as stimulation of facial hair growth, pigmentary changes, and scarring.

PRINCIPLES AND SAFETY

INTRODUCTION

Laser emits radiation whose properties are fundamentally different compared to radiation of other sources. Laser radiation is monochromatic in a range from 100 nm to 3 mm, appears as strictly parallel beam, can be either continuous or pulsed in a range from seconds to femtoseconds (10^{-15} s), and can show intensities of more than 10^{10} W/cm^2.

A few years after development of lasers in 1960, physicians such as Leon Goldman started to apply this new and exciting radiation in dermatology. Since 1963, numerous physicians have investigated the use of various types of lasers to treat different skin disorders. When laser radiation is absorbed in tissue, radiation energy is predominantly converted to heat. Because of its exceptional nature, laser radiation can be applied to cut, vaporize, coagulate, or ablate skin. It was identified as able to achieve selective destruction of targets inside skin. Laser pulses precisely destroy even very small targets in skin such as small vessels or melanosomes. By manipulating the appropriate laser parameters such as wavelength, pulse duration, and radiant exposure, the destruction of a target occurs without damage to the adjacent tissue, which substantially minimizes the risk of side effects like scarring. The selection of the appropriate laser parameters for an effective and precise destruction of targets in skin were summarized as the rules of selective photothermolysis.[1]

A newer light source appeared in dermatological practice some years ago: the intense pulsed light source (IPL).[2,3] It mainly consists of a flashlamp that emits white light ranging from about 250–1,400 nm. The spectrum is narrowed (~500–1,000 nm) by applying optical edge-filters (cut-off filters) and water film in front of the flashlamp. In contrast to lasers, IPL emission shows a broad spectral range of up to 500 nm and the pulse duration is limited to milliseconds. IPL radiation can be successfully applied for some dermatological indications by achieving partially selective photothermolysis.

LASER PRINCIPLES

Electromagnetic radiation can be described as a plane wave that is propagating in space with a constant velocity c of 299,790 km/s. The major properties of radiation are wavelength λ and frequency ν, which are correlated:

$$c = \lambda \cdot \nu$$

Radiation also can be considered as particles, which are called photons, with a specific energy

$$E = h \cdot \nu = \frac{h \cdot c}{\lambda}$$

where h is Planck's constant ($6.6\ 10^{-34}$ Js). The energy of radiation increases with decreasing wavelength. The spectrum of electromagnetic radiation exhibits a broad range, with wavelengths ranging from a few nanometers to thousands of meters. Only a small part of the spectral range is visible for human eyes (400–700 nm); this, and only this, is light.

The generation of laser radiation is a complex process. The acronym LASER is derived from the most important elements: ***L****ight* ***A****mplification by* ***S****timulated* ***E****mission of* ***R****adiation*.

The process of spontaneous emission of photons describes the emission of radiation from a usual light source such as light bulb. After excitation, atoms or molecules can emit photons at different times, in any direction and usually with different wavelengths. Therefore, such a radiation is incoherent, divergent and spectrally broadband.

In contrast, a laser medium consists of identical atoms or molecules (photon emitter, Table 239-1), which are excited by different means such as electrical discharge (gas lasers) or optical radiation (flashlamp pumped lasers). These photon emitters are placed in a substrate, which is either gas, liquid, or solid state. Together the photon emitters at a certain concentration and the substrate represent the laser medium. After excitation, which is called pumping, the atoms or molecules return from the excited to the ground state and thereby emit photons with a specific wavelength λ_L that is determined by the energy difference ΔE of the excited and the ground state with

$$\Delta E = \frac{h \cdot c}{\lambda_L}$$

If one considers the same transition in all atoms or molecules in a specific laser medium, the emitted photons have the same wavelength λ_L leading to the monochromatic nature of laser radiation. If the ground state and the excited state are spectrally broadened, then laser transition is possible in a certain wavelength range and a laser is tunable to different wavelength λ_L within this spectral range.

The combination of such identical transitions and photons with the same wavelength λ_L in a confined volume (laser medium) allows another process to come to the fore: the stimulated emission of photons, as described and published by Albert Einstein in 1917.[4]

TABLE 239-1
Laser, Media and Parameters

Name	Wavelength (nm)	Photon Emitting Medium	Substrate	Type	Typical Mode Pulse Duration
Excimer laser	308	Excited dimer molecules (Xe-Cl)	Different gases	Gas	Pulsed µs–ms
"KTP" laser (Nd:YAG laser) frequency doubled) with KTP crystal)	532	Nd^{3+}	Crystal: Yttrium-aluminum Garnet ($Y_3Al_5O_{12}$)	Solid state	Pulsed ms–ns
Dye laser	585–600	Dyes, e.g., Rhodamines	Organic solvents	Liquid	Pulsed ms
Ruby laser	694	Cr^{3+}	Al_2O_3	Solid state	Pulsed ms–ns
Alexandrite laser	755	Cr^{3+}	Chrysoberyl ($BeAl_2O_4$)	Solid state	Pulsed ms–ns
Diode laser	Different wavelengths (e.g. 810, 940)	InGaAs AlGaAs	Semiconductor material	Solid state	Pulsed ms
Nd:YAG laser	1,064	Nd^{3+}	Crystal: Yttrium-aluminum Garnet ($Y_3Al_5O_{12}$)	Solid state	cw, pulsed ms–ns
Er:YAG laser	2,940	Er^{3+}	Crystal: Yttrium-Aluminum Garnet ($Y_3Al_5O_{12}$)	Solid state	Pulsed ms
CO_2 laser	10,600	CO_2	Different gases	Gas	cw, pulsed ms

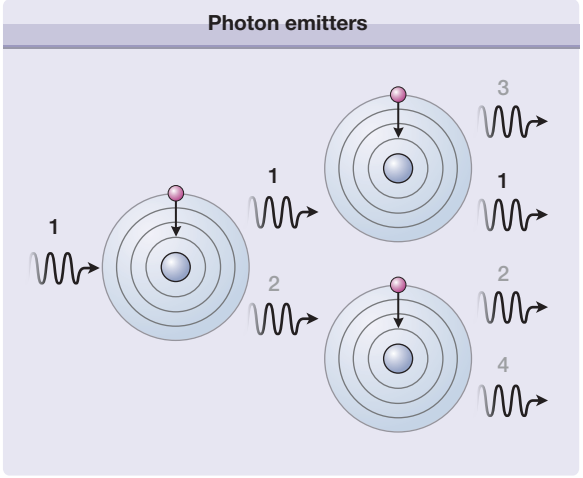

Figure 239-1 All photon emitters in a laser medium are excited, which is indicated by an electron in the highest energy level of an atom. A first photon (1) stimulates the next atom to emit a photon (2); these two photons provoke the next photons (3 and 4).

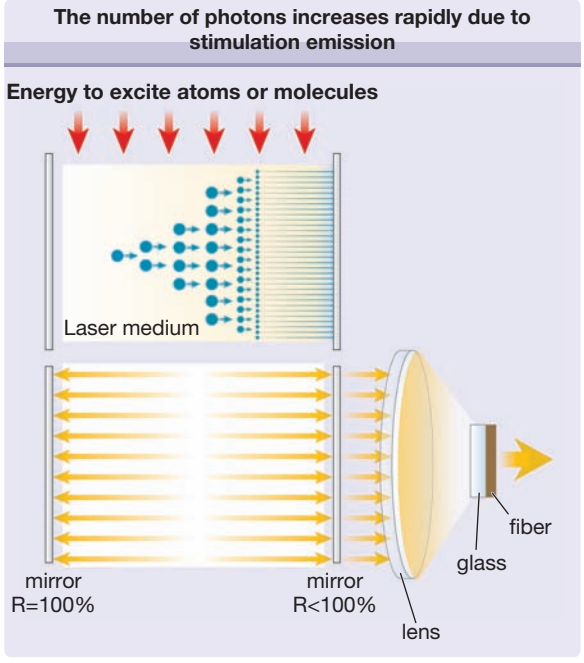

Figure 239-2 The number of photons increases rapidly due to stimulated emission (*top*). As the laser medium is placed between two mirrors, the stimulation of emission of radiation is continued by reflection of photons back and forth (*bottom*). The reflectivity (R) of one mirror is less than 100% and a small fraction of radiation can traverse this mirror (therapeutic radiation). This laser radiation is focused by a lens and fed into an optical fiber, which delivers it to the patient.

Figure 239-1 shows the basic process of stimulated emission of radiation. One photon stimulates the next atom or molecule to emit a photon. The resulting two photons stimulate the next two atoms or molecules that results in four photons and so on. A laser medium consists of up to 10^{20} photon emitting atoms or molecules, which provides an immense number of stimulated photons. For example, a laser pulse with energy of 1 Joule and a wavelength in the visible spectrum contains about 10^{19} photons. Thus, the light amplification is actuated by the stimulated emission of radiation, as described by the acronym LASER. The process of light amplification does not change the energy of photons but increases their number exponentially.

To promote the stimulated emission of radiation and hence to optimize the process of light amplification, the laser medium is placed in an optical resonator that consists of two or more mirrors (Fig. 239-2). Due to the reflection of laser photons inside the resonator, the laser starts to oscillate and the number of photons continues to increase exponentially. Laser action can be achieved when the gain of photons in the laser medium is higher than the loss caused by spontaneous emission or absorption of photons. The temporal behavior of the laser emission depends on the temporal behavior of the excitation of the atoms or molecules. That is, when the energy supply to the laser medium is continuous, the emission of the laser is continuous wave (cw). When the energy supply is limited to a certain time interval by gas discharge or flashlamp, we speak of pulsed excitation, and the laser emits pulses accordingly. The laser pulse duration can vary from microseconds to milliseconds.

To achieve very short pulse durations in the nanosecond range, the resonator is additionally equipped with an optical polarizer and a nonlinear crystal. The polarizer sets the linear polarization of the laser beam that passes through the crystal. However, if an appropriate electrical voltage is applied to the crystal, the polarization of the photons is changed inside the crystal and subsequently blocked by the optical polarizer. This prevents photons from running back and forth inside the resonator (oscillation), which hampers light amplification and which is equivalent to a low circuit quality of the resonator. In such a case, the stimulated emission is minimized and the pumping of the laser medium produces a maximum number of excited atoms or molecules in the laser medium. When this maximum number is achieved, the electrical voltage of the crystal is switched off within nanoseconds and the photons can easily pass the crystal, which is equivalent to a high circuit quality of the resonator. Now, the laser oscillation immediately starts and the light amplification yields a very high number of photons per time unit due to the high number of excited atoms or molecules in the laser medium. The outcome of this circuit quality switch (Q-switch) is a very intense laser pulse with pulse duration in the range of nanoseconds.

IPL PRINCIPLES

The major component of an IPL is the flashlamp that emits radiation from the ultraviolet to the far-infrared part of the electromagnetic spectrum (Fig. 239-3). The broad emission spectrum is narrowed to match the absorption spectra of the different chromophores in skin. The infrared part is usually blocked for wavelengths longer than 950 nm using water in front of the

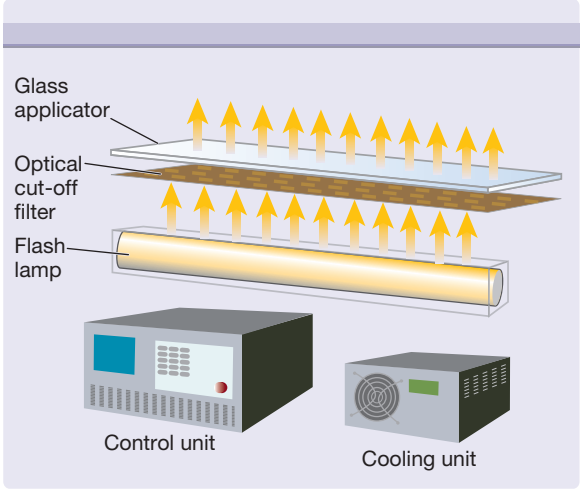

Figure 239-3 The flashlamp of IPL emits radiation that is filtered by a cut-off filter and water in front of the flashlamp. During therapy, the glass applicator is in contact with the skin surface. The control unit operates radiant exposure and pulse duration.

glass applicator. The short wavelengths are blocked by an optical edge filter (cut-off filter), which is only transparent for radiation with wavelengths longer than the cut-off wavelength (e.g., 500 nm, 650 nm). The choice of cut-off filter depends on the chromophore and the target in the skin. A 500 nm cut-off is usually employed for vascular lesions, while a 650 nm cut-off is preferred for the melanin chromophores employed in hair removal. This cut-off also reduces the unwanted interaction with oxyhemoglobin in the vessels.

BASIC PARAMETERS OF OPTICAL RADIATION

The main parameters of optical radiation are wavelength, optical power, intensity, the exposure time and radiant exposure. In the medical literature the phrase fluence is frequently used instead of radiant exposure. The correlation of these parameters are shown in Table 239-2, where the unit for energy is Joule (J); optical power Watt (W); intensity (W/cm^2); radiant exposure (J/cm^2); the exposure time second (s); and the area of irradiation on skin surface (cm^2). After being transported through a glass fiber or articulated arm, laser radiation is usually applied as circular spot to the skin surface by means of a lens in a holder. The spot size and the energy of the laser radiation determine the radiant exposure (J/cm^2). The distal end of a bare glass fiber can be placed inside tissue through a hollow needle for interstitial laser application. The IPL applicator directly contacts the skin through an ultrasonic gel. Thus, the radiant exposure of IPL emission is determined by the size of the applicator and the energy of radiation (J/cm^2).

ENERGY AND INTENSITY. The photon is the smallest unit of radiation. The energy of a single photon at 532 nm (fd Nd:YAG laser, KTP) is about 4 10^{-19} J, which requires a high number of such photons in the order of 10^{19} photons to generate a single laser or IPL pulse. Table 239-3 shows examples of typical intensities that are emitted by IPL or lasers in medical applications. These intensities are substantially higher as compared to typical radiation sources in our daily life, such as light bulbs or solar radiation.

EXPOSURE TIME. To achieve various therapeutic objectives, physicians use different exposure times of radiation, which range from a few nanoseconds to seconds. In case of cw lasers, the exposure time is in the range of seconds, which correlates simply to the time span of pressing the laser foot switch. In most medical treatments, the exposure time is predefined by the pulse duration of a single laser or IPL pulse. In case of pulsed radiation, the exposure time is equivalent either to a single pulse or to a train of single pulses. The broad range of pulse durations implies a broad range of intensities that is important for safety issues. Therefore, lasers are classified by cw (>0.2 s), pulsed (0.2 s–>1 µs), or giant pulsed lasers (Q-switched lasers) (1 µs–1 ns) in safety regulations.

RADIANT EXPOSURE. The most frequently modified parameter in laser treatments is the radiant exposure or fluence. It is the product of light intensity and exposure time (Table 239-2). When taking the total range of medical treatments into account, the radiant exposure varies from about 1–400 J/cm^2 for pulsed radiation. This range can be exceeded for

TABLE 239-2
Parameters of Optical Radiation

Parameter	Formula	Units
Energy	Energy = power × time	J = W × s
Intensity	$\text{Intensity} = \frac{\text{power}}{\text{area}}$	$\frac{W}{cm^2}$
Radiant exposure ("fluence")	$\text{Radiant exposure} = \frac{\text{power} \cdot \text{time}}{\text{area}}$	$\frac{J}{cm^2} = \frac{W \cdot s}{cm^2} = \frac{W}{cm^2} \cdot s$

TABLE 239-3
Typical Parameters for Medical Lasers

Radiation	Intensity $\frac{W}{cm^2}$	Exposure Time ms	Radiant Exposure $\frac{J}{cm^2} = \frac{W}{cm^2} \cdot s$
IPL	1,500	10	15, broadband
fd Nd:YAG laser (e.g., telangiectases)	500	50	25
Pulsed dye laser (e.g., port wine stains)	12,000	0.5	6
Q-switched ruby laser (e.g., tattoos)	25×10^8	0.00002	5

cw applications. Table 239-3 shows a few examples for different intensities and exposure times that are employed in the treatment of different skin lesions. It is striking that the values of radiant exposures are within a rather narrow range, whereas the respective intensities and pulse durations vary in an inversely proportional manner by orders of magnitude.

SKIN OPTICS

Propagation of optical radiation through normal media such as air or glass can be described in a straightforward fashion, in particular, for monochromatic and collimated laser light. Reflection, refraction and absorption dominate the propagation. However, when optical radiation penetrates turbid media like skin, we also must consider scattering of radiation inside tissue that hampers light propagation in a complex manner.

When optical radiation strikes skin, part of the photons is reflected back due to the different refractive index of air and skin. This effect necessitates the wearing of safety goggles during laser therapy. Photons inside the skin do not propagate straight on but frequently and abruptly change their direction due to collision with skin constituents, which is called scattering (Fig. 239-4). The mode and the extent of scattering depend on the size of the scattering objects and the wavelength of the radiation. The size of the scattering objects range from a few nanometers (small cell organelles, cell membranes) to a few microns (large cell organelles, cells, collagen) and to a hundreds of microns (hair follicle, sweat glands). The small objects follow the principle of isotropic Rayleigh scattering, the large objects the non-isotropic scattering. In both processes, the extent of scattering decreases with increasing wavelength. With increasing wavelength, photons are less deflected on their path into skin. Thus, the longer the wavelength, the higher is the penetration depth of radiation in skin. Ultraviolet B radiation (around 300 nm) penetrates skin up to a few tenths of millimeters only, whereas infrared radiation (e.g. Nd:YAG, 1,064 nm) achieves a penetration depth of up to a few millimeters. However, the increase in penetration depth with increasing wavelength reverses for wavelengths longer than about 1,100 nm because radiation is increasingly absorbed by water in skin.

Fortunately, the scattering in skin is mainly forward and many photons penetrate the skin. Unfortunately, the scattering changes the beam geometry in the skin and thereby substantially affects the dosimetry. It is complex to determine the number of photons that reach a target (for example, a vessel) in the skin. The higher the number of photons reaching the target, the more heat can be produced inside the target.

The propagation of broadband radiation such as IPL emission is more complex than that of lasers. Photons with different wavelengths in the broadband emission (~500–950 nm) penetrate skin to different depths. While propagating through the skin, photons can be absorbed by the different chromophores at any time.

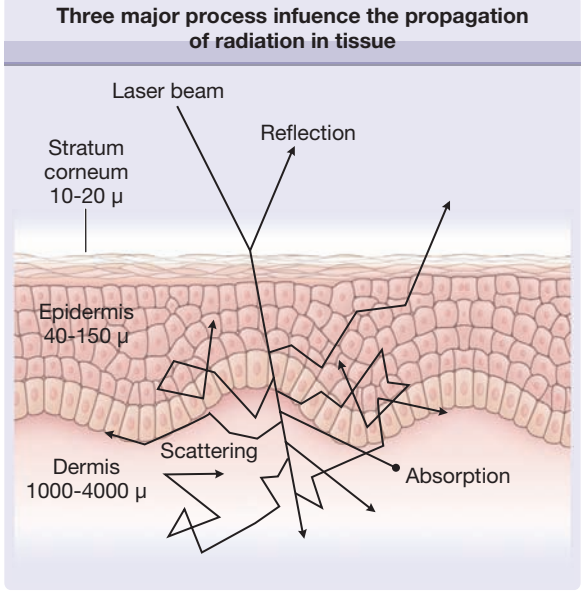

Figure 239-4 Three major processes influence the propagation of radiation in tissue: reflection, absorption, and scattering.

INTERACTION OF RADIATION WITH SKIN

For monochromatic lasers, photons with single wavelength are absorbed according to the absorption coefficient of the respective chromophores at this single wavelength (Fig. 239-5). The absorption of broadband radiation of IPL is complex (Fig. 239-6). The photons with wavelengths in the range of 500–950 are absorbed to a different extent. This clearly complicates dosimetry of IPL in clinical use. In addition, the different IPL in the market emit radiation with considerable different spectra, even though the same cut-off filters are used. This precludes a comparison of radiation dosimetry for different IPL, which impedes clinical studies.

When monochromatic laser radiation or broadband IPL emission is absorbed by the different skin chromophores oxyhemoglobin, melanin, or water, the radiation energy is converted to either heat or chemical reactions. Nd:YAG laser (frequency doubled at 532 nm) and pulsed dye lasers (585–600 nm) preferentially interact with oxyhemoglobin. Radiation of ruby laser (694 nm), alexandrite (755 nm), and diode laser (around 810 nm) is less absorbed by oxyhemoglobin and more suitable for pigmented lesions including hair removal. Radiation of Nd:YAG laser (1,064 nm) is minimally absorbed by all chromophores. Nevertheless, at high radiant exposures (J/cm^2), this laser can be used for unspecific coagulation of tissue (cw mode) or vascular lesions (pulsed mode). The latter is also possible for diode and alexandrite lasers. Infrared lasers such as Er:YAG and CO_2 lasers interact solely with water heating up tissue for vaporization or ablation.

In contrast to lasers, IPL emission is broadband and may be absorbed by all chromophores simultaneously. Using a 500 cut-off filter, the radiant exposure (J/cm^2) is assembled by photons of different wavelengths

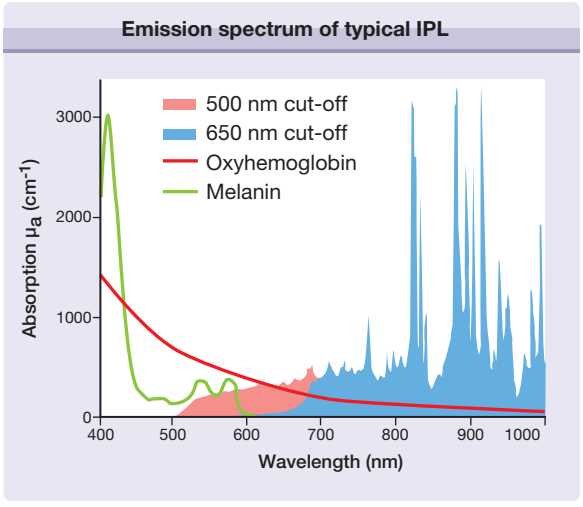

Figure 239-6 The emission spectrum of a typical IPL should match the absorption spectrum of the respective chromophores. 500-nm cut-off filters provide an overlap with the absorption of oxyhemoglobin; 650-nm cut-off filter predominantly with melanin.

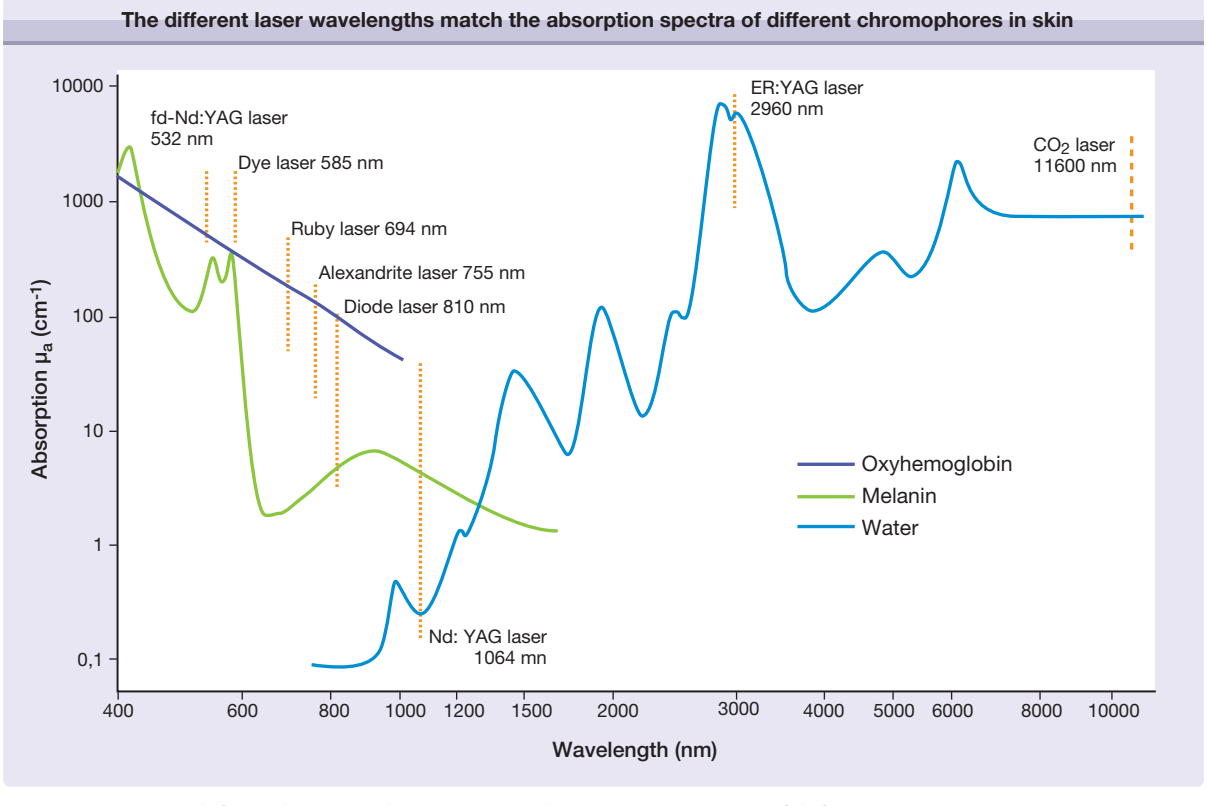

Figure 239-5 The different laser wavelengths match the absorption spectra of different chromophores in skin.

(~500–950 nm), which are diversely absorbed by a skin chromophore like oxyhemoglobin. In addition, these photons reach different depths in skin as explained in skin optics. Thus, the conversion of IPL radiation to heat energy in a target at a certain depth is quite different as compared to laser radiation.

While photochemical reactions require only a small intensity, photothermal reactions necessitates a high intensity. After being absorbed in a chromophore of a specific target (e.g., oxyhemoglobin in a blood vessel), the energy of these photons causes an increase of temperature inside the target. At the same time, the elevated temperature provokes a flow of heat energy to outside the target. This counteracts the heat generation and thereby limits the temperature increase to a maximum value.

For low intensities and long exposure times (pulse duration), the application of laser or IPL radiation causes moderate temperature increase. The temperature ranges from body temperature to 100°C (coagulation), which is achieved with exposure times from milliseconds to continuous wave (cw). When tissue is heated toward the boiling point, radiation causes vaporization of the skin. The use of short CO_2 laser pulses heat up tissue very rapidly leading to a rapid vaporization. This effect precisely causes small holes with minimal thermal damage of the adjacent tissue.

The use of sufficient high intensity and pulse duration of microseconds is suitable to perform skin ablation at temperatures higher than 100°C. When using very high intensities (10^7–10^9 W/cm^2) and very short pulse durations (nanoseconds), the temperature of the target can reach hundreds of degrees celsius. This very short and intense heating may cause explosion of the target. Since the total energy of the laser pulse is limited, ablation and explosion in laser medicine can be restricted to a very small volume. Such high intensities at short pulse durations are accomplished only with lasers and not with IPL.

When pulsed radiation is delivered to skin, the radiant exposure (J/cm^2) stays in a narrow range of about two orders of magnitude. In contrast to that, the intensity and the pulse duration may vary with 5 orders of magnitude at least (Table 239-3). As a rule of thumb, we can say that the higher the intensity (W/cm^2) and the shorter the pulse duration, the higher the maximum temperature inside the targeted volume. By changing the parameters intensity and pulse duration, the temperature can be adapted to achieve coagulation, vaporization or explosion of a specific target in skin.

SELECTIVE PHOTOTHERMOLYSIS

It is a major goal to destroy precisely a specific target (such as vessel, pigment) in skin without permanent damage to the adjacent skin structures. This goal can be achieved by applying pulsed radiation and the principle of selective thermolysis.[1] To destroy selectively a target by heating, the following issues must be considered. The wavelength of the applied radiation should be preferentially absorbed in the chromophore of the target (Fig. 239-6), which is difficult to accomplish for broadband IPL emission (Fig. 239-7). The energy of the radiation pulse should be high enough to achieve thermal destruction of the entire target.

The pulse duration should be comparable to the thermal relaxation time (t_R), which mainly depends on the diameter of the target (D)

$$t_R = \frac{\rho c}{16k} D^2 \sim D^2$$

where ρ, c, k are thermal parameters of the target).[5] The thermal relaxation time is the time it takes to decrease the temperature in the target to 50% of the maximum value. The thermal relaxation time is roughly proportional to the square of the mean diameter of the target. Many of the calculated times match the pulse durations that are used in clinical practice (Table 239-4).

Pigmented lesions containing small melanin or tattoo pigment particles are treated with nanosecond pulses of Q-switched lasers. Besides the short pulse duration, the treatment requires high light intensities to achieve explosion of the pigment particles in the skin.

The use of millisecond pulse duration of either IPL or laser is appropriate to coagulate small blood vessels with diameter of 50–150 µm.[6–8] Figure 239-7 illustrated coagulation of a blood vessel in the dermis. Pulsed radiation penetrates the skin and the radiant exposure (J/cm^2) is reduced from the known value (J/cm^2 at skin surface) to a smaller value due to scattering. The reduced value represents the radiant exposure to be absorbed in the blood vessel. Initially, only the temperature in the vessel increases, coagulating

TABLE 239-4
Thermal Relaxation Times for Common Laser Targets in Skin

Target	Mean Diameter	Thermal Relaxation Time
Pigment (melanosome)	~0,1 µm	5 ns
Small vessel (e.g., port-wine stain)	~50 µm	1.1 ms
Hair follicle	~0,2 mm	18 ms
Large vessel (e.g., leg veins)	~1,5 mm	1,023 ms

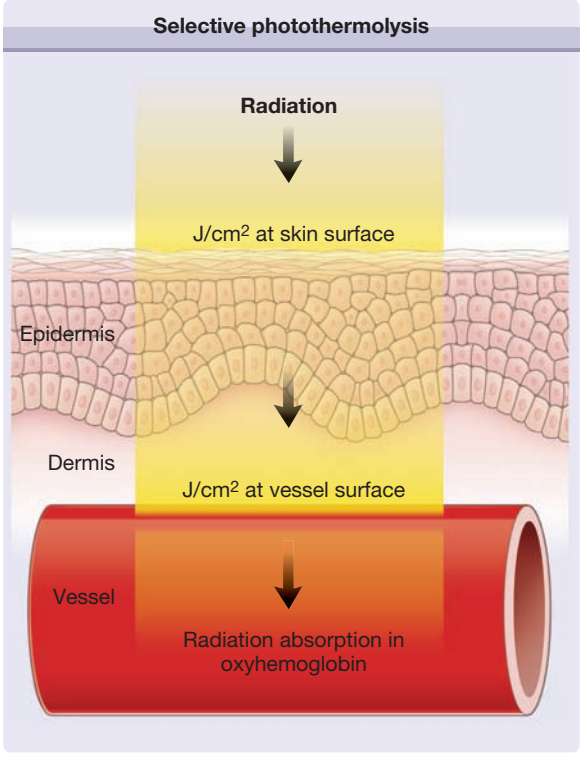

Figure 239-7 The interaction of pulsed radiation with a vessel in skin demonstrating the concept of selective photothermolysis.

the vessel. Due to the temperature increase inside the vessel, however, heat energy starts to flow to the adjacent dermis. At this point, the radiation pulse should be terminated to achieve selective vessel destruction. Pulse duration longer than the thermal relaxation time results in excessive heat flow to the dermis, which may cause unnecessary adverse reactions.

The thermal destruction of hair follicles is achieved by using radiation pulses in the range of 10–50 ms.[9–11] The same range of pulse durations is applied for the treatment of large vessels such as leg veins.[12] However, the calculated value (Table 239-4) does not match this range. In case of voluminous targets, the selective photothermolysis must be aligned to a new parameter, which is the cooling down of heated target. The larger the target, the slower is the cooling down and hence the higher the probability of effective coagulation.[12]

FRACTIONAL PHOTOTHERMOLYSIS

Laser radiation is usually applied on the skin surface as a circular spot showing spot sizes in the range of millimeters. The use of fractional photothermolysis leads to spatially distributed zones of microthermal injury within the treatment area, called microscopic treatment zones (MTZs). These are generated in the skin by focused laser irradiation. MTZs consist of sharply confined tissue denaturation with a diameter of about 100 µm that is surrounded by viable tissue, at intervals of about 200 µm.[13] MTZs are produced either in the ablative or in the nonablative mode. Fractional photothermolysis is a new concept for skin restoration. The MTZs are placed not manually but using computer-assisted scanner device to produce a periodic grid of thermal injuries.

SKIN COOLING

Laser therapy of skin disorders require high radiant exposure to be delivered to the skin surface. Most of the targets are located at the epidermal-dermal junction or within the dermis. To reach these targets, the photons have to traverse the epidermis, which can partly absorb the incoming radiation. In addition, excess heat, caused by the absorption of radiation in the dermis, may provoke damage of dermal and epidermal structures. To avoid unwanted thermal damage especially to the epidermis, the skin surface is frequently cooled before, during, and after laser impact by a variety of measures.

The simplest and cheapest cooling is accomplished by applying ice cubes on the skin surface prior to or even during laser impact.[14] An application time of 10 seconds can result in skin surface temperature of about 10°C. About the same results are achieved by applying actively cooled metal or glass to the skin surface[15] Instead of contact cooling, some laser systems are equipped with spray cooling. Shortly before laser impact, a burst of cold gas (usually tetrafluoroethane) is applied to skin surface reducing the temperature of the epidermis to about 5°C.[10] Cooling is also achieved by exposing the treatment area to cold airflow that is provided by a special air conditioner.

SAFETY

It was recognized early that radiation of any wavelength can pose a risk to humans, in particular, to unshielded eyes and skin.[16,17] This risk is caused by the absorption of photons leading to photochemical or photothermal alterations of tissue.[18,19] These alterations may affect tissue integrity for a short period of time or damage tissue permanently. When lasers or intense pulsed light sources are used to treat skin lesions, a variety of safety measures are required.

The use of lasers in medical care is governed by rules and standards that are established in the Safety of Laser Products of the International Electrotechnical Commission (IEC) (http://www.iec.ch/) or American National Standards Institute (ANSI) (http://www.ansi.org/). The safety rules are based on IEC 60825-1 or ANSI Z136.1 for all laser systems, including medical lasers. Lasers have been classified in four groups based on the accessible emission limits (AEL). The rules are applicable to safety of laser products emitting laser radiation in the wavelength range 180 nm to 1 mm. These regulations unfortunately do not cover the use of IPL; there is no existing FDA performance standard for IPL products. We provide some advice regarding IPL safety, based on comparisons with laser systems. IPL systems emit high radiant exposures (J/cm^2) that

are comparable to lasers and have therefore the potential to cause substantial damage to the eyes and skin.

When using lasers for tissue vaporization, laser plume must be evacuated by using an appropriate device to avoid contact with infectious material.

EYE SAFETY

The high radiant exposures, high intensities and short pulse durations in laser therapy not only can harm the skin but also can severely damage the eyes even causing complete loss of eyesight. The side effects of radiation to the eyes are comparable to those effects at the treatment site. It is inevitable that radiation partly reaches the eyes due to reflection and scattering at the treatment site. Other reasons are accidental and careless handling of lasers and IPL during treatment.

In the spectral range of about 370–1,000 nm, radiation readily penetrates the cornea and the lens reaching the choroid and retina. The radiation of this spectral range is well absorbed by the hemoglobin in the choroid vessels that may lead to thermal damage of the retina. Refraction by the lens and cornea increases the intensity of the incoming radiation by several orders of magnitude.

For wavelengths shorter than 370 nm and longer than 1,000 nm, radiation is predominantly absorbed in water (Fig. 239-1) and do not completely traverse lens and cornea. The short wavelengths can cause injury of the cornea (cornea ablation) or cataract formation in the lens. With increasing wavelengths above 1,000 nm, the penetration of radiation decreases leading again to cataract formation (Fig. 239-3). For wavelengths around 3 µm, the water absorption is maximal for causing cornea ablation. At even longer wavelengths, vaporization of the cornea may occur.

The eyes try to protect themselves from damage that could be induced by excess radiation energy. The eyelid is closed automatically in case high radiation energy is detected. However, the corresponding time span is about 250 ms, which is longer than most of the pulse durations used for lasers and IPL. Radiation that is invisible for the eyes (UV, IR) will not trigger an eye blink.

Users of lasers or IPL should always keep in mind that even small intensities reaching the open pupil can cause severe damage of the retina, which, in most cases, is irreversible and may entail a complete loss of vision. Radiation of lasers or IPL can also damage skin outside the treatment area.

For nearly all medical laser systems, even scattered radiation can be dangerous to eyes. To shield the eyes, it is mandatory to wear safety goggles during treatment with lasers or IPL according to EN 207 in Europe or to ANSI Z136 in the United States. To achieve maximal safety for the eyes, it is important to adjust the optical filters of the safety goggles to the radiation source used (laser or IPL). The important parameters of the radiation sources are wavelength, pulse duration, intensity, and radiant exposure. These parameters of a laser or IPL system determine the characteristics of the safety goggles. Each laser or IPL requires special safety goggles that are labeled for their use, which are wavelength range of protection, laser mode, and scale number of protection. The manufacturer of lasers or IPL must provide sufficient information about the appropriate safety goggles, which can be found in the handbook of each laser or IPL device.

SAFETY OF LASERS AND IPL SYSTEMS

All laser systems, including the medical lasers, sold in Europe must be certified to EN 60825-1. In the United States, several organizations concern themselves with laser safety including ANSI and the Center for Devices and Radiological Health (CDRH). There are some basic categories of controls useful in laser environments. These are engineering controls, personal protective equipment, administrative and procedural controls, special controls, and correct labeling of the laser products. It is required and mandatory to appoint a laser safety officer (LSO). This person has the authority to monitor and enforce the control of laser hazards and effect the knowledgeable evaluation and control of laser hazards. The LSO administers the overall laser safety program where the duties include items such as confirming the classification of lasers and ensuring that the proper control measures are in place, approving substitute controls and conducting medical surveillance. The LSO should receive detailed training including laser fundamentals, laser bioeffects, exposure limits, classifications, control measures (including area controls, eye wear, barriers, etc.), and medical surveillance requirements. Nearly all medical lasers are assigned to class III or class IV. The class of a laser can be found on the label present on the laser device and in its handbook. Class III means moderate power lasers (cw: 5–500 mW, pulsed: 10 J/cm^2 or the diffuse reflection limit, whichever is lower). In general, Class IIIB lasers will not be a fire hazard, nor are they generally capable of producing a hazardous diffuse reflection. Specific controls are recommended. Class IV means high power lasers (cw: >500 mW, pulsed: 10 J/cm^2 or the diffuse reflection limit) are hazardous to view under any condition (directly or diffusely scattered) and are a potential fire hazard and a skin hazard. Significant controls are required of Class IV laser facilities (http://www.osha.gov/dts/osta/otm/otm_iii/otm_iii_6.html). When using medical lasers, it is unavoidable that part of the beam path from a Class IIIB or Class IV laser is not sufficiently enclosed and/or baffled to ensure that radiation exposures will not exceed the MPE. Then a "laser-controlled area" is required. Although recommendations for the safe use of IPL in medical practice are currently not available, many of the items mentioned for lasers can be applied as well for IPL, in particular regarding eye protection.

THERAPEUTICAL APPLICATION

Since the introduction of lasers in dermatology by L. Goldman[20] and the development of selective photothermolysis in the 1980s,[1] laser therapy has become an

indispensable therapeutic modality and more than 80 indications are documented.

PORT-WINE STAINS (PWS)

PWS are asymmetric usually congenital capillary vascular lesions present in up to 2% of newborns. In childhood, they are pale red macules and patches. In adults they tend to become darker (port wine) and develop an irregular surface sometimes with blue-red papules and nodules. PWS are probably secondary to abnormal vascular innervation leading to a reduced vascular tone.[21–26]

In hypertrophic PWS with nodular surface, besides the vascular abnormalities extensive epithelial, neural, and mesenchymal harmartomatous changes have been observed suggesting a genetically determined multilineage development field defect.[27]

More recent studies indicate that RASA1 mutations cause capillary and arteriovenous malformations and hereditary capillary malformations and limb enlargement without arteriovenous malformation.[28–30]

Vascular endothelial growth factor (VEGF) and VEGF-receptor 2 expression is significantly increased in PWS compared to controls, indicating that VEGF and VEGF-R2 may contribute to vessel proliferation and vasodilatation.[31]

PWS are often associated with other malformations (Sturge-Weber-Krabbe syndrome, Cobb syndrome, Klippel-Trenaunay syndrome, Parkes-Weber syndrome).

Acquired PWS are rare but may be caused by trauma, hormonal imbalances or medications.

The introduction of the pulsed dye laser (PDL) in the 1980s ($\lambda = 585$ nm, $t = 0{,}45$ ms, $\varnothing = 5$ mm) greatly improved the treatment options for PWS. In the past two decades, important advances include the use of wavelengths of 585–600 nm, longer exposure times and increasing the diameter of the beam. In addition cryogen spray cooling is used to protect the epidermis, allowing a higher fluence to be delivered to the dermis.

Standard parameters for treating a PWS are a wavelength between 585 and 600 nm, a fluence of 4–20 J/cm^2, a pulse duration of 1.5–10 ms, a beam diameter between 7 and 10 mm and cryogen cooling of the skin surface, also known as dynamic cooling device (DCD). Larger beam diameters require a lower fluence. In some studies, longer wavelengths produced better results than 585 nm.[32–34]

The results depend on the age of the patient, the location, the color of the PWS and the number of treatment sessions.[35,36] The success rate for children and adolescents is around 65% with the best results obtained when treatment is started in the first year of life (Fig. 239-8). Reyes and Geronemus[37] treated 73 children less than 14 years old; 45% got over 75% lightening and 42% obtained 50% improvement. A complete disappearance can be expected in only 15% of patients. In a prospective study by van der Horst et al[38] the benefit of early treatment could not be confirmed, although these authors did not employ a laser system with dynamic cooling.

The location of a PWS is also a significant factor. PWS on the face and back respond much better than those at other sites. Those on the legs respond worst. Even on the face, there is considerable variation. PWS in the midface and distribution of the second trigeminal branch lighten less than those in the periorbital region, forehead, neck and nape.[39–41] The size also affects the response. Small lesions respond better than large ones, and, often in the latter case, uniform lightening is impossible to achieve.[42,43] Repeated treatments

Figure 239-8 **A.** PWS in a 6-months-old female baby prior to PDL therapy. **B.** Result of five PDL therapies at the age of 3 years.

lead to an improved response, and sometimes more than 10 sessions may be required.

The risk of scarring with PDL is quite low, around 1%. It is higher in patients on isotretinoin therapy. The main complications are hypo- or hyperpigmentation and rarely the development of a pyogenic granuloma.[44–47] After the treatment is concluded, up to 15% of the patients may develop partial recurrences of their PWS, but not to the same extent and size as prior to treatment.[48–50]

When PWS are resistant to PDL, there are other laser options. Deeper vessels can be treated with the alexandrite laser (755 nm) and the pulsed Nd:YAG laser (1,064 nm).[51–54] McGill et al were able to produce additional improvement in 10 of 18 patients treated with PDL with an alexandrite laser.[55]

In a study comparing pNd:YAG laser and PDL, both systems produced 50%–75 % improvement. Patients preferred the Nd:YAG laser because it caused less purpura. On the other hand, the risk of scarring was clearly higher with the pNd:YAG laser, which should be used for PWS only by experienced laser therapists.

KTP lasers can also produce improvement in PSW but the results are worse than with PDL and the risk of scarring is greater.[56]

There is also good experience using IPL to treat PWS.[3,57,58] In a comparison study in 20 patients, both PDL and IPL produced improvement but the extent of lightening was significantly better with the PDL.[59] In contrast, in our own study, IPL was slightly superior to PDL.[60]

In individual patients with a nodular component to their PWS, vaporization of the individual lesions with the cwCO_2 laser has proven helpful.

HEMANGIOMAS IN INFANCY

Hemangiomas are benign proliferative tumors, which occur in about 5% of children. They are more common in premature infants and following amniocentesis. In general, they are not present at birth but appear in the first weeks of live as pale or telangiectatic macules, which then rapidly develop into nodular tumors. After a growth period of 9–10 months, there is a stable period, followed by a regression phase that can last until 10 years of age. About 50% of patients have residual lesions such as scars, fibrofatty nodules, or telangiectases. Complications of hemangiomas include ulceration, bleeding, and distortion of orifices (nose, eyes, mouth, and anogenital region). We distinguish between superficial, cutaneous-subcutaneous, and deep subcutaneous hemangiomas. They may be circumscribed nodules, plaques in a segmental distribution or multiple. The tumors cells express FCR II (CD32), merosin, and GLUT1, a pattern similar to placental cells.

Congenital hemangiomas are much less common; they are divided into noninvoluting congenital hemangiomas (NICH) and rapidly involuting congenital hemangiomas (RICH).

The treatment of hemangiomas is controversial, as most of them regress spontaneously.[36] Nonetheless, numerous studies have shown that small and initial hemangiomas respond very well to PDL (Fig. 239-9). Growth is arrested in over 60% of treated tumors with just a few PDL sessions: only 15% disappear completely.[61–64] Ulcerated hemangiomas also respond well to laser therapy; they become lighter and re-epithelize quicker.[65] Deep subcutaneous components of the hemangiomas do not respond.[66]

In a prospective randomized and controlled study, 121 children with uncomplicated hemangiomas were treated with PDL (585 nm, pulse duration 0.45 ms, spot size 3–5 mm, fluence 6-7.5 J/cm^2, no cooling). After a year 30% of the lesions in the treated group had completely disappeared; in the control group, it was only 5%. Residual changes were found in 42% of the treated children and 44% of the control group. Complications were much higher in the treated group with 45% versus 15% in the controls. In the treated group, the hemangiomas had increased in size by 61%; in the control group, 160%.[67]

In another study, a PDL with a longer pulse duration and surface cooling (595 nm, 7-mm spot size, pulse duration up to 20 ms, 9–15 J/cm^2 fluence) was compared to a standard PDL without cooling (585 nm, 7 mm, 0.45 ms, up to 7 J/cm^2); treatment with the longer pulse time led to better results with fewer side effects.[68]

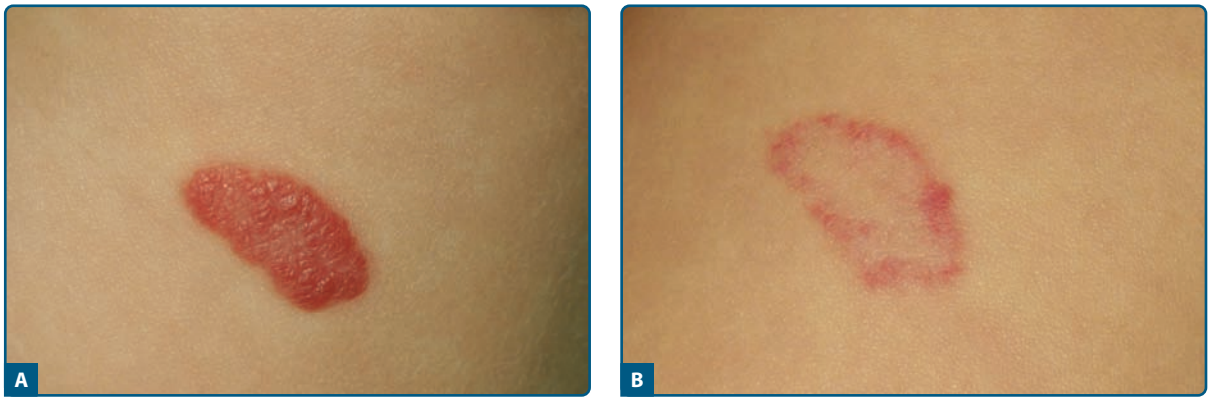

Figure 239-9 **A.** Childhood hemangioma in a 2-months-old female baby. **B.** After two PDL treatments, stoppage of growth and induction of regression.

Figure 239-10 **A.** Rubeosis faciei (red face) in a 45-years-old female patient. **B.** Improvement in two PDL test spots. **C.** Result of one complete treatment.

Because of the introduction of propranolol to treat infantile hemangiomas, it is necessary to reexamine the role of lasers in this problem. Cutaneous-subcutaneous hemangiomas and rapidly proliferating hemangiomas in complicated locations respond well to systemic propranolol. They are no longer an indication for cwNd:YAG laser or intralesional laser therapy with bare fibers. Propranolol can be combined with PDL.[69,70]

Residual telangiectases after the regression of hemangiomas can be improved with either PDL or IPL.

TELANGIECTASES

Telangiectases are permanently dilated small venules, which may be solitary or matted together to form larger flat lesions. Primary or essential telangiectasia is often familial, but no underlying cause has been found. Special forms are progressive, essential disseminated telangiectasia, which increase in numbers on lesions on the extremities, trunk and face, as well as unilateral nevoid telangiectasia syndrome (UNTS).

Telangiectases are a good indication for laser and IPL therapy. PDL with large beam size and midrange fluences are employed; the pulses are set to lightly overlap. Many patients consider the resulting purpura after PDL as inacceptable. Pulse stacking has been tried, using a series of impulses all beneath the purpura threshold to reduce problems. The number of sequential impulses is based on the visible vasoconstriction. Using these techniques, good clinical effects can be obtained without increasing the complication rate.[71] In a comparative study, long-pulsed PDL proved more effective than two IPL devices.[72]

KTP lasers also produce good results for this indication.[73,74] Infrared laser such as diode lasers or the pulsed Nd:YAG laser can also be used. In a comparison study, a 940-nm diode laser was more effective than a KTP laser.[75]

The pulsed Nd:YAG laser is best suited for vessels with a diameter of more than 1 mm; the treatment is relatively painful and the risk of scarring greater than with other lasers.[77,78]

When telangiectases are grouped together and more diffusely red, IPL can be very effective (Fig. 239-10). A major advantage is that the large rectangular impulses can be very precisely placed next to each other.

Poikiloderma of Civatte is also a good indication for PDL and IPL; we prefer the latter.[79]

STARBURST VEINS AND VARICOSITIES OF THE GREAT SAPHENOUS AND SMALL SAPHENOUS VEINS

A phlebology evaluation is required prior to treating these venous problems. Vessels with a diameter of up to 1 mm are a good indication for PDL with a variety

of wavelengths (585, 590, 595, and 600 nm) and a longer pulse duration. For this purpose, oval handpieces with a spot size of 2 × 7 mm are available. Fluences between 12 and 20 J/cm^2 are used, and skin cooling is mandatory; despite these measures, sometimes hyperpigmentation cannot be avoided.[80,81]

The alexandrite laser is well established for treating starburst veins. Using relatively high fluences (60–80 J/cm^2) and pulse durations of 3 ms with surface cooling, 65% of patients experienced an improvement of at least 75% when the vessel diameters were between 0.3 and 2 mm. Hyperpigmentation developed in 35%.[82] In a study comparing alexandrite, diode, and pulsed Nd:YAG lasers for starburst veins with a caliber of 0.3 and 3 mm, the Nd:YAG laser was most effective.[83]

Treatments with a 940-nm diode laser produce greater than 75% improvement in 46% of patients.[84,85] For vessels greater than 1 mm in diameter, the pulsed Nd:YAG laser with surface cooling is very effective.[77,83,86–88] In direct comparison studies, the pulsed Nd:YAG laser was just as effective as sclerotherapy.[89–91]

A new use for lasers in phlebology is sealing the great saphenous and small saphenous veins with endoluminal laser therapy. Diode lasers, Nd:YAG lasers, and radio frequency ablation devices have all been employed. In a prospective randomized study, radiofrequency ablation produced just as good results as operative vein stripping.[92–95]

OTHER VASCULAR LESIONS

The superficial component of congenital or acquired lymphangioma circumscriptum can be vaporized with the CO_2 laser. Although improvement is produced, sometimes for many years, the lesions eventually recur.[96–99]

Venous lakes respond well to treatment with PDL KTP, diode or Nd:YAG lasers.[100]

Low-flow venous malformations can be treated with cw Nd:YAG or long-pulsed Nd:YAG lasers or with the intralesional bare fiber technique.[101–104]

Small angiofibromas in tuberous sclerosis can be treated with the KTP laser. When multiple lesions are being treated, then ablative approaches such as a flash scanned CO_2 laser or Er:YAG laser are preferred.[105–110]

Cherry angiomas respond well to KTP laser and PDL.[111] The pulsed Nd:YAG laser can also be used.

The ectatic vessels of hereditary hemorrhagic telangiectasia (Osler-Rendu-Weber syndrome) are best treated with the KTP, diode, or long-pulsed Nd:YAG lasers. The pNd:YAG laser can also be used for larger ectatic vessels but the treatment is painful.[112]

The matted telangiectases in angioma serpiginosum respond well to PDL and IPL therapy, but recurrences are common.[113]

BENIGN TUMORS

Xanthelasmas and Syringomas can be coagulated with a KTP laser[114] or destroyed with the cw-CO_2 laser; there is a certain risk of scarring. Better choices, because they cause less thermal damage, are pulsed or flash scanner-CO_2 laser systems. Another reliable approach is the very exact ablation with the Er:YAG laser.[115,116]

Trichoepitheliomas are usually skin-colored, so that coagulation with a semiselective coagulating laser is not very helpful. Ablation with the CO_2 or Er:YAG laser makes it possible to obtain good cosmetic results even when treated multiple aggregated lesions.[117–119]

Neurofibromas can also be removed with the CO_2 laser if they are not too large. Using relatively high power, the dome-shaped neurofibroma is circumferentially incised around its base; then the neural tissue generally herniates up with a little lateral pressure, so it can be vaporized or destroyed at its base. Although large deep defects may result, they heal amazingly well.[120]

Eruptive vellus hair cysts can be vaporized with the CO_2 laser. In patients with *steatocystoma multiplex*, one can open the cysts with a focused CO_2 laser beam, express the contents, and then coagulate the cyst wall with a defocused beam. Cosmetically pleasing results are not always possible.[121]

Similarly, a *digital mucous cyst* can be opened with a focused beam of a CO_2 laser and then emptied of its gelatinous contents. Then the base and wall of the cyst can be vaporized with the defocused beam. Using this method makes it possible to completely remove digital mucous cysts without a complicated surgical approach.[122]

EPIDERMAL AND ORGANOID NEVI

VERRUCOUS EPIDERMAL NEVI. Soft papillomatous epidermal nevi can be treated relatively effectively by coagulation with an argon or KTP laser or ablation with a CO_2 or Er:YAG laser. In contrast, the hard or verrucous epidermal nevi often fail to respond to laser therapy and typically recur.

A KTP laser can be used to completely coagulate small circumscribed nevi. For more extensive nevi, a chessboard or line-by-line pattern is recommended. About 80% of large but soft epidermal nevi can be successfully treated in this manner.[123]

Destruction with the CO_2 laser (cw, pulsed or with flash scanner) is especially useful for markedly exophytic components of nevi.[124,125] (See Fig. 239-11) The Er:YAG laser makes possible a very exact removal of relatively flat lesions on the face without any significant side effects.[126,127] A test area should be tried before a complete lesion is treated, especially in problem areas like the neck and face, since hypertrophic scars can develop. After successful removal, the appearance may remain stable for years, but up to one-third of patients eventually develop some degree of recurrence.[127]

For hard verrucous nevi or ILVEN, a CO_2 laser ablation is worth trying, although only about 30% of patients get a good response.[123] For ILVEN, treatment with PDL (585 nm) can reduce the pruritus and produce partial remissions.[128]

SEBACEOUS NEVI. The exophytic part of sebaceous nevi can be removed with CO_2 lasers (cw,

Figure 239-11 **A.** Extensive papillomatous epidermal nevus in the groin of a 32-years-old patient. **B.** Late result 8 months after CO_2-laser-vaporization.

pulsed, or flash scanner) as well as with the Er:YAG laser. The intradermal component remains behind, so that the color of lesion is not changed and recurrences are common. Surgical excision is thus preferred if it seems likely to leave a good cosmetic result or if there is concern for malignant degeneration.

INFECTIOUS DISEASES

Genital Warts. The vaporization of genital warts is one of the most common indications for the CO_2 laser. Condylomata acuminata are generally vaporized at settings of 10–20 W; very exophytic lesions may require higher settings. By using short pulses and low fluences, it is possible to remove warts in problem areas such as over perianal ectatic veins or on hemorrhoids.

Prior to treatment, the entire area should be soaked with 3%–5% acetic acid solution for a few minutes to bring out clinically inapparent lesions, which turn white and can then be seen and treated. Viral DNA is found in the perilesional clinically normal skin around a wart; thus, we recommend superficially ablating a 5- to 10-mm rim of normal skin around each lesion.

One should avoid deep destruction because such lesions heal slowly and painfully, and may scar, or even lead to functional impairment.[129] Viral DNA is present in the laser plume[130]; therefore the patient, physician, and nursing personal must all be protected by masks and vacuum exhaust systems.

Genital warts can also be vaporized with the Er:YAG laser. One disadvantage is the tendency of the well-vascularized papillomas to bleed, so that this laser is best suited for flat lesions.

The Nd:YAG laser can also be used to treat genital warts.[131,132] They should be coagulated until they turn completely white. Postoperatively, the lesions become necrotic and drop off; the exudative wounds may take weeks to heal. Because of both the long and painful recovery period and the risk of scarring, we only use the Nd:YAG laser in patients infected with HIV and hepatitis C virus, as there is no risk of infection through a smoke plume.

As far as the recurrence rate is concerned, laser therapy is not superior to other destructive measures such as electrosurgery or argon-plasma coagulation.[133,134] No matter what technique is used, the recurrence rate for genital warts is 40%–60%, and even as high as 80% in some series.

Patients with bowenoid papulosis (an HPV-induced intraepithelial neoplasm) can often be treated successfully with the CO_2 laser, avoiding a mutilating procedure. Recurrences are once again common; because of the greater risk of development of an invasive carcinoma, close clinical control is mandatory.

Common Warts. Common warts, just like genital warts, can be easily vaporized with the CO_2 laser.

Filiform warts can be removed with 5–10 W and a diagonal cutting plane. The adjacent normal skin can be protected with moist compresses. The base of the wart is removed exactly down to the skin surface, often using a lower setting. Deeper removal is more likely to cause scarring.

Thicker and more keratotic warts should be treated with keratolytic agents prior to laser therapy. The macerated white skin over the wart can be vaporized at relatively high settings (15–20 W) to produce superficial vaporization and charring, but is not completely removed. After a few seconds of treatment, the horn plug can be removed with a forceps from the base of the wart. Sometimes one must reheat the lesion again

to facilitate this. The well-vascularized and circumscribed base of the wart is then vaporized with a lower setting until the lesion is entirely destroyed, as evidenced by a restored papillary pattern to the dermis. Cure rates of 50%–70% are reported for the vaporization of warts.[135–137] Since the treatment brings considerable postoperative pain and can produce painful scars, especially for plantar warts, it should be reserved for warts, which have failed to respond to consequent standard therapy. On weight-bearing surfaces, we view laser vaporization as a last resort.

Warts can also be treated with PDL. Here the dilated capillary loops in the wart are destroyed, hastening its demise. Just as with vaporization, the thickened stratum corneum must first be removed with keratolytics, as the laser beam cannot penetrate this tissue. Multiple sessions are always needed; the cure rate is between 60% and 70%[138,139] with especially good results for facial warts.[140]

Mollusca Contagiosa. The treatment of mollusca contagiosa with the PDL appears very effective. After 1 or 2 treatments with fluences of 6 and 8 J/cm^2, cure rates between 95% and 100% are described.[141,142] The treatment is also well tolerated by children; topical anesthetics or cold aircooling are helpful. Even with far lower fluences of 4 J/cm^2, similar results (96%–100%) have been reported.[143]

INFLAMMATORY DERMATOSES

Lichen Sclerosus et Atrophicus. The removal of genital or extragenital lesions of lichen sclerosus et atrophicus with the CO_2 laser leads to regression or cure in most patients,[144–146] if the standard therapy with topical steroids were ineffective. The vaporization must extend into the normal underlying dermis. Recurrences can be seen both at the border and in the healed areas. They usually appear after 2–3 years, and the patient can be treated once again in the same way.[146]

Cutaneous Lupus Erythematosus. The selective destruction of vessels with a flashlamp pumped, pulsed dye laser can produce improvement in lupus erythematosus. Areas of chronic erythema and telangiectases,[147] as well as plaques[148] may respond. A test site should be treated before larger areas are tackled, as lupus erythematosus can be exacerbated by the laser exposure.[149]

Chondrodermatitis Nodularis Helicis. Vaporizing the cutaneous nodule and the underlying damaged cartilage with the CO_2 laser under local anesthesia is an effective way of treating this troublesome disorder. The defect usually heals without complications and the patient is free of symptoms. With larger lesions, a depressed scar is unavoidable.[150,151]

Psoriasis Vulgaris. While vaporization of chronic stationary plaques of psoriasis with the CO_2 laser is possible, there is not a great deal of clinical experience. Because of the high infection rate[152] and the risk of scarring,[153] laser vaporization should only be considered for isolated therapy-resistant plaques.

The treatment with PDL is directed against the abnormal large vessels in the dermal papillae of psoriatic lesions. The success rate is around 50% after repeated treatments at 2- to 3-week intervals; the response is generally short-lived and complete responses are uncommon.[153–155]

Psoriasis is better treated with excimer lasers or lamps, which deliver high-intensity UV IIA radiation at 308 nm (Table 239-5). Only the psoriatic lesions are treated, so that normal skin is not exposed. In addition, a higher dose of UV can be delivered to the lesions. The higher the individual UV dose, the better the response, although the side effects also become more common including dermatitis, blistering, and hyperpigmentation. High-dose therapy plans are more effective, but less acceptable to the patients because of blistering and crusting. They are also somewhat controversial, because with low and medium dosages, one tries to avoid blistering and crusting, just as with classical UV therapy for psoriasis.

The 308-nm phototherapy of psoriasis is unquestionably effective, just like the classic 311-nm UV therapy. When high doses are used, the duration of therapy is shorter and the cumulative dose lower. Long-term effectiveness is comparable to standard measures, with disease-free intervals of 4–6 months,[156–162] although some groups have reported responses lasting up to 2 years.[163,164]

Using the excimer laser is very time-consuming because of the relatively small spot size and the device is very expensive. In summary, the laser therapeutic approaches to psoriasis are mostly experimental and not clinical standard.

Hailey-Hailey Disease. Surgical methods such as dermabrasion or excision have long been used in Hailey-Hailey disease. Similarly wide vaporization with the CO_2 or Er:YAG laser with local or general anesthesia is also effective.[165] The damaged skin must be removed, completed, noted by reaching the chamois-colored superficial dermis; otherwise, prompt recurrences are the rule. Laser vaporization can provide relief for up to several years, even though recurrences at the edge or within the lesion must be expected. A test patch should be treated prior to embarking on more widespread therapy and evaluated after 6 months in order to exclude patients whose lesions quickly recur and those who develop hypertrophic scars.

Acne Vulgaris. Laser and IPL therapy of acne vulgaris has recently attracted considerable attention. The information on different devices and their effectiveness is incomplete, or even in some instances contradictory.[166,167]

PDL have been employed in two randomized studies with conflicting results. Seaton et al[168] compared a treated group (n = 31, 5 mm spot size, 1.5 or 3 J/cm^2) to a group treated with simulated or placebo therapy (n = 10). After just one treatment, 12 weeks later, the treated group showed a significant reduction in the Leeds acne score for the total lesions and number of inflammatory lesions. In contrast, Orringer et al[169] were unable to show any improvement using a half-face study with one or two treatments (7 mm, 2.5–3 J/cm^2).

TABLE 239-5
Commonly Used Dermatologic Lasers

Laser (nm)	Target	Effect in Target	Mode (Pulse Duration)	Applications
Excimer (XeCl) (308)	DNA, proteins	Photochemical reactions	Pulsed (μs)	Comparable to narrow band UVB (311 nm)
Argon (488/514)	Vascular lesions Tissue	Semiselective coagulation Coagulation	Pulsed (ms)	Telangiectases, spider nevi, venous lakes Syringoma, xanthelasma, epidermal nevi
Frequency-doubled Nd:YAG (532)	Vascular lesions	Selective coagulation ("KTP" laser)	Pulsed (ms)	Telangiectases, spider nevi, venous lakes
Frequency-doubled Nd:YAG (532)	Pigmented lesions	Selective and fast heating (explosion)	Pulsed (ns)	Benign melanin-containing lesions, tattoos (red)
Flashlamp pulsed dye (585–600)	Vascular lesions Tissue	Selective Coagulation	Pulsed (ms)	PWS, telangiectases, rosacea, spider nevi Scars, keloids, warts, photoaging
Ruby (694)	Pigmented lesions	Selective and fast heating (explosion)	Pulsed (ns)	Benign melanin-containing lesions, tattoos (black, blue, green)
Alexandrite (755)	Vascular lesions Tissue Pigmented lesions	Selective coagulation Selective and fast heating (explosion)	Pulsed (ms) Pulsed (ns)	Large vessels (leg veins, hypertrophic PWS) Hair removal Benign melanin-containing lesions, tattoos (black, blue, green)
Diode (810)	Vascular lesions Tissue	Selective coagulation	Pulsed (ms)	Large vessels (leg veins, hypertrophic PWS) Hair removal
Nd:YAG (1,064)	Vascular lesions Vascular lesions Tissue Pigmented lesions	Unspecific coagulation Selective coagulation Selective and fast heating (explosion)	Continuous wave (cw) Pulsed (ms) Pulsed (ns)	Vascular malformations, tumors Large vessels (leg veins, hypertrophic PWS) Hair removal Benign melanin-containing lesions, tattoos (black, blue, green)
Diode (1,450)	Tissue	Selective coagulation (nonablative)	Pulsed (ms)	Skin remodeling, photoaging
Er:YAG (2,960)	Tissue	Selective and fast heating (ablation)	Pulsed (ms)	Skin resurfacing, epidermal ablation
CO_2 (10,600)	Tissue	Unspecific coagulation (vaporization) Selective and fast heating (ablation)	cw Pulsed (ms)	Vaporization of tissue Skin resurfacing, epidermal ablation

The 1,450-nm diode laser has been approved by the FDA for acne therapy. This device administers 12–14 J/cm^2 to the face and 18 J/cm^2 to the back coupled with spray cooling. Even though a single treatment can be effective[170]; generally, multiple treatments at intervals of several weeks are preferred. In 19 acne patients with facial lesions, one treatment led to a 37% reduction in lesions; two sessions, 58%; and three sessions, 83%[171] Four sessions produced a reduction of at least 50%, which held for 6 months in 13 patients, once again with facial acne.[172] After a single treatment (n = 20), Mazer and Fayard[170] observed an average improvement of 79% that was almost stable (74%) after 12–18 months. Similar results were obtained on the back; in a half-side

study, 24 weeks after 4 treatments, there was a significant, almost complete improvement on the treated side ($n = 15$).[173]

Rosacea. Rosacea appears to respond to PDL. After two treatments (585 nm, 1.5 ms, 5 mm spot size, 8 J/cm^2), the symptoms of pruritus, burning, flushing, and dryness all improved by about 60%.[174] After three treatments (585 nm, 450 µs, 6 J/cm^2), the erythema had improved by 50%; the telangiectases, 75%; and the flushing, 55%. The overall severity of the rosacea clearly improved, but not the number of inflammatory lesions.[175] The benefits are not very long lasting.[176]

Vitiligo. One therapy option for stable vitiligo is the transplantation of the autologous cultured cells. With the Er:YAG laser the necessary de-epithelization can be accomplished quickly and elegantly, analogous to a very fine dermabrasion.[177]

Treatment with the 308-nm excimer laser is another option. Hadi et al treated 55 vitiligo lesions in 32 patients (2× weekly, starting with 100 mJ/cm^2 with careful increase by about 50 mJ/cm^2 per treatment depending on side effects). More than 75% repigmentation was achieved in 53% of patients with an average of 23 sessions. About 20% of the lesions completely repigmented.[178] Facial lesions responded far better than those on the extremities or trunk.

Hong et al[179] compared excimer laser irradiation with narrowband UVB therapy in 8 patients with a half-side model. The 308 nm laser therapy produced a quicker and significantly better repigmentation than the UVB. The face once again responded best; the extremities were worst.

Other studies show similar results.[180–183] Thus, the effectiveness of the 308-nm excimer laser in vitiligo seems well established. One advantage is that the adjacent normal skin s not exposed and does not tan; in conventional UVB therapy, this enhances the contrast between normal and vitiliginous skin. The response rate depends heavily on the location of the lesions (face, neck, trunk better than extremities) and the treatment takes a long time, at least 12 weeks.

Adding topical tacrolimus to the excimer laser therapy improves the response. In one study, there was over 75% repigmentation in 70% of the lesions treated with both modalities, as compared to 20% in the group treated just with laser.[184,185]

Alopecia Areata. The 308 nm excimer laser has also been tried recently for alopecia areata. Gundogan et al[186] treated two patients, each with 12 sessions, and were able to achieve almost complete regrowth. The regrown hairs remained stable for 18 and 5 months, but there were no control areas. Zakaria et al[187] treated nine patients but were able to obtain complete regrowth in only two, with >75% improvement in two, >50% in one, and no response in four.

SCARS AND KELOIDS

Hypertrophic Scars. Since hypertrophic scars are well vascularized, they are usually treated with PDL. Even with repeated treatments, the hypertrophic tissue usually regresses but a little, but the pruritus and spontaneous pain may improve more.[188] Removal with an ablative laser is generally not advised because of the risk of recurrence.

Keloids. Erythematous keloids can be treated such like hypertrophic scars with the PDL. In addition, the cw-CO_2 laser can be used for tumor reduction in large keloids before starting cryotherapy and compression therapy. Otherwise, we do not consider keloids an indication for laser therapy.

Acne Scars, Atrophic Scars and Other Superficial Skin Irregularities. The exact nature of the scar helps determine what approach is most likely to be helpful. Flat dish-like scars or sharply punched out scars that are less than 1 mm deep respond best to laser therapy. Deep or burrowed scars respond much less well, as all laser approaches are relatively superficial.

When confronted with broad scars, flat acne scars on the face, or flat reticular scars, an ablative laser system can be used in a manner similar to dermabrasion.[189] When treating older patients, one wants the side effect of "collagen shrinking" to tighten the skin; this is undesirable when treating scars in younger individuals. Thus one should choose laser systems that produce little thermal damage, as this ensures quicker healing and fewer side effects. The usual choice is the Er:YAG laser, but CO_2 lasers with flash scanner and a short tissue interaction time also seem promising.

Other lasers can also be used; the fluence, number of passes, and overlapping of the pulses (when applicable) should be kept as small as possible to reduce thermal damage and minimize side effects.

If the indications are appropriate and the operator skilled, suitable scars can be treated with satisfactory to good results. General clinical improvement of 50%–70% can be obtained; sometimes the 90% level is reached.[190–193]

Almost all laser and IPL systems that are available for nonablative skin rejuvenation can also be used for acne scars. Most experience exists with the 1,320-nm Nd:YAG with spray cooling and the 1,450-nm diode laser. Unfortunately, the results vary greatly; improvement from as high as 70% down to only 10% have been reported after multiple sessions.[194–198] In summary, all of the nonablative treatments are inferior to ablative approaches, but also have few side effects. Good results with ablative fractional laser therapy are also possible in nonacne atrophic scars.[199]

Fractional laser therapy falls somewhere in between nonablative and ablative approaches. It is capable of producing 26%–50% improvement without side effects.[200] The ablative variant of this approach also appears superior to the nonablative, but is once again more aggressive with more side effects.

Striae Distensae. It is worth trying a PDL for erythematous striae, although the supporting data is unclear. Both improvement, especially in early, still erythematous striae,[201,202] as well as lack of effectiveness has been reported.[203] Fractional laser therapy with 1,550 nm appears somewhat more effective.[204]

EPILATION

PRINCIPLES. The basic principle of photoepilation is the absorption of light by the pigmented structures of the hair follicle with resultant thermal damage. The target chromophore is eumelanin; pheomelanin is found in red and blond hairs and has such different absorption characteristics that these hairs, just like light and white hairs, are hard to remove with photoepilation.

Exactly which structures have to be destroyed to ensure long-term epilation is still not certain.[205] According to DiBernardo[206] both the hair bulb and the bulge region must be destroyed since they contain pluripotential stem cells, which could lead to regeneration of hairs. Tope[207] speaks of permanent follicular destruction when just the bulge and its stem cells are destroyed, as this is the region where anagen is initiated and hair production started. Ross et al[208,209] indicates that destroying the bulb induces the catagen and telogen phases, so that hairs regrow, but lighter and thinner. On the other hand, when the bulge is destroyed, then miniature or vellus-like hairs result.

Photoepilation generally causes a slower regrowth of hairs as well as some degrees of miniaturization, but only rarely produces complete follicle destruction and permanent alopecia.

Optimal thermal damage can only be obtained when the follicles (and the hairs) are sufficiently pigmented; in addition, the radiation parameters must make it possible to deliver sufficient energy to the follicle. Longer wavelengths between 700 and 1,000 nm penetrate deep into the dermis reaching the follicle and are well absorbed by melanin. Large spot sizes enhance the depth of penetration further. The optimal impulse duration is not known, but appears to vary depending on system and wavelength, but probably is in the millisecond range (a few ms to 100 ms).[205,210,211]

DEVICES FOR PHOTOEPILATION

Alexandrite Laser (755 nm). In comparison to the ruby laser, which did not prove effective for epilation, the alexandrite laser delivers 20% less energy to melanin and proportionally more to oxyhemoglobin; thus, reducing the epidermal damage, especially for dark skin. The epidermis is further protected by cooling during the procedure. The spot size can be varied from 5–12.5 mm and makes possible the rapid treatment of larger areas.

Diode Laser (800/810 nm). At this wavelength, the energy is well absorbed in the follicle but less absorbed by competing chromophores like oxyhemoglobin or water. In addition, a penetration depth of 3 mm can be reached. The laser light is scarcely absorbed by the epidermis, making the device well suited to dark skin. The long impulse duration (up to 50 ms) and high fluences make epidermal cooling mandatory.

Pulsed Nd: YAG Laser (1,064 nm). This laser penetrates very deep (5–7 mm), so that even deep-lying follicles receive enough energy for epilation. There is also very little epidermis absorption, making the device well suited for dark skin (FDA approval also for skin types IV–VI)[212] Once again surface cooling is essential to reduce pain and side effects. Of the devices used for laser epilation, the Nd:YAG laser has the fewest side effects but is most painful.

High-energy Flashlamps (590–1,200 nm). These sources have a broad emission spectrum extending into the near infrared region, which allows for excellent depth of penetration and have the largest spot sizes (around 5 cm^2) of all the photoepilation units, which make rapid treatment possible. In the epilation mode, a cut-off filter at 600 nm is usually employed in order to filter out shorter wavelengths destined to be absorbed in the epidermis. The impulse durations are 0.5–25 ms, while 20 ms is usually chosen. Many different systems are available, and one should follow the manufacturer's recommendation. A cooling gel is used to improve the coupling of light into the skin, cool the epidermis, and reduce pain. This is a method well suited for all skin types and with few complications.[213,214]

SIDE EFFECTS. Just after treatment one sees discrete erythema and perifollicular edema. Temporary hypo- and hyperpigmentation is common, varying with the system. Occasionally folliculitis, vesicles, crusts and rarely tiny scars may develop. Uncommon complications are a paradoxical hypertrichosis either in or adjacent to the treatment area or leukotrichia.[215–217] Melanocytic nevi in the treatment field are best not treated, especially if there is a history of dysplastic nevi or familial melanoma, since there are reports on changes in nevi after photoepilation.[218]

RESULTS. It is hard to compare the many studies on laser and IPL epilation because of the different devices, treatment parameters, hair colors, treatment areas and intervals. Reductions in the amount of hair are achievable with all the devices (Fig. 239-12).

The current status of photoepilation can be summarized as follows[211,219–222]:

- Reduction of hair numbers between 40% and 80% (100%) after multiple treatments.
- Multiple treatments produce better results.
- The loss of hairs is generally not permanent; to maintain an epilated condition, the therapy must be repeated at intervals.
- Dark and thick hairs respond better than light and thin hairs.
- When hairs regroup after epilation, they are often thinner and lighter.
- While permanent epilation is possible, it can never be promised or guaranteed.

MELANOTIC AND MELANOCYTIC SKIN LESIONS

LENTIGINES. Lentigines can be treated with the Qs-ruby-, Qs-Nd:YAG at 532 and 1,064 nm and

Figure 239-12 **A.** Hypertrichosis of the upper lip in a 35-years-old female patient. **B.** Reduction of hair growth after five IPL treatments.

Qs-alexandrite lasers. Lower fluences than required for tattoos can be employed; for example, the Qs-ruby laser uses 4–6 J/cm^2 at 40 ns. Blisters or crusts are rare; the area is generally healed in a few days. The results are good to outstanding,[223–225] while side effects are rare. The Er:YAG and the CO_2 laser with flash scanner can be employed to superficially ablate lentigines.[226]

CAFE-AU-LAIT-MACULES, NEVI SPILI, AND BECKER NEVI. The same laser systems used for lentigines are employed, but the results are variable and hard to predict. Both incomplete lightening and recurrences are possible.[227–231] A test spot should be treated and observed for an adequate period of time to assess both efficacy and likelihood of recurrence.

NEVUS OF OTA, NEVUS OF ITO. The Qs-ruby laser produces good results for nevus of Ota and nevus of Ito. In addition the results are generally stable.[232] The time of intervention appears important. When children less than 10 years old are treated, fewer sessions are needed and the complication rate is lower.[233] The Qs-alexandrite and the Qs-Nd:YAG laser appear to produce somewhat worse results with more side effects.[234] Acquired bilateral Nevus of Ota-like macules (Hori spots) respond very well to laser therapy and can generally be completely removed in just a few sessions.[235–237]

MELANOCYTIC NEVI. The superficial removal of melanocytic nevi with an ablative laser often leads to recurrences,[238] while destruction deep into the dermis invariably causes scarring. In addition, no histological examination is possible. Thus, ablative lasers are not suitable for treating melanocytic nevi. An exception is the early dermablation of congenital melanocytic nevi with the Er:YAG laser analogous to a dermabrasion, as described by Petres and other authors.[239] When deep dark congenital nevi are superficially ablated for the first weeks of life, they often become much lighter, even though recurrences are common,[240] and the associated hypertrichosis is not influenced.

The treatment of melanocytic nevi, whether congenital or acquired, with pigment-selective lasers (Qs-ruby, Qs-Nd:YAG, Qs-alexandrite lasers) can completely destroy strictly junctional nevi. The dermal component cannot be removed both because of the limited penetration of the lasers and the invariable presence of relatively nonpigmented nests of melanocytes, which are not affected; thus recurrences are very common.[241–245] It is unclear if the melanocytes that survive a laser treatment have an increased risk of malignancy; long-term studies are needed.[246–248]

There are many reasons why we do not consider melanocytic nevi an indication for laser therapy, except in special cases: clearing often requires many sessions and is not impressive, residual nevus cells are always left behind, the long-term effects are unknown and no histological evaluation is possible.

Lasers can be tried in giant congenital melanocytic nevi when no other therapy options are open. Using the combination of long pulsed and Qs-ruby lasers over many treatments has produced very good results in some cases.[249]

MELASMA. Both the pigment-selective lasers and IPL have produced disappointing results in melasma or chloasma; in addition, the risk of reactive hyperpigmentation is great.[229,250–253] Somewhat better results seem possible with fractional laser therapy, although the results are highly variable and not always good.[200,254]

TATTOOS AND OTHER EXOGENOUS PIGMENTATION

DECORATIVE TATTOOS. Procedures often used to remove tattoos like excision, dermabrasion, salabrasion or CO_2 laser ablation always cause scarring. The introduction of the Qs laser technology has revolutionized the field, making it possible to remove tattoos almost without scarring.[255]

The exact mechanisms by which lasers remove tattoos are still poorly understood. Laser therapy leads to changes in the optical qualities of the tattoo pigment, either by destruction or by changes through thermal, photochemical, or photoacoustic reactions.[256–259] The

Figure 239-13 **A.** Professional tattoo at the back of a 34-year-old male patient. **B.** Result of eight treatments with a Qs Ruby laser.

additional improvement that occurs weeks later probably has a cellular explanation. Histologic studies have demonstrated that macrophages or their lysosomes laden with tattoo pigment rupture and the free but degraded pigment particles can be transported to the lymph nodes. Whatever pigment remains at the site of the tattoo is rephagocytosed and after 4 weeks, is once again intracellular.[257,260] This process of damaging pigment, moving it about, and then finally cellular reuptake probably explains the clinical clearing.[256,259,260]

The usual choices are Qs-ruby (694 nm), Qs-Nd:YAG (1,064 and 532 nm) and Qs-alexandrite lasers (755 nm), all with pulse durations in the ns range. The ruby lasers work best for black, blue-black, and dark blue tattoos (Fig. 239-13). For blue and green tones, the results are

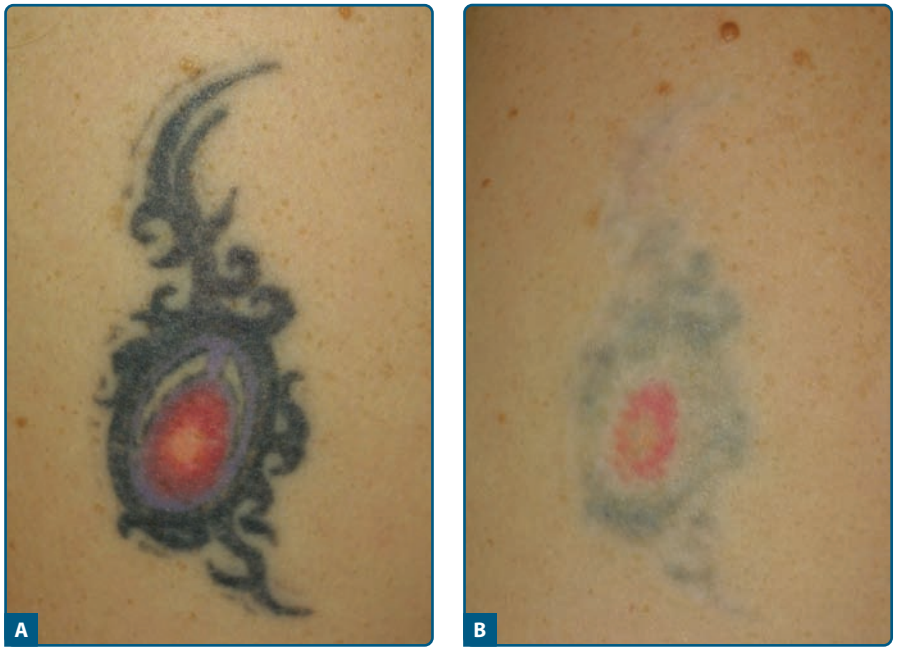

Figure 239-14 **A.** Professional tattoo at the upper arm of a 31-year-old female patient. **B.** After five treatments with a Qs Ruby laser, lighting of the black color, no change in the red color.

TABLE 239-6
Lasers for Tattoo Removal

Tattoo Colours and Suitable Q-Switched Lasers

Laser	Wavelength	Pulse Duration	Tattoo Colour
Nd:YAG laser	532 nm	10 ns	Red
Ruby laser	694 nm	30 ns	Black, blue, green
Alexandrite laser	755 nm	50–100 ns	Black, blue, green
Nd:YAG laser	1,064 nm	10 ns	Black, blue

highly variable. Red, yellow-orange, and light blue tattoos respond poorly to the ruby laser (Table 239-6, Fig. 239-14).[230,261,262]

With the Qs-Nd:YAG laser, the clinical improvement at 1,064 nm is comparable to the ruby laser.[263,264] Using 532 nm makes it possible to destroy some red tattoo pigments.[257,261,265]

The 755-nm laser produces good results for blue-black tattoos, as well as with green, red, and purple colors.[258,259,261,265,266]

The treatment can generally be done without anesthesia; the impulses are placed close together without overlapping. Right after the treatment, there is a broad-based swelling with whitening of the skin, while histological examination shows vacuole formation by steam bubbles. The whitening disappears in a few minutes. When higher fluences are used, sometimes there are punctate hemorrhages. Blisters and crusts commonly develop a few days after the treatment. Topical antiseptic agents should be used after the treatment to reduce the risk of infection.

The complete destruction of a tattoo requires multiple sessions, no matter which laser system is chosen. The literature suggests that at least 3 and usually 10 or more sessions are needed.[265,267] Amateur tattoos generally have less pigment so they respond quicker and better than do professional ones. Blue-black tattoos absorb nearly all the available wavelengths and respond better than do more colorful tattoos.[255] Multicolored tattoos are often impossible to remove completely, even when several lasers are employed. Green, purple, and yellow tones are most stubborn.[265,267,268]

Scarring is rare, but slight atrophic changes in the skin surface are possible. Patients hardly notice them in their elation. The most troublesome side effect is a change in color of a treated tattoo, which does not disappear. Lighter colors (red, pink, white) can become black, gray-black or dark green[258,269,270]; the same phenomenon can also be seen less often with yellow, green, purple, and violet pigments.[261] While the resultant darker pigment may respond to additional laser treatments,[270] this is not always the case. Some patients get a permanent aesthetic worsening.[269] If there is any doubt about the responsiveness of a color, a test patch is advised.

In vitro, it has been shown that when two commonly used red azo dyes are treated with lasers, toxic or carcinogenic degradation products are formed.[271,272] Whether this is relevant for the clinical treatment of tattoos is unclear, but cannot be completely excluded. The clinical relevance of these products is probably quite low since they are produced in extremely small amounts.

ACCIDENTAL TATTOOS. Without question, the best approach to accidental tattoos (powder burns, explosions, road dirt after falls) is prompt removal. Ideally, the area is pretreated with wet compresses and then cleaned with scrub brushes, as well as fine tweezers or punch excisions for residual pieces. This should be completed within 24 hours of the accident.

For residual pigment or when the early treatment was not accomplished, the same Qs lasers used for decorative tattoos can be employed with good benefit. Dirt, soot, coal, and powder usually respond well; harder materials such as metal fragments or stones usually do not. Generally, a test area should be treated to see if a laser treatment is likely to offer benefits.

PIGMENTATION FROM MEDICATIONS

Minocycline, amiodarone, and doxorubicin hyperpigmentation generally respond well to treatment with the pigment-selective Qs lasers.[273–276] On the other hand, a Qs laser treatment, no matter what the indication is, can cause patchy hyperpigmentation in patients who have taken gold products systemically; this is termed laser-induced chrysiasis.[277,278]

Chapter 240 :: Radiotherapy

:: Roy H. Decker & Lynn D. Wilson

RADIOTHERAPY AT A GLANCE

- Radiotherapy is a collection of versatile treatment modalities including brachytherapy, external beam radiation, and charged particle therapy.
- The clinical effects of radiotherapy include acute and late skin changes:
  - Acute effects include inflammatory reactions and desquamation.
  - Late effects include fibrotic changes and atrophy of skin adnexa.
  - Radiation-induced malignancy is a rare but serious side effect presenting at a median 10 years after treatment.
- Radiotherapy is indicated for selected benign, proliferative disease after more conservative measures have failed.
- Radiotherapy is a valuable option for primary or adjuvant therapy of malignant skin disease.

The first documented use of radiation as a therapeutic treatment was for a cutaneous malignancy, in a patient with squamous cell cancer of the nose, in 1900. Over the next century, radiotherapy was widely used in the treatment of both malignant and benign disorders of the skin, in both adults and children. As the long-term consequences of radiotherapy became evident, particularly the risk of radiation-induced malignancy, its use in the treatment of children and benign diseases declined. Radiotherapy continues to have a small but important role in the management of benign proliferative diseases of the skin, but is more commonly used as a valuable adjunct or alternative to surgery for both premalignant and malignant lesions.

RADIATION MODALITIES

There are several choices for radiation modalities, some commonly available and others only in specialized centers. The selection is made on the basis of the anatomic location and size of the target, tumor biology, the nature of critical surrounding structures, and availability. In particular, with respect to the cutaneous targets, the depth of the lesion plays a large role in determining the optimal therapy.

High-energy photons, in the form of γ- or X-rays, are most commonly produced by a linear accelerator (linac) and are available in a spectrum of energies. Incident radiation deposits its energy as it passes through matter, becoming attenuated as a function of distance and the density of the tissue. Higher energy beams deliver increased dose at depth in tissue, and proportionally less at the surface. Lower energy radiation deposits dose primarily at the target surface, sparing deeper matter. The most commonly available treatment energies are in the megavoltage range, which deposit their dose at a range practical for the treatment of targets in human tissue. Such beams were designed to relatively spare surface structures such as skin, which would otherwise be dose limiting, in the interest of delivering higher dose to deeper target structures. This is in contrast to more superficial radiation energies, which are often more appropriate for cutaneous targets. Depth dose curves demonstrating the absorption of X-rays as a function of their energy are demonstrated in Fig. 240-1A. Most linear accelerators in clinical use provide radiation in the range of 6–18 megavolts (MV).[1]

Orthovoltage X-rays refer to lower energy photons with maximum energy in the range of 125–400 kilovolts (kV), often used in dermatologic applications because the dose at the skin surface dose is maximized. The dose is then rapidly attenuated as the beam penetrates deeper into soft tissue. Half of the incident energy has been absorbed within the first few centimeters, ideal for treating superficial targets and minimizing dose to deeper normal tissue. Orthovoltage X-rays are produced by specialized treatment units, and are not as commonly available as megavoltage treatment units.

Grenz rays are even lower energy X-rays in the range of 5–15 kV, and therefore deposit their dose at more

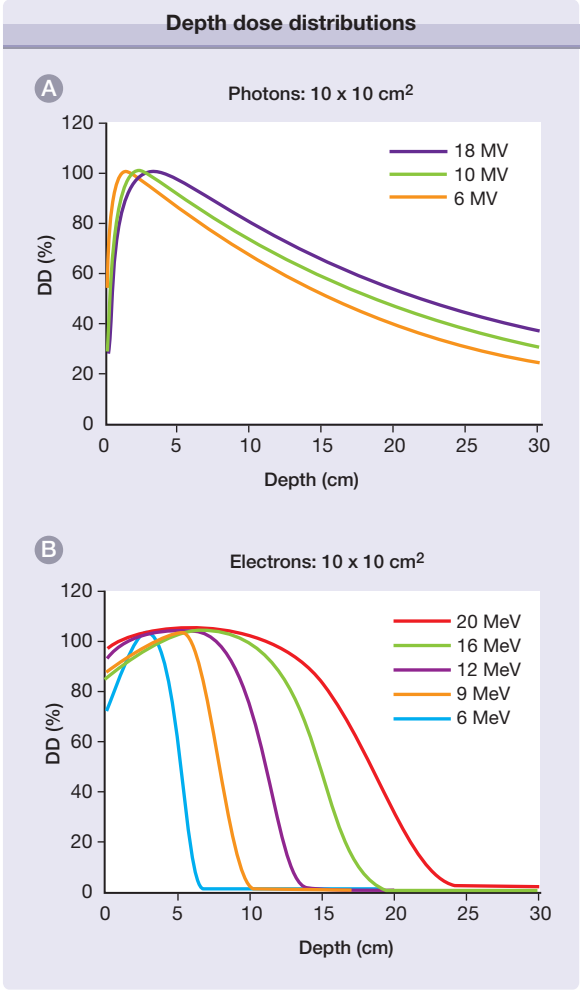

Figure 240-1 Depth dose distributions. **A.** The percent of the maximum radiation dose (DD) deposited at depth in tissue (in cm), as a function of the photon (X-ray) energy. As photon energy increases, the percent dose at superficial depth decreases, and the percent dose in deeper tissue increases. **B.** A similar relationship for electron therapy. In contrast to photons, the percent dose deposited at both superficial and deep tissue increases with electron energy. Note the difference in scale; electron energy is almost completely absorbed at shallower depths, compared to photons.

shallow depths than orthovoltage. These were historically used to treat superficial, benign skin disease. In these cases, the majority of the target processes are occurring within 1 mm of the skin surface. Grenz rays are no longer recommended as first-line therapy for routine treatment of benign cutaneous disease.

Charged particle therapy is also commonly used in cancer treatment, including both electrons, which are commonly available, and protons, available at select regional centers. Electrons are the product of the same linear accelerators used to produce megavoltage energy photons. Electron beams are commonly used in dermatologic applications as they are capable of delivering high skin-surface dose, and the deposited dose rapidly falls to negligible values at depth in tissue. Electron-depth dose, like that of photons, is a function of voltage. Higher energy electrons deliver dose to a greater depth, similar to the depth/dose relationship of photon energy. Unlike the skin-sparing properties of higher energy photons, as electron energy increases the skin dose also increases. The depth dose characteristics of electrons are described in Fig. 240-1B.

Protons are charged particles that are the product of large and expensive cyclotrons or synchrotrons, available at a small number of specialized centers. Due to their large mass, there is little side scatter during penetration of a proton beam. The dose is largely delivered within a few millimeters of the end of the particle range (the Bragg peak), rather than at shallower or deeper depths. By modulating the energy of the proton beam, radiation absorption can be more precisely delivered to deep tumor targets, with less incidental radiation of surrounding normal tissue.

MODULATION OF EXTERNAL BEAM RADIATION

Radiation treatment planning involves a complex set of decisions regarding the appropriate radiation modality, radiation energy, beam orientation, patient positioning, and the use of treatment devices. The latter can help increase the radiation dose to targeted structures, and block or reduce radiation exposure of normal tissue. "Bolus" is tissue-density material commonly used in radiation treatment of superficial skin malignancies. It can be custom designed in varying thicknesses and applied to the patient's skin during daily treatment. It serves several potential purposes: for higher energy X-rays (e.g., MV energy), or low-energy electrons, the surface dose is low compared to that in deeper tissue. By placing the appropriate thickness of bolus, the skin dose can be raised to therapeutic levels. This is demonstrated in Fig. 240-2. Another function of bolus can be to attenuate the incident beam to lower the dose to deeper structures, for example, during treatment of a skin cancer on the temple, to decrease the dose that penetrates into the underlying brain. Bolus material can also be used to compensate for complex topography, and smooth the dose distribution for treatment of the skin around the nose and ears, as seen in Fig. 240-3.

Beams can be shaped by a variety of devices depending on their energy. Megavoltage treatment beams may be shaped by custom-designed, 7-cm thick, lead alloy blocks to conform to the desired shape; most modern linear accelerators have a multileaf collimator (MLC), which contains sliding leaves of tungsten that conform to the desired treatment aperture. Electron beam radiation is normally blocked with custom-made lead or lead alloy blocks. Orthovoltage radiation is blocked using thinner custom lead shielding, typically placed on the patient's skin. Examples of blocking devices are shown in Fig. 240-4.

Traditionally, external beam radiation beams are designed using blocks or static MLCs to conform to a target that is delineated clinically or using CT or other imaging. Multiple beams, beam angles, and energies

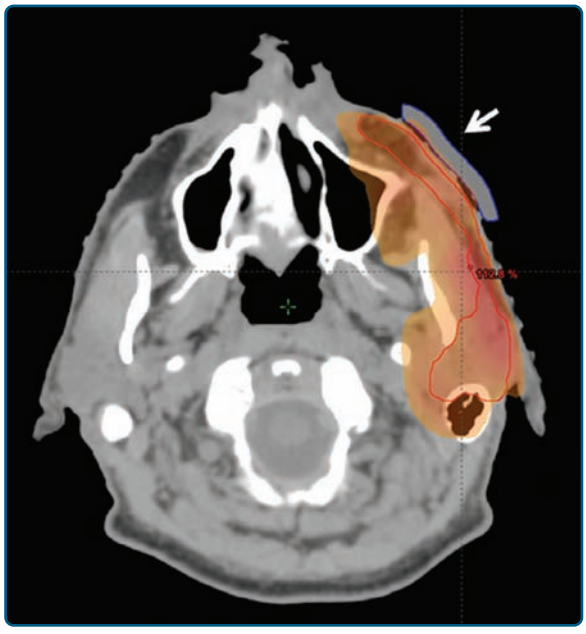

Figure 240-2 Bolus to increase the skin dose. A 61-year-old male underwent resection of a deeply invasive squamous cell carcinoma overlying the zygoma, with involvement of parotid lymph nodes and facial nerve. The tumor bed was treated, along with the remaining parotid gland and course of the facial nerve, using megavoltage photons. A tissue-density bolus (*white arrow*) was placed over the tumor bed to increase the skin dose to 100% in that area.

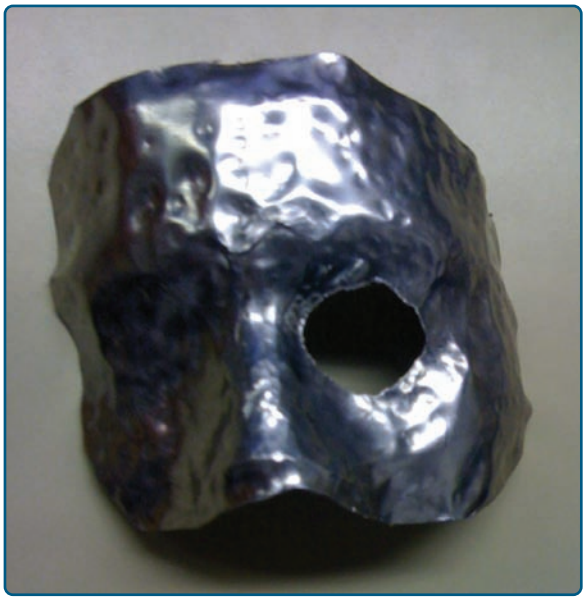

Figure 240-4 A custom lead shield placed on the patient's face, with a cutout to allow orthovoltage treatment of a cutaneous malignancy of the left lower eyelid.

are chosen to avoid specific normal structures, and the dose is calculated with iterative changes until an acceptable plan was generated. An "inverse planned" method is now increasingly used when the tumor target lies in proximity to a dose-limiting structure. Intensity modulated radiation therapy (IMRT) incorporates individual radiation beams that are not static; the aperture changes during the treatment to finely adjust

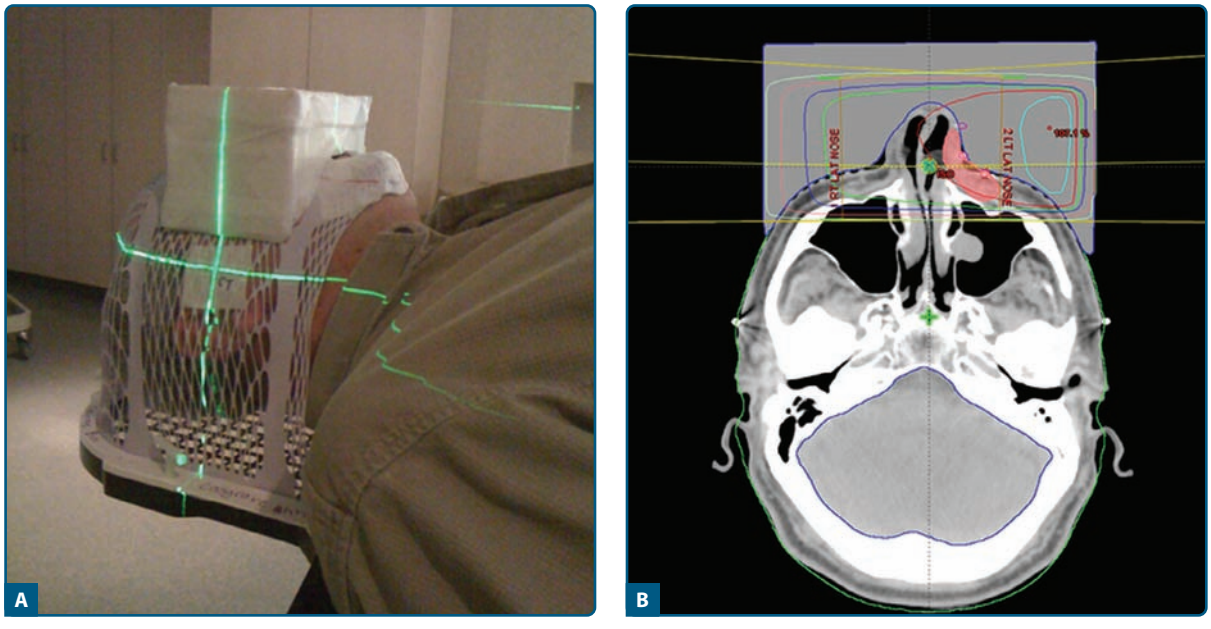

Figure 240-3 Bolus as a tissue compensator. A deeply invasive basal cell carcinoma was excised from the left nasal ala. **A.** The patient was immobilized for treatment in a thermoplastic mask. A rectangular, tissue-density, box was constructed overlying the nose to compensate for the irregular tissue contours in this area. **B.** The patient was treated with right and left lateral megavoltage photon beams, weighted left greater than right. The 100% isodose line (*red line*) covers the tumor bed (*red-shaded area*) with full dose at the skin surface and good dose homogeneity.

beam fluence. This requires a dynamic MLC, in which the leaves slide during beam-on time. During the pretreatment-planning phase, the treating physician contours the target volume and those of the normal tissue organs at risk. Dose constraints for each contoured structure are chosen, and the physician, physicist, and dosimetry staff use dedicated treatment planning software algorithms to optimize the treatment plan. This is a time intensive, expensive technique that can generate plans to treat complex shaped tumor targets and spare adjacent critical normal tissue structures.

MECHANISM OF ACTION

The most common form of radiotherapy used in clinical practice are X-rays, or γ rays. Both represent photon particles or electromagnetic waves that differ only in the method of their generation: γ rays are emitted by nuclear reactions, whereas X-rays are emitted by energy transitions in orbital electrons. Ionizing radiation includes that part of the electromagnetic spectrum of sufficient energy to impart energy to target tissue by the ejection of orbital electrons. This is the primary means of energy absorption in human tissue following exposure to therapeutic radiation. Since cells are largely composed of water, it is in water molecules that the majority of the ionization occurs and the result is the generation of short-lived free radicals, such as hydroxyl radicals. The effectiveness of radiation in tissue is therefore dependent upon the availability of oxygen. This is clinically manifest in reduced radiation response in hypoxic tissue, and is the reason that higher radiation doses are used in the postoperative setting when there is diminished microcirculation.

The primary mediator of cell death in response to ionizing radiation, in both tumor and normal tissue, is damage to DNA by indirect ionization by radiation-induced free radicals.[2] Indirect DNA damage is characteristic of sparsely ionizing radiation including not only X-rays, but also commonly used charged particles such as electron and proton therapy. In contrast, densely ionizing radiation (e.g., neutrons, αparticles) with a higher linear energy transfer (LET) deposit their energy densely along their incident tracks, and therefore more commonly induce double-strand DNA breaks directly, without the intermediate ionization of cellular water.

The initial deposition of radiation energy in tissue and the resulting DNA damage occur within thousandths of a second of exposure. The biological response to DNA damage includes modulation of cell death, differentiation, and survival pathways, and activation of DNA repair. These biologic processes occur orders of magnitude more slowly than the initial DNA damage. The ultimate cellular response to radiation can be repair, senescence, differentiation, or cell death. The latter may occur via apoptosis, a relatively rapid process, but more commonly occurs as a mitotic cell death. Misrepair of double-stand DNA breaks generates chromosomal abnormalities, and cells die during failed mitosis, often several generations later.

DOSE AND FRACTIONATION SCHEDULE

The Systeme International d/Unites (SI) unit of radiation dose is the *gray* (Gy), which is defined as a joule of energy absorbed per kilogram of tissue. An alternate unit of absorbed dose, largely replaced by the gray, is the rad (an acronym for radiation absorbed dose); one gray is equal to 100 rads. Dose is specified to the target volume as defined by the treating radiation oncologist. Most epithelial malignancies are treated to a total dose in the range of 50–80 Gy, lymphoid malignancies typically respond to doses of 15–40 Gy. Select benign conditions can be treated with lower doses; hypertrophic scars and keloids are commonly prescribed doses in the range of 4–20 Gy.

Fractionation refers to the delivery of specified radiation dose in temporally separate treatments, and is recommended to both increase the efficacy of effects on target tissue and to allow normal irradiated tissue to repair radiation damage. Thus, the schedule of radiation fractionation can be used to both increase efficacy of the dose to the target and minimize radiation damage to normal tissue. Common fractionation schemes using conventional radiotherapy deliver treatments at intervals ranging from twice daily to once per week.

The effectiveness of radiation treatment is highly dependent upon the treatment schedule; both the total number of days over which the treatment is spread and the fraction size. The common daily fraction size is 1.8–2 Gy per day, treated 5 days per week. Different fractionation schedules can be compared using a mathematical conversion to a biologically effective dose (BED), using a formula that accounts for the number of fractions, fraction size, and the DNA-repair characteristics of the target tissue.

CLINICAL AND MOLECULAR ASPECTS OF RADIATION DERMATITIS

Skin changes after radiation exposure follow a predictable course dictated by radiation dose, timing, and the biology of the human inflammatory reaction.[3] The earliest reaction is erythema that may occur and resolve within hours, and is normally only evident after relatively high-dose exposure. The threshold dose is 2 Gy or greater skin dose, and is not normally noted after daily fractionated treatment of visceral organs with skin-sparing megavoltage radiation. This effect is noted in therapeutic courses aimed at cutaneous targets, where the skin receives full dose, or during treatment regimens that use large fraction sizes. Microscopically, there is a vasodilation and a transiently increased capillary permeability that results in mild erythema and edema at 2–24 hours following exposure. Prior to the adaptation of SI units of radiation dose, skin erythema dose (SED) was used as a crude clinical measure of patient radiation exposure. This

transient acute reaction is no longer commonly noted due to the increased use of high-energy, relatively skin-sparing, radiation energies, and the increased use of lower fraction sizes. Acute, transient skin erythema is still reported following interventional diagnostic and therapeutic procedures with prolonged fluoroscopy times.

The more sustained, common, and relevant reactions take place over a matter of weeks following initial exposure. Acute radiation dermatitis progresses through characteristic stages of severity based on the accumulation of radiation-induced changes to dermal vasculature, appendageal structures, epidermal stem cells, and the activation of inflammatory pathways. Radiation dermatitis is a distinct adverse event graded by the National Cancer Institute Common Terminology Criteria for Adverse Events (CTCAE). This scale is graded on severity, and primarily describes the acute reaction of skin exposed to therapeutic radiation. Chronic skin changes may occur months to years after exposure, and include a spectrum of changes characterized by fibrosis and atrophy. Common acute and late adverse events attributable to radiation are summarized in Table 240-1.

Grade 1 dermatitis first manifests as faint skin erythema within the treatment area. Erythema is seen in two contexts: first, there may be a transient vasodilation in the hours after a single fraction skin exposure of 2 Gy or higher. More commonly, erythema or hyperpigmentation develops over the first 2 to 3 weeks of fractionated radiation with accumulated exposure. Vasodilation and increasing vascular permeability occur early, and the resulting perivascular inflammation results in clinically characteristic erythema and edema. Moderate-to-brisk erythema is grade 2.

With continuing or higher dose radiation exposure, damage to the basal cells in the epidermis may progress until this stem cell population is lost in localized areas, which results in dry desquamation (CTCAE grade 1). Further damage to the basal layer leads to more widespread desquamation, and the production of a fibrinous exudate due to increased arteriole permeability, loss of basement membrane integrity, and edema in the underlying dermis. This is characteristic of moist desquamation. The CTCAE differentiates moist desquamation based on whether it is patchy and localized to areas subject to trauma such as skin folds (grade 2), or confluent and present in a more widespread area (grade 3). Radiation damage to the underlying dermis may lead to ulceration, bleeding, or necrosis (grade 4). Skin adnexal cells are relatively radiosensitive, and may not regenerate following exposure. The process of epilation begins within days of radiation exposure. Sebaceous glands have similar sensitivity, and eccrine sweat glands become dysfunctional shortly afterward in a fractionated radiation treatment course. Histologically, these glandular structures demonstrate apoptosis, necrosis, and loss of normal mitotic activity. Chronically, there can be fibrotic replacement and loss of the supporting microvasculature. This leads to both acute and chronic hypohidrosis or anhidrosis.

Regeneration of areas of desquamation occurs through replacement of epidermal basal cells either from islands of intact cells within the epidermis or by the migration of such cells from adjacent, uninvolved areas. Normal healing of the radiation wound becomes clinically evident approximately 2 weeks after exposure, consistent with the basal cell turnover time. Widespread confluent mucositis (grade 3), or more severe toxicity such as necrosis of the epidermis or

TABLE 240-1
Commonly Observed Adverse Events Attributable to Radiation

Adverse Event	Grade 1	2	3	4	5
Radiation Dermatitis	Faint erythema Dry desquamation	Moderate-to-brisk erythema Patchy moist dequamation (mostly confined to skin folds and creases) Moderate edema	Moist desquamation (other than skin folds and creases) Bleeding induced by minor trauma or abrasion	Skin necrosis Ulceration of full thickness of dermis Spontaneous bleeding	Death
Alopecia Atrophy Dry Skin Hypo or Hyperpigmentation Induration or Fibrosis Telangiectasia	Thinning or patchy Detectable Asymptomatic Slight or Localized Increased Density on Palpation Few	Complete Marked Symptomatic Marked or Generalized Moderate Impairment; marked increase in density; minimal retraction Moderate	— — Interfering with ADLs — Dysfunction Interfering with ADLs; very marked density; retraction or fixation Many and Confluent	— — — — —	— — — — —

ADLs = Activities of Daily Living.

underlying dermis, may not undergo complete regeneration of the structural and adnexal elements. Instead, there can be prolonged inflammation, fibroblast activation, and collagen deposition. This fibrosis is often termed a consequential late effect, since it is a consequence of the severity of the acute reaction. It is in contrast to the more common late fibrosis, which arises following the regeneration of relatively normal-appearing skin and can occur years after treatment.

Late radiation toxicity occurs months to years following exposure, following a period during which the skin may not exhibit significant abnormalities. The risk and severity of true late skin changes are a function of the irradiation dose and volume. A landmark study of normal tissue radiation tolerance determined that the risk of grade 4 or greater acute toxicity (i.e., ulceration or necrosis) was 5% when 10 cm^2 of skin was treated to 70 Gy, or when 30 cm^2 was treated to 60 Gy.[4] Comorbid medical disease may exacerbate this risk; clinical risk factors associated with increased symptom severity include advanced patient age, diabetes, peripheral vascular disease, tobacco use.[5] The concurrent administration of radiosensitizing drugs significantly increase the severity of acute radiation dermatitis and prolong healing of the radiation wound. Collagen vascular diseases with a fibrotic cutaneous component (e.g., scleroderma and systemic lupus erythematosus) are associated with a pronounced and often debilitating late subcutaneous fibrosis following radiation treatment.[6,7] Certain genetic syndromes, particularly inherited defects in DNA damage repair (e.g., ataxia telangiectasia) predispose to a severe, acute, and late radiation response in exposed normal tissue.

The late skin toxicity with the most functional consequence is subcutaneous fibrosis. Replacement of the subcutaneous adipose tissue with fibrous tissue leads to loss of normal range of motion, contraction, pain, and poor cosmesis. Even in cases where dermal and subcutaneous fibrosis is not clinically evident, there may be atrophy of the skin adnexa. Hair follicles, sebaceous, and sweat glands may be absent in previously irradiated skin because these are not regenerated during normal radiation wound repair. Loss of glandular elements leads to anhidrosis when extensive skin areas are irradiated, such as in total skin electron therapy. The microvasculature of the dermis and subcutis may exhibit abnormal myointimal proliferation, leading to hypoperfusion. Tortuosity within small vessels, and micro thrombi, results in visible telangiectasia. Irregular regeneration of the basal layer of the epidermis may be evident as dyspigmentation. Paradoxically, there may be a decrease in the population of resident skin fibroblasts in atrophic skin, with loss of the normal collagen structure leading to impaired tissue remodeling, increased skin fragility and poor wound healing.

The pathophysiologic mechanism of late changes, particularly fibrosis, in response to radiation is incompletely understood.[8,9] Transforming growth factor-beta (TGF-β) is a secreted protein that serves a complex regulatory role in normal tissue inflammation and remodeling by controlling proliferation, differentiation, and secretory function. TGF-β levels are increased within hours of radiation exposure, and this elevation has been correlated with late fibrotic changes. Abrogation of downstream mediator SMAD3, a proinflammatory signaling molecule induced in response to TGF-β, appears to protect tissue from late fibrotic changes after radiation exposure in laboratory models. TGF-β is a complex regulator of inflammation that increases fibroblast proliferation, differentiation, and activation, and thereby increasing secretion of extracellular matrix components. TGF-β promotes its own secretion by fibroblasts in a self-amplifying cascade, and decreases the production of matrix proteinases. Epithelial cell proliferation is diminished, and there is chemotaxis of mast cells and macrophages. The result is increasing production, processing, and deposition of collagen (fibrosis), and loss of epithelial reconstitution of normal tissue structure.

The initiating event in TGF-β activation in response to radiation is poorly understood. Latent TGF-β in the extracellular matrix may be activated by proteolytic enzymes that act in the presence of radiation-induced reactive oxygen species. Other potential sources of TGF-β include endothelial cells, fibroblasts, epithelial cells, and tissue macrophages, which may release TGF-β in direct response to radiation, or as a generalized response to tissue damage.

RADIATION RECALL REACTIONS

Radiation recall is a phenomenon first described several decades ago, describing a cutaneous reaction in the area of previous radiation exposure, in response to specific systemic agents. The most commonly cited chemotherapeutic agents are anthracyclines, taxanes, and gemcitabine. Other systemic agents implicated in radiation recall reactions include standard chemotherapeutic agents, newer targeted therapeutics, hormonal agents, as well as nononcologic medications; a list of such agents from case reports is compiled in Table 240-2.

The clinical manifestations of radiation recall occur with the initial administration of the systemic agent: within minutes to days with intravenous drug, or days to weeks with oral medication. The timing of presentation may be related to the drug dose, and both the severity and timing of the reaction may be related to the prior radiation dose. The duration of the response may range from weeks to months. Interestingly, readministration of the same systemic agent does not consistently lead to recurrence of the phenomenon.[10]

While a recall reaction can occur in any organ, skin is the most common site. It occurs in a well-demarcated area defined by the borders of the previous treatment field, and can occur despite the lack of any clinically significant skin reaction during the previous radiation treatment. The clinical signs and symptoms mimic an acute radiation dermatitis, ranging from erythema to desquamation and necrosis. A localized maculopapular rash, characteristic of a hypersensitivity reaction, has also been described.

The pathogenesis of radiation recall is not well understood. An early hypothesis was that tissue stem

TABLE 240-2
Radiation Recall Reactions

Agents implicated in inducing a radiation recall reaction include chemotherapy drugs, targeted and hormonal agents, and nononcologic medications.

- Chemotherapy
  - Arsenic Trioxide
  - Bleomycin
  - Capecitabine
  - Cyclophosphamide
  - Cytarabine
  - Dacarbazine
  - Dactinomycin
  - Daunorubicin
  - Docetaxel
  - Doxorubicin
  - Epirubicin
  - Etoposide
  - Fluorouracil
  - Gemcitabine
  - Hydroxyurea
  - Idarubicin
  - Lomustine
  - Melphalan
  - Methotrexate
  - Paclitaxel
  - Vinblastine
- Targeted anticancer drugs
  - Bevacizumab
  - Pemetrexed
- Hormonal agents
  - Tamoxifen
- Nononcologic drugs
  - Gatifloxacin
  - Isoniazid
  - Levofloxacin
  - Simvastatin

cells remained depleted long after radiation, making the tissue more sensitive to cytotoxics. This does not explain, however, radiation recall reactions elicited by noncytotoxics or the lack of a reaction to subsequent drug exposure in some cases. The clinicopathologic manifestations are best explained by a localized, acquired hypersensitivity reaction. Prior radiation therapy may alter the normal dermal immunologic response by changing basal and stimulated cytokine production. This is consistent with histologic findings of acute inflammation (vasodilation, infiltration of inflammatory cell mediators) in affected tissue. Radiation recall dermatitis responds to treatment with topical or oral corticosteroids.

CLINICAL APPLICATIONS OF RADIATION

BENIGN DISEASE

The use of ionizing radiation for benign disease has decreased considerably, due both to improvements in alternative therapy as well as an increasing awareness of the rare but serious side effects of radiotherapy.[11] This includes not only fibrotic changes in the affected skin, but more significant is the risk of secondary malignancy. It is estimated that the relative risk of malignancy following radiation treatment increases by 10%–50%; the absolute risk remains very low. These malignancies occur at a median of 10 years following treatment. The risk appears to be greater in younger patients, and in those treated to anatomic areas at highest risk for malignancy (i.e., breast or thyroid tissue). For this reason, radiotherapy should be considered in benign disease only after other therapeutic options have been exhausted, should be avoided when possible in children and young adults, and should be delivered with attention to sparing radiation exposure to sensitive normal tissue.

Radiotherapy is effective symptomatic treatment of several inflammatory dermatoses, including eczema, psoriasis, and lichen planus at relatively low dose exposure (i.e., less than 10 Gy of fractionated treatment). These conditions are only rarely treated with radiation, given the number of other anti-inflammatory options. Benign lymphoproliferative disorders are sensitive in a similar fashion, and disorders such as lymphomatoid papulosis, lymphoid hyperplasia, and lymphocytoma cutis have an excellent response to radiotherapy. These may be treated with radiation after other options have been exhausted, and are approached using lymphoma regimens. Other benign proliferative processes that can be treated with radiotherapy include keratocanthomas, and hemangiomas. A list of diagnoses for which radiotherapy may be indicated can be found in Table 240-3.

A number of large series and one randomized trial have examined the efficacy of localized, low-dose irradiation for the prevention of recurrence of hypertrophic scars or keloids following excision.[12–14] This should be undertaken after failure of other therapies.

TABLE 240-3
Cutaneous Indications for Primary or Adjuvant Radiotherapy[a]

Benign	Malignant
Eczema	Squamous carcinoma
Psoriasis	Basal cell carcinoma
Lichen planus	Melanoma
Benign lymphoid hyperplasia	Merkel cell carcinoma
Keratocanthoma	Eccrine and apocrine carcinoma
Keloids/hypertrophic scars	Cutaneous T- and B-cell lymphoma
	Kaposi Sarcoma
	Angiosarcoma
Premalignant	
Actinic keratoses	
Lentigo melanoma	
Bowen disease	
Erythroplasia of Queyrat	
Lymphocytoma cutis	

[a]Radiotherapy is not recommended as first-line therapy for all the listed indications, particularly the benign disorders.

The most common treatment regimen is to use kilovoltage X-rays or electrons to a total dose of 10–20 Gy delivered over several days. The treatment is usually initiated within 24–48 hours of excision. The recurrence risk after surgery and radiation is approximately 20% or less. The use of radiation without excision on existing keloids is not as effective.

MALIGNANT DISEASE

BASAL AND SQUAMOUS CARCINOMA. Radiation has been used as primary treatment for basal and squamous cell carcinoma, as an alternative to excision, with local control rates of 90% or greater for small lesions.[15] There is concern for progressive late skin atrophy and necrosis decades after radiation, and for this reason surgical excision is usually felt to be a better option in younger patients (i.e., those less than 55). The control rate for primary treatment is a function of tumor size and T stage. For small lesions radiation is felt to offer local control that approximates that seen with excision.

Radiation is also an effective adjuvant treatment, following excision or Mohs micrographic surgery. The clearest indication for treatment is positive margins; other considerations include tumor depth greater than 4 mm in the case of squamous cell cancer and tumor size greater than 2 cm. Involvement of cartilage or bone is a strong predictor of local recurrence and consensus guidelines recommend adjuvant treatment. Perineural invasion has been correlated with both local and nodal recurrence following excision, and is an indication for treatment.[16,17] Involvement of large, named nerves should prompt consideration of extension of the clinical target volume to include the proximal nerve tract. Other relative indications for treatment include poorly differentiated tumors, adenosquamous subtype, and limitations imposed on excision by anatomic location. Patient factors include the presence of neurologic symptoms, implying underlying nerve involvement, and immunosuppressed host status. For squamous cell carcinoma, locally advanced lesions may have a significant risk of nodal metastasis. In patients being treated adjuvantly or definitively for locally advanced primaries with risk factors, draining lymphatics should be electively included.

Dose fractionation schemes represent a balance between patient convenience and the relative risk of poor cosmesis. A total of 60–66 Gy in 2 Gy fractions is appropriate for gross disease, with higher doses indicated for lesions greater than 2–4 cm. Published experience with relatively hypofractionated treatment has shown equivalent locoregional control after 45–50 Gy in 2.5 Gy fractions, or radiobiologically equivalent doses in fraction sizes of 3 or 4 Gy.

Tumors or postoperative areas that are at superficial depth may be treated with orthovoltage radiation to spare the deeper normal tissue. An alternative is electron therapy, with the appropriate bolus to maximize the surface dose. When the target volume is deeper, then megavoltage X-rays, with appropriate bolus, may be required. Target structures such as lymph node basins or nerve tracts, in close proximity to critical normal structures, may require IMRT.

MELANOMA. The role of radiotherapy in the management of localized melanoma has not been conclusively established. Radiotherapy is frequently used for palliation of unresectable lesions, and there is evidence that selected patients at increased risk of local or regional failure may benefit from adjuvant radiation.[18] Risk factors such as tumor thickness greater than 4 mm, ulceration, satellitosis, positive surgical margins, mucosal origin, perineural invasion, and desmoplastic histology are predictive of local relapse after wide excision. Patients with positive lymph nodes at high risk of recurrence after node dissection may benefit from postoperative radiation directed at the nodal basin.[19,20]

Melanomas are frequently treated with hypofractionated radiation, with fraction sizes of 4–6 Gy (i.e., 30 Gy in five fractions) using megavoltage X-rays. The recurrence risk for melanoma after radiation is significantly higher than that for squamous or basal cell carcinoma.

CUTANEOUS LYMPHOMAS. Cutaneous T-cell lymphomas include numerous subtypes, the most common of which are mycosis fungoides (MF) and anaplastic large cell lymphoma. MF is exquisitely sensitive to radiotherapy and patients may present with localized or disseminated skin disease. Anaplastic large cell lymphoma (CD-30 positive) is also a common CTCL, but has an incidence which is less frequent than MF. The clinical presentation is also somewhat different, and these cells generally demonstrate a CD-4 positive phenotype (which can be seen in MF), and also express cutaneous lymphocyte antigen. As opposed to MF, these cells are typically not epidermotropic and do stain positive for CD-30. Lymphomatoid papulosis is also CD-30 positive and may be associated with anaplastic large cell lymphoma. Anaplastic lymphoma kinase (ALK) is usually not overexpressed in patients suffering specifically from cutaneous lymphoma of the CD-30 positive variety, though it may be expressed in patients with noncutaneous anaplastic large cell lymphoma.

There are also a variety of subtypes of cutaneous B-cell lymphoma, but the most commonly encountered are diffuse large B-cell, marginal zone, and follicular center cell. Diffuse large B-cell lymphoma may express CD-20 and CD-79 and lesions involving the lower extremities may express BCL-2, BCL-6, and MUM-1. Marginal zone lymphoma can be identified via expression of CD-20 and CD-79 and often BCL-2, but typically BCL-6 is not noted as a marker in this case. The follicular center cell variant may express CD-20 and CD-79, but expression of BCL-2 and MUM-1 is unusual.

Localized radiotherapy fields may be incorporated into the management of patients with limited disease but, in some cases, patients have extensive areas of skin which are involved and a total skin electron beam therapy (TSEBT) technique may be incorporated for adequate disease control.

Localized radiotherapy is typically provided utilizing an electron technique and bolus material is applied to the skin in an effort to maintain an appropriate

deposition of dose at the skin surface. Typically the 90% isodose curve is utilized to provide homogeneous coverage of the area in question of the skin and margins of 2–3 cm radially are incorporated into the treatment plan. Doses of 30–36 Gy in 2 Gy fractions are used. With this type of regimen for most CBCLs, the complete response (CR) rate is greater than 95% with 5-year local control of approximately 75%.[22,23] Some patients may not be able to logistically receive daily therapy over several weeks, but are in need of palliation of lesions which are bleeding, uncomfortable, unsightly, or impairing function. Such patients may be candidates for an abbreviated regimen of 2 Gy × 2 to a total of 4 Gy, which has been found to provide excellent response rates with reasonable durability in selected patients with low grade CBCL.[24]

TSEBT is significantly more complicated to provide and is typically utilized in patients suffering from extensive MF. It provides excellent response rates for patients with various levels of disease and has also been successful in patients with tumors of the skin, assuming that a supplemental boost be provided to the region involved by tumor. More superficial patches and plaques have an excellent response rate to TSEBT when it is used in the management of patients with MF and the response rate is 100%. The CR rate is variable and decreases with the degree of thickness associated with cutaneous lesions. A typical course of therapy is provided over approximately 8–10 weeks and, based on a Stanford technique, involves 36 fractions to the total skin utilizing six fields with blocking of the eyes, hands, fingernails and feet based on dosimetric parameters resulting from the individualized treatment program.[25]. The patient is treated in a variety of standing positions. TSEBT is best performed in centers that have a significant amount of experience with the technique given its degree of complexity. An important feature to be considered following response to TSEBT is a maintenance program, and such maintenance can be provided in a variety of forms. For MF patients with T1 and T2 level disease, effective regimens, which have been documented in the literature, include the use of PUVA and mechlorethamine.

Both cutaneous T- and B-cell lymphomas are very sensitive to radiotherapy, and it is generally accepted that all lesions will respond and that localized CBCL lesions have a CR rate approaching 100%. CTCL lesions have CR rates that are also excellent but are more dependent on extent of disease.

Complementary and Alternative Dermatology

Chapter 241 :: Complementary and Alternative Medicine in Dermatology

:: Alan Dattner

COMPLEMENTARY AND ALTERNATIVE MEDICINE AT A GLANCE

- Complementary medicine is a holistic approach to diagnosis and treatment.
- Many dermatologic therapies developed in ways similar to the complementary approach and were subsequently scientifically validated.
- Attention to the environment and its impact on the patient is a fundamental principle of complementary dermatology. This means our world dermatology organizations have an obligation to speak out about what is harming the skin, health, as it is related.
- Herbal therapeutics, supplements, diet, and digestive system aid are four of the primary interventions used in holistic dermatology.

Complementary and alternative medicine (CAM) in dermatology encompasses a wide variety of methods of diagnosis and treatment that either supplement or substitute for conventional dermatologic practice. It is also referred to as *holistic dermatology* because it considers and addresses the entirety of the individual, including the physical, mental, emotional, and spiritual aspects of the individual's life, as appropriate. Holistic dermatology draws on an expanded knowledge base that includes CAM, conventional practice, and the latest research findings. Its diagnostic and therapeutic choices are made by combining these three knowledge bases, in what might also be termed *integrative dermatology*.

The alternative healthcare systems considered by holistic dermatology may include time-honored practices such as ancient traditional Chinese medicine, Ayurvedic medicine, American folk medicine, homeopathy along with more recently developed techniques from chiropractic, energetic medicine, functional medicine, and psychosomatic modalities. Furthermore, holistic dermatology includes any other technique that works or makes sense based on science or observation.

Increasingly, patients are using CAM methods in addition to conventional dermatological treatment as cosmeceutical, nutraceutical, and even pharmacological manufacturers more routinely offer these products. CAM practitioners and dermatologists are being called upon to respond to their patients' expectations, preferences and demands for therapeutic modalities and treatments that avoid or minimize use of prescription drugs, and are safe, natural, and effective.

Alternative medicine often embraces treatment that not only presages but also may ultimately be incorporated into conventional practice. Good CAM practice is rooted in basic science, clinical experience and good medicine, but it often lacks the sanctioned level of proof we have come to demand for scientific, allopathic dermatology. Further, CAM practices arise and are developed differently from conventional practices. For example, when a growing body of anecdotal experience is supported by the understanding of underlying mechanisms of pathology, particular CAM approaches to illness are employed, even before the methods are validated in the usual ways. Many of these methods are difficult to study or assess using conventional research methods because they relate to the individual rather than to the disease or condition itself.

Many CAM methods and practices have slowly been incorporated into more conventional practice and some have gained widespread acceptance and use. Examples include the increasing use of probiotics, which had its tentative beginnings in the 1980s, to counter *Candida* overgrowth in the gut, which was later shown to enhance barrier function in the intestines and skin. The CAM use of essential fatty acids (EFA) as anti-inflammatory agents preceded the growing literature on this subject.

CAM practice also identified trans-saturated fats as disrupters of cellular functioning, inhibiting the δ-6-desaturase and thus the production of anti-inflammatory prostaglandins. This tenet of CAM medicine was set forth by Horrobin and others in the 1980s, decades before products containing transfats were removed from the shelves and castigated as deleterious for health.[1,2]

Similarly, kitchen herbalists and small companies were producing herbal skin applications long before the current popularity of cosmeceuticals. And while historically CAM practices have gradually been adopted by mainstream practitioners, in dermatology, the pace of adoption has quickened in recent years. Perhaps most telling is that much of the herbal pharmacopoeia of CAM dermatology referenced in the last edition of this text is now described in the dermatologic literature or is available in products designed for the skin.

HERBAL MEDICINE

Eclectic practice and off-label use of pharmaceutical drugs has always been a part of dermatology, perhaps more so than in medicine in general. These practices provide novel and often effective approaches to disorders of uncertain etiology by incorporating methods from other spheres or from observed benefit. Many of the commonly used pharmacological agents used in conventional allopathic medicine are derived from herbal medicine.[3] The American "herbal" tradition dates to the Eclectics, a school of physicians who, during the nineteenth and early twentieth century codified the use of Western herbs according to specific indications.[4] Today a wide variety of herbs is used, and the methods of selecting specific herb combinations also originate in other traditions. For example, psoralens have been used in China and India for repigmentation of the skin for more than 4,000 years. Other herbs used in treating the skin include mayapple (podophyllin) for condyloma, horse chestnut for leg veins, bloodroot (sanguinaria) for skin tumors, and oatmeal (*Avena sativa*) to soothe rough, itchy, or inflamed skin.[3]

In addition to specific herbal remedies, some of the philosophical tenets of herbal medicine have been incorporated as key concepts in dermatology. For example, the principle of using a crude preparation as opposed to a purified single ingredient as tends to be used in a pharmaceutical product, was one of Sulzberger's observations regarding the use of tar.[5] It was the crude tar product from the distillery and not its purified derivative that had activity in treating psoriasis. In fact, variation in batch efficacy was assumed to be an indication of the heterogeneous nature of the preparation.

A virtual explosion in the availability of herbs in cosmeceuticals, herbal supplements, and new pharmaceuticals has occurred during the past 15 years. This growth has been accompanied by a substantial increase in peer-reviewed publications seeking to clarify the mechanism of action of herbs and their components and case studies detailing knowledge inferred from their traditional use. Each herb has a number of different activities and actions, which depend on growth conditions, the extent to which they have been challenged to fend off pathogens and predators, method of extraction, and the culture that utilized the herb or herbal preparation.

One of the advantages of knowing the traditional uses of herbs and their rich history of folk use is the ability to more fully appreciate their spectrums of action. For example, oats, *A. sativa*, are well known for their soothing anti-inflammatory effects on the skin as a topical soak. The milky white sap from green oats is known for its calming properties as a relaxant to the nervous system. In the context of its use as a folk and home remedy, it is easier and intuitively correct to seek out oat extracts for their calming effects on the nervous tissue in the skin, i.e., soothing and anti-pruritic actions as well.

ANTIOXIDANTS

Antioxidants prevent damage from both exogenous and endogenous free radicals. Ultraviolet radiation from the sun is a major source of free radical damage to the skin, but is beneficial for the production of vitamin D. A symphony of antioxidants prevents excessive damage to either the somatic tissues or DNA of the cells. Plants also must develop their own complex of antioxidants in order to withstand excessive damage from the sun. A young sprout or a plant placed prematurely in full sun will wither and die. It is the complex of antioxidants and light absorbing pigments that plants develop which function to protect them from this damage. Therefore, some argue that eating whole plants, with their functional spectrum of antioxidants, is more protective than isolating the most active fraction, such as β-carotene, and administering it alone.

Nutritional supplementation can supply external antioxidants, or support the generation of endogenous antioxidants. Carotenoids and polyphenols (bioflavonoid) are two major classes of plant-derived antioxidants. Bioflavonoids are especially protective of the capillaries and blood vessels. Oxidative damage and glycation damage induce metalloprotease activity, which destroys the integrity of collagen and elastic tissue in both the skin and the vasculature, and antioxidant protection may slow this process.

APPROACH TO DISEASE

The hallmark of CAM is a search for the elements in the causal chain of functional disturbances that lead to a skin disorder. For inflammatory disorders, an attempt is made to identify exposures, which could stimulate and/or disturb immune responses with secondary targeting of skin structures. CAM focuses on correcting probable underlying causes, often with treatments that are not proven in the traditional scientific method. The patient not only assumes the responsibility of making the necessary lifestyle changes but also the risk of using protocols that are neither conventional nor necessarily well researched.

Individual specificity is key to CAM dermatology. Long before knowledge of specific pathogens and genetic polymorphisms, other systems of healing such as Ayurvedic medicine developed classification and treatment paradigms that are still used today, and extend well beyond diagnosis. The long-awaited studies and meta-analyses of CAM in dermatologic disorders such as psoriasis[6] will continue to be of very limited usefulness because they persist in classifying

patients solely by disease and fail to choose herbs and supplements for time-tested indications in traditional systems, or based on CAM or individual-specific disease mechanism parameters. Appreciation of these distinctions will lead to the design of research studies that truly indicate how to integrate CAM into dermatology as well as how to accurately evaluate the efficacy of CAM practices.

"FOOD ALLERGY" DETERMINATION AND ELIMINATION. In addition to classic immunoglobulin E-mediated allergic response, the term *food allergy* also includes other types of allergy such as immune complex, delayed, and Toll-like receptor activation. There is also nonallergic sensitivity. Food allergies develop to the many common foods such as wheat, milk, soy, yeast, and corn. Some believe that a hallmark of food allergy is food craving with repetitive eating of the same food each day.[19] A 5-day elimination and rechallenge on the sixth day is an effective way to determine if the food under consideration is the cause of the symptoms of concern.

Other symptoms beyond the skin could include digestive upset, nasal stuffiness, fatigue after eating, or even "brain fog." *Brain fog* is a popular term for a sense of mental confusion, sluggishness, and slowness that may sometimes include a feeling of unreality or disorientation. Small peptides from casein digestion known as *caseomorphins*, which can also derive from gluten, rice, bovine albumin, and even spinach, have psychoactive properties.[20] Treatment involves elimination, substitution with other foods, and food rotation. Enhancing digestion with digestive enzymes and adding metabolites to enhance the gut permeability barrier (and reduce the impact of leaky gut) helps to prevent sensitization to disease inducing cross-reactive antigens.[21,22]

Food Allergy Diagnosis. Diagnosing food allergy is best initiated by a careful history of the specific foods that preceded a reaction; these include foods consumed a few hours or even few days prior to the reaction. A food and reaction diary helps to reinforce memory and document instances of food consumption and reactions. Elimination and challenge is the gold standard for identifying food allergens. Intradermal testing can be helpful, and is far more useful than scratch tests because the latter detect IgE or immediate allergy only.

ESSENTIAL FATTY ACIDS. EFAs play an essential role in skin health. EFAs are the precursors of the eicosanoids produced when phospholipase cleaves a lipid fragment, arachidonate, from the cell membrane. Arachidonate, a common pathway byproduct from most foods, leads, via cyclooxygenase, to production of the proinflammatory prostaglandin E_2(PGE_2), or via lipoxygenase to production of proinflammatory leukotrienes.[25] Specific ω-6 unsaturated EFAs such as γ linolenic acid, found in borage oil, evening primrose oil, and human breast milk, lead to formation of the anti-inflammatory PGE_1. ω-3 unsaturated fatty acids such as those found in fish oils contain eicosapentaenoic acid (EPA), which leads to formation of the anti-inflammatory and anticlotting PGE_3. Flaxseed oil has an ω-3-EFA known as *α-linolenic acid,* which requires two carbon chain elongation to become EPA, requiring activity of the δ-6-desaturase enzyme. That enzyme has cofactor requirements of zinc, magnesium, vitamins C, B3 and B6, and low insulin levels. ω-3 EFAs also play a role in formation of the barrier lipid in the brick and mortar structure of the stratum corneum barrier. Partially hydrogenated oils not only lead to proinflammatory PGE_2 formation, but also inhibit the δ6-desaturase, which is crucial for formation of anti-inflammatory γ-linolenic acid.

Shifting the balance toward anti-inflammatory EFAs by removing foods with proinflammatory oils and increasing foods and supplements with anti-inflammatory oils (e.g., cod liver oil) is a strategy useful in most conditions involving inflammation and dry skin. It is especially useful in seborrhea and eczema. Rare problems with excessive fish oil include increased bleeding tendency[26] and high-birth weight, postmature babies.[27]

A number of studies have shown the effectiveness of ω-3-EFAs in psoriasis and other inflammatory and autoimmune diseases.[28] EFAs also confer powerful protection from UV exposure and have been used to reduce inflammation and promote wound healing in burn victims.[29,30]

HOMEOPATHY

Homeopathy pushes the boundaries of the scientific mind because it works by invoking the energy of the substance rather than the substance itself, with greater dilutions having greater potency.[32] A key aspect of homeopathy is that substances diluted homeopathically often, but not always, work by counteracting the very symptoms that the undiluted substance produces. For example, Nux vomica is used to counteract nausea, and *Coffea*, from coffee, is used to induce sleep. Some herbalists also use the information from the provings, the homeopathic repertory, for seeking further insight into the characteristics of herbs.[33]

COMPLEMENTARY AND ALTERNATIVE MEDICINE APPROACHES TO SPECIFIC DERMATOLOGIC CONDITIONS

Several dermatologic disorders, particularly those that are inflammatory in nature, may benefit from the CAM approach.

SEBORRHEIC DERMATITIS

(See Chapter 22)

Seborrheic dermatitis[34] involves inflammation in sebaceous follicular areas of the scalp, eyebrows, and nasolabial folds. All of these regions harbor the yeast

Malassezia, which is normal follicular flora. There is evidence that *Malassezia* is cross-reactive with *Candida albicans*,[35] and it is postulated here that a cross-reactive attack against antigenic epitopes on the *Candida* and other yeasts and molds becomes directed against the *Malassezia* organisms in the follicle, causing the inflammation that incites the erythema and desquamative changes characteristic of seborrhea.

An altered pattern of EFAs in infantile seborrheic dermatitis implicates impaired function of the δ-6-desaturase.[36] Some of the B vitamins previously reported as helpful in seborrhea may function as cofactors for this enzyme.[37–39] The tendency toward inflammation is exacerbated by a predominance of arachidonic acid precursors in the cell membranes derived from dietary sources. Treatment by substituting EPA-rich fish oil in the diet and removing partially hydrogenated and saturated oils can reduce this inflammatory state by favoring the generation of anti-inflammatory PGE_3.[40–42] Flaxseed oil is another ω-3-fatty acid and PGE_3 precursor, but the active ω-3-EFA in it, α-linolenic acid, requires chain elongation to be converted to EPA, and this process is not uniform among individuals.[43]

ATOPIC DERMATITIS

(See Chapter 14)

Atopic dermatitis is an inflammatory disorder of the skin linked to asthma and hay fever. In the past, dermatologists observed cases in which food was considered a trigger, but were generally puzzled that there did not seem to be a specific food that caused the eczema. One challenge was that eczema could be aggravated by one food, and then after diet change, would be exacerbated by the newly substituted food.

One theory articulated by practitioners of CAM relates to what is known as *leaky gut*.[44] Disruption of the gut barrier can result from inflammation of the intestinal lining. This inflammation may be caused or precipitated by parasites, *Candida* overgrowth, food sensitivity, foods containing lectins that punch holes in cell membranes, or pathogenic microorganisms. In addition, nonsteroidal anti-inflammatory drugs are irritating to the gut lining, as are alcohol and aspirin. Any food introduced repeatedly into such an environment can lead to sensitization to that food. In these cases, it is believed that the uncontrolled atopic becomes sensitive to whatever he/she eats repeatedly to avoid that which caused trouble initially. For example, the milk-allergic infant switched to soy protein soon becomes "allergic" to soy. Inflammation in the gut wall stimulated by soy causes allergy to whichever nutrient is next exposed to the gut immune system. This "vicious cycle" could account for the name *atopic*, which was used to describe the changeable nature of the factors initiating the dermatitis.

Treatment consists of removing abnormal microbes and restoring normal flora, removing irritants, eliminating exacerbating foods, enhancing enzymatic breakdown of foods (digestion), coating the gut with mucilaginous herbs, and providing the nutrients needed to support an intact gut barrier.

Proper colonization of the gut with *Lactobacillus acidophilus* and similar strains has a protective effect against atopy.[45] A corollary of this observation is that repeated use of antibiotics favors overgrowth of *C. albicans*, and simple starches and sugars support *Candida* growth. It is presumed that consumption of large amounts of yeast, mold, and their byproducts, such as bread, beer, wine, and cheese, could both induce high-dose antigen tolerance to intestinal *Candida*, and perhaps even sensitize to other antigenic determinants. High-dose tolerance is a lack of immunoreactivity to specific antigenic determinants or substances due to the presence of large quantities of these determinants in the system. Treatment consists of removing the dietary factors that favor *Candida* and then treating with herbal or other natural remedies to reduce the yeast population. *Artemisia annua* and short-chain fatty acids such as undecylenic or caprylic acid are a few such treatments. Next, probiotics may be added to prevent *Candida* from overtaking gut flora.

Only when these measures have been taken should pharmaceuticals be used in a progressive fashion. Otherwise, there is the risk of selecting for resistant strains. Nystatin may be considered, followed by ketoconazole and fluconazole. Nystatin should be slowly increased in dosage from 500,000 units/day in divided doses to 6 million units, over 10–12 days. Highly yeast-sensitive individuals absorb cell content material through an already leaky gut wall and are known to develop exacerbation of previous symptoms and sometimes fever, with a Herxheimer-like reaction. All of these drugs have more potential effectiveness when the environment is changed by dietary restrictions on sugars, simple carbohydrates, and foods high in or derived from yeast.

Anti-inflammatory EFAs, such as EPA from fish oils, appear to help some atopics.[46] Hempseed oil, rich in ω-3- and –6-EFAs, improved the serum fatty acids, and the condition of atopics, in a study conducted in Finland.[47] There has been a consistent increase in the number of studies showing that γ-linolenic acid from borage or evening primrose oil[48] effectively resolves various aspects of atopic dermatitis, and there is clear indication that it is beneficial for some patients with eczema. The results of a small study performed in Germany showed that GLA supplementation from EPO reduced total IgE in the first year of life, but did not prevent atopic dermatitis. Another study found decreased GLA levels in children with eczema and elevated IgE levels and others with atopy, but not in eczema patients with normal IgE levels.[49] Meta-analyses to the contrary[50] are likely contaminated by issues discussed under EFAs, above, and should not dissuade physicians or patients from a proper trial of EFAs in atopic patients, once oxidative stress has been calmed down. Furthermore, a balance of anti-inflammatory EFAs is likely most effective for allergic individuals. It should be remembered that the industrialization of our food supply over the past half-century, including partial hydrogenization of nearly

all food products that required shelf life, hardening oils for convenience in food, importing southern oils where unsaturated northern oils were local, and farm feeding grains to fish, poultry, and livestock that previously consumed local cold grown plants naturally rich in unsaturated fatty acids, all have served to dramatically reduce the proportion of anti-inflammatory EFAs in our diets and thus cell membranes. Some of the increase in atopy, inflammatory, and autoimmune disorders we are now seeing may be in response to the "hair trigger" this shift is placing on the prostenoid aspect of the immune response.

There has been scant attention paid to primary prevention of atopic dermatitis. Although conventional wisdom has held that breastfeeding is associated with reduced incidence of atopic dermatitis in children, recent research questions this, especially when the mother herself is allergic. In fact, it seems likely that dietary allergens present in breast milk of these allergic mothers may actually trigger or contribute to the development of atopic dermatitis in offspring. For this reason, it may be prudent to suggest that mothers of infants at risk for atopic dermatitis avoid dietary allergens. There also is some evidence of benefit from the use of probiotics and supplementation with EFAs.[51]

ACNE

(See Chapter 80)

Before the availability of tetracycline, diet change was a mainstay in acne treatment. With the advent of antibiotics for acne, many dermatologists argued that the stress produced by restricting favorite foods was itself acne causing, and consensus evolved to minimize the role of diet in acne. This view was supported by seminal papers that demonstrated that common agents such as chocolate did not cause acne.[52] More recent data do reveal a relationship between milk consumption, both full-fat and especially nonfat, and acne in teenage girls[53] and boys[54,55] Darby and others posit that hormones normally present in milk as well as added to enhance milk production may be responsible for this effect. This includes progesterone-related hormones and 5-α-pregnanedione, which is converted directly into dihyrotestosterone.[56] Milk protein allergy causing an inflammatory response that blocks the infundibular apparatus also may contribute.[44] It now appears that diet may influence a number of mechanisms related to acne development.[57]

Bovine milk production by postpartum cows contains placenta-derived progesterone and dihydrotestosterone precursors. Other hormones in addition to steroids in milk also may stimulate acne. The most frequently implicated substance is IGF-1 (insulin-like growth factor), which also increases during the teenage years as a result of growth hormone. IGF-1 is present in organic milk and increased in milk from cows treated with bovine growth hormone. IGF-1 increases lipogenesis in sebocytes.[58] It stimulates 5-α-reductase and androgen synthesis. It has also been shown that excess carbohydrate consumption increases insulin, which increases IGF-1, which in turn worsens acne.[59] IGF-1 and dihydrotestosterone levels in women both correlate with acne.[60]

Melnik has elegantly suggested the role of deficiency or displacement of nuclear transcription factor Fox01 from suppressing the androgen receptor and the promoter of PPAR-γ as the key initiator of the activation of the genes for sebocyte proliferation, sebum synthesis, and inflammatory cytokines.[61] He observes that retinoids increase Fox01, and that all known acne-inducing factors work by decreasing it.

Milk elimination and reduced carbohydrate ingestion can produce a substantial improvement in some acne patients, as does reduction of proinflammatory fats from fried and partially hydrogenated sources. In women with perimenstrual flaring, reduction of dietary estrogens, and pseudoestrogens may be helpful.

The holistic perspective posits that the initiator of the inflammatory process that leads to acne is derived from antigens and informational molecules derived from an improper diet and environment, and that the mechanism of inflammation, so elegantly described in the classic and emergent literature, is a key precipitating step in that cascade.

Recent evidence indicates that inflammation in the pilosebaceous unit may precede the follicular plugging and *Corynebacterium acnes* proliferation,[62,63] and that the predominant presence of CD^+ memory/effector cells suggests a specific antigenic T-cell inflammatory, rather than nonspecific, immune response. Timed immunofluorescent studies reveal a type IV delayed hypersensitivity response, and, therefore, point to a soluble antigen stimulus initiating the acne lesion.[64] A primary response to antigen in a structure that concentrates antigenic material from the blood, which ultimately comes predominantly from the digestive tract, makes acne an inflammatory disorder that should respond to the alteration of gut-derived antigens described in this chapter.

There is evidence from animal studies that carbon-14-radiolabeled α-linolenic acid, dietary ω-3-EFA found in flaxseed, is preferentially found in the coat of guinea pigs, suggesting sebaceous excretion of this dietary lipid.[65] There is reason to believe that all of the lipids, and indeed all of the other molecular moieties that are secreted or synthesized into secretions in the pilosebaceous unit, are derived either from diet, body stores, microbial metabolites, or topical absorption. The infundibular apparatus concentrates and excretes both water-soluble wastes in the sweat, and lipid and proteinaceous material in the sebum. Medications, such as ketoconazole, have been found in sebum.[66]

HIDRADENITIS SUPPURITIVA

Hidradenitis suppuritiva (HS) may respond to treatment that enhances digestive function, gut barrier function, and elimination of reaction to allergenic foods. HS is increasingly being recognized as a disorder of immune function, at least in the local tissues.

SECTION 40

Surgery in Dermatology

Chapter 242 :: Anatomy and Approach in Dermatologic Surgery

:: Sumaira Z. Aasi & Brent E. Pennington

INTRODUCTION TO DERMATOLOGIC SURGERY AT A GLANCE

- Profound knowledge of the anatomy, particularly of the head and neck region, is essential.
- Preoperative assessment includes a thorough medical, drug, and medication history.
- Asepsis and antisepsis are required.
- The choice of the anesthetic is determined by the nature and duration of the procedure and by patient factors such as allergy or renal or hepatic impairment.
- Side effects of local anesthetics are pain, a vasovagal reaction, or (uncommon) allergic reactions. Anesthetic toxicity is rare.
- Infiltrative anesthesia, nerve blocks, and topical anesthesia (for minor procedures) can be performed.
- Types of suture material and suturing technique depend on the surgical procedure.
- Postoperative care is essential.

Dermatologic surgery has rapidly become a cornerstone of the practice of dermatology. Factors such as the epidemic of skin cancer, the interest in maintaining a youthful appearance for an aging population that is living longer, and the financial pressures to perform surgery in less expensive outpatient settings have led to an increase in the number of surgical procedures performed in dermatologic practice.

ANATOMY

Anatomy is often called the language of surgery.[1,2] Knowledge of anatomy is critical for a number of reasons, including communicating precisely with colleagues, performing efficient and safe procedures, obtaining optimal functional and aesthetic reconstruction, understanding the lymphatic drainage, and anticipating the metastatic spread of malignancies. As the majority of cosmetic and surgical procedures are performed on the face, and because of its complexity, this chapter focuses on the superficial cutaneous anatomy of this critical region.

COSMETIC UNITS AND LANDMARKS

Landmarks and cosmetic units help localize areas of the face accurately and precisely for purposes of communication with colleagues and to perform the surgery itself. For instance, it is more helpful to describe a lesion on the face if it is said to be located on the "left nasal sidewall" versus left nose or "right triangular fossa" versus right ear. Cosmetic units are zones of tissue that share cutaneous features such as color, texture, pilosebaceous quality, pore size, and degree of actinic exposure. These cosmetic units are demarcated by junction lines that can be discrete (eyebrows) or subtle (nasofacial sulcus). Cosmetic units can also be further divided into subunits. Because of the tissue similarity, it is often best to reconstruct a surgical defect within a cosmetic unit or subunit or borrow tissue from nearby units. In addition, scar lines can be hidden easily in junction lines between the cosmetic units. The more complex regions of the face that have multiple subunits include the nose, ears, and lips (Figs. 242-1 and 242-2).

The subunits of the nose include the glabella (the area between the eyebrows), the root (the deep sulcus below the glabella and uppermost portion of the nose), dorsum or bridge (the area overlying the nasal bone), lateral side walls (the sides of the nose), nasal tip, the nasal ala (the nostril), alar groove and nasolabial crease (the grooves that demarcate the alae superiorly from the lateral nasal sidewall and alae inferiorly from the lip, respectively), and the columella (the mobile linear structure separating the alae inferiorly) (see Fig. 242-1).

The lateral surface of the ear is rimmed by the helix, a curved cartilaginous structure that begins at the crus

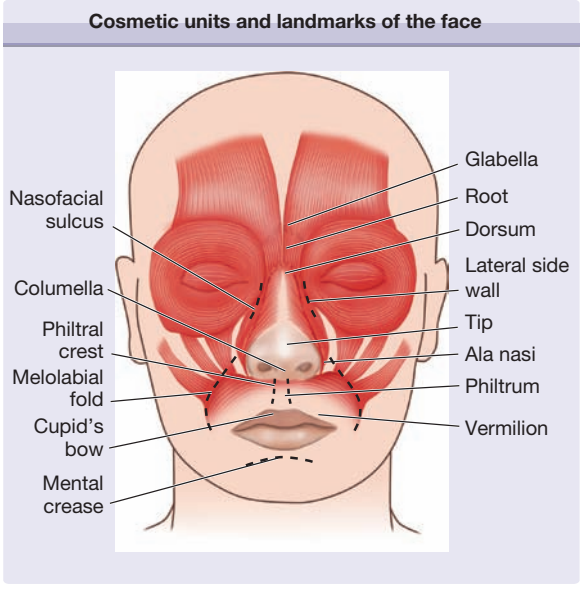

Figure 242-1 Cosmetic units and landmarks of the face.

just above the external auditory canal and continues around the ear to end at the fleshy lobule. The central concavity within which the external auditory meatus lies is the concha. The concha is divided by the crus of the helix into a superior portion, the cymba, and an inferior portion, the cavum. The posterior border of the concha is formed by another cartilaginous structure called the *antihelix*. Superiorly, the antihelix originates from two legs (*crus* is Latin for *leg*): (1) the superior crus and (2) inferior crus. The region between the crura is referred to as the triangular fossa. The groove between the helix and antihelix is the scaphoid fossa. The triangulated cartilaginous structure just anterior to the auditory canal is called the *tragus*, and just posterior to this is the triangulated end of the antihelix, referred to as the *antitragus*. The inferior region between the tragus and antitragus is the intertragic notch (see Fig. 242-2).

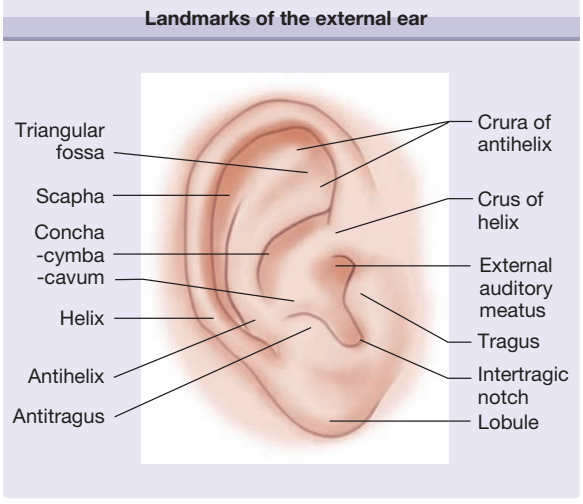

Figure 242-2 Landmarks of the external ear.

The cutaneous upper lip has a concave depression in the center, called the *philtrum*, which is bounded by two ridges, the philtral crests. There is a prominent crease, the mental crease, which divides the cutaneous lower lip from the chin. The boundary between the red mucosal surface of the lips and the cutaneous surface is called the vermillion border. The raised contoured area of the inferior portion of the philtrum is a critical aesthetic landmark known as the *Cupid's bow* (see Fig. 242-1).

RELAXED SKIN TENSION LINES

Relaxed skin tension lines (RSTLs) are another characteristic of the face that help guide surgical reconstruction and allow the structural camouflage of scar lines. RSTLs are creases on the face that form over time due to factors such as loss of elastic tissue tone, lengthening of the collagenous fibrous septae that connect the dermis to the underlying facial muscles, development of excessive skin, gravity, and ultraviolet radiation exposure. Fig. 242-3 illustrates a surgical defect on the upper lip of an elderly woman with prominent RSTL. RSTLs are most obvious on the face because unlike other muscles in the body that connect tendons and bones, facial muscles attach to the overlying skin. These lines can be induced by facial muscle movement in the young but inevitably become more pronounced with age. RSTLs usually run perpendicular to the underlying muscles. In most situations, the long axis of the excision should be placed parallel to the RSTL because they are often in the direction of the least tension for a scar. It is preferable to design flaps such that the majority of the scar lines fall within the RSTL.

DANGER ZONES

There are three main danger zones that are critical to understand while performing surgical procedures

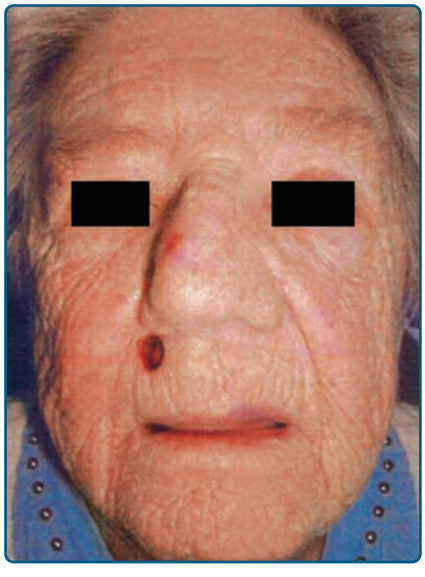

Figure 242-3 Relaxed skin tension lines of the face.

on the head and neck. Each of these zones involves a motor nerve and the muscles it innervates. It is important to confirm the proper function of these muscles before performing a procedure in these areas so that it can be readily determined whether an injury occurred during surgery.

TEMPORAL BRANCH OF THE FACIAL NERVE. The temporal branch of the facial nerve is at greatest risk for injury where it crosses the zygomatic arch. Injury to the temporal branch of the facial nerve leads to an inability to elevate the eyebrows and brow ptosis and paralysis. Asymmetric appearance of the forehead can also occur because there will be a loss of the lines and wrinkles on the affected side. One easy method to delineate the danger area of the temporal nerve is to draw a line from the earlobe to the lateral edge of the eyebrow, and another line from the tragus to just above and behind the highest forehead crease (Fig. 242-4). In the area between these lines, over the zygomatic arch is where the nerve is superficial, and it is critical in this area to undermine just below the dermis in the superficial fat above the fascia.

MARGINAL MANDIBULAR NERVE. Damage to the marginal mandibular nerve results in contralateral and upward pull on the mouth while the affected ipsilateral side of the mouth is fixed in a grimace with a lip droop. As it crosses the angle of the mandible at the inferoanterior border of the masseter, the marginal mandibular nerve is covered only by skin, subcutaneous fat, and fascia, which may be thin in this location, particularly in the elderly.

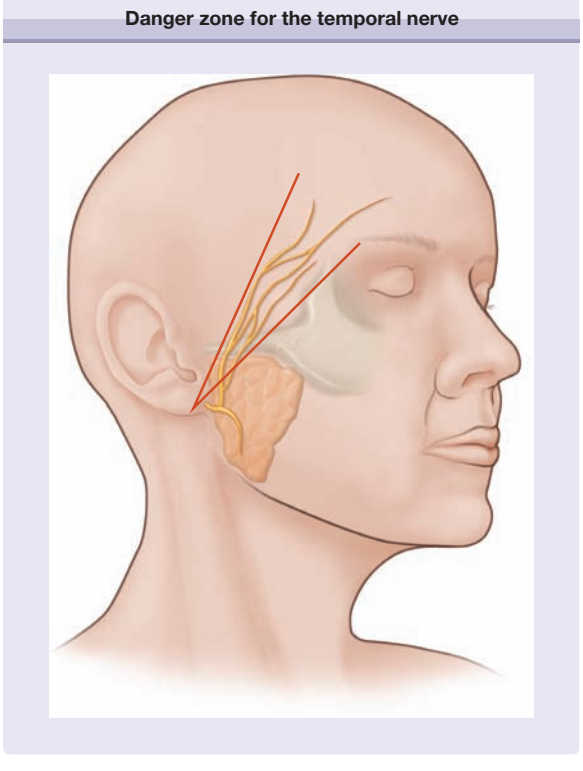

Figure 242-4 Danger zone for the temporal nerve.

SPINAL ACCESSORY NERVE. Injury to the spinal accessory nerve leads to the paralysis of the trapezius with winging of the scapula, shoulder drop, inability to shrug the shoulder, difficulty with abducting the arm and chronic shoulder pain. Transection of the spinal accessory nerve can occur when operating in the posterior triangle of the neck. This region is delineated by the clavicle inferiorly, the sternocleidomastoid muscle anteriorly, and the trapezius muscle laterally and posteriorly. One can anticipate the location of the spinal accessory nerve by drawing a line connecting the angle of the mandible with the mastoid process. A vertical line is then drawn from the midpoint of this line 6 cm inferiorly. The point at which this line intersects the posterior border of the sternocleidomastoid muscle is Erb's point. The spinal accessory nerve emerges approximately from this point and lies superficially here, covered only by skin and fascia.

UNDERMINING PLANES

SUPERFICIAL MUSCULOAPONEUROTIC SYSTEM. The term *fascia* refers to connective tissue that contains both fibrous and fat tissue in various amounts. Superficial fascia is the subcutaneous tissue that is immediately below the dermis. The deep fascia consists of more compact and highly organized collagen fibers. The superficial musculoaponeurotic system (SMAS) is the fascial system that envelops the muscles of the face. It stretches over the cheeks between the temporalis and frontalis muscles above and the platysma muscle below. The SMAS also attaches to the orbicularis oculi muscles anteriorly, the trapezius muscle posteriorly, and includes the fascia of the forehead and galea of the scalp. Most of the superficial muscles of the scalp and face insert into the skin either directly through fibrous bands running in the subcutaneous tissue or indirectly by attachment to the SMAS, which, in turn, is attached to the skin. In the lateral areas of the face, the SMAS is organized and more visible but becomes less discrete medially. Because of its attachment to the skin superficially and muscles deep, the SMAS coordinates a wide range of facial expressions. In addition, the SMAS is an important landmark because most major arteries and nerves run within or deep to it. Thus, dissection above the SMAS allows one to safely avoid injuring branches of the facial nerve.

SCALP. The scalp is classically divided into five layers that are often referred to by the mnemonic SCALP. These layers from superficial to deep are: *s*kin, sub*c*utaneous tissue, *a*poneurosis (galea aponeurotica), *l*oose connective tissue, and *p*eriosteum. Because the majority of the nerves and vessels of the scalp are superficial to the subgaleal space, this is an ideal undermining plane. However, it is also known as the *danger zone* because hematomas and infection can develop here and pass through the emissary veins into the meninges.

FOREHEAD. The forehead is best undermined immediately above the superficial fascia of the frontalis

muscle. There may be little subcutaneous fat in this area. The temple should be undermined in the high fat/subdermal region to avoid damaging the temporal branch of the facial nerve.

EYELIDS. The eyelids possess the thinnest skin of the body. The skin of the eyelids lies directly on the orbicularis muscle. Undermining should be performed above the muscle fascia to avoid causing significant bleeding and scars/contractures that can lead to ectropion.

CHIN AND LIPS. The large, thick muscles of the lips and chin can make undermining challenging. The chin, in particular, has muscles broadly attached directly to the skin. Sharp undermining performed just above the superficial muscular fascia is appropriate. These areas are at high risk for bleeding, made even more precarious by functions such as talking and chewing.

NOSE. The nose requires different levels of undermining in different regions. The dorsal nose can be easily undermined above the periosteum, especially when performing reconstruction with flaps. The distal, more sebaceous portion of the nose must be undermined in the subfibrofatty layer to allow the greatest tissue movement.

CHEEKS. The cheeks can be safely mobilized in the high or mid subcutaneous fat. Care must be taken when undermining in the hair-bearing regions of the cheek in men, however. Here, undermining should be performed in the deep subcutis to avoid transecting hair follicles.

NECK. The neck can be safely undermined while staying above the superficial fascia. One must be careful in the posterior triangle of the neck. This region is delineated by the clavicle inferiorly, the sternocleidomastoid muscle anteriorly, and the trapezius muscle laterally and posteriorly. The spinal accessory nerve lies superficially here, covered only by skin and fascia.

SENSORY NERVES

The trigeminal nerve (cranial nerve V) provides the majority of the sensory innervation of the face (Fig. 242-5). It exits the skull via three foramina located bilaterally in the midpupillary line, the supraorbital, infraorbital, and mental foramina. The first branch, the ophthalmic nerve (V_1), has several branches that supply the innervation to the superior portion of the face: the supraorbital, supratrochlear, infratrochlear, external nasal, and lacrimal nerves. The supraorbital (lateral) and supratrochlear (medial) nerves supply the forehead and anterior scalp and are branches of the frontal nerve (the largest branch of the ophthalmic nerve). They exit from two notches along the orbital rim: (1) supraorbital foramen or notch laterally, and (2) supratrochlear notch, medially. The infratrochlear branch (of the nasociliary nerve) supplies the glabella, nasal root, and bridge. The external nasal branch (or the dorsal nasal nerve) is a branch of the anterior ethmoidal nerve of the nasociliary branch of V_1. The external nasal branch supplies the dorsal nose and provides the anatomical explanation of Hutchinson sign that can occur in some cases of herpes zoster of the ophthalmic nerve. Vesicles on the nasal tip indicate that the eye may be involved because the nasociliary branch of V_1 sends branches both to the nasal tip and the cornea. The lacrimal branch supplies sensation to the upper eyelid.

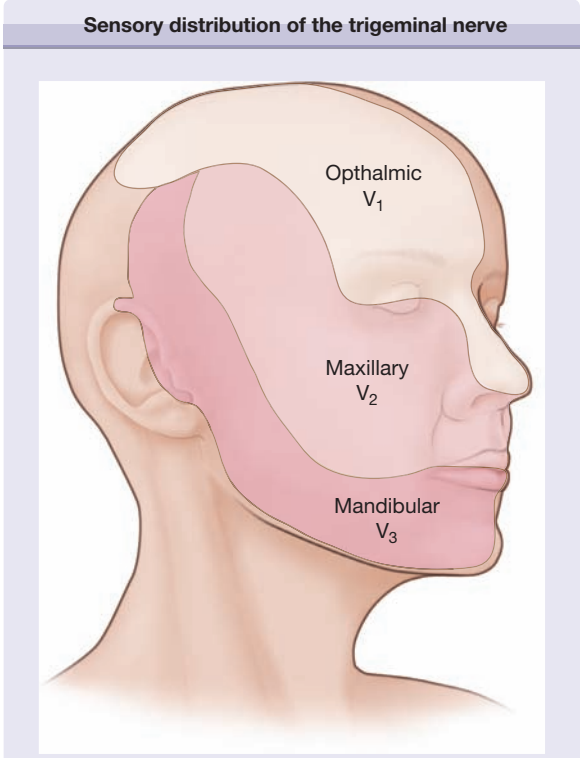

Figure 242-5 Sensory distribution of the trigeminal nerve.

The second branch of the trigeminal nerve is the maxillary nerve (V_2). The maxillary nerve supplies sensation to the lateral nose, lower eyelid, superior cheek, and anterior temple. The maxillary nerve gives off two main branches that supply the skin of the face. The zygomatic branch of the maxillary nerve gives rise to the zygomaticofacial nerve, which exits the skull through the lateral zygomatic bone and supplies a small area of the lateral canthus. In addition, the zygomatic branch also gives rise to the zygomaticotemporal nerve, which exits the skull through the anterior temporal fossa and supplies skin of the anterior temporal region. The largest branch of the maxillary nerve is the infraorbital nerve that exits the skull through the infraorbital foramen of the maxilla. This supplies sensation to the eyelid and superior cheek.

The third branch of the trigeminal nerve is the mandibular nerve (V_3). Its branches provide sensory innervation to the lower lip, chin, mandibular and preauricular cheek, anterior ear, and the central temporal scalp. The mandibular nerve gives off three major cutaneous branches: (1) the auriculotemporal, (2) buccal, and (3) mental nerves. The auriculotemporal

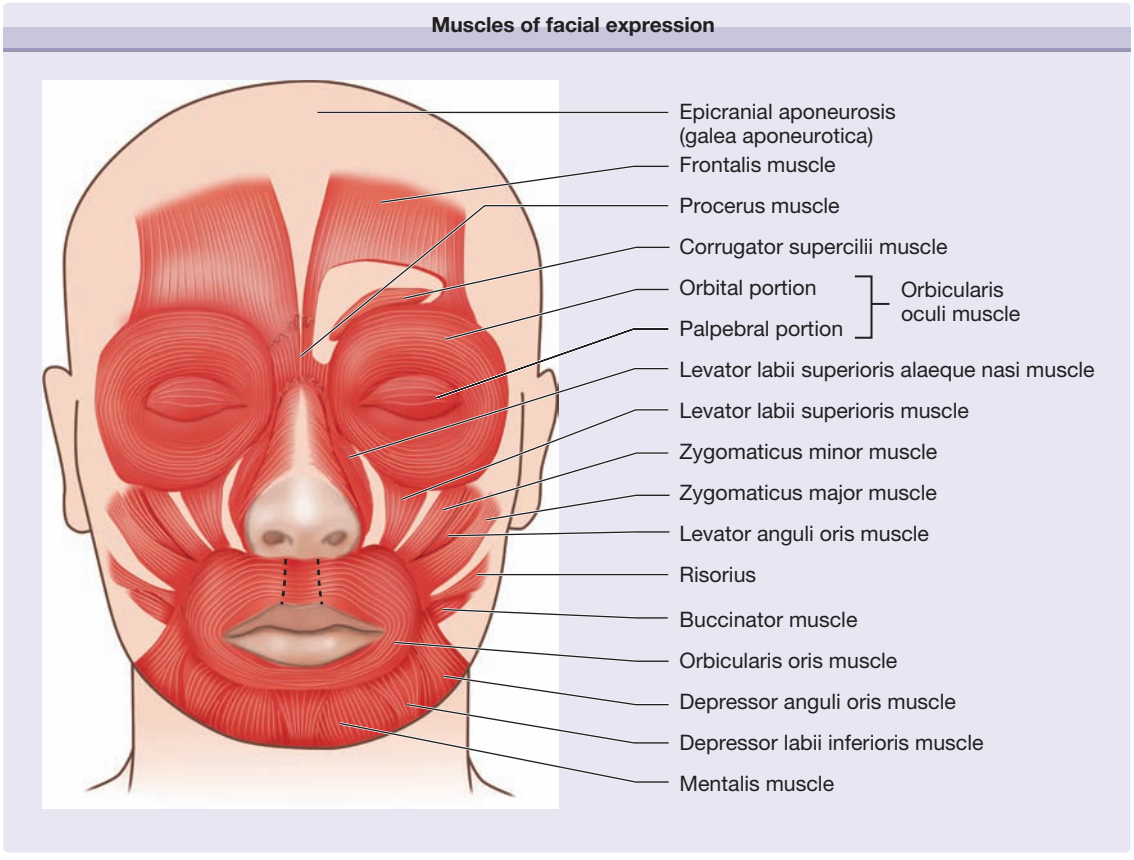

Figure 242-6 Muscles of facial expression.

nerve innervates most of the temple, the temporoparietal scalp, the anterior ears, parts of the external ear canal, and the tympanic membrane. The buccal nerve lies deep to the parotid gland and supplies the skin over the buccinators, buccal mucosa, and the gingiva. The mental nerve exits through the mental foramen and is a continuation of the inferior alveolar nerve. The mental nerve supplies sensation to the lower lip and chin.

MUSCLES

The scalp has two muscles overlying it, the frontalis anteriorly and the occipitalis posteriorly. These muscles are joined by a thick fascia centrally over the scalp, the galea aponeurotica. The frontalis muscle also covers the forehead and elevates the eyebrows. The eyebrows move medially and downward with contraction of the corrugator supercilii muscles. The procerus lies between the supercilii muscles and draws the skin of the forehead inferiorly to create the horizontal creases at the root of the nose. The orbicularis oculi muscle surrounds the eye and consists of an orbital and palpebral portion. The orbicularis oculi muscle serves to close the eyes with the palpebral part with both reflexive and voluntary control and the orbital part with voluntary control. The central sphincter-like muscle around the mouth is the orbicularis oris. This muscle helps purse the lips to form certain sounds and whistle. The lip depressors are depressor anguli oris, depressor labii inferioris, and the mentalis. The lip elevators are the zygomaticus major, zygomatic minor, levator anguli oris, levator labii superioris, and the levator superioris alaeque nasi. The risorius helps retract the corner of the mouth. The buccinators and masseter muscles help with mastication (Fig. 242-6).

MOTOR NERVES

The facial nerve (cranial nerve VII) provides innervation to all the muscles of facial expression. It exits the skull via the stylomastoid foramen, which lies deep in the infra-auricular sulcus and anterior to the mastoid process. The facial nerve enters the parotid gland at the level of the intertragic notch and usually divides into five branches within the substance of the gland. The well-known mnemonic "*t*o *Z*anzibar *b*y *m*otor *c*ar" can be used to remember the five main branches: (1) *t*emporal, (2) *z*ygomatic, (3) *b*uccal, (4) *m*andibular, and (5) *c*ervical. For the most part, these nerves enter the muscles they innervate posteriorly and deep. A nice rule of thumb is that if one transects a nerve lateral to the midpupillary line, permanent paralysis can result and if the nerve is cut medial to this demarcation, most nerves will regenerate or have arborizations that will help provide additional innervation.

The temporal branch of the facial nerve exits the superior part of the parotid gland and crosses the zygomatic arch to innervate the frontalis, upper portion of the orbicularis oculi, and corrugator supercilii. Injury to the temporal branch leads to an inability to raise the eyebrows and brow ptosis. The zygomatic branch innervates the orbicularis oculi, nasal muscles, lip elevators, and the buccinators. Damage to the zygomatic nerve results in lower eyelid ptosis and an inability to close the eyes completely. The buccal branch also innervates the buccinators and lip elevators, as well as the orbicularis oris and risorius. Damage to the buccal branch leads to an inability to whistle. The marginal mandibular branch crosses the angle of the mandible at the inferior-anterior border of the masseter. It innervates the depressors of the mouth.

VASCULAR SUPPLY

The blood supply of the face is almost entirely derived from branches of the external carotid artery (Fig. 242-7). Just posterior and medial to the angle of the mandible, the facial artery branches off the external carotid artery. The facial artery continues anteriorly and superiorly toward the angle of the mouth, giving off the inferior labial artery and superior labial arteries that supply the lips. The continuation of the facial artery in the nasofacial sulcus is called the *angular artery*. The angular artery continues superiorly to enter the orbit immediately over the medial canthal tendon where it anastomoses with the ophthalmic artery, a branch of the internal carotid artery. After giving off the facial artery, the external carotid artery then passes deep to the sternocleidomastoid muscle and enters the body of the parotid gland where it gives off the posterior auricular artery that supplies the postauricular scalp, the maxillary artery, and the superficial temporal artery. The terminal branch of the maxillary artery exits the infraorbital foramen with the infraorbital nerve as the infraorbital artery to supply the lower eyelids and infraorbital cheek.

The terminal branches of the internal carotid artery are the ophthalmic artery branches, the supraorbital artery, and the supratrochlear artery. The supraorbital artery emerges from the supraorbital foramen, whereas the supratrochlear artery emerges more medially. The internal and external carotid systems join in two places: (1) where the supratrochlear branch and the dorsal nasal artery anastomose with the angular artery and (2) where the forehead branches of the supraorbital and supratrochlear arteries anastomose with branches of the superficial temporal artery.

The veins of the face parallel and lie posterior to the arteries. Unlike the veins of the trunk and extremities, facial veins have no valves. This allows blood to flow in either direction. Thus, in the central face where there are anastomoses between branches of the ophthalmic vein and of the angular vein, infection has easy access to travel along the ophthalmic vein to the cavernous

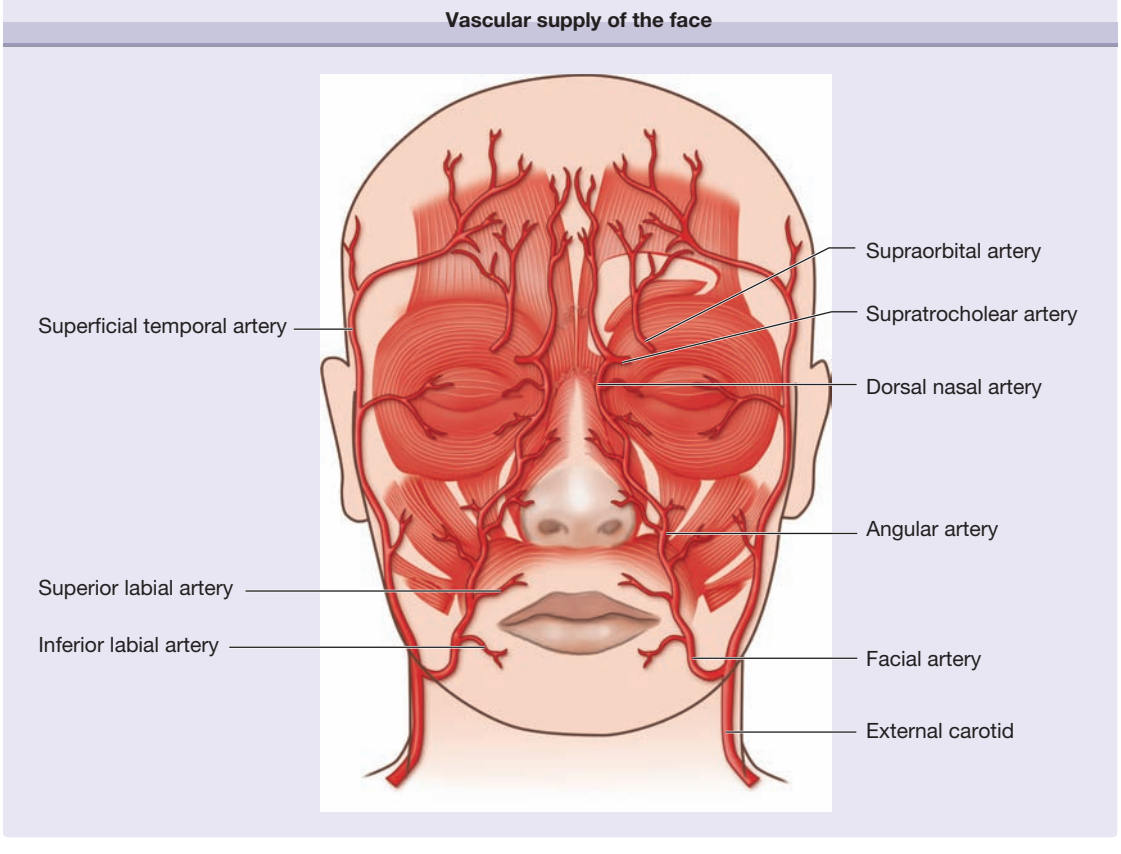

Figure 242-7 Vascular supply of the face.

sinus. The angular vein also communicates with the deep facial vein and pterygoid plexus.

LYMPHATICS

The lymphatic vessels of the face generally drain from superficial to deep and medial to lateral and caudad. While the general drainage patterns are described here, variations can occur. The posterior scalp drains to the postauricular and occipital nodes. The lateral and superior face, the forehead, and the lateral eyelids drain to the parotid nodes. The medial and inferior face, including the medial eyelids and lateral lips, drain to the submandibular nodes. The middle two-thirds of the lower lip and the chin drain to the submental nodes. These nodes can be optimally palpated by performing a bimanual exam with a gloved hand feeling through the floor of the mouth.

The lymph nodes of the head and neck eventually drain into a terminal series of nodes (deep cervical nodes) and finally into the lateral internal jugular chain.

PREOPERATIVE ASSESSMENT

Preoperative assessment is critical for a successful procedure. It allows one to anticipate and possibly correct factors that predispose to adverse outcomes and minimize complications. A fairly thorough medical, drug, and medication allergy history provides an accurate picture of the patient's health status. Questioning the possibility of pregnancy in women of childbearing age should not be overlooked, as local anesthetics and antibiotics may be contraindicated. Patients with inherited bleeding disorders can also be identified and, when possible, given clotting factors to correct for these disorders. Uncontrolled hypertension may predispose to increased intraoperative and postoperative bleeding. In addition, poorly controlled diabetes and immunosuppression with use of systemic steroids for medical conditions, such as autoimmune disorders or organ transplantation, may affect healing time. Information from the social history can also have a bearing on the surgery. For instance, healing can be adversely affected if the patient smokes, and this may impact the decision to perform a flap or graft. Alcohol consumption can increase the risk of bleeding because of its qualitative effect on platelets. Finally, knowledge of the patient's resources and support at home is helpful when providing instructions for postoperative care.

ANTIBIOTICS

A well-planned and executed surgical procedure can be significantly compromised by an infection. Infections can lead to poor cosmesis, inconvenience, added expense, and patient dissatisfaction. Because every surgical procedure violates the epidermal barrier, no surgical procedure is absolutely sterile. Hence, all surgical wounds are contaminated by bacteria because of the inevitable resident flora in humans. However, not all contaminated wounds become infected. Infection depends on a large number of factors: the pathogenicity of the microbe, the quantity of the microbe, the length of surgery/timing of infection, the presence of foreign material (sutures, devitalized tissue), presence of dead space, poor suturing/surgical technique, poorly designed reconstruction, compromised vascular supply, and the host and wound's resistance to infection. Usually a wound that contains greater than 10^5 bacteria per gram of tissue is considered infected.[3] The American College of Surgeons has defined wounds as: clean (nontraumatic, without break in aseptic technique), clean-contaminated (minor break in aseptic technique, wounds in oral cavity, axillae, perineum), contaminated (acutely inflamed, major break in aseptic technique), and dirty (encountering pus, fecal, or urinary discharge). Antibiotics can be considered for some clean-contaminated, contaminated, and dirty wounds. Most wounds in dermatologic surgery are clean-contaminated wounds and do not require antibiotics. The most common organism is *Staphylococcus aureus* and a first generation cephalosporin (or clindamycin for the penicillin allergic) is appropriate when necessary. Studies show that to prevent or change the course of infection, antibiotics must be given within 2–3 hours after inoculation and that antibiotics give maximal suppression against infection if given before bacteria colonize tissue. In addition, there is concern that, with increasing time, the wound is sealed off with blood clots and fibrous exudates, and the antibiotic is unable to reach the wound effectively. Routine use of antibiotics postoperatively is discouraged due to the risk of encouraging the development of antibiotic resistance amongst bacteria.

Although specific criteria for the use of prophylactic antibiotics to prevent endocarditis do not exist for dermatologic procedures, most dermatologic surgeons follow the revised American Heart Association guidelines. Cardiac conditions for which prophylaxis is reasonable include prosthetic cardiac valve, previous infective endocarditis, congenital heart disease (limited particularly to unrepaired cyanotic congenital heart disease, completely repaired congenital heart defect with prosthetic material during the first 6 months after the procedure, repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device) and cardiac transplantation recipients who develop cardiac valvulopathy. Appropriate antibiotic regimen for prophylaxis for cutaneous procedures is 2 g of cephalexin (or 600 mg of clindamycin in penicillin-allergic patient) 1 hour before the procedure.[4]

MEDICATIONS

The use of blood anticoagulants, such as warfarin, dipyridamole, clopidogrel, and aspirin, are common in the aging population. In the past, patients were often told to discontinue their blood thinners before surgery. However, recent reports show that discontinuing these medications prior to dermatologic surgery can lead

to episodes of thrombotic events such as stroke and pulmonary embolism.[5] Furthermore, remaining on such medications does not lead to significant adverse events. However, patients who are taking aspirin and other nonsteroidal anti-inflammatory drugs for non-physician-recommended "preventive" purposes are advised to discontinue these drugs preoperatively. These agents are typically withheld for 7–14 days prior to surgery.

Many patients may be taking herbal or over-the-counter drugs that also interfere with clotting. These are not often considered "drugs" by patients, and thus they may not volunteer taking such supplements unless they are specifically asked. Some common preparations in this category include vitamin E, garlic, gingko, ginseng, feverfew, or ginger. Alcohol can also interfere with platelet aggregation, and it is important to instruct patients to avoid drinking a few days before and after the surgery. Most dermatologic surgeons advise patients to avoid alcohol, herbal products, and nutritional supplements several days before surgery.

Nonselective β blockers (i.e., propanolol) can occasionally potentiate the effect of epinephrine and lead to complications such as malignant hypertension and bradycardia.

Other preoperative considerations include latex allergy or allergy to topical antibiotics or adhesives in tapes. Use of systemic steroids can prolong the wound healing time.

PACEMAKERS AND DEFIBRILLATORS

Electrosurgery is widely used in dermatologic surgery to obtain hemostasis. However, electrosurgery can disrupt the function of pacemakers and implantable cardioverter-defibrillators (ICDs) by oversensing, inhibiting firing, device reprogramming, battery depletion, or direct damage to the device.[6] Thus, it is important to identify patients with such devices and to use proper precautions. Fortunately, newer pacemakers and ICDs have improved shielding and are more resistant to the electromagnetic interference that can be produced by electrosurgery. ICDs are more sensitive to electromagnetic interference, and this interference can cause the defibrillator to discharge, leading to significant morbidity and possible mortality for the patient. If electrosurgery is necessary, recommendations, such as using short bursts of electricity (less than 5 seconds) and avoiding its use directly around the area of the pacemaker, may minimize risks. In addition, bipolar electrosurgery creates little interference and is safer. Heat cautery does not cause any interference and is the safest but is not as effective for hemostasis with larger or complicated procedures.

SMOKING

Smoking should also be discussed preoperatively with patients. Tobacco use creates vasoconstriction, which impairs wound healing and jeopardizes the reconstruction, especially with more complicated procedures such as flaps and grafts. Patients should be strongly encouraged to cease tobacco use at least 1 week before surgery and 1 week postoperatively. It is also important to clarify that a nicotine patch is not ideal, and patients must avoid nicotine exposure through patches or gum.

SURGICAL HISTORY

A discussion of scars and healing after previous procedures can be informative for the patient and surgeon. The physician can determine if the patient is predisposed to forming hypertrophic scars or keloids and plan reconstruction and postoperative care appropriately. The patient may have a misunderstanding of wound healing and feel that a well-healed visible scar on a high-tension area is a keloid. This can be an opportunity to anticipate patient expectations and educate them on the process of wound healing.

SURGICAL TECHNIQUE

SKIN PREPARATION AND ASEPTIC TECHNIQUE

The normal skin is colonized by a host of bacteria, primarily aerobic cocci. *Staphylococcus aureus* is the most common cause of cutaneous wound infections in dermatologic surgery. Other bacteria commonly identified on the skin include *Staphylococcus epidermidis, Pseudomonas, Propionibacterium,* streptococci, and micrococci. *Pseudomonas* is frequently the pathogen identified in infections of cartilaginous regions such as the ear. The aim of aseptic solutions is to significantly reduce the amount of normal bacterial flora, as complete sterilization of the skin is not possible due to the presence of bacteria in pilosebaceous units. The ideal antiseptic would be nonirritating, nontoxic, nonsensitizing, be effective against all resident and transient microbes, and long-lasting. In prepping the field, shaving the hair creates multiple superficial microabrasions in which bacteria may reside and is associated with an increased incidence of local wound infections. Hair removal, if needed, has the lowest risk of associated infection if done by clipping or depilatory agents.[7]

Iodophors, which act through oxidation of cell membranes by free iodine, are common topical antiseptics. The most common form of this antiseptic is povidone-iodine. This antiseptic has broad antimicrobial activity against both Gram-positive and Gram-negative bacteria, as well as fungi, viruses, and mycobacteria. Iodophors have bactericidal activity that persists for several hours after application. On contact with blood or serum, the bactericidal activity is lost, but some bacteriostatic activity is retained. This class offers relatively rapid onset of action with full bactericidal activity being achieved within 1–3 minutes for most bacteria. Side effects of povidone-iodine include allergic contact dermatitis, irritant contact dermatitis, and possible tissue necrosis with prolonged exposure to large amounts in open wounds.

Chlorhexidine also functions through disruption of cell membranes. It has broad antimicrobial activity with excellent Gram-positive coverage and very good Gram-negative activity. It has some degree of activity against viruses but little effect on mycobacteria or fungi. Chlorhexidine offers a more rapid onset of action than povidone-iodine, providing almost immediate bactericidal activity upon application, which persists for many hours after application. It provides superior decontamination of the skin as compared to iodophors with resulting decreased rates of postoperative infection.[8] As a result, chlorhexidine is preferred over povidone-iodine as a surgical antiseptic agent if the surgical site does not limit its usage. The primary side effect of chlorhexidine is the potential for ototoxicity and keratitis. As a result, it should not be used around the eyes or ears. Similar to iodophors, prolonged exposure of chlorhexidine in open wounds has been reported to be toxic to the tissue.

Isopropyl alcohol and ethyl alcohol are effective antiseptics for minor skin procedures. They function through the denaturation of microbial proteins. They display good activity against Gram-positive and Gram-negative bacteria, mycobacteria, viruses, and fungi. Alcohols have a rapid onset of activity at the site of application, but there is no persistence of this activity over time. The antimicrobial activity of alcohols is not as extensive as that of chlorhexidine or iodophors. In addition, the flammable nature of alcohols limits their use in procedure requiring electrocautery.

Hexachlorophene is rarely used as a skin antiseptic solution. It has excellent Gram-positive activity but limited activity against Gram-negative organisms or fungi. It is also readily absorbed through the skin and has the potential for neurotoxicity, especially in infants.

LOCAL ANESTHESIA

Effective anesthesia is critical to the successful performance of dermatologic surgery. The overwhelming majority of cutaneous surgical procedures can be performed with local anesthesia. Local anesthesia provides the benefits of rapid onset of action, ease of use, decreased cost, and minimal associated morbidity and mortality.

Nerves transmit stimuli through the opening of sodium channels, which results in an influx of sodium ions into the nerve cell. This influx results in depolarization of the axon generating an action potential. Local anesthetics exert their effect on nerves by blocking the sodium channels on nerve axons. This blockage inhibits depolarization and the formation of an action potential. Local anesthetics affect the smaller unmyelinated C-type nerve fibers, which carry the sensation of pain and heat, more rapidly and effectively than myelinated A-type nerve fibers, which transmit the sensation of pressure and innervate muscle fibers. Thus, adequate anesthesia can be achieved while motor function and pressure sensation are maintained.

Local anesthetics structurally are composed of three subunits: (1) a hydrophobic aromatic ring, (2) a hydrophilic amine group, and (3) an intervening group connecting the hydrophobic and hydrophilic units. The hydrophobic aromatic ring is responsible for the molecule's ability to diffuse through axonal membranes. The hydrophilic amine maintains the solubility of the compound in aqueous solution and accounts for blockage of the sodium channels of nerve axons. The region connecting the hydrophilic and hyphobic regions may be either an amide group or an ester group. Amide anesthetics, which include lidocaine, prilocaine, bupivacaine and mepivacaine, are metabolized in the liver through dealkylation and hydrolysis by microsomal enzymes. Ester anesthetics, which include procaine, benzocaine, tetracaine, and cocaine, are metabolized by plasma pseudocholinesterase and are excreted renally.

SELECTING THE APPROPRIATE ANESTHETIC

The nature of the procedure determines which local anesthetic is ideal (Table 242-1). The primary variables to consider in choosing between anesthetics are the onset of action and the duration of anesthesia. Patient factors to consider in this selection are a history of allergy to an anesthetic class or renal or hepatic impairment. For simple biopsies and excisions, a rapid-onset anesthetic, like lidocaine, with medium duration of action provides effective anesthesia. For more extensive procedures, an anesthetic with a longer duration of action, such as bupivacaine, may be desired. Some practitioners choose to mix a rapid-onset anesthetic with one of long duration into one injectable solution.

EPINEPHRINE

Local anesthetics, with the exception of cocaine, are vasodilators. This vasodilatory effect produces unwanted bleeding at the operative site. Epinephrine with its potent vasoconstrictive effects is often added to local anesthetic preparations to reduce bleeding. Concentrations ranging from 1:100,000–1:500,000 are effective in reducing bleeding at the surgical site. In addition to its hemostatic effect, epinephrine reduces the dispersion of the local anesthetic from the operative site. This prolongs the duration and efficacy of the anesthesia by 100%–150%. It also limits the potential for systemic toxicity, as less anesthetic is allowed to enter the systemic circulation.

Epinephrine is a potent agonist of α- and β-adrenergic receptors. Absolute contraindications to its use with local anesthetics are pheochromocytoma and hyperthyroidism. Relative contraindications to the use of epinephrine include severe coronary artery disease, uncontrolled hypertension, peripheral vascular disease, pregnancy, and acute angle glaucoma. In addition, epinephrine should be used with caution in patients on β blockers, monoamine oxidase inhibitors, phenothiazines, and tricyclic antidepressants as these individuals demonstrate greater sensitivity to its effects. Although uncommon, severe hypertension may be encountered in patients on β blockers due to the unopposed α-receptor stimulation of the epinephrine.

The use of epinephrine-containing local anesthetics on anatomic regions with minimal collateral circulation,

TABLE 242-1
Local Anesthetics

Generic Name	Primary Use	Relative Potency	Onset	Duration[a] Plain	Maximum[b] Dose Plain (mg)	Maximum[b] Dose with Epinephrine (mg)
Bupivacaine	Infiltration	8	2–10 minutes	3–10 hours	175	250
Dibucaine	Topical	—	Rapid	Short	—	—
Etidocaine	Infiltration	6	3–5 minutes	3–10 hours	300	400
Lidocaine	Infiltration/ topical	2	Rapid	1–2 hours	300	500 (3,850 dilute)
Mepivacaine	Infiltration	2	3–20 minutes	2–3 hours	300	400
Prilocaine	Infiltration	2	Rapid	2–4 hours	400	600
Prilocaine/ lidocaine	Topical	—	30–120 minutes	Short	—	—
Benzocaine	Topical	—	Rapid	Short	—	—
Chloroprocaine	Infiltration	1	Rapid	0.5–2.0 hours	600	—
Cocaine	Topical	—	2–10 minutes	1–3 hours	200	—
Procaine	Infiltration	1	Slow	1.0–1.5 hours	500	600
Proparacaine	Topical	—	Rapid	Short	—	—
Tetracaine	Infiltration	8	Slow	2–3 hours	20	—
Tetracaine	Topical	—	Rapid	Short	—	—

[a]In clinical practice, the duration of anesthesia appears to be less than stated above, especially for head and neck areas, and addition of epinephrine prolongs anesthesia by a factor of two.
[b]Maximum doses are for a 70-kg person.

such as the digits, penis, and nasal tip, is a matter of controversy. Reports of local tissue necrosis in these areas with limited perfusion attributed this result to the potent vasoconstrictive effects of the epinephrine. More recent observations indicate this necrosis to actually be the result of excessive volume of anesthetic used, which physically tamponades the vessels. Thus, local anesthetics with epinephrine are now considered safe for use on the digits, penis, and nasal tip, when used judiciously in small volumes. Consideration may be given to using a lower concentration of epinephrine (1:500,000) for those sites with severely limited perfusion.

Self-limited, systemic side effects may also be experienced with the administration of epinephrine-containing anesthetics. These include anxiety, fear, palpitations, tachycardia, diaphoresis, tremor, and hypertension. Serious side effects of excessive epinephrine administration include arrhythmias, cardiac arrest, and cerebrovascular hemorrhage. These serious side effects are extremely rare when used at appropriate dosages in individuals without significant contraindication.

SIDE EFFECTS

The most common side effect of local anesthetics is the pain of its administration. Premixed local anesthetic preparations containing epinephrine are manufactured as an acidic solution with a pH of between 3 and 5 in order to maintain the stability of epinephrine. Injection of this acidic solution into tissue often produces significant discomfort. To avoid this, the pH of the solution can be adjusted before injection closer to the physiologic pH of 7.4 through the addition of sodium bicarbonate. The standard formula for this is the combination of one part of 8.4% sodium bicarbonate with 10 parts lidocaine. This buffered solution must be used soon after preparation as the epinephrine gradually degrades at a rate of approximately 25% per week. Alternatively, the epinephrine and anesthetic may also be mixed immediately before use, which also provides a neutral solution. In each instance, the neutral or slightly alkaline solution has the added advantages of quicker onset of action and increased anesthetic effect as the pH of the solution is closer to the pKa of the anesthetic, meaning more of the anesthetic is in its active ionized cationic form.

Slow injection of the anesthetic through a small gauge needle (27 gauge to 30 gauge) also minimizes the pain of injection. Smaller syringes, such as 1–3 mL, create less pressure at the site of anesthetic administration. Based on the gate theory of pain perception, repeated pinching or vibration of the immediate surrounding area lessens the perception of the stick at site. Verbal distraction of the patient is also useful in lessening the anxiety and discomfort of the anesthetic.

Injection of anesthetic into the subcutaneous tissue is less painful than injection into dermal tissue; however, a quicker onset of action and longer duration of anesthesia are observed with dermal injection. If a large area is to be anesthetized, the initial injection should be placed near the origination of sensation and proceed distally. Subsequent injections, if necessary, should be made through previously anesthetized tissue. For large areas, consideration should also be given to the use of nerve blocks to minimize discomfort.

One side effect of local anesthetic administration that is not uncommon is the vasovagal reaction. This may be manifested as pallor, weakness, bradycardia, hypotension, diaphoresis, and nausea. Placement of the patient in Trendelenburg position usually results in complete resolution of these symptoms within several minutes. A cool compress on the forehead and fanning the patient are often helpful in comforting the patient during this episode. Patients should be injected in a recumbent or Trendelenburg position to minimize the likelihood of a vasovagal response. These positions also allow providers to be better prepared to deal with the reaction should it occur. Pain and anxiety of anesthetic injection can precipitate a vasovagal reaction; thus, the aforementioned techniques for lessening the discomfort of injection are critical in reducing the likelihood of a vasovagal response.

Allergy to a local anesthetic is an uncommon side effect in dermatologic surgery. Amide anesthetics are more likely to be the culprit of allergic reactions whereas allergic reactions to ester anesthetics are exceedingly rare. True allergic reactions are typically immediate type I immunoglobulin E-mediated reactions, which may produce urticaria, angioedema, bronchospasm, tachycardia, hypotension, and, possibly, cardiovascular collapse. For severe reactions, administration of epinephrine and cardiopulmonary support is indicated. Less commonly, type IV-delayed hypersensitivity reactions may be observed. These present similar to an allergic contact dermatitis in the days following the injection of the anesthetic.

For those patients in whom an allergy to an anesthetic is unclear, intradermal prick testing to ester anesthetics, amide anesthetics, and any added preservatives, such as sodium metabisulfite and methylparabens may be helpful. Alternatively, for smaller procedures, the intradermal injection of diphenhydramine hydrochloride solution provides temporary anesthesia without risk of an allergic response. Antihistamine side effects, including significant drowsiness, may be encountered with its use. The intradermal injection of normal saline with preservative may also be used for very brief procedures. The temporary anesthesia it provides is attributed to a combination of the tamponade effect on nerves and the mild anesthetic effect of the preservative benzoyl alcohol.

Anesthetic toxicity is a rare complication given the typical volumes required for dermatologic surgery. Signs of toxicity are usually not observed with dosages less than 5.0 mg/kg of plain lidocaine and 7.0 mg/kg of lidocaine with 1:100,000 epinephrine. For tumescent anesthesia, the maximum safe dose increases to 55.0 mg/kg of 0.05% –0.1% lidocaine with 1:1,000,000 epinephrine. The initial presenting signs are circumoral numbness and tingling, tinnitus, lightheadedness, nausea, and numbness of the distal extremities. With additional anesthetic, more extensive central nervous system depression may occur with hallucinations, seizures, and respiratory depression. Cardiovascular toxicity may also occur, but does so at much higher levels of anesthetic than the initial central nervous system toxicity. The manifestations include hypotension, arrhythmias, and cardiac arrest.

Both central nervous system and cardiovascular toxicity are directly related to serum levels of the anesthetic. Thus, direct intravenous or intra-arterial injection is to be avoided when anesthetizing an area. This can be done by drawing back on the syringe after needle insertion prior to infiltration of the anesthetic to confirm that the needle is not in a vascular structure. The risk of toxicity can be elevated by other medical problems affecting the metabolism of the anesthetic. In particular, patients with liver disease experience increased serum levels of amide anesthetics due to an impaired ability to metabolize and clear the anesthetic. Thus, a lower dosage of an amide anesthetic or a switch to an ester anesthetic is advisable in these patients.

TOPICAL ANESTHETICS

Several local anesthetics are also available as topical preparations. When used properly, these agents provide suitable anesthesia for minor dermatologic procedures, such as shave biopsies or superficial laser treatments. Their efficacy on normal skin is limited by their ability to penetrate the stratum corneum. Thus, most of the preparations require extended application times and/or occlusion for effectiveness.

LMX is a topical lidocaine cream in a liposomal vehicle. It is available in 4% and 5% concentrations. Eutectic mixture of local anesthetics (EMLA) cream consists of a combination of 2.5% lidocaine and 2.5% prilocaine. LMX and EMLA have been shown to be more effective than other topical preparations of 4% tetracaine gel and Betacaine-LA (a mixture of prilocaine and lidocaine in a liquid paraffin ointment). LMX typically requires an application time of 30 minutes with or without occlusion, whereas EMLA requires 1 hour with occlusion. Multiple studies have demonstrated the 30-minute application of LMX without occlusion to provide equal anesthesia as 1-hour application of EMLA with occlusion. Caution should be exercised in the use of large amounts of prilocaine-containing topical preparations in infants or those with an impaired skin barrier, as prilocaine has the potential to induce methemoglobinemia.

Cryogens, such as ethyl chloride, also provide brief anesthesia at a site for minor procedures or the insertion of a needle. Similarly, an ice cube placed on an injection site often significantly reduces the discomfort of injection in the anxious patient.

Mucosal membranes are readily anesthetized using topical preparations due to the ease of penetration in the absence of a stratum corneum. Tetracaine or proparacaine drops rapidly provide effective anesthesia of

the conjunctiva and cornea for insertion of eye shields. Benzocaine and lidocaine preparations provide prompt anesthesia for intraoral procedures or before nerve blocks.

NERVE BLOCKS

The use of regional nerve blocks can be of immense value to the dermatologic surgeon. Regional nerve blocks allow large cutaneous areas to be anesthetized with small volumes of anesthetic. They are based on the injection of a local anesthetic into the immediate vicinity of a sensory nerve as it emerges from deeper planes of tissue. This provides effective anesthesia for the patient while minimizing the discomfort of multiple injections. Nerve blocks have the added benefits of limiting the possibility of anesthetic toxicity as well as minimizing tissue distortion. The primary risk of nerve blocks is nerve trauma with resultant neuropraxia.

The standard anesthetic used for regional blocks is 1% lidocaine with 1:100,000 epinephrine; however, bupivacaine may be added if more lasting anesthesia is desired. A 1 inch, 30 gauge is suitable for the performance of most nerve blocks. The proper execution of nerve blocks is predicated on a thorough knowledge of the anatomy of the region being anesthetized.

The cutaneous sensation of the face is primarily supplied by the trigeminal nerve, with a small fraction of the periphery being supplied by the cervical plexus. As its name implies, the trigeminal nerve consists of three major divisions: (1) the ophthalmic (V_1), (2) maxillary (V_2), and (3) mandibular (V_3) divisions. Each of these divisions has major branches, which are amenable to regional nerve blocks.

The ophthalmic division of the facial nerve gives off the supraorbital, supratrochlear, and infratrochlear nerves. The supraorbital nerve exits through the supraorbital foramen, which is a readily palpable bony notch located along the orbital rim just medial to the midpupillary line. The supratrochlear branch exits along the orbital rim approximately 1.5 cm medial to the supraorbital notch. The infratrochlear nerve exits just above the medial canthus. All three of these branches can be anesthetized with a single injection by inserting the needle 2–3 mm lateral to the supraorbital notch and advancing medially through the subcutaneous tissue to the medial canthus. The anesthetic is then injected as the needle is slowly withdrawn in one smooth motion. This single injection provides anesthesia to the ipsilateral forehead, frontal scalp, upper eyelid, medial canthus, and superior nasal sidewall and root.

The infraorbital nerve, a branch of the mandibular division, exits through the infraorbital foramen, which is located in the midpupillary line approximately 1 cm below the infraorbital rim. This nerve may be blocked by either an intraoral or a percutaneous approach. The percutaneous method involves insertion of the needle directly over the infraorbital foramen and advancement directly down to the maxillary bone, where the anesthetic is delivered. With the intraoral approach, the sulcus located just above and lateral to the canine tooth is identified by manual palpation. The needle is inserted in the superior portion of this sulcus and advanced upward approximately 1 cm in the midpupillary line. At this position, the anesthetic is slowly injected. The intraoral approach is less painful than the percutaneous one, and may be further aided by the use of a topical lidocaine or benzocaine gel on the oral mucosa. This block provides anesthesia to the ipsilateral lower eyelid, medial cheek, upper lip, and upper teeth.

The mental nerve is a branch of the mandibular division, which exits through the mental foramen just medial to the midpupillary line. This nerve is easily accessed via an intraoral injection. It is located just opposite of the first bicuspid on the mucosa of the lower lip, and is often visible to the naked eye as a thin glistening white strand. It is anesthetized with an injection in the immediate vicinity of its inferior portion. This provides anesthesia to the ipsilateral lower lip and chin.

In addition to the above branches, there are other branches of the trigeminal nerve that are also amenable to regional nerve blocks. These include the buccal, auriculotemporal, anterior ethmoidal (external nasal branches), and zygomaticotemporal nerves. A block of the greater auricular nerve off the cervical plexus provides anesthesia to the posterior auricle and angle of the mandible.

Nerve blocks can be a valuable tool for nonfacial locations as well. In particular, digital nerve blocks are very useful for procedures involving the digit or nail unit. The cutaneous sensation of a digit is supplied by two nerves coursing down each of the lateral aspects of the digit. For a block, the needle is inserted perpendicularly into the lateral aspect of each side of the digit and advanced until bone is reached. At this position, a small volume of anesthetic is administered. The delivery of a large volume (greater than 1 mL) of anesthetic in the digits can result in tamponade of the digital circulation with subsequent necrosis. This tamponade effect now appears to be more critical factor in cases of digital necrosis than the use of epinephrine.

ELECTROSURGERY AND ELECTROCAUTERY

(See Chapter 246)

SUTURE MATERIALS. The proper selection of suture material for any dermatologic procedure is vital to its successful outcome. There are several intrinsic characteristics of each suture material, which will influence this selection process (Table 242-2). Sutures are produced in both absorbable and nonabsorbable forms. An absorbable suture is classified as one, which loses half of its tensile strength within 2 months. Absorbable sutures are primarily used for the approximation of dermal and subcutaneous tissue. As wounds have achieved less than 10% of their final tensile strength at 2 weeks, these sutures maintain the structural support of wounds during the initial healing phase. The time that a suture maintains its tensile strength is dependent on the material of which it is composed.

TABLE 242-2
Suture Materials

	Type	Memory	Tissue Reactivity	Tensile Strength Half-Life
Nonabsorbable				
Cotton	Twisted	Low	Very high	—
Nylon	Monofilament	High	Low	—
Nylon	Braided	Low	Low	—
Polybutester	Monofilament	High	Low	—
Polyester, uncoated	Braided	Low	Low	—
Polyester, coated	Braided	Low	Low	—
Polypropylene	Monofilament	Very high	Very low	—
Silk	Braided/twisted	Very low	High	—
Stainless steel	Monofilament/braided/twisted	Very high	Very low	—
Absorbable				
Catgut, fast absorbing/mild chromic	Twisted	Very high	High	2 days
Catgut	Twisted	Very high	High	4 days
Catgut, chromic	Twisted	Very high	High	1 wk
Polyglactin 910	Braided	Very low	Low	2 wk
Polyglycolic acid	Braided	Very low	Low	2 wk
Poliglecaprone 25	Monofilament	Low	Very low	1 wk
Polyglyconate	Monofilament	Low	Very low	1 mo
Polydioxanone	Monofilament	High	Very low	1 mo

Data from Melton JL, Hanke WC: Wound closure materials. In: *Principles and Techniques of Cutaneous Surgery*, edited by GP Lask, RL Moy. New York, McGraw-Hill, 1996, p. 77; and Garrett AB: Wound closure materials. In: *Cutaneous Surgery*, edited by RG Wheel. Philadelphia, Saunders, 1994, p. 199.

Nonabsorbable sutures are predominantly used for external suturing with subsequent removal in the days after the procedure. In this instance, these sutures are used more for fine epidermal approximation than structural support. On occasion, nonabsorbable sutures are also used for the placement of subcutaneous tissue, muscle, and fascia, when a more permanent placement of the tissue is desired.

Sutures are produced as monofilaments (single-strand) or multifilaments (multiple-braided strands). Monofilaments offer the advantage of increased ease of pull-through tissue, less risk of infection, and decreased tissue reactivity. The disadvantage of monofilaments is the increase in memory, or the tendency for a material to revert to its original shape. This memory results in decreased ease of handling of the suture and decreased knot security for monofilaments. Multifilaments, or braided sutures, offer ease of handling and increased knot security. However, the strands of a multifilament have the capability to trap fluid and bacteria resulting in an increased risk of infection with their use.

In general, the smallest suture, which provides adequate tensile strength for a defect, should be utilized. Suture size is measured in multiple of zeros based upon the diameter of the suture material. The higher the number preceding the zero, the smaller the diameter of the suture. Typically, 5-0 and 6-0 sutures are used on regions of low tension, such as the face, eyelids, and ears. Areas of higher tension, such as the trunk, extremities, and scalp, require 3-0 and 4-0 sutures. Areas of intermediate tension, such as the neck, may be closed with either 4-0 or 5-0 sutures. There are a wide range of needles whose nomenclature varies with manufacturer. In general, most skin surgery procedures are best performed with plastic surgery needles.

SUTURING TECHNIQUE.

Meticulous suturing technique is fundamental to obtaining excellent aesthetic and functional results. Properly placed sutures allow for approximation of wound edges, wound-edge eversion, minimization and redistribution of tension, elimination of dead space, maintenance or restoration of natural anatomic contours, and avoiding permanent suture marks on the skin surface. The suturing technique selected for a specific wound closure depends on the anatomic location, tension, thickness of the wound edges, and goals of the surgeon.

Interrupted Sutures.

The simple interrupted suture is the most basic and versatile suture used by dermatologic surgeons. Absorbable, buried interrupted sutures are used as part of the layered wound closure. These sutures provide support for the wound until tensile strength has increased sufficiently to prevent wound dehiscence and reduce tension on the wound edges. To achieve good eversion of the wound edges, these are best placed in the deep dermis and subcutis in a heart-shaped configuration (Fig. 242-8).[9] Wounds in which one skin edge appears higher than the other can be appropriately aligned by taking a larger bite from the lower edge and a smaller, more superficial bite from the higher edge.

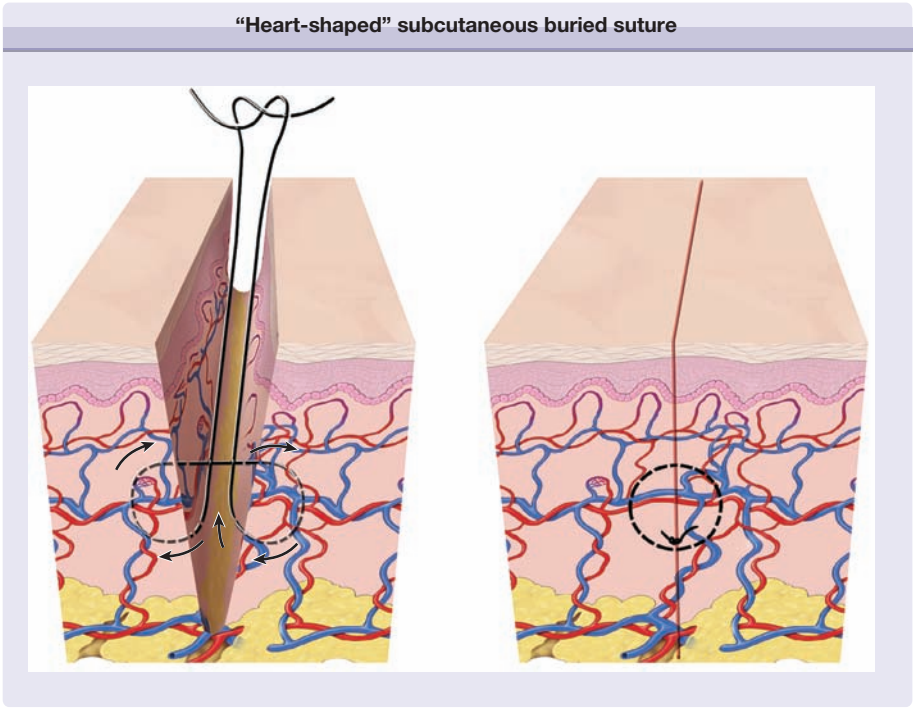

Figure 242-8 "Heart-shaped" subcutaneous buried suture.

Epidermal simple interrupted sutures, used to obtain optimal alignment of the epidermal edges of the wound, are more time-consuming to place and remove than continuous running sutures. In settings where wound healing may be impaired because of the patient's underlying medical condition or in areas of high tension, interrupted sutures may be preferred. This type of suture usually provides greater tensile strength and less potential to cause edema, induration, and impaired microcirculation than running sutures. In addition, in areas of high tension, the risk of wound dehiscence can be assessed by removing alternate sutures. If it seems that dehiscence is likely, the remaining sutures may be left in place for 3–4 additional days.

The vertical mattress suture provides wound-edge eversion, reduces dead space, and minimizes tension across the wound (Fig. 242-9). It achieves the same effect as a buried dermal suture and an epidermal suture. Because this suture requires four entry points in the skin, significant crosshatching can be expected if the suture is not removed within 5–7 days. This suture by nature is a tightly placed suture and can be difficult to remove because of its tendency to become embedded in the skin.

The horizontal mattress suture has been used to reduce tension across wound closures that are under significant tension (Fig. 242-10). This technique also creates wound eversion. This suture can be placed as an initial tension-reducing or -holding suture and to bring the wound edges closer together, so that subcutaneous sutures can be placed to distribute tension and close the wound. At this point, if the tension has been adequately distributed, the horizontal mattress suture may be removed. If tension across the wound persists, the horizontal mattress suture may be left in place for a few days while early wound healing proceeds and removed before suture tracks have had a chance to form. The main disadvantage of this suture is the possibility of wound-edge necrosis as this suture can easily strangulate the dermal plexus between its limbs. This problem is minimized by taking large bites with the needle to encompass large amounts of tissue, by using bolsters, by tying the suture only as tight as necessary to accomplish the task of bringing the wound edges together, and by removing the suture as soon as possible. Before contemplating the use of a horizontal mattress suture for tension reduction, the surgeon should consider other means of reducing tension across the wound, including appropriate use of undermining and closure orientation, flaps from areas of tissue excess, preoperative or intraoperative tissue expanders, serial excisions, and subcutaneous sutures.

The half-buried horizontal mattress suture is primarily indicated for the positioning of various corners and tips including flap tips, M-plasty tips, and V-Y closure tips. It can also align the edges of tangential flaps and flaps with ischemic wound edges. The buried limb of this suture is placed in the potentially ischemic area in order to minimize interference with the dermal vascular plexus. A superficial simple interrupted suture through a flap tip may also work without resulting in increased risk of flap tip necrosis.

Running Sutures. The simple running suture can be used in situations where the wound edges are of equal thickness without tension, closely approximated, and with an absence of subcutaneous dead space. This suture is most useful for wounds that have already

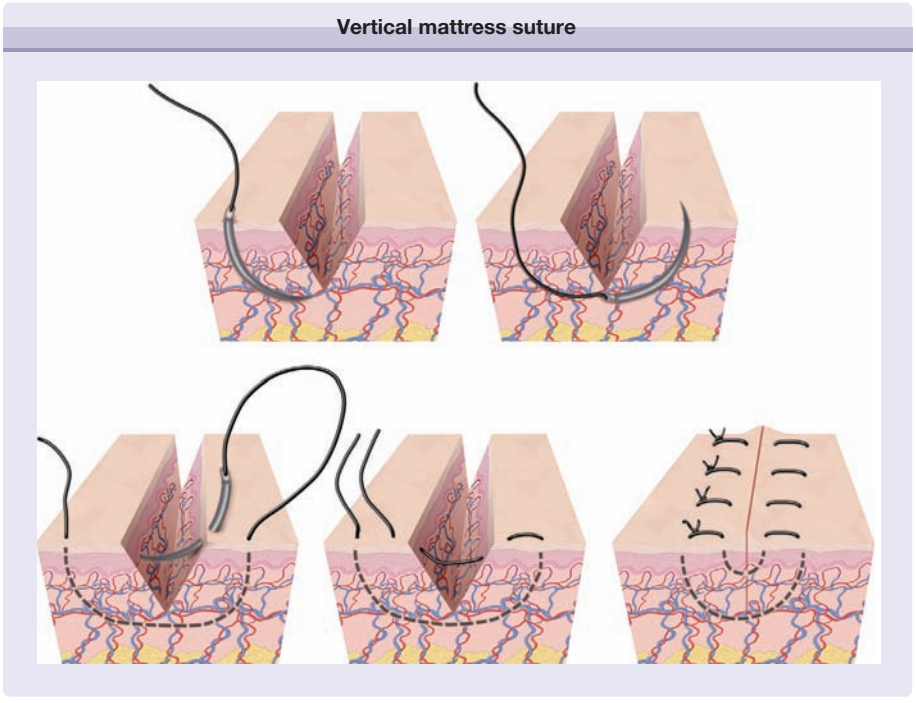

Figure 242-9 Vertical mattress suture.

been closed by buried sutures, for the attachment of full-thickness or split-thickness skin grafts, and in areas of thin skin such as the eyelids, ears, neck, and scrotum. By eliminating all but two knots, there is less suture material resting against the skin, resulting in the development of fewer scars from suture marks. However, fine adjustments along the suture line are difficult to make and the suture has a tendency to pucker when very lax and thin skin, such as eyelid skin, is being sutured. In thin skin, the knots at each end may be tied over small bolsters to prevent them from cutting into the tissue.

The running locking suture is a variant of the simple running suture in which, after the placement of each loop, the needle is passed through the previous loop prior to starting the next loop. It is intended for the closure of well-vascularized wounds under a moderate amount of tension. The wound edges should be stiff and of equal thickness without a tendency for inversion. It is stronger than a simple running suture. However, if it is placed too tightly or if significant postoperative swelling develops, tissue strangulation with wound-edge necrosis may ensue.

The running subcuticular suture is a buried running suture that is usually not absorbable. It is ideal for the closure of wounds in areas such as the trunk and extremities where the suture must remain in place for more than 7 days. As the suture is buried, there are no suture marks and the suture may be left in place for several weeks, even months. When

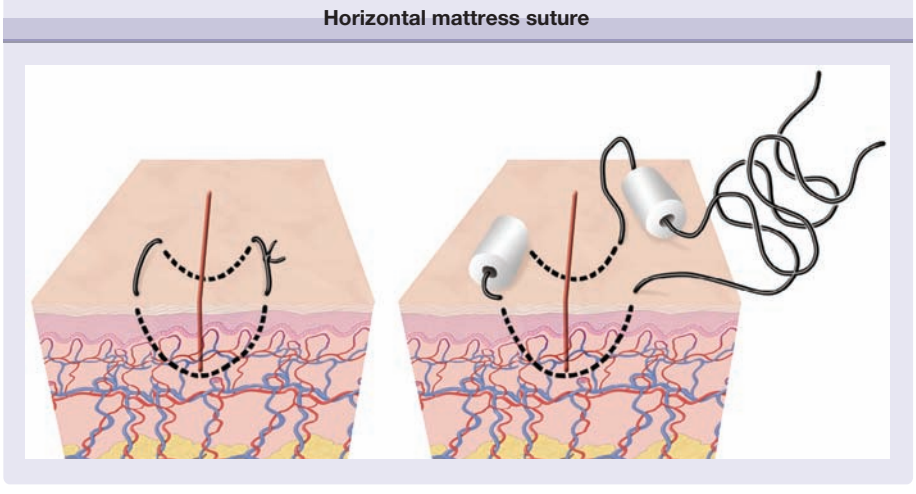

Figure 242-10 Horizontal mattress suture.

absorbable suture material is used, it may be left in place until it is absorbed. As this suture is capable of only modest wound-edge alignment, it should be reserved for wounds in which the tension has been eliminated with deep sutures and the wound edges, of approximately equal thickness, are closely approximated. The running subcuticular suture should be placed with a nonreactive monofilament suture such as polypropylene to facilitate suture removal and prevent suture breakage within the wound. Some surgeons use a permanent suture left in place indefinitely, as this can reduce scar stretching. If nonabsorbable sutures are selected clear, nonreactive suture material should be used.

SUTURE REMOVAL. Timing of suture removal must balance two factors: (1) leaving the sutures in place long enough to allow wound healing and prevent dehiscence and (2) removal before the development of suture track marks along the scar line. These suture track marks occur because reepithelialization occurs around the suture. In general, the less the blood supply to an area and the greater the tension across a wound, the longer the sutures should be left in place. On the face and ears, most skin sutures should be removed within 5–7 days. Eyelid sutures can be removed in 3–5 days. Neck sutures should be removed in 7 days and scalp sutures in 7–10 days. On the trunk and extremities, risk of wound dehiscence takes precedence over suture marks. Sutures on the trunk and upper extremities should be left in place for 7–14 days. Lower extremities may require up to 21 days of suture support, though, with proper deep suture placement, epidermal sutures can generally be removed in 7–10 days.

Absorbable sutures are not removed, but some patients develop suture reactions, consisting of sterile suture abscesses and suture extrusion through the wound. If this happens, the suture should be picked up carefully with small forceps and cut out of the wound. Any purulent material should also be drained.

STAPLE CLOSURE. Staple closure of wounds is an alternative to suture closure. The staples have the advantage of very quick placement, minimal tissue reaction, and very strong wound closure. Staples are most often used with long wounds, especially on the scalp, where the suture line is hidden by scalp hair. Potentially contaminated wounds that are closed with staples appear to be more resistant to infection than wounds closed with sutures. Staples provide efficient wound closure; but when exact wound-edge alignment is required, sutures should be used. Staples are easily removed with a staple remover.

POSTOPERATIVE CARE

Most wounds can be cleaned appropriately with tap water and mild soaps. A diluted acetic acid solution can be helpful to prevent *Pseudomonas* infection in sites predisposed to this. Small amounts of hydrogen peroxide can help debride wounds that have developed significant crusting and exudate. However, in large amounts, hydrogen peroxide can be toxic to the development of new cells and thus inhibit wound healing. Most wounds are also best dressed with petrolatum and a nonadherent dressing. Petrolatum is relatively inert, nontoxic, nonsensitizing, and nonirritating. Although not common knowledge for the layperson, it has been well proven for years that covered or occluded wounds reepithelialize and heal faster than dry wounds.[10] There is a significant risk for allergic contact dermatitis with topical antibiotics, and they have not been shown to be superior to petroleum jelly in preventing wound infections. For wounds with significant drainage, dressings such as gauze, foam dressings, or alginates provide absorption.

Chapter 243 :: Excisional Surgery and Repair, Flaps, and Grafts

:: Jessica M. Sheehan, Melanie Kingsley, & Thomas E. Rohrer

EXCISIONAL SURGERY AND REPAIR, FLAPS, AND GRAFTS AT A GLANCE

- Excisional surgery is one of the most common surgical procedures in dermatology
- The goal of excisional surgery is to remove the lesion with appropriate margins and obtain the best cosmetic result.
- The planning and execution of dermatologic surgery procedures must balance risk and benefit and consider all options to achieve a particular outcome. Wounds should be closed under minimal tension, with scars placed along cosmetic unit junctions or skin tension lines, without distorting critical anatomic structures and landmarks.
- The closure must preserve sensory and motor nerve function.
- An elliptical or fusiform excision is the fundamental procedure in dermatologic surgery and typically allows for a linear, side-to-side closure.
- Flap or graft repair may be considered when linear closure is not feasible.
- Flaps are commonly classified according to their primary movement as advancement, rotation transposition, or interpolation.
- The three basic types of skin grafts are full-thickness, split-thickness, and composite.

The goal of any excisional surgery is to remove the lesion with appropriate margins and leave the least noticeable scar possible. In order to consistently attain aesthetically pleasing results, time must be taken long before the first incision to appropriately plan the procedure. While excisional surgery is as much an art form as it is a science, there are many principles to keep in mind when planning the surgical excision and closure. Wounds should be closed under minimal tension, with scars placed along cosmetic unit junctions or skin tension lines, without distorting critical anatomic structures and landmarks (eyelid, eyebrow, nose, lip, hairline, etc.). Biologically, the closure must be such that the mobilized skin and associated adenexal structures are viable, and there is maximal preservation of sensory and motor nerve function.

Knowledge of underlying anatomy is critical in both the design and execution of the excision (see Chapter 242).

The planning and execution of dermatologic surgery procedures varies from case to case. A skilled surgeon evaluates the risks and benefits of various options in each patient and anticipates potential complications. Key elements of dermatologic surgery procedures include proper patient selection and preparation; comprehension of risks and necessary precautions; obtaining effective local anesthesia; use of sterile or clean technique; informed procedure design and meticulous technique in performing the incision and repair; diligent postoperative wound care and patient education.

RISKS AND PRECAUTIONS

It is important that both the patient and practitioner be aware of the risks of dermatologic surgery. In fact, professional standards dictate that these risks be documented for proper patient consent.[1] The main risks of excisional surgery include pain and discomfort; bleeding, bruising, and hematoma formation; nerve damage; wound infection; wound dehiscence; and undesirable scar or contracture.

- While the injection of local anesthesia is not without pain, there are several ways to minimize the discomfort. Some of the most effective ways to diminish pain on injection is the addition of sodium bicabonate to the anesthetic agent, using small-gauge needles, inserting the needle into the skin through a pore, and injecting very slowly and into the subcutaneous tissue. In addition, starting at the proximal aspect of the neural innervation and working distally will help minimize discomfort. Postoperative pain is typically minimal and controlled with over-the-counter analgesics such as acetaminophen. Meticulous operative technique will also help minimize postoperative pain. More severe pain may require the prescription of narcotics.
- Excessive bleeding, subsequent bruising, and possible hematoma formation are also risks. Most dermatologic surgeons now recommend that medically necessary anticoagulation, including aspirin, clopidogrel, heparin, and warfarin, be continued perioperatively.[2] Herbal supplements such as ginseng or garlic, vitamin E, aspirin, and nonsteroidal anti-inflammatory agents that are not prescribed by

a physician should be discontinued 2 weeks prior to surgery if possible.[2] The consumption of alcohol should also be restricted immediately before and after the procedure. Meticulous hemostasis with electrocautery or coagulation, ligation of larger arteries, and the application of a compression bandage minimize the risk of bleeding.

- Risk of infection exists whenever the skin barrier is breached. Wound infection is relatively uncommon[3] and occurs more frequently in particular patient populations, such as those who are diabetic, smokers, or immunosuppressed, and at certain surgical sites, such as the ear or lower leg.[4] Sterile technique and atraumatic tissue handling minimizes this risk. Prophylactic antibiotics may be administered for high-risk patients, or if the wound base or suture perforates into nonsterile areas, such as the nasal or oral cavities. Guidelines for antibiotic usage are outlined in Table 243-1).
- Wound dehiscence occurs in wounds under high tension, or in cases of poor wound healing or infection. This risk is reduced by proper planning of the closure, the use of buried subcutaneous sutures, fascial plication to relieve tension on wound edges where indicated, and minimizing activity and immobilization of the wound edges for 1 to 2 weeks after surgery.
- Undesirable scars are always a possibility. While many steps can be taken to minimize the appearance of the final scar, it is important for the patient to understand that all excisional surgery will result in the formation of some form of a scar. Many factors must be considered with respect to formation. Free margins must be respected and never distorted. Closures are best hidden when they are placed on along cosmetic unit junctions and contained in as few cosmetic units as possible. The long axis of the excision and/or design of a repair should

TABLE 243-1

Guidelines[a] for Patient Selection for Antibiotic Prophylaxis for the Prevention of Endocarditis and Prosthesis Infections as well as Surgical Site Infections

Risk Stratification for Endocarditis and Prosthesis Infection

High-Risk Patient	Low-Risk Patient
History of bacterial endocarditis	History of CABG surgery
Prosthetic valve	Pacemaker, defibrillator
Any cardiac valvular dysfunction Hypertrophic cardiomyopathy	No valvular dysfunction (including history of rheumatic fever or Kawasaki disease)
Mitral valve prolapse with regurgitation, all mitral valve prolapse in men >45 years	Mitral valve prolapse without regurgitation Physiologic heart murmur
Cardiac malformation	Atrial septal defect or ostium secundum
CNS shunts	>6 mon since repair of ASD, VSD, PDA
Shunt/fistula near inflamed/infected tissue	Arterial grafts/stents
Orthopedic prosthesis	Nonorthopedic prosthesis (i.e., penile prosthesis, breast implants)

Antibiotic Prophylaxis for the Prevention of Endocarditis and Prosthesis Infection

Risk	Procedure	Skin Condition	Location	Prophylaxis
High	Mohs	Any	Any	Yes
High	Excision, biopsy, ED&C, ablative laser, cryotherapy	Intact or eroded[a] Infected/Inflamed	Skin Mucosa Any	No Yes Yes
Low	Any	Any	Any	No

Potential Antibiotic Prophylaxis for the Prevention Surgical Site Infection

Inflamed or infected skin close to surgical site
Flap or graft reconstruction on nose and ear
High-tension closures
Below-the-knee procedures
Hand surgery
Multiple simultaneous procedures
Mucosal/anogenital sites in immunocompromised patients

[a]Unless prosthetic valve.

be placed in the direction of rhytides or relaxed skin tension lines. It is best to plan an excision with the patient in an upright position, and animation using the underlying muscles of facial expression may also be helpful. On the trunk or extremities, the direction of skin tension may be tested by moving/pinching the area. The incision should be made perpendicular to the skin surface, and an even depth of resection and undermining across the base of the wound should be maintained. Remove standing cones of redundant tissue. Buried vertical mattress sutures should be placed to attain good wound eversion and minimize the tension on the wound edges as it heals. Wounds heal under the optimal conditions of a clean, occluded environment.

EQUIPMENT

PROCEDURE ROOM

- Basic: mechanical table, overhead procedure lights, electrocautery, vital signs monitor, Mayo stand (1 or 2), receptacle for contaminated waste.
- Optional: depending on the location and scope of the procedure, suction may be needed.

SURGICAL TRAY

The specific instruments selected depend on the scope of the procedure and personal preference of the surgeon. It is helpful to set up the basic elements on the tray in the same layout each time. Consistency in placement of sharps prevents inadvertent injury with contaminated instruments to the surgeon or the assistant.

A basic excisional surgery tray (eFig. 243-0.1 in online edition) contains:

- Instruments: curette, No. 3 or No. 7 Bard-Parker scalpel handle with a No. 15 or No. 10 blade (or a Beaver blade in some cases), small forceps (e.g., Bishop-Harmon) and/or smooth-toothed Adson forceps, delicate standard skin hook or double-prong skin hook, curved iris scissors, blunt-tipped undermining scissors, hemostat, towel clamps, needle holder, suture scissors. For larger procedures, such as flaps, additional hemostats or hooks may be needed. Special procedures will need other instruments added to this tray (e.g., split-thickness skin grafts require a dermatome).
- Disposable material: marking pen, gauze sponges, cotton tip applicator sticks, scratch pad for electrocautery tip, electrocautery handpiece and tip, surgical drapes, foam or magnetic pad for discarded needles
- Suture

PREPARATION

Before starting a surgical procedure, it is important to review the patient's medical history, drug allergies, and current medications, including over-the-counter medications. The entire procedure should be explained in detail, and the patient must sign an informed consent. Vital signs should be taken and recorded.

The patient should be positioned in a manner that allows maximum exposure of the surgical site and is comfortable enough that the patient can remain still for the procedure. It is also important to be sure the patient is positioned in an optimally ergonomic way for the surgeon. Patients should be positioned so that the surgeon and assistance are comfortable and not leaning excessively over the table. A back flexion angle of greater than 15° increases the risk of significant back injury. Likewise, the patient should be elevated to a height that is comfortable for the surgeon. While many occupational therapists suggest working at a height that is in line with the elbow, most find bringing the working surface up higher to reduce the angle of the surgeon's neck to be significantly more comfortable. Operating with a cervical neck angle greater than 15° can lead to serious neck injuries and disabilities (eFig. 243-0.2 in online edition).

If hair removal is deemed necessary, it may be trimmed. The operative field is cleansed in a sterile fashion with one of several scrubs, including chlorhexidine (with or without isopropyl alcohol), iodophors, or triclosan.[5] The boundaries of the skin prep should be much wider than the planned incision and take into account the path of suture material in the surgical field. For procedures on the face, the patient should be advised to keep the eyes closed and caution should be used not to get any of the prep into the eyes. Sterile towels or a sterile drape should be placed around the edges of the field. In addition, draping the eyes may add additional comfort to the patient by helping avoid the glare of the operative lights.

ANESTHESIA

Most excisions are performed with local anesthesia only.[6] The most common agent utilized is 1% or 2% lidocaine, injected in a ring around the involved area. Other anesthetics used include bupivicaine, mepivicaine, or articaine. The addition of epinephrine 1:100,000 causes local vasoconstriction and helps increase the amount of total anesthesia that may be safely administered, increases the duration of anesthetic activity,[7] and decreases intraoperative bleeding. Plain lidocaine should be used when the administration of epinephrine is contraindicated, such as in patients with known cardiac arrhythmias, unstable angina, and narrow-angle glaucoma. It should be used with care in patients who are hypertensive, pregnant, or with known anxiety disorders.

The administration of local anesthetic is painful, particularly on sensitive sites such as the perioral and perinasal areas. There are several ways to decrease this discomfort.[8] Lidocaine is slightly acidic, and the addition of sodium bicarbonate 1:10 raises the pH of the solution closer to physiologic levels. Liquid injected at room temperature or warmer is less uncomfortable than that delivered at cooler temperatures. At the

injection site, the application of ice or vibration may also decrease the sensation of pain. Placement of the needle through an enlarged pore, especially on the nose, may also limit discomfort. Superficial dermal injection induces anesthesia more quickly than that injected into the deep dermal-subcutaneous tissue region, yet since the tissue is less distensible, it is uniformly more painful. Therefore, lidocaine should first be delivered to the deep dermal-subcutaneous tissue and then more superficially as the needle is withdrawn. Anesthesia should be delivered slowly through a small caliber needle. A 30-gauge needle typically is used in these circumstances. The surgical site should also be anesthetized from the proximal to the distal aspect of the local sensory nerve if possible. For example, when injecting around a lesion on the forehead, start the injections at the inferior aspect and move more superiorly with subsequent injections. In this manner, by the time the superior injections are performed, the area may already be numb since the supraorbital nerve had been anesthetized from the inferior injections.

For larger procedures, nerve block anesthesia is helpful because a large area can be anesthetized with a limited volume of anesthesia. Tissue distortion is also limited with nerve block anesthesia, and the vascular perfusion of the flap is not impaired.

EXCISIONAL SURGERY

ELLIPICAL EXCISION

Excisional surgery is one of the most frequently performed dermatologic surgery procedures. Specifically, the elliptical or fusiform excision allows for a linear, side-to-side closure. Mastery of elliptical excision and closure is fundamental to more advanced procedures, including variations on the ellipse itself and planning and executing more complex flaps. An elliptical excision is indicated for the removal of small- to moderate-sized benign or malignant neoplasms as well as for excisional biopsy and scar revision.

PLANNING THE ELLIPSE. In planning the excision, the lesion to be excised should first be identified and confirmed by the patient. Using an appropriate marker a circle is drawn around the lesion with the appropriate margins. The size of the surgical margin is dependent on the nature of the lesion.[9,10]

Once the margins of the lesion have been marked, the ellipse is planned. When planning a fusiform excision with linear closure, one must consider several factors, including the impact of the procedure on form and function. Free margins are of primary concern. Any distortion of a free margin will be aesthetically unacceptable. Closures should be planned such that tension vectors are perpendicular to free margins so no distortion occurs. For optimal cosmetic results, the long axis of the fusiform excision should be oriented along the relaxed skin tension lines, which are generally perpendicular to the direction of the pull of the underlying muscle (Fig. 243-1). These lines should be identified while the patient is sitting upright, and may be highlighted by asking the patient to make certain facial expressions. If the relaxed skin tension lines are not obvious, the direction of laxity may be identified by manipulating tissue manually. Relaxed skin tension lines rarely follow published diagrams, and closures should mimic the subtle arcs in the facial lines of expression. When possible, excisions should be restricted to one of the major cosmetic units (e.g., forehead, nose, periorbital area, lips and perioral area, chin, and cheeks) (Fig. 243-2). Placing the incision line at the junction of the cosmetic units may also minimize the appearance of the resultant scar. An adequate reservoir of surrounding tissue or skin laxity must be present. When the elliptical excision and closure that has been designed cannot include these conditions consideration must be given to other forms of repair such as flaps, grafts, partial purse sting closures, or healing by second intention.

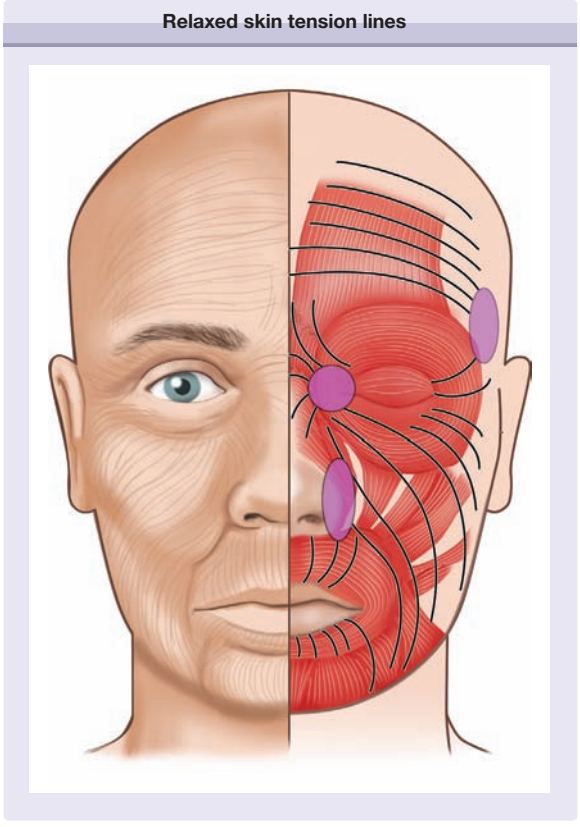

Figure 243-1 Relaxed skin tension lines. Relaxed skin tension lines generally form perpendicular to underlying muscles of facial expression. Closure lines heal better and with a thinner less noticeable scar when placed in relaxed skin tension lines.

The simple ellipse is based on an optimal length to width ratio of 3.5:1 to minimize the formation of redundant tissue at the apices, otherwise known as "dog-ears," "puckers," or "standing cones skin." The ratio may be increased to 4:1 or greater in locations with less tissue distensibility or decreased to 3:1 in areas where the tissue is more lax. The apical angle between the two arciform incisions ranges from of 37°–74°, depending on the length to width ratio.[11] As

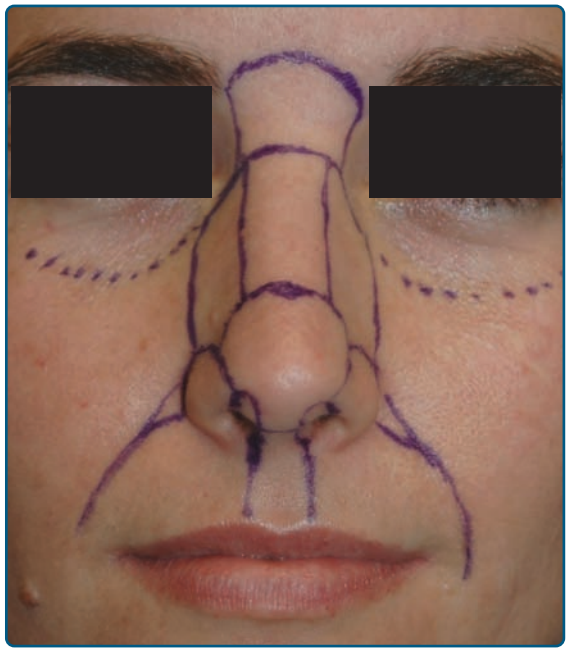

Figure 243-2 Cosmetic units. The face can be divided into many cosmetic units. The cosmetic units are differentiated from each other by alterations in skin texture, color, or contour. Incisions hide very well when placed in cosmetic unit junctions.

the ratio becomes larger, the apical angle decreases; thus, for a ratio of 5:1, which may be needed for scalp surgery, the apical angle approaches 30° (Fig. 243-3).

It is important to note that as a wound is closed in a linear fashion, the length of the resultant scar will be longer than the distance between the two distal points drawn out in the preoperative design of the ellipse. The arc of the two sides of the closure that are brought together is necessarily longer than a straight line drawn between the distal points of the ellipse. Mathematically, with the angles used in excisional surgery, the arcs are roughly 20% longer than the straight line drawn down the middle of the ellipse. In most cases this becomes

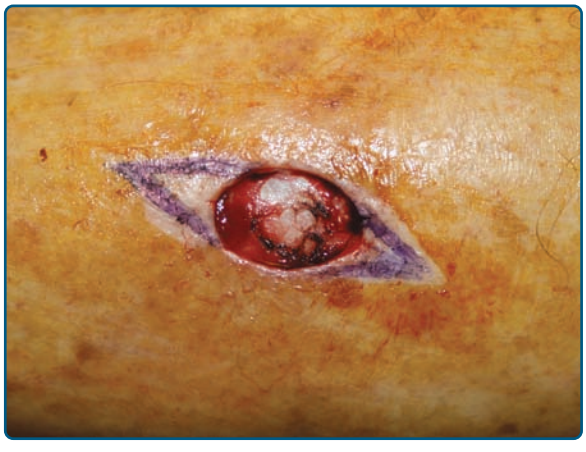

Figure 243-3 Acute apical angle. Certain areas such as the convex surface of an extremity or the nasal dorsum require a length to width ratio of greater than 3:1.

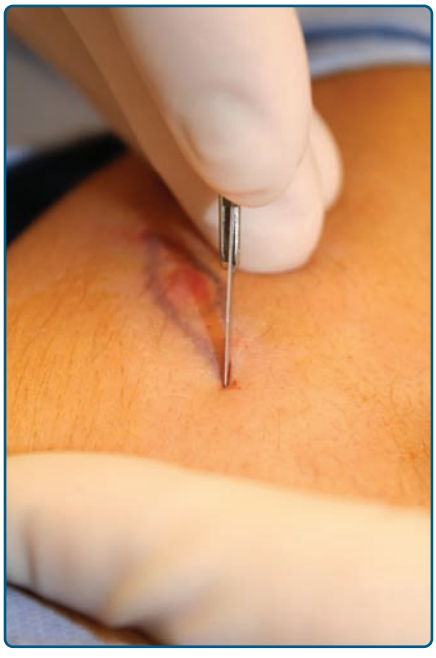

Figure 243-4 Incision. Incisions should be made 90° (perpendicular) to the skin surface and continued down through the dermis into the subcutaneous tissue.

irrelevant as there is contraction along the long axis of a scar and the tissue around the closure distends and absorbs this small difference without any noticeable distortion. In areas such as the upper lip, however, this small difference may be enough to distort the lip margin and be disfiguring. Lengthening the elliptical closure and bringing it around the lip to the wet mucosal margin will often help hide this potential distortion.

TECHNIQUE. After the ellipse is planned and drawn, the field is anesthetized, prepped, draped, and the first incision is made using a scalpel (Fig. 243-4). In most instances, a number 15 blade is used to score the epidermis or to cut through to the fat on the first pass; however, thick back skin may require the use of a No. 10 blade. The surgery begins with the point of the blade at the apex distal from the surgeon's position. As the incision progresses toward the arc of the ellipse, the belly of the blade is held perpendicular to the skin surface, preventing a beveled incision. As the opposite apex of the incision is approached, the blade rocks back up onto its tip, which allows the surgeon to clearly see the apex of the incision under the advancing hand. This prevents extending the incision beyond the planned apex. To prevent bunching of the tissue ahead of the pressure exerted by the blade, traction on the surrounding skin is held with the nondominant hand; in addition, an assistant may aid with traction. The depth of the excision is, again, dependent on the nature of the neoplasm being excised. When a side-to-side closure is planned, the depth of the incision must be full thickness, or into the superficial subcutaneous fat. The proximal apex of the ellipse is grasped gently with a toothed forceps to elevate the tissue. The base of the specimen is dissected in an even plane with a scalpel or scissors. The depth at the apices should be

the same as the depth at the center; there is a tendency to remove the specimen with the depth at the apices more superficially. When the depth of the excision is not uniform, a more noticeable standing cone of tissue may surround the tips as the wound is closed.

CLOSURE. Undermining is performed to increase mobility of the surrounding tissue, aid in wound eversion, decrease tension on the wound edges, and diffuse scar contraction.[12] The subcutaneous tissue is undermined at the same level around all edges of the wound, including the apices, utilizing iris or blunt-tipped scissors. The tissue may be snipped or bluntly dissected by inserting the tip of the scissors and spreading. The plane of undermining will vary depending on body site but should be uniform in depth at all edges. Knowledge of anatomy is extremely important and careful attention must be given to surrounding vital structures. Patients receiving anticoagulants or with reduced platelet number or function may benefit by limiting the extent of undermining as the risk of bleeding and hematoma formation is decreased.

Electrocoagulation or electrocautery is employed to attain meticulous hemostasis of the bed of the wound. A skin hook is used to elevate the wound edges to expose vessels that were injured during the excision or undermining. Blood that accumulates in the wound must be cleared with gauze or cotton swabs to allow for visualization of pinpoint bleeding and to allow for a relatively dry field. The cautery tip may be applied directly to the vessel until bleeding ceases. Alternatively, indirect coagulation is achieved by using small forceps to grasp the vessel and applying the cautery tip to the forceps. Indirect cautery limits the residual thermal damage surrounding the cauterization and may speed wound healing. Theoretically it could reduce the risk of infection but in facial skin, where much dermatologic surgery is performed, the excellent blood supply often minimizes the risk of infection. No matter which method is used, care should be taken to stop all significant bleeding while minimizing cautery char. Larger, more high-pressured arteries may require ligation with absorbable suture.

Suturing technique (see Chapter 242) reduces and redistributes wound tension, everts the skin edge, eliminates dead space, and maintains or restores natural anatomic contours, while minimizing the formation of permanent suture marks on the skin surface. Most wounds are closed in two layers: (1) absorbable deep sutures and (2) nonabsorbable superficial sutures. Deeper wounds or those with significant dead space may benefit from a third, deep layer in the subcutaneous fat or fascia.

Ideally, the wound is closed by first placing the deep sutures using the rule of halves to minimize the formation of dog-ears (Fig. 243-5). The first suture is placed in the center of the wound. Each half of the remaining defect is closed in a similar manner, which is repeated until a suitable numbers of sutures have been placed. A wound gains only 7% of its final strength after 2 weeks.[13] As most skin sutures are removed within 1 to 2 weeks of placement, absorbable buried sutures are an important part of a layered wound closure.[14] Buried sutures typically dissolve over the course of months and provide support for the wound until epidermal tensile strength has increased sufficiently to prevent wound dehiscence.

Buried vertical-mattress sutures aid significantly in wound eversion by reducing or eliminating tension on the wound edge and producing thinner less noticeable scars (Fig. 243-6). This type of buried suture should be used in nearly all closures. Subcutaneous sutures help minimize or eliminate dead space and align deep structures such as skeletal muscle or fascia. They can

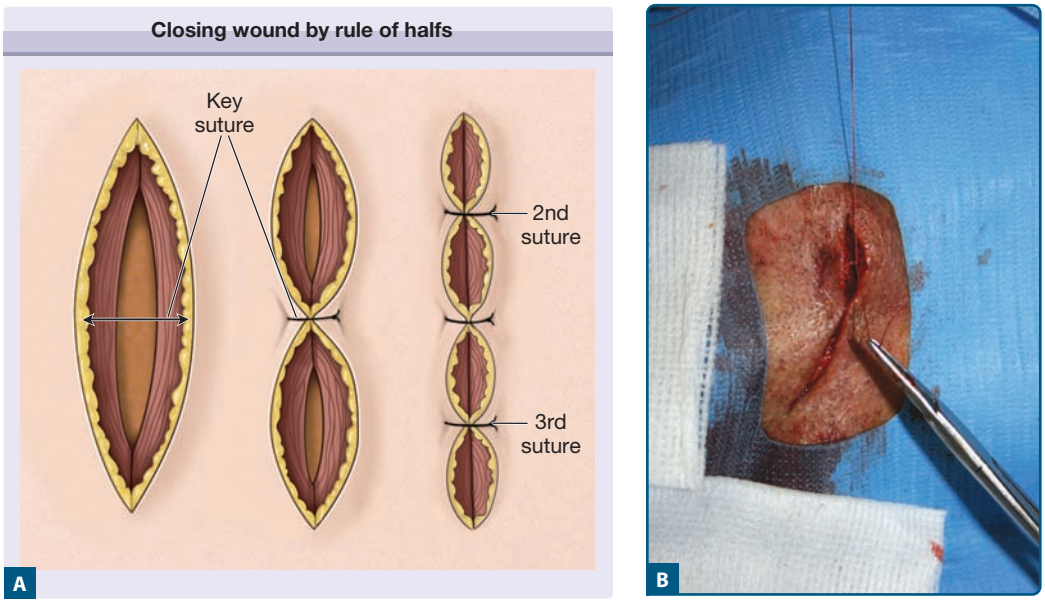

Figure 243-5 **A** and **B.** Closing wound by rule of halves. Sutures are placed at the midpoint of any open area of the defect.

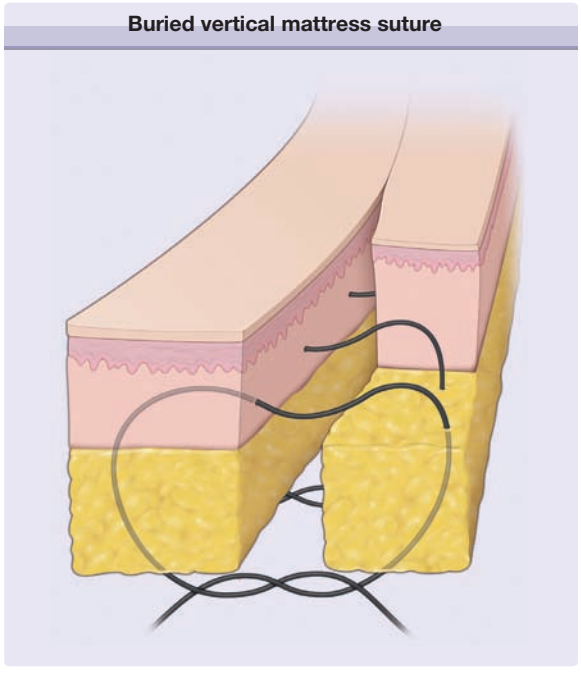

Figure 243-6 Buried vertical mattress suture. The buried vertical mattress suture gives excellent eversion to the wound edge and should be used for most if not all subcutaneous sutures.

also be used to anchor overlying tissue to underlying fixed structures, such as periosteum, to prevent distortion of free margins or maintain proper facial contour and function. This is exemplified by anchoring a melolabial flap to the maxillary periosteum. When tying a buried suture, it is important not only to keep both free ends of the suture on the same side of the loop created, but also to tie the suture in such a manner that draws the knot down on the same side so it will tuck up under the loop and not get hung up on it (Fig. 243-7). Buried sutures should align the wound edges such that they are perfectly approximated with good wound eversion before the placement of epidermal sutures.

Epidermal sutures are placed to approximate the margins of the skin edge. They should be evenly spaced and placed at roughly the same distance from the wound as the combined dermal epidermal depth. Therefore, sutures placed on the eyelid will be much closer together than those placed on the thick skin of the back. Most practitioners use a running nonabsorbable minimally-reactive monofilament suture, such as polypropylene, that requires subsequent removal.[15] Alternatives include running absorbable fast-acting gut[16], absorbable or nonabsorbable running subcuticular sutures[17], simple interrupted nonabsorbable sutures, and polymethylmethacrylate tissue glue. Simple interrupted sutures are more time-consuming to place and remove than a running suture. In settings, where wound healing may be impaired due to the patient's advanced age or underlying disease, interrupted sutures compared with running sutures may be preferred, as interrupted sutures may have, with all other factors being equal, greater tensile strength and less potential to cause edema, induration, and impaired microcirculation.[18]

SUTURE REMOVAL.

The risk of crosshatch marks across the suture line can be minimized by removing the sutures within a week of placement, before the formation of epithelial suture tracks develop. On the face and ears, most skin sutures are removed within 5 to 7 days. Neck sutures should be removed in 7 days and scalp sutures in 7 to 10 days. On the trunk and extremities, risk of wound dehiscence mandates that epidermal sutures may be left in place longer, typically 10–14 days, to provide additional support. In repairs under high tension or when dehiscence is likely, sutures may be left in place for 3–4 additional days. However, if sufficient buried sutures have been placed and the wound as well approximated at 7–10 days, epidermal sutures can be removed. The use of a running subcuticular suture for well-approximated wounds will prevent the formation of suture tracks and should be used in most cases that require sutures be left for more than 7 days.

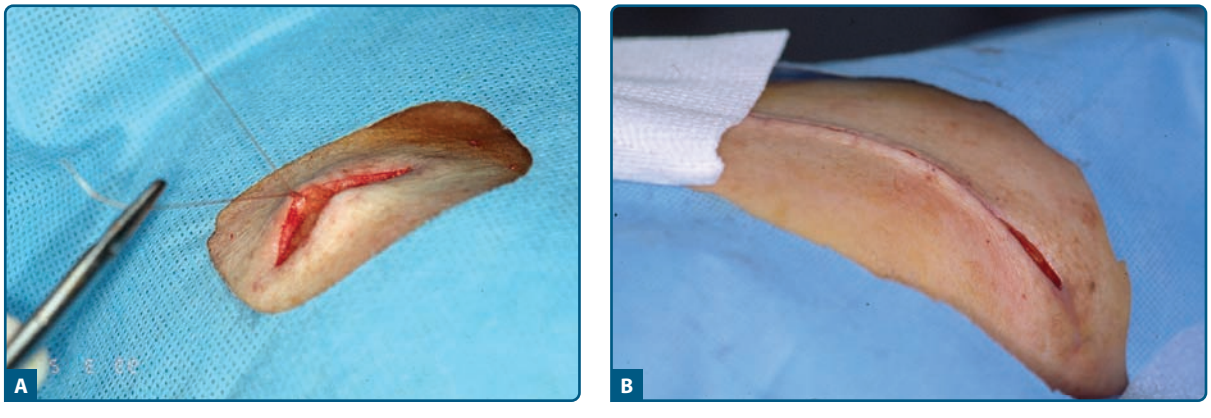

Figure 243-7 **A** and **B.** Tying deep sutures. It is important to keep the knot forming from the two free ends on the same side of the loop in the middle so they do not get hung up on the loop. This will allow the knot to cinch up under the loop and draw the wound edges together. The wound should be together with skin edges nicely opposed and everted.

EXCISION WITHOUT CLOSURE

There are certain locations and situations where allowing a wound to heal by second intention is the preferred method of closure. Wounds in patients who are poor surgical risks for reconstructive surgery, where there is relatively minimal tissue mobility (scalp, distal lower extremities), and where there is a high risk of infection healing by second intention may be indicated. (eFig. 243-7.1 in online edition).

Wounds located in concave areas such as the medial canthus, ear concha, alar crease (if small), temple region, and postauricular sulcus lend themselves well to healing by second intention.[19] Wounds allowed to heal by second intention contract significantly and may decrease in size as much as 50% or more.[20] Superficial wounds heal with less wound contraction, because there is less deposition of collagen. Therefore, a very superficial wound, even on a convex surface such as the forehead or the nose, can potentially heal well. Because all wounds contract to some degree, it is important that there be no free margin along one side of the wound that can be elevated during wound contracture and cause distortion at the site. This may be encountered along the eyelid margins, ear margins, eyebrow, nasal ala, and lip vermillion border. These areas are almost always better managed with appropriate reconstructive surgery.

When a lesion is excised with the intention of allowing the wound to heal by second intention, appropriate margins should be included and the resulting defect will typically be circular in nature. The incision through the skin is beveled inward to provide exposure of the base of the wound. The depth need not reach the subcutaneous fat if the lesion can be removed satisfactorily by transecting the dermis.

Wounds that are allowed to granulate are more resistant to infection and do not form a hematoma. In addition, the size of the final scar is kept to a minimum by negating the need to remove standing cones. These wounds, however, require more time to heal than those that are closed primarily and exhibit increased contracture. In some cases there is an unpredictable cosmetic result.[20] Employing a purse string suture can significantly decrease the size of the wound and abbreviate the healing time considerably.

REVISION OF STANDING CONES OF TISSUE

Under certain circumstances, a circular excision may be performed when the orientation of the ellipse is difficult to anticipate. This may occur when the precise direction of relaxed skin tension lines and least tension is difficult to determine, when the length of the ellipse for an optimal outcome is unclear, or when alternative repairs may be considered, such as a local flap. Nonelliptical defects require revision of the cones or dog-ears. First, the wound is closed with a few centrally placed sutures; bilateral standing cones of excess tissue form on either side of the central closure. In addition, tissue redundancies may persist at one or both ends of a planned fusiform excision if the apical angle is too wide, if the sides are of unequal lengths, or on convex surfaces and the techniques for addressing these redundancies are similar under both clinical circumstances [21] Skillful repair of the redundant standing cones extend the incision line by removing an additional triangle of tissue at the tip (Fig. 243-8). The apex of the standing cone is lifted with forceps or

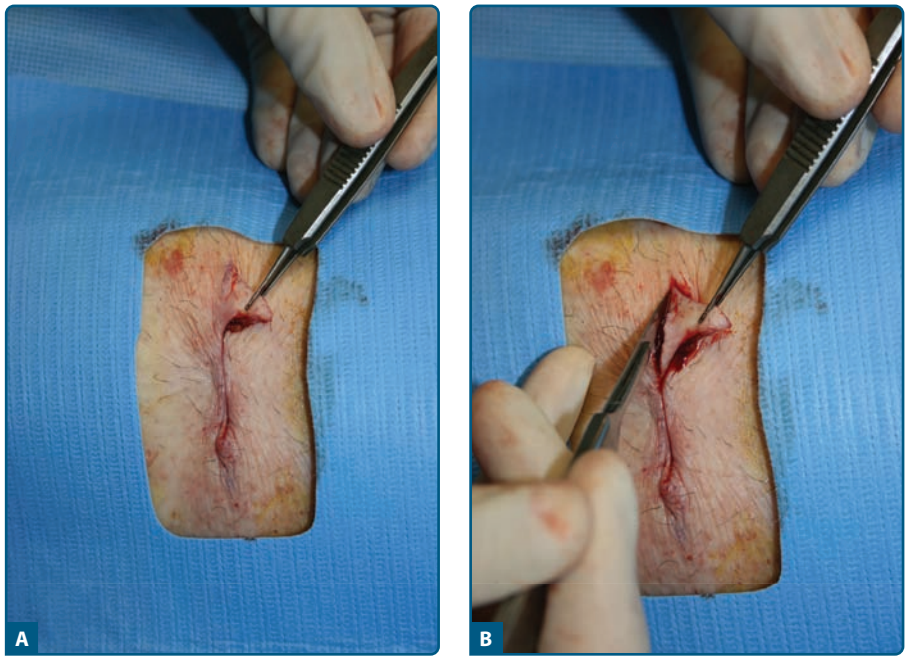

Figure 243-8 **A** and **B.** Standing cones. Redundant tissue may be removed by incising one side, draping the excess skin over the wound, and excising the resultant triangle.

Figure 243-9 **A–C.** S-plasty closures are often used to give a wound a curvilinear line and to alter the tension vectors so they do not all pull along the long axis of the wound and cause noticeable contraction. The S-plasty is especially useful on convex surfaces where wound contraction may cause the scar to sink down and appear depressed.

a skin hook and manipulated to determine where to place the incision that releases the redundant tissue. The incision is made with a scalpel and the dog-ear is undermined. The free end of the cone is pulled over the incision and the remaining incision is made such that the resultant wound edges lie flat.[22] The freed cone is termed a *Burow's triangle*. This technique results in a linear extension of the scar. Variations on the revision of tissue cones include a curved extension, an angled extension, and an M-plasty.

VARIATIONS OF THE ELLIPSE

CURVED ELLIPSE. The classic fusiform excision creates a linear scar. At times, it is aesthetically preferable to create a curvilinear scar. The curvilinear repair is useful on the cheek and around the chin. The curved ellipse is created by intentionally designing it with one side longer than the other. The wound is closed by the rule of halves.

S-PLASTY. An S-shaped repair is useful on convex surfaces such as the extremities where a linear repair may result in persistent standing cones or indentations. The tension vectors of a standard elliptical incision are perpendicular to the long axis of the ellipse. Since wounds contract along their long axis, designing the closure with an S-plasty, displaces the tension over a greater length and a variety of angles (Fig. 243-9) and does not create a contracting in one direction with resulting indentation over a convex surface such as an extremity.

M-PLASTY. An M-plasty allows the length of a scar to be shortened. Rather than extending the end of an ellipse or removing a Burow's triangle, the redundant tissue may be excised inward, forming a M-shaped scar. The long axis of the incision is reduced by the length equivalent to the inverted triangle which makes the center of the M. This technique is useful for confining a scar to a single cosmetic unit, that is, the chin, or when an incision approaches a free margin. The scar may be camouflaged in locations where rhytides bifurcate, such as the crow's feet in the periorbital area or around the lips. It is important to advance the inverted triangle up into the rest of the ellipse to take full advantage of the scar-shortening effect.

PARTIAL CLOSURE. Partial closure is used when more extensive repairs are limited by lack of local tissue reservoirs or the patient's health or coagulation status. The wound is closed from the ends toward the

center. When wound tension prevents further closure, the area remains open to heal by second intention. The final scar is usually linear and may resemble a spread scar in the middle. Alternatively, a purse-sting suture is placed around the wound and tissue is drawn together circumferentially. The purse-string suture is closed just to the point of minimal tissue buckling. Additional guiding sutures may then be placed across the partially closed wound to attain better alignment and even further closure.

SERIAL EXCISION. In some cases, the length of an ellipse required to excise a lesion with a 3 or 4:1 ratio is too long for an acceptable cosmetic or functional outcome. In such instances, the lesion may be removed with a series of staged excisions. A partial excision is performed, ideally an ellipse that accommodates the full length of the lesion, with primary linear closure. During the following months, the surrounding tissue stretches and the tension in the area decreases. Additional excisions are performed in a similar manner, removing the remaining lesion as well as the scar or scars created from the first steps of the procedure. This is typically used to minimize the length of the final scar in large circumference neoplasms that are benign or low risk.

FLAPS

When simple primary closure cannot be done because a wound is too large, there is excessive tension, or an unacceptable functional or cosmetic result would ensue from a linear scar, a tissue-movement procedure, such as a flap or a graft, should be considered. A local skin flap is a portion of full-thickness skin and subcutaneous tissue transferred from an adjacent donor site into the surgical defect. The flap maintains its blood supply via a vascular pedicle that remains connected to the donor site.

Random pattern flaps, the most widely used in dermatologic surgery, are supported by the small arterioles and capillaries of the subdermal vascular plexus found in the mid-to-superficial fat. Therefore, undermining and flap mobilization must be done at or below this level to ensure adequate blood supply. If undermining occurs too superficially, the intradermal vaculature alone will often not be able to support a flap. In certain areas other than the face, the perfusion pressure of even the subdermal vascular plexus is often not sufficient to support a random pattern flap. Fortunately, the blood supply of the face is rich, estimated to be ten times greater than necessary to support the skin's basic metabolic needs so it can support a wide variety of random pattern flaps.

The vascular perfusion pressure, that is the force of blood flow through a vessel, is greatest at the proximal end of a vessel and decreases steadily as it travels more distal into the flap. To ensure flap survival, the perfusion pressure must be great enough to keep the distal capillaries of the flap open. If the pressure falls below a certain critical level, the capillaries close and insufficient blood is supplied to the distal end of the flap.

For years, it was believed that the viable length of a flap was directly proportional to the width of the pedicle. In 1970, Milton discovered that axial flaps in a pig model under the same conditions of blood supply survive only to a finite length regardless of width.[23] Daniel and Williams, as well as Stell confirmed Milton's findings and concluded that there was an upper limit of flap length that cannot be increased by increasing the pedicle width.[24,25] The maximal flap length is determined by vascular supply, not simply pedicle width. The greater the perfusion pressure in the flap pedicle, the longer the flap can be without undergoing necrosis.[26] In addition, the greater the perfusion pressure in the pedicle, the narrower the pedicle may be. Axial pattern flaps have the highest perfusion pressure at the base and therefore can support very narrow long flaps (generally greater than 4:1 length to width ratio). Musculocutaneous flaps have the next greatest vascular perfusion pressure, followed by fasciocutaneous flaps, and finally random pattern flaps. Stell discovered the greatest length of a viable axial flap was 60% greater than that of a random pattern flap. In general, random pattern flaps on the face should have a maximal length to width ratio of 3:1.[27,28] This is however only a rough guideline and individual patient characteristics such as tobacco use, sebaceous nature of skin, prior radiation or surgical procedures, and precise location all affect vascular perfusion. To help ensure flap survival the pedicle length-to-width ratios should not exceed 2:1 on the trunk and extremities.

The two movements involved in repairing a defect with a flap are the primary movement, which is the action of placing the flap into the defect and the secondary movement of tissue in the donor area, which closes the secondary defect and facilitates primary flap movement. Both movements are important in terms of distributing tension in the proper direction and over a larger area so as to minimize tension on the flap itself, which might compromise its survival.[29] Flaps are commonly classified according to their primary movement—advancement flaps, rotation flaps, transposition flaps, and interpolation flaps. This classification underplays the reality that many flaps have more than one primary movement, e.g., a rotation flap usually has a component of advancement to fill the distal portion of a wound. Therefore, another way to classify flaps is by whether the primary movement is sliding, which displaces tissue redundancy at a site distant from the defect (advancement and rotation) or lifting, where a flap is moved over intact skin, reorienting wound tension (transposition and interpolation).

As with elliptical excisions, the flap should be planned paying attention to the concepts discussed above, such as free margins, skin laxity, relaxed skin tension lines, cosmetic units, and attention to function. The flap and possible resultant Burow's triangles should be drawn out with a marking pen while the patient is in an upright position. It is advisable to plan the flap prior to administering anesthesia, as the injected volume may distort the tissue and alter its movement.

Flap incisions should be made perpendicular to the skin and the recipient wound edges should similarly be

squared off. The thickness of the flap should be uniform and should approximate the thickness of the wound edge. The area around the flap should be widely undermined.

ADVANCEMENT FLAPS

The primary movement of an advancement flap is the one-dimensional sliding of tissue directly into a defect. In essence, incisions are made tangentially to the defect to free up neighboring tissue. With the wound edge acting as the free margin of the flap, the tissue is advanced into place, displacing tissue cones. While some adjacent tissue laxity may be tapped into with an advancement flap, the tension vectors of the closure remain the same and therefore the primary advantage of an advancement flap is the displacement of closure lines into more cosmetically acceptable locations.

SINGLE ADVANCEMENT. The simplest example of a pure advancement flap is the U-plasty, whereby double, parallel incisions are made tangential to what is most often a round defect. The flap is undermined, advanced into the defect, and secured with sutures, creating a U-shaped scar (eFig. 243-9.1 in online edition). Redundant tissue cones may be sewn out using the rule of halves or removed as Burow's triangles at the base of the flap. While the U-plasty is occasionally used to make the majority of lines in the repair of a forehead defect run in the horizontal direction with the natural skin tension lines; the fact that it does not alter tension vectors and does not significantly free tissue up limits its usefulness.

An L-plasty or O-to-L advancement is a single tangent flap where an incision is made at one end of a defect extending outward for some length, and the tissue mobilized is then advanced into the defect (Fig. 243-10). Tissue redundancy is created on the side of the defect opposite the flap incision and must be removed. While this type of advancement flap may tap into some distant laxity, it is generally minimal. Advancement flaps also do not change the tension vectors of the closure. Advancement flaps spread the tension out over a longer distance and offer some of the closure line to be perpendicular to the vector of tension. O-to-L advancement flaps are particularly useful with defects where the limb of the flap may be incorporated into RSTLs or cosmetic unit junctions or where a linear closure may otherwise cross a free margin or cosmetic unit junction, as may be the case on the eyebrow, nose, or upper lip.

A larger single advancement flap is the cheek advancement flap, used to repair medium-to-large defects of the medial cheek and/or lateral nose (Fig. 243-11). The incision may be placed in the alar crease or nasolabial fold by removing tissue above and below the defect to allow the cheek to advance into the nasofacial sulcus. It is usually advantageous to tack the leading edge of a cheek advancement flap into periosteum at the nasal sidewall cheek junction, even if the defect is on the nasal sidewall. Tacking the flap to periosteum at the nasal sidewall cheek junction will take pressure off the leading edge and recreate the natural concave surface of the area and prevent unnatural webbing. When a defect involves both the cheek and the ala, a cheek advancement flap may be used to cover the defect on the cheek and a full-thickness skin graft may be used to repair the alar part of the defect (Fig. 243-12). This will keep the cosmetic units separate and place the scar lines along the cosmetic unit junctions.

Helical rim advancement flaps may be used to repair defects of the helix, utilizing the tissue laxity of the lobule. Traditionally, this flap was created with a through and through incision inferior to the defect along the scaphoid fossa, terminating in the lobule, and creating a narrow pedicle to be advanced (conceptually similar to the U-plasty). The survivability of this flap is

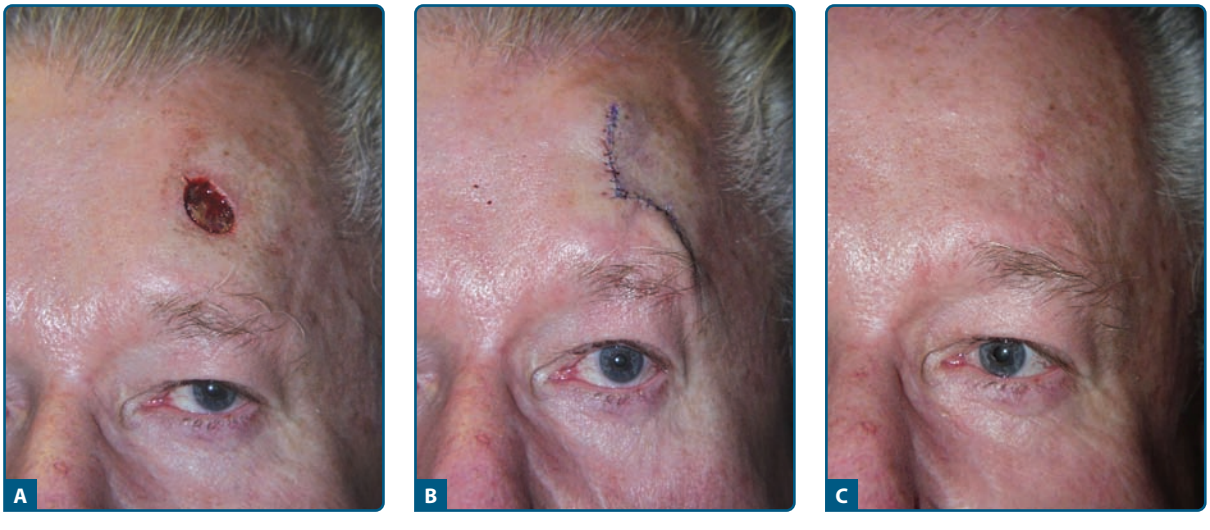

Figure 243-10 **A–C.** A to L advancement flap. Here, one line of the closure is drawn and incised perpendicular to the closure.

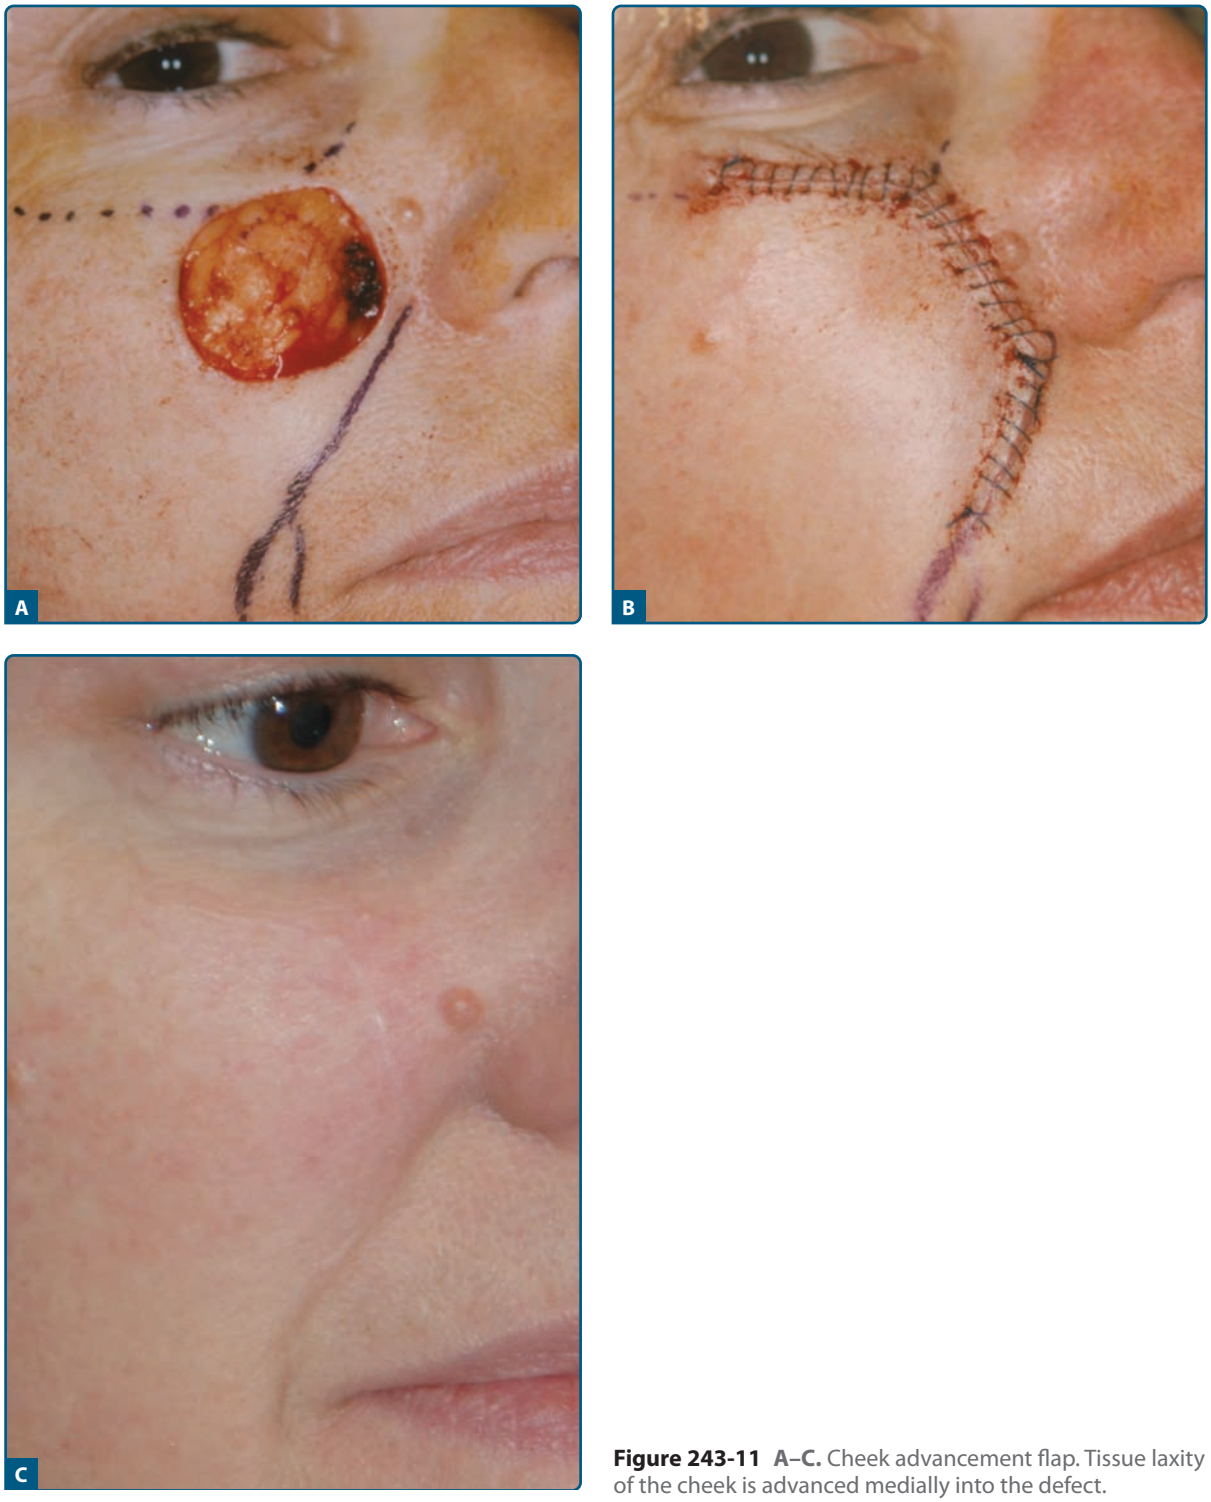

Figure 243-11 **A–C.** Cheek advancement flap. Tissue laxity of the cheek is advanced medially into the defect.

proportional to the length-to-width ratio and could only be performed on inferior helical defects where this ratio will not exceed 3–4:1. A more popular modification of this flap is to use a single tangent incision along the scaphoid fossa, leaving the posterior auricular skin intact[30] (conceptually analogous to the L-plasty) (Fig. 243-13). This allows for the maintenance of a more reliable blood supply via the tissue inferiorly and posteriorly and permits the repair of defects more distant from the lobule. It is important to have good eversion when closing this flap at the helical rim as forces of contraction during healing will tend to invert the wound edge and create an aesthetically unpleasant notch.

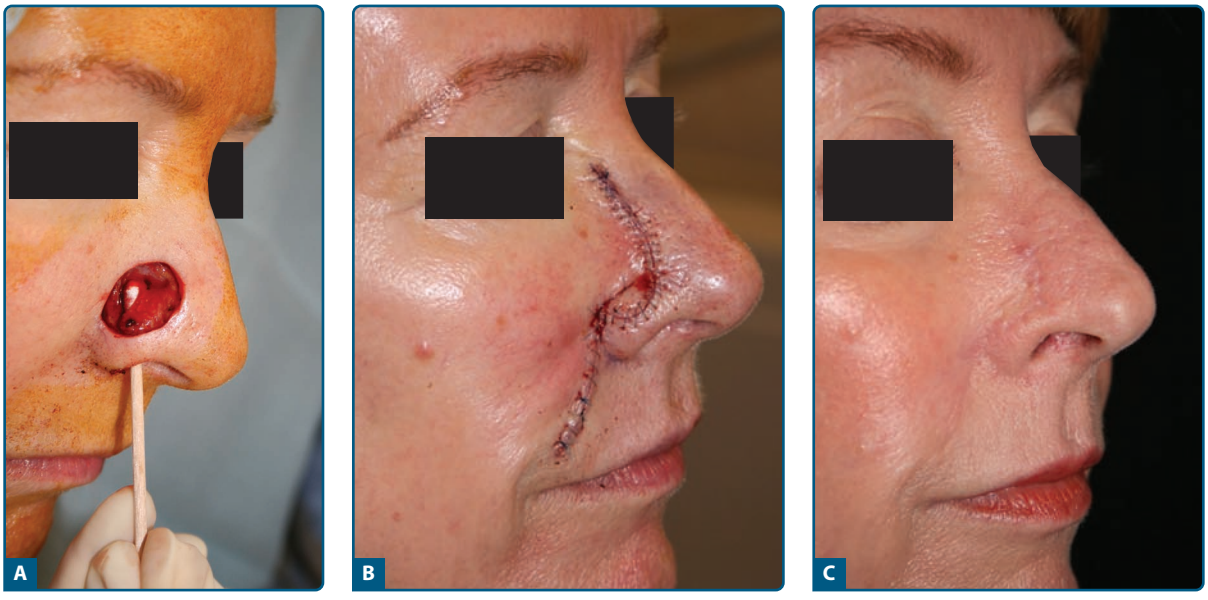

Figure 243-12 **A–C.** Cheek advancement flap with full-thickness skin graft. When the defect involves both the cheek and the ala, it is often best to utilize separate closures for each of the cosmetic units. Here a cheek advancement flap was used to close the part of the defect on the cheek, and a conchal bowl full-thickness skin graft was used to close the alar aspect of the defect.

BILATERAL ADVANCEMENT. If two sets of parallel incisions are made symmetrically on both edges of the defect, a bilateral advancement flap, termed an *H-plasty*, has been created. This flap is essentially a bilateral U-plasty and is occasionally used on the forehead and upper lip to hide incision lines along relaxed skin tension lines and cosmetic unit junctions.

Another commonly employed bilateral advancement flap is an O-to-T flap, also termed an *A-to-T* or a *T-plasty* (eFig. 243-13.1 in online edition), analogous to a bilateral L-plasty. This flap is essentially a bilateral O to L flap. The standing cone is removed from one end of the defect, creating a triangle, or transforming on "O" into an "A". Single incisions extend from the base of this triangular defect, and the two sides of the triangle slide together along this baseline. The T-plasty is best performed with the broad base along a free margin or cosmetic unit junction (e.g., lip, eyebrow).

CRESCENTIC ADVANCEMENT FLAP. The crescentic advancement flap utilizes the removal of small crescent of tissue along an advancement flap to either

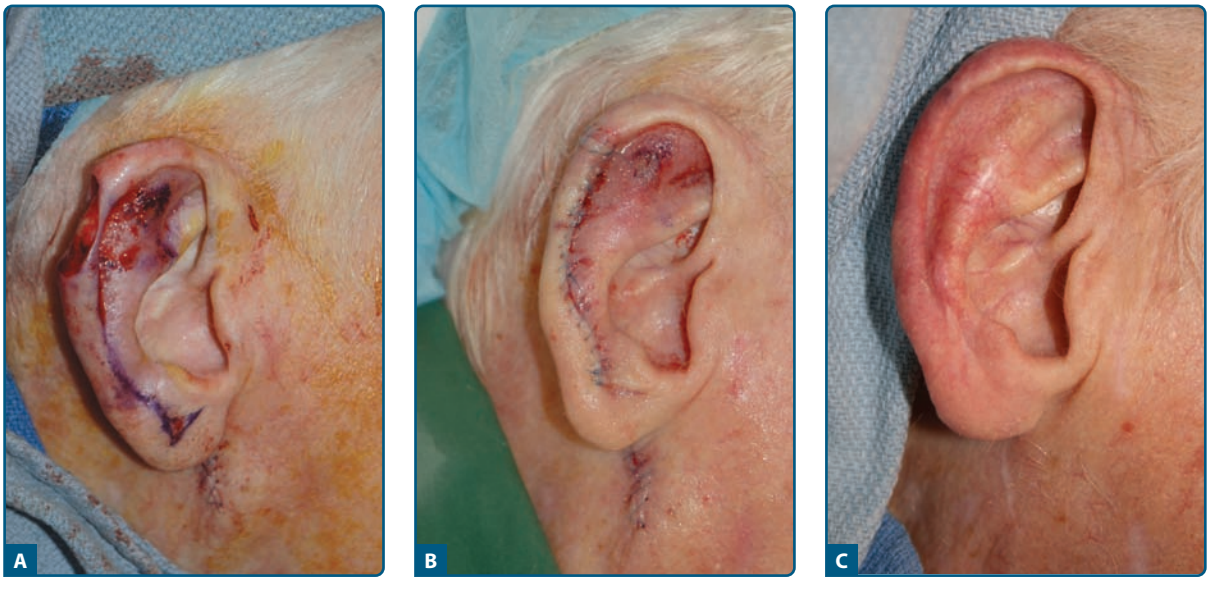

Figure 243-13 **A–C.** Helical rim advancement flap. An incision is made along the anterior helical rim down to the ear lobule. A "dog ear" is taken out on the posterior aspect of the ear. The helix is advanced superiorly to close the defect with everting sutures. This allows for consistent reconstruction of the helical rim.

Figure 243-14 **A–C.** Crescentic advancement flap. A crescent of tissue is removed around the lateral aspect of the ala and the cheek is advanced medially.

better hide the scar line or increase the length of the line to prevent distortion. This flap is particularly useful for the repair of upper lip and perialar defects. The superior standing cone is removed in a crescentic shape around the ala such that the superior scar line is placed in the perinasal sulcus (Fig. 243-14).[31] For defects on the upper cutaneous lip, the inferior cone is removed along relaxed skin tension lines and extended through the vermilion border and around to the wet mucosa to prevent a downward distortion of the vermilion. A modification of the crescentic advancement includes the repair of a small, perialar defect of the medial cheek where both cones are removed around the ala, and the entire scar line is placed in the nasal sulcus, similar to the cheek advancement. Another modification includes incorporating a crescent along the vermilion border to an advancement flap closing a defect just superior to the vermilion border. Removing a crescent here increases the length of flap and helps minimize the differences in length between the flap and the total length of the closure (flap + defect). This will take some of the horizontal tension off the flap and minimize distortion of the lip and modeolus (Fig. 243-15).

ISLAND PEDICLE FLAP. A subcutaneous island pedicle flap, also referred to as a V-to-Y advancement flap, may be considered as a variation of an advancement flap that has had all of its connections to the epidermis and dermis severed, maintaining its blood supply through a subcutaneous tissue pedicle (eFig. 243-15.1 in online edition).[32] The flap is designed

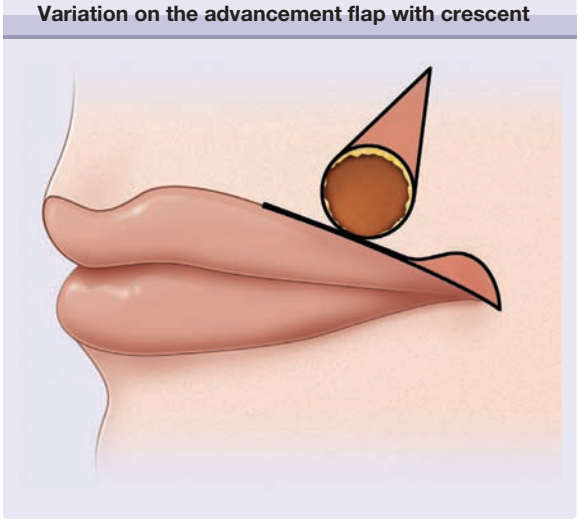

Figure 243-15 Variation on the advancement flap with crescent. Removing the crescent of tissue elongates the incision and compensates for the length mismatch of the incision vs. the incision + defect.

within cosmetic units when possible and, as with all repairs, it is optimal for the incision lines to run along cosmetic junctions. The island pedicle flap is frequently used on nasal and perioral closures where free margins are at risk for distortion. The tension vectors of an island pedicle flap are primarily in the same direction as that of a primary closure; however, they are displaced distal to the wound (i.e., superior to the nasal tip, superior or lateral to the vermilion border) and help avoid distortion of the area around the defect.

An island pedicle flap is created by extending two nonparallel tangential incisions to meet at an approximate 30° angle, similar to when planning a Burow's triangle. The difference is that the incision lines stay parallel for a short distance before converging, creating a slightly larger triangle than would be created with a Burow's triangle. This extra length gives tissue that closely approximates the size of the defect and minimizes local distortion. The triangle may be designed larger or smaller depending on how much tension sharing is desired. The incisions are made just to the superficial subcutaneous tissue. The tip and sides of the flap are undermined widely extending outward from the flap in the subcutaneous plane. The triangular flap is also undermined slightly to help mobilize it. The flap is then advanced into the defect and sutured into place. In order for the flap to fit properly into a circular defect, either the corners of the flap must be trimmed or the defect squared off. The flap must be undermined with attention both to the mobility of the tissue as well as to the maintenance of a subcutaneous vascular pedicle. While the initial design should have a broad pedicle, if mobility is limited the pedicle may be progressively diminished (particularly at the trailing tip of the flap).

When closing defects on the nasal dorsum and tip, a muscular flap is often created laterally on one or both sides. For this musculocutaneous island pedicle flap, undermining is performed both above and below the nasalis muscle. If there is not enough laxity to close the defect without upward tension on the nasal tip, the muscular flap is released horizontally at the superior and inferior edge to create a muscular sling that advances with the flap into place. The muscular attachment gives a robust blood supply to the flap and helps ensure its survival.

ROTATION FLAPS

In a rotation flap, skin moves into the defect by rotating around a pivot point (Fig. 243-16). This is classically used to close relatively large defects on the cheek, temple, or scalp. The design of the traditional rotation flap uses a curvilinear incision along an arc adjacent to the primary defect. Adjacent lax tissue is recruited while the closure tension is redirected in multiple directions away from the primary defect. The flap is designed with attention to its length and curvature.[33] Rotation flaps often require long incision lines, as a larger arc of the rotation vector allows closure with minimal tension on the flap's tip while simultaneously decreasing the width of the secondary defect. The ideal arc of a rotation flap extends up to five times the width of the defect and makes up approximately one quarter of the circumference of a circle.

As the flap is raised and undermined, the adjacent tissue laxity allows the flap to rotate into the primary defect. The stiffness about the pivot point may hinder the flap's movement,[33] and undermining the area of pivotal restraint improves flap mobility. If restraint of motion keeps the tip from moving into the distal defect, a back cut can increase tissue movement in areas of limited tissue laxity, such as the nose. The back cut cannot extend so far across the base of the flap that it interferes with blood flow into the flap.

DORSAL NASAL ROTATION FLAP.

Also known as the *Rieger flap*, this flap is employed to repair nasal defects involving the distal dorsum or tip.[34] The tissue

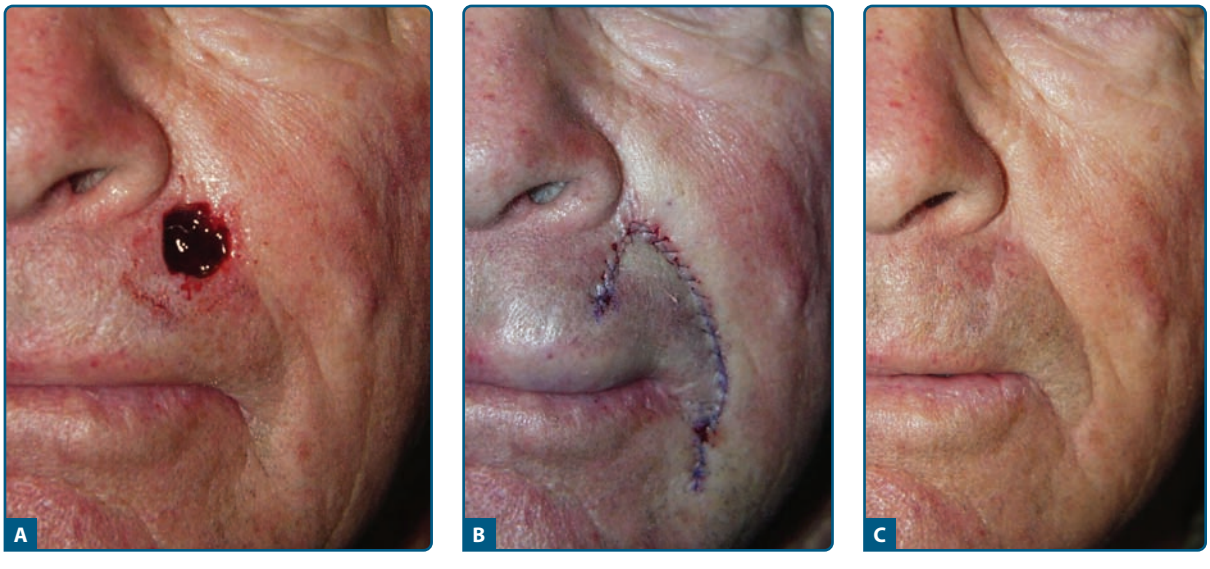

Figure 243-16 **A–C.** Rotation flap. An arcuate incision is made from one end of the defect and the flap is rotated into the defect. Rotation flaps help spread tension vectors out in multiple directions radiating from the arc.

Figure 243-17 **A–C.** Hatchet flap. The hatchet flap is a rotation flap with a cutback. The cutback gives the flap extra length and aides in its movement.

reservoir of the nasal root and glabella allows for the movement of the dorsal nasal skin superior to the defect. A long, sweeping arc is created that extends into the nasofacial sulcus and terminates in the glabella. A back cut in the glabella improves the rotational mobility of this flap and is termed a *hatchet flap* (Fig. 243-17). If the arc of this flap is not long enough or there is too much tension on the leading edge of the flap, elevation of the nasal tip will result. Wide undermining at the level of the perichondrium is required.

BILATERAL ROTATION FLAP. At times, the size of the defect or the tension on the flap mandates a bilateral rotation flap, in which tissue is rotated into a defect from two opposite sides. The vectors of rotation may be mirror images of each other, recapitulating the premise of the A–T advancement flap. This may be utilized for large defects on the scalp and larger defects on the lower lip (Fig. 243-18). The vectors of movement may also be in opposition, creating an O-to-Z flap.

TRANSPOSITION FLAPS

A transposition flap is a random pattern flap, which borrows skin laxity from an adjacent area in order to fill a defect in an area with little or no skin laxity. In its travel from the donor site to the recipient site, the flap

Figure 243-18 **A–C.** Bilateral rotation flap of the lip. Incisions are made bilaterally along the vermillion border and a redundant tricone of tissue is removed posteriorly into the wet mucosal lip. Both wings of the flap are rotated together and sutured with braided suture.

is lifted or "transposed" over a segment of intervening tissue. When the secondary defect is closed, the transposition flap pushes tissue into a defect rather than pulling it, as with the advancement and rotation flaps. While moving to the recipient site, the flap actually follows a rotational path and must be designed so it does not rotate too far and pull too tightly on its pedicle.

Transposition flaps have several advantages over other closures. Their primary function is to redistribute and redirect tension. This is useful in the closure of defects, which would otherwise close under high tension or distort a nearby anatomical structure leading to functional or aesthetic impairment. Transposition flaps are usually smaller in size than advancement and rotation flaps. The resulting scars are geometric broken lines that may be less noticeable than longer linear closures in certain areas. This geometric broken line scar, however, may also be thought of as a disadvantage because such a scar is difficult to completely place along a relaxed skin tension line or cosmetic unit junction. One of the major advantages of transposition flaps are that they utilize adjacent skin and provide an excellent color and textural match.

The most common transposition flaps in cutaneous surgery include rhombic flaps (and their variations), bilobed flaps, and banner flaps such as the nasolabial flap. Knowledge of the tissue dynamics used in these three basic transposition flaps can be carried over to the planning and execution of the numerous variations of these flaps.

RHOMBIC FLAP. First described by Lindberg in 1963, the classic rhombic flap was designed to create a secondary defect perpendicular to the primary defect.[35] When closed, it would not only provide tissue to the primary defect, but also redirect the tension vector by 90°. This allowed the primary defect to be closed under almost no wound edge tension. Subsequent modifications by DuFourmental and Webster provide more tension sharing between the primary and secondary defects. These modifications are useful in situations where some laxity around the primary defect is available.[36]

The classic Lindberg rhombic flap is designed by conversion of the primary defect into a four-sided parallelogram with each side of equal length and tip angles of 60° and 120°.[35] This rhombus forms the recipient site for the flap as well as the template on which to plan the flap incisions. In its classic configuration (Fig. 243-19), the incisions are designed by extending a line (line a-b) outward from one of the obtuse tips for a length equal to that of one side of the rhombus. From the free end of the extended line (point b), a second line (line b-c) is drawn. The tip angle in this configuration is 60°. The flap is lifted and transposed into place. The tension vector is redirected from that of closing the primary defect, to that of closing the new secondary defect created in the design of the flap. This allows the tension vector to be shifted and redirected by 90°.

There are four possible flap designs off of the short axis of any rhomboid defect (Fig. 243-20). Which of these four flap configurations is selected depends on

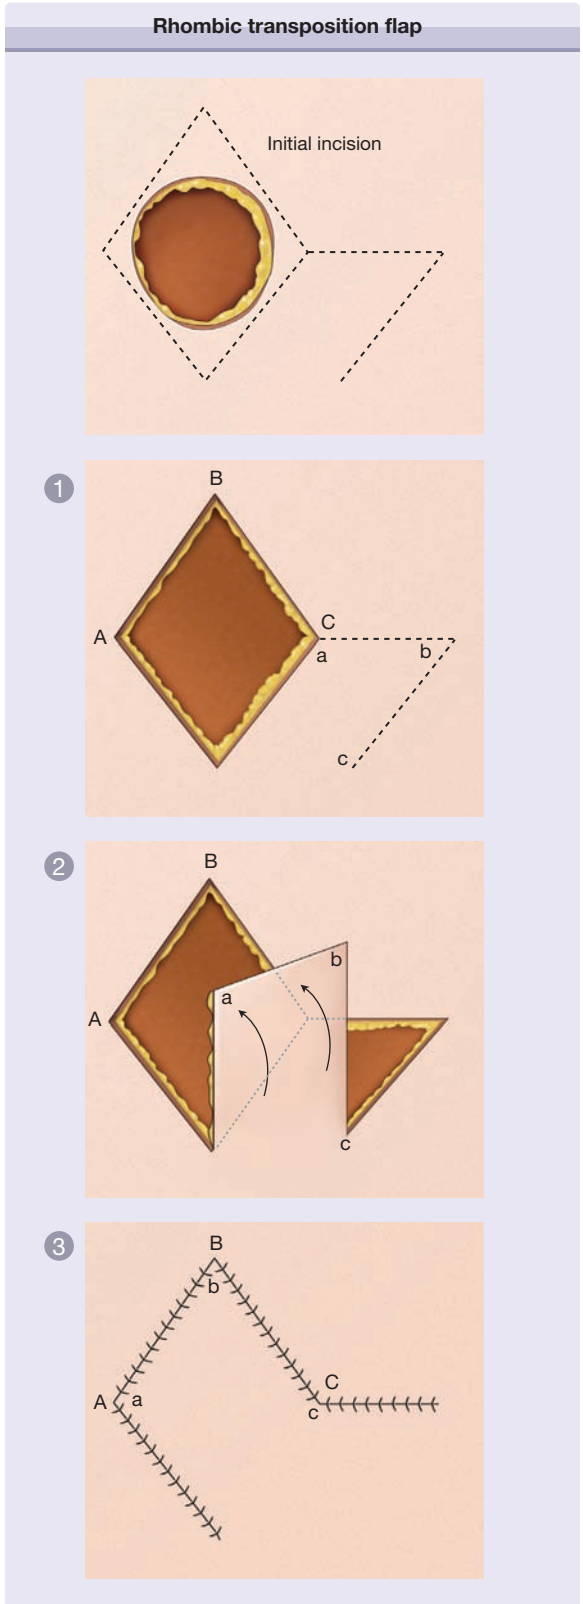

Figure 243-19 Rhombic transposition flap. Classic rhombic flaps alter the vectors of tension in a closure by 90° and leave a broken geometric scar shape. The tension is taken completely by the closure of the secondary defect as the flap is pushed into the primary defect.

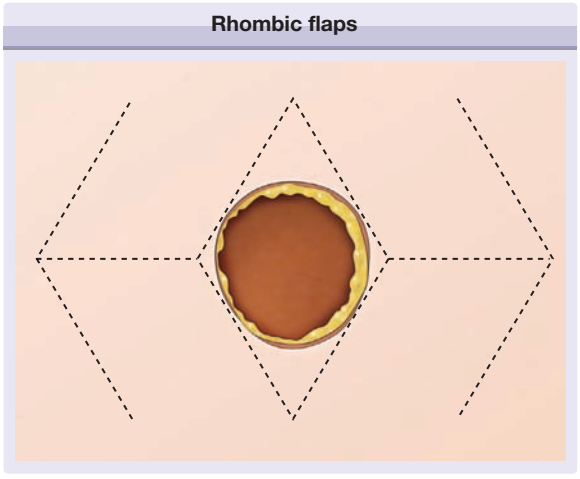

Figure 243-20 Rhombic flaps may be drawn in any of four directions off of the short axis of any rhomboid shaped defect.

several factors that affect the final outcome. These factors include adjacent anatomic structures, adjacent skin type, and where the scar line will be best hidden. Though the classic rhombic transposition flap can be designed and executed off of the long axis of the rhombus, there are two advantages to designing it off of the short axis of the defect. First, it keeps the flap as small as possible while filling the defect completely. Second, it minimizes the arc through which the flap must rotate to fit into the defect.

In designing the flap from the circular defect, the length of the line extended out from the defect should be drawn longer than the diameter of the circular defect. This will account for the fact that the diameter of the circular defect is shorter than the short axis of a rhombus drawn around the defect. A second line of the same length is drawn, keeping the tip angle at 60° to complete the flap. The triangle of tissue redundancy created by the rotation of the transposition flap is removed by trimming a Burow's triangle at the pivot point. The transposed tissue may be rounded to fit the circular defect, or the defect may be squared off to accommodate the angular flap. This choice can be made based upon which option yields the best aesthetic result.

As with any closure, understanding the tension forces is essential to the planning, execution, and outcome of the repair. There are two main tension forces associated with the classic rhombic flap. The first set of tension forces are realized during the approximation and closure of the secondary defect. The second set of tension forces are generated at the tip of the flap when moving it into the primary defect. These forces are due to the resistance to rotation at the flap's pedicle as well as shortening of the length of the flap during rotation into the recipient site. Dzubow describes these forces as pivotal restraint.[33] Securing the flap into the recipient site under high tension is not advised because it may lead to tip ischemia and necrosis. Two modifications in design can be utilized to assist in minimizing the shortening of the flap and subsequent tension at the flap tip.

- By lengthening both the leading edge and the secondary limb of the flap, the flap can be enlarged and lengthened. This lengthening can compensate for the shortening resulting from pivoting at the base, thus, reducing tension at the tip when secured in the recipient defect.
- An alternate method to lengthen the flap is by designing the flap with a slightly more obtuse (greater than 120°) flap angle. Widely undermining around the flap also assists in the redistribution of tension vectors as well as redistribution of contractile forces during the healing phase.

THE DUFOURNMENTAL FLAP.

The DuFournmental flap modification differs from the classic rhombic transposition flap (Fig. 243-21) in that it utilizes a narrower flap tip angle and a shorter arc of rotation, allowing easier closure of the secondary defect, and some sharing of the tension between the primary and secondary defects. Given that there is generally some tissue laxity at the site of the surgical defect, the DuFournmental modification is utilized by this author more than any of the classic rhombic flap.

As with the classic rhombic flap, it is designed by extending the first line from the short axis of the rhomboid defect. However, the angle at which the first line is extended differs from the classic rhombic flap in that it bisects the angle formed by the first line of the classic rhombic flap (which extends straight out from the short axis of the rhombic defect) and the line formed by extending one of the sides of the rhombus from the same corner of the rhombus. The length of the first line is equal to that of a side length of the rhombus. The second line originates from the free end of the first

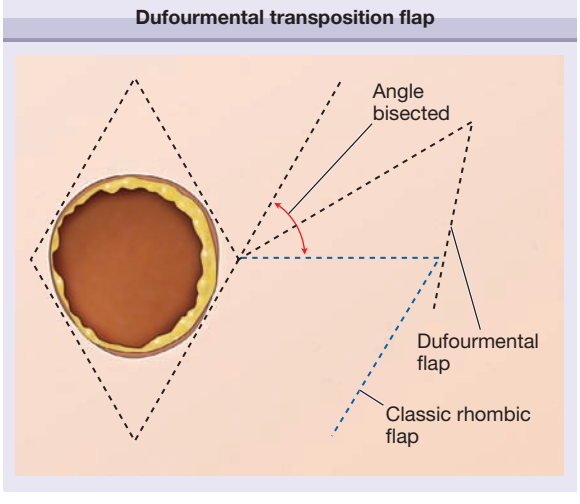

Figure 243-21 DuFourmental transposition flap. The flap is designed with a narrower tip angle and a shorter arc of rotation. This allows easier closure of the secondary defect and allows some sharing of tension between the primary and secondary defects. The vectors of tension are altered by 45° not the full 90° seen in a classic rhombic flap.

line, and is drawn parallel to the long axis of the rhombus. This second line's orientation results in a slightly widened pedicle, a decrease in the tip volume, and a decrease in the degree of rotation necessary to execute the flap. The tissue redundancy at the base of the leading edge of the flap can be removed by taking a slightly larger Burow's triangle.

THE 30° ANGLE WEBSTER FLAP. The 30° angle Webster modification of the classic rhombic flap utilizes a more acute angle than other rhombic transposition flaps allowing for even greater tension sharing between the primary and secondary defects. A Webster 30° angle flap is planned similarly to the DuFourmental flap; however, its distal tip angle is designed to be 30° (Fig. 243-22). This gives the flap a slimmer design and narrower pedicle. The flap area is only 50% of the area of the primary defect; therefore, it only relieves half of the tension from the primary defect. This modification is used in situations where a fair amount of laxity exists in the horizontal axis of the rhombic shaped defect. Since this design places more tension on the primary defect, care must be taken not to close with too much lateral tension or distort adjacent anatomic structures.

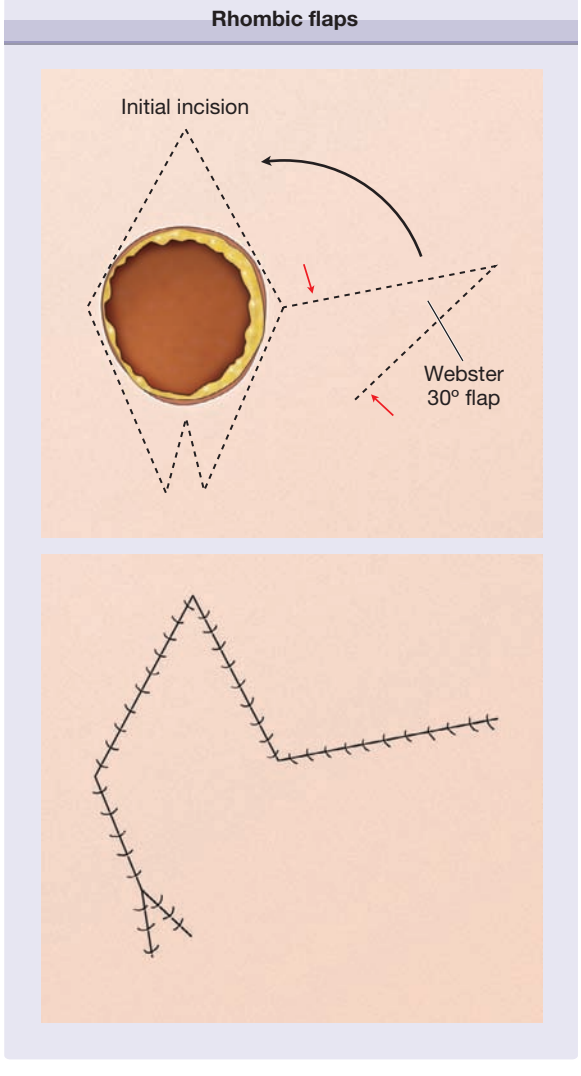

Figure 243-22 30° Webster flap. The angle of the rhombic flap is made even more acute and more of the closure tension is shared with the primary defect.

Rhombic transposition flaps are very versatile and may be used to reconstruct a variety of defects. Transposition flaps are generally used when there is insufficient laxity in the immediate surrounding area of closure and/or the tension vectors need to be redirected. This is particularly important when repairing defects near free margins such as the eyelids and the nose. The most common areas they are employed include the nasal dorsum, nasal sidewall, medial and lateral canthus, lateral forehead, temple, cheek, perioral region, inferior chin, and the dorsal hand.

THE BANNER FLAP. Banner type flaps are random pattern finger-shaped cutaneous flaps that, like other transposition flaps, tap into adjacent skin to borrow laxity and fill a defect.[37] This flap is most commonly planned as a melolabial transposition to repair defects of the nasal ala or from the pre- or postauricular area to close defects on the ear. For an optimal cosmetic result, the scar is generally placed at the junction of two cosmetic units, providing excellent camouflage (in the nasolabial fold or preauricular sulcus) (Fig. 243-23).

The fundamental design of the banner flaps consist of a finger-shaped flap drawn with a width that is equal to the width of the defect and a length equal to the distance from the pivot point to the far edge of the defect. The flap is transposed and rotated in an arc around the pivot point to fill the defect. Since this is a long random pattern flap with a narrow pedicle, the risk of vascular compromise may be high if the entire length of the flap is used and its pedicle originates from an area of minimal vascularity. To minimize risk of vascular compromise, the flap is typically designed to rotate through an angle of 60 to 120° instead of the originally described 180°. Additionally, when designing the backcut and removing the redundancy at the base of the flap, it should be designed in a direction away from the pedicle of the flap to avoid further narrowing of the pedicle thereby maximizing flap viability. Typical locations for use of Banner type flaps include the nasal ala, the superior helix of the ear, and the medial anterior ear.

BILOBED FLAP. The bilobed flap used today is a highly evolved transposition flap. The bilobed flap was first described by Esser in 1918. It became a workhorse flap only after the modifications described by Zitelli were published in 1989 (Fig. 243-24). The design of the bilobed flap actually consists of two transposition flaps executed in succession, which follow the same direction of rotation over intervening tissues. The basic premise of this flap is to fill the defect with the primary lobe, while filling the secondary defect with the secondary lobe, leaving a triangle-shaped tertiary defect to be closed primarily. This series of transposition flaps allows the surgeon to further the reach of the flap, and borrow laxity from donor sites at a greater distance from the defect while decreasing the arc of rotation of the pedicle.

Figure 243-23 **A–C.** Banner transposition flap. A finger-shaped flap is incised and draped into the primary defect. These closure lines are generally placed along cosmetic unit junctions such as the preauricular sulcus.

The Zitelli modification of the bilobed flap is designed by placing the lobes over a 90° arc from the center of the defect, with the primary lobe rotating from a pivot point that is created by removing a Burow's triangle at one pole of the defect .[38] The width of the primary lobe should be equal to the width of the defect and should be long enough to just extend past the edge of the defect. The secondary lobe must be trimmed to match the secondary defect left by the transposition of the primary lobe.

As with the rhombic flap, the bilobed flap redirects the principal tension vector and takes advantage of tissue laxity of the donor site. This flap is predominantly used for small-to-medium sized defects of the lower nose as the tension is redirected to a near vertical vector, preventing distortion of the alar rim (eFig. 243-24.1 in online edition, Fig. 243-25).

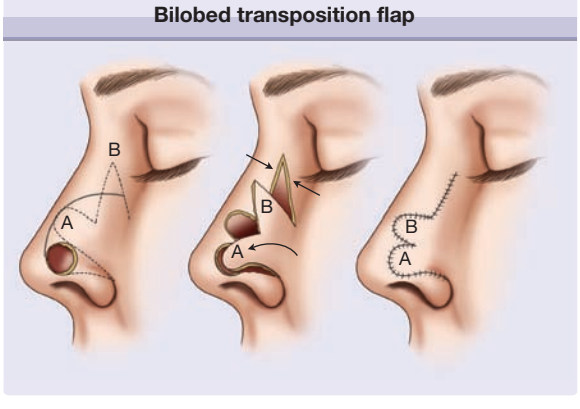

Figure 243-24 Bilobed transposition flap. The bilobed flap is designed with two adjacent transposition flaps elevated and rotated into position. The Zitelli modification (shown here) is designed placing the lobes over a 90° arc.

INTERPOLATION FLAPS

Interpolation flaps are more complex repairs that import pedicle-based tissue from a site distant to the defect. They are typically utilized on defects that are either too wide or too deep to reconstruct with local flaps or grafts. Many interpolation flaps may be classified as axial flaps if their vascular pedicle is based on a large, named artery. They are also commonly referred to as staged flaps as more than one stage is required to complete the repair. Interpolation flaps require careful planning, substantial time in executing, and significant, albeit temporary, disfigurement of the patient.

The first stage of an interpolation flap involves the design and creation of the flap, including repair of the secondary defect. The flap is designed around a substantial artery and therefore is able to support a larger mass of tissue than random flaps. Because the flap is used to repair defects distant from the donor site, the vascular pedicle must temporarily be left in place to ensure adequate blood supply. The distal end of the flap is thinned to match the depth of the defect and sutured in place. The area is bandaged and kept moist. The second stage generally takes place 2- to 3-weeks later, by which time the flap has established a local blood supply from the donor site. The pedicle is then divided from the donor site and the proximal portion of the flap is secured into the original defect. Due to granulation tissue formation, this portion of the flap may need to be thinned out subcutaneously to approximate the depth of the defect. The pedicle is also separated from the donor site which will then require further steps for complete repair.

PARAMEDIAN FOREHEAD FLAP. The paramedian forehead flap is useful to repair large, deep nasal defects that may or may not require cartilage grafts. Tissue is mobilized from the forehead, based on one

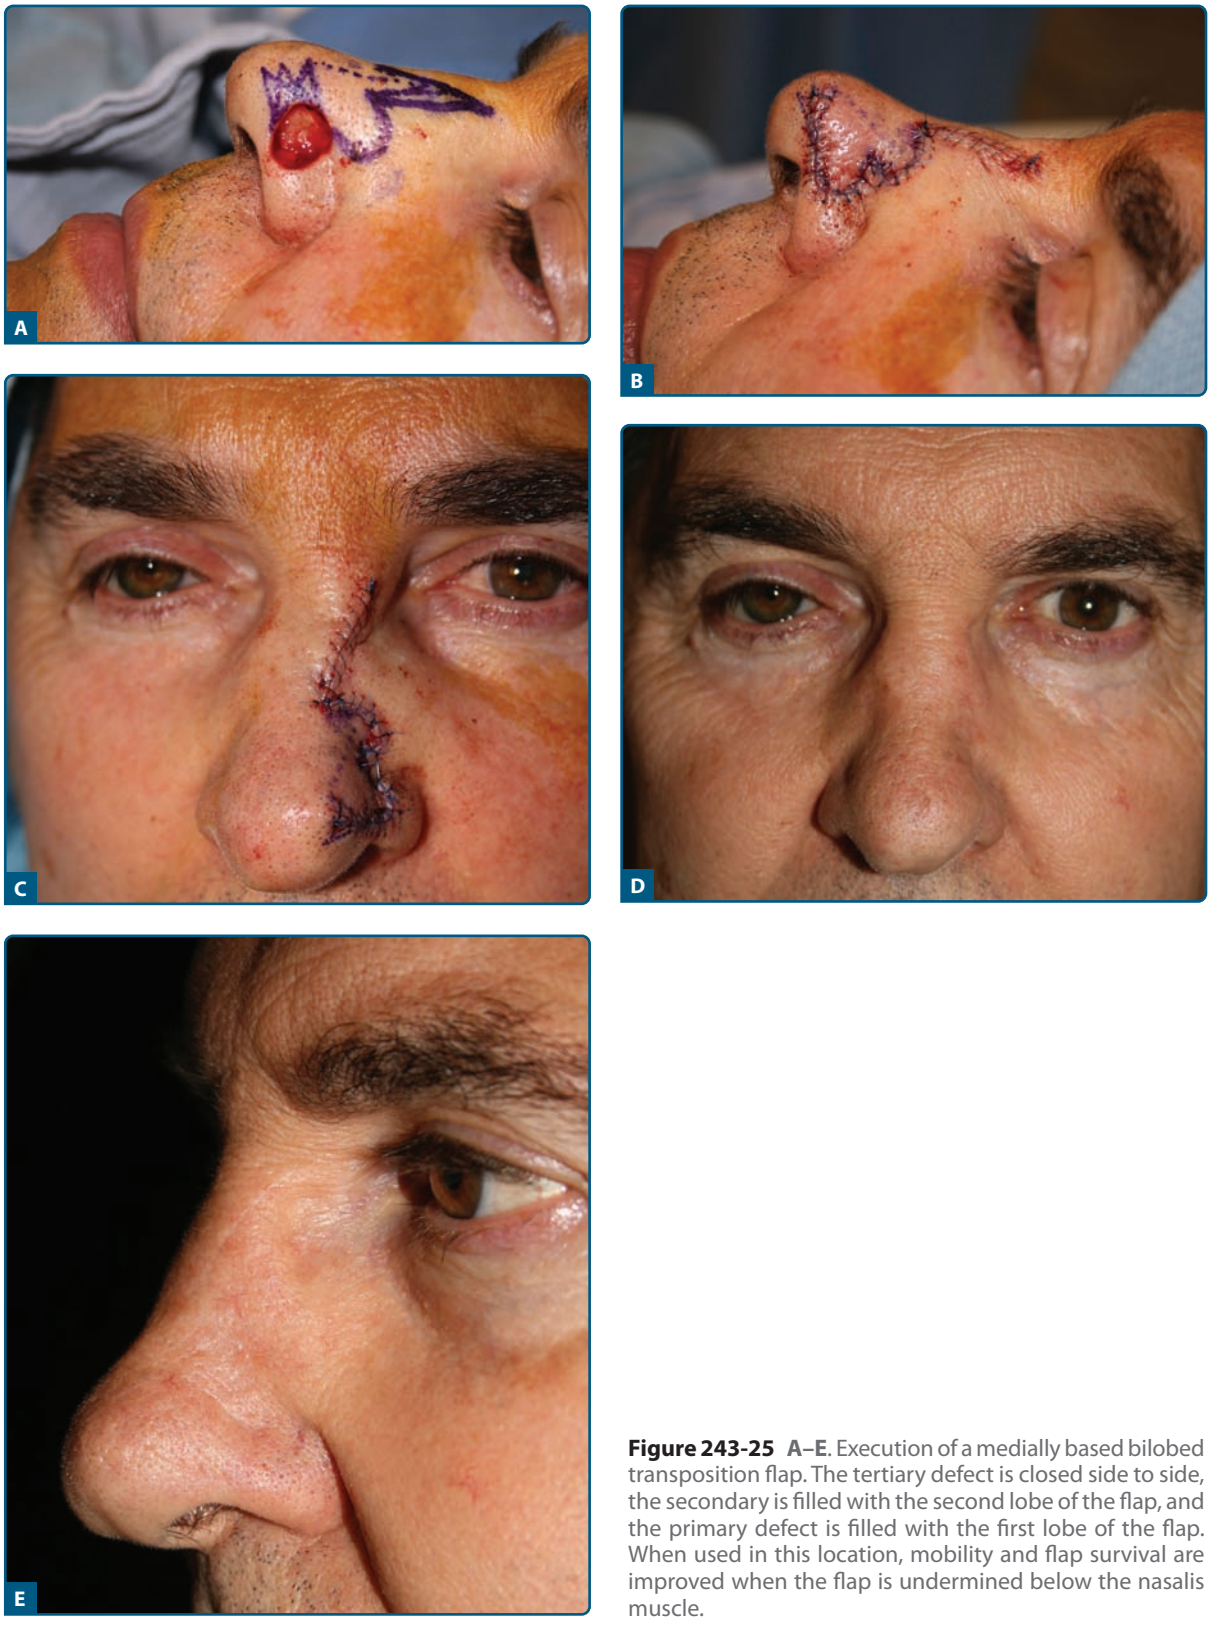

Figure 243-25 **A–E.** Execution of a medially based bilobed transposition flap. The tertiary defect is closed side to side, the secondary is filled with the second lobe of the flap, and the primary defect is filled with the first lobe of the flap. When used in this location, mobility and flap survival are improved when the flap is undermined below the nasalis muscle.

of the supratrochlear arteries, and transposed to repair large distal nasal defects with the pedicle remaining attached in the glabellar region (Fig. 243-26). The supratrochlear artery is located at the medial border of the eyebrow, approximately 1.5–2 cm from the midline.

The aesthetics of the repair are often improved when the defect is enlarged to include the total cosmetic subunit. The portion of the flap that will fill the defect is the superior portion closest to the hairline; the width here should be equal to the widest portion of the defect, although the pedicle itself need be no wider than 1–1.5 cm. Its height must be equal to the distance from the base of the flap to the distal edge of the defect. In designing the flap, it is important that the vertical height of the forehead is able to accommodate the necessary length of the flap. The tissue is rotated approximately 180° around its pedicle and should be rotated medially as to minimize obscuration of the medial visual field of the ipsilateral eye; therefore, the flap will require less rotation if it is harvested from the forehead supplied by the supratrochlear artery contralateral to the defect.

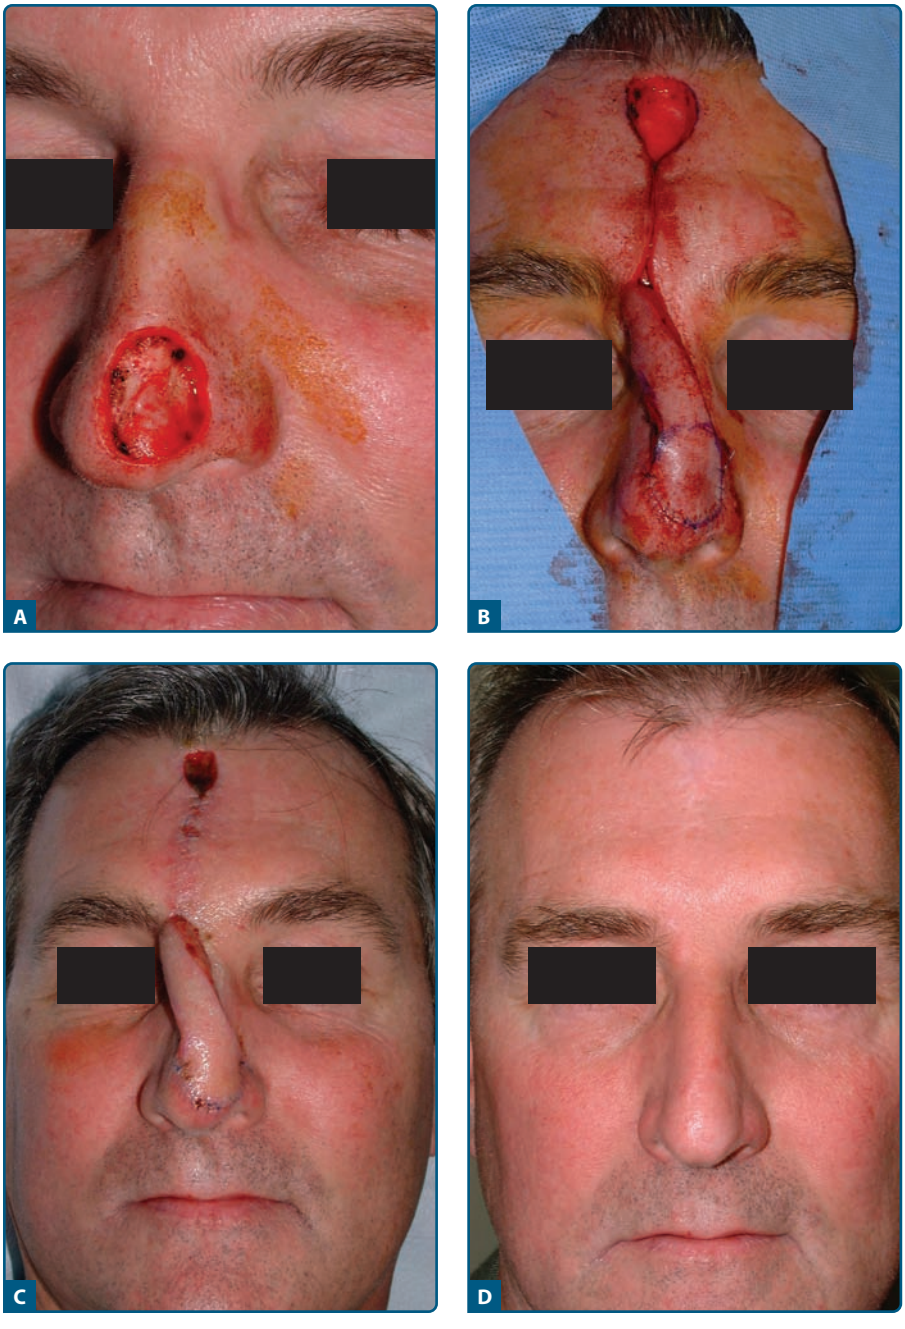

Figure 243-26 **A–D.** Paramedian forehead flap. For deep defects on the nose, a pedicled flap is created on the forehead based on the hearty vasculature of the supratrochlear arterial system and rotated down into place. The pedicle is divided and removed approximately 3 weeks after the inset of the flap (c).

Figure 243-27 **A–D.** Nasolabial interpolation flap. The pedicle is created from excess skin lateral to the nasomelial fold and rotated into the defect. The pedicle is divided and removed approximately 3 weeks after the inset of the flap (c).

The donor site is undermined and closed primarily as far superiorly as it will close. The distal aspect of the flap is debulked to the depth of the defect and secured at the distal margin with sutures. The proximal margin, by design, cannot be secured until the pedicle is divided. The donor site is repaired with a side-to-side closure, resulting in a long linear scar. The superior portion of the defect will be the widest, as it is here that the width of the defect must be accommodated, and thus, generally this portion of the wound is too tight to be closed and is left to heal by secondary intention. The pedicle should be circumferentially wrapped with Vaseline or Xeroform gauze or Surgicel to prevent desiccation.

The second stage takes place 3 weeks subsequently. The pedicle is separated from the brow, the wound edges are freshened, and the donor defect is closed. After the pedicle is separated from the defect, the tissue is further debulked and trimmed, and the remaining edge is secured.

NASOLABIAL INTERPOLATION FLAP.

This flap is utilized to repair complex defects of the ala, particularly in instances when cartilage grafting is also required to restore the structural integrity of the alar rim. The flap is harvested from the medial cheek and nasolabial fold and is based on branches of the angular artery (Fig. 243-27).

The aesthetics of the repair is often improved when the defect is enlarged to include the entire alar lobule. The flap is designed around a pedicle that will be placed at the alar groove, extending as an ellipse that will be easily closed in the nasolabial fold. Through-and-through nasal defects will require the repair of the mucosa, and thus, the width of the flap must take this into account. This myocutaneous flap is dissected from the donor site, rotated downwardly, debulked and trimmed, and secured to the widely undermined defect.

As with the paramedian forehead flap, the pedicle may be wrapped with Vaseline or Xeroform gauze or Surgicel. Three weeks later, the pedicle is separated, the wound edges are freshened, and the donor defect is closed. After the pedicle is separated from the defect, the tissue is further debulked and trimmed, and the remaining edge is secured.

The reverse nasolabial flap, also known as a *Spear's flap*, is employed when the defect involves the alar groove. The motion of this flap is an upward rotation,

opposite of the traditional nasolabial interpolation flap.

ABBÉ FLAP. The Abbé flap is also known as the *lip-switch flap* and is reserved for repair of large, deep defects, typically of the upper lip. It is particularly useful for defects that involve up to half of the lip without crossing the midline and those that penetrate into the muscularis. The Abbé flap is harvested from the ipsilateral lower lip and is based on the inferior labial artery. This artery is located deep to or within the orbicularis oris muscle and runs along the mucosal aspect of the vermillion border.[39]

The vermillion border and flap design must be properly marked out. The defect should be full thickness (including muscularis and oral mucosa) and may be enlarged to encompass the total cosmetic unit, which includes the ipsilateral upper cutaneous lip. The flap, also designed to be full-thickness to fill the enlarged defect, is rotated upon a vascular pedicle that makes up the lateral aspect of the flap. The inferior labial artery will be visualized as it is transected at the mobilized (medial) edge of the flap. The pedicle itself should be about 1 cm thick, containing the robust blood supply.

The donor site is undermined and closed first to facilitate the movement of the flap. It should be closed in layers as in the repair of a lip wedge resection: mucosa, muscularis, subcutaneous, then cutaneous. The flap is rotated superiorly and also inset with a layered closure. Careful attention should be given to aligning the vermillion borders at the donor site and defect.

The pedicle of the Abbé flap should not be circumferentially wrapped, but kept moist with occlusive ointment. As with other interpolation flaps, the pedicle will remain in place for at least 3 weeks. During this time, the oral aperture will be significantly distorted, and the patient must be counseled. The pedicle is divided and the final repair takes place, again with careful attention to the placement of the vermillion borders.

RETROAURICULAR FLAP. The retroauricular flap is a two-staged interpolation flap useful for large defects of the helix. Defects in this location typically involve the perichondrium and are not suitable for grafts. This flap is considered a random flap as it is not based on a large named artery. It is harvested from the richly vascularized skin of the postauricular scalp and is advanced over intervening intact skin to fill the helical defect; the pedicle remains attached to the posterior scalp (Fig. 243-28). The flap should be thinned to match the depth of the defect and carefully sewn into place. The pedicle is circumferentially dressed, and the patient is warned of likely postoperative bleeding and discomfort. The donor site is not repaired until pedicle take-down and often, due to its inconspicuous location, is allowed to heal secondarily.

GRAFTS

Skin grafts are transplanted skin from a donor to recipient site with the goal of closing a surgical defect or wound. They are typically used in reconstruction after removal of a cutaneous malignancy; however, they are also used in the treatment of chronic skin ulcerations, full-thickness burns, epidermolysis bullosa, and vitiligo. Grafts are completely detached from the donor site and receive all nutrients from the wound bed of the recipient site. The three basic types of skin grafts are full-thickness skin grafts (FTSG), split-thickness skin grafts (STSG), and composite grafts. FTSGs consist of epidermis with full-thickness dermis, while STSGs consist of epidermis with partial-thickness dermis. Composite grafts are full-thickness skin grafts with cartilage attached to the graft. Skin grafts are also categorized by their donor origin. These include autografts (donor = recipient), allografts (human to human), and xenografts (animal to human).

FULL-THICKNESS SKIN GRAFTS

FTSGs are useful for defects in which complex linear closures or a flap would not be suitable, where close monitoring of the site is advisable, and in certain areas where they provide optimal aesthetic reconstruction. When possible, FTSGs are chosen over STSGs because of their similarity in thickness and texture to surrounding skin and their relative lack of significant wound contraction. Since STSGs generally result in a depressed, hypopigmented, scar without normal epidermal texture, they are reserved for larger wounds that cannot be covered with FTSGs. When wounds are too deep for even a FTSG to cover without creating a depression (when the depth of the wound exceeds the thickness of a graft), second intension healing may be employed for a period of time to build the base of the wound up to the point where a FTSG would completely fill the defect.

FTSGs have essential nutrient requirements and, therefore, should not be placed at a site where the vascular supply is poor. FTSGs will not survive if transplanted directly over bone, cartilage, or tendon.

DETERMINING DONOR SITE. When planning your graft, there are many factors to be taken into consideration. The donor site should be well matched to the skin surrounding the defect in terms of thickness, texture, sun exposure, and adnexal structures.[40] Donor sites can be differentiated by thickness, for example, thin (eyelids, postauricular sulcus), medium thickness (preauricular, conchal, cervical), and thick (supraclavicular, clavicular, nasolabial fold, forehead).[41] However, examining for tissue similarity, such as adnexal structures and sun exposure, is also pertinent.

Common sites for FTSGs for nasal defects include preauricular, postauricular, nasolabial fold, forehead, and conchal bowl skin. Preauricular skin can be used to repair most nasal defects, has similar sun exposure and skin quality and heals with minimal scar visibility.[42,43] Conchal bowl grafts are particularly well matched for nasal tip and alar defects due to the similarity in texture and concentration of sebaceous glands

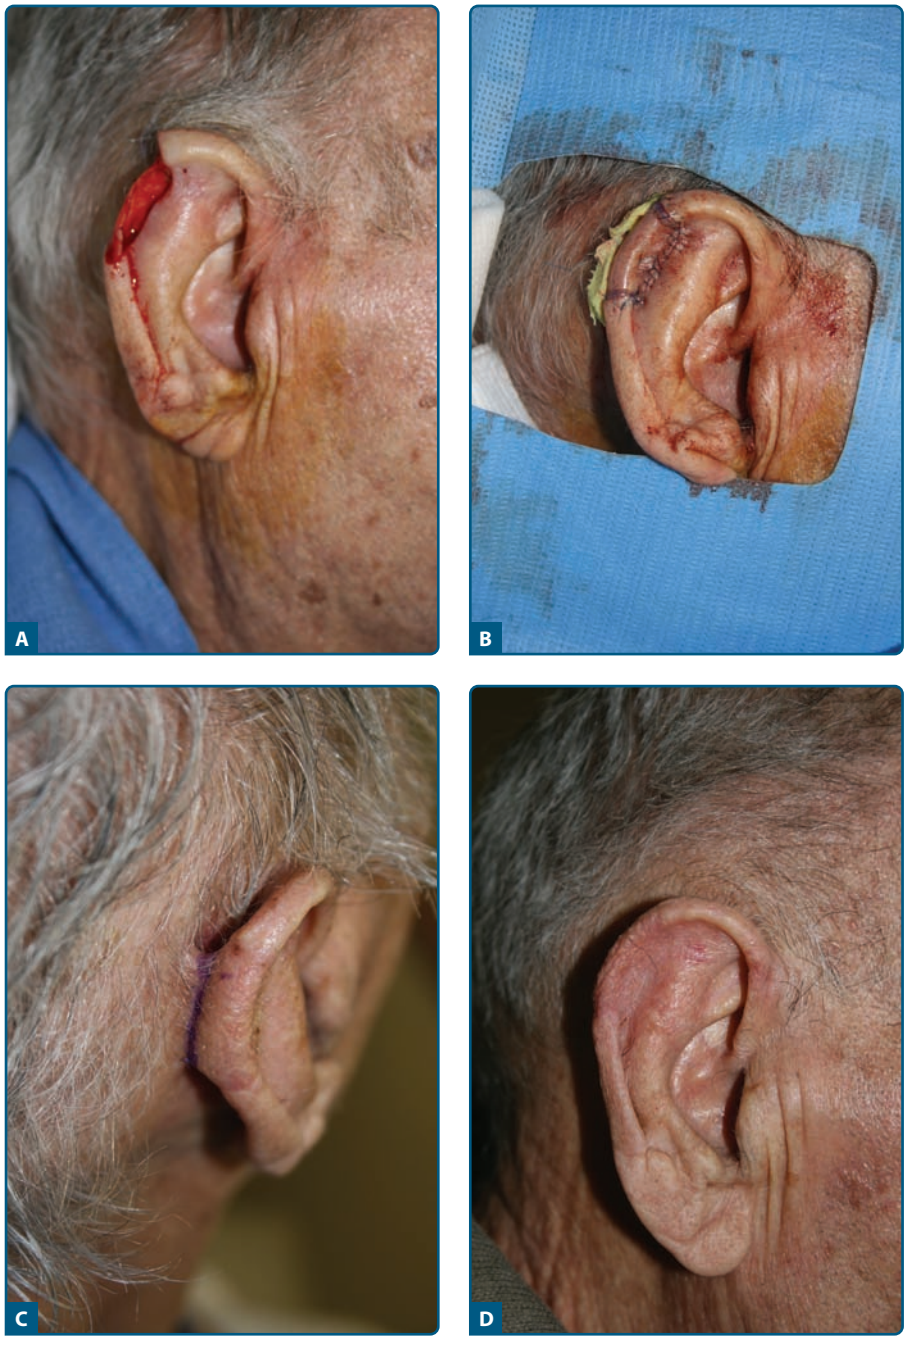

Figure 243-28 **A–D.** Retroauricular pedicle flap. A pedicled flap is developed posterior to the ear in a shape similar to the U-Shaped advancement flap. The flap is advanced over the postauricular sulcus and over the auricular cartilage of the helix and sutured into place. The pedicle is divided and set back into place 3 weeks after the inset of the flap (c). The area surrounding the postauricular sulcus is allowed to heal in by second intention.

(Fig. 243-29) as well as the ability to allow the donor site to heal by secondary intention.[44] Nasolabial fold and forehead skin offer excellent matches but leave secondary scars in more visible areas.

HARVESTING. Once the donor site has been established, the graft can be harvested. To ascertain the size and shape of the graft needed to fill a given defect, many surgeons will create a template using a nonstick dressing, pressing it against defect. The template is cut out and then traced with a marking pen onto the donor skin. Although some authors have recommended grafts be designed 3% to 5% larger than the defect to accommodate contraction of the graft skin once it is removed[45]; oversizing grafts can lead to unsightly pincushoining. For this reason, the authors size their grafts at or just under the size of the defect. If the donor site is to be closed primarily, an ellipse is planned around the designed graft (see Section "Excisional Surgery").

Figure 243-29 **A–D.** Conchal bowl full-thickness skin graft. The graft is harvested from the conchal bowl because, like skin of the nasal tip and ala, the sebaceous density in the conchal bowl is high. The defect in the conchal bowl is allowed to heal by second intention.

Defatting the graft before securing it to the recipient bed is critical. The subcutaneous tissue is poorly vascularized and, therefore, hinders graft survival. Defatting can be performed with an iris scissors by trimming away the yellow fat to expose the shiny white dermis. If the area being repaired is uneven, thin areas of fat may be left on the graft to more closely approximate the natural contours. Alternatively, at times, it may be necessary to thin the dermis slightly to ensure similar thickness between graft and donor tissue. If this is the case, minimal thinning is recommended to avoid structural damage of adnexae. Once the graft has been prepared, it should be placed in the recipient bed as soon as possible. The recipient bed should have good hemostasis without devitalizing the tissue with overuse of cautery.

Grafts generally need to be trimmed at the edges to ensure a perfect match to the donor site. Survival of the graft is also dependent on the surgical technique during placement. The graft must be manipulated and grasped gently.

Small caliber nonabsorbable or fast-absorbing cat gut sutures are commonly utilized for FTSGs on the face. Insertion of sutures should be from graft to recipient tissue to minimize graft movement and best approximate wound edges. It is helpful to place the initial four sutures at intervals of approximately 90° from each other to ensure proper placement and to secure the graft. These are followed by interrupted sutures or, at times, running sutures to complete closure. When grafts are large or placed over concave areas, basting sutures help keep good graft to bed contact. This will stabilize the graft and minimize sheering forces. Several authors recommend the use of bolster dressings. While bolster dressings may assist in prevention of

hematomas and seromas they also compromise vascularity and can increase the risk of necrosis.

For larger defects or those with exposed bone or cartilage at the periphery, a purse-string approach may be introduced. A purse-string suture is placed subdermally along the defect edges, then tightened to advance edges into the defect circumferentially. This technique helps protect exposed tissue as well as reduce the defect size, thereby allowing the surgeon to use a smaller graft.

Sutures should be removed in one week for grafts on the face. Healthy grafts are pink in color. Although a purple color indicates relative hypoxia, most grafts with this color will survive. A white color on the surface of a graft generally represents maceration and may do fine when no longer occluded. If the white color is full thickness, it may represent necrosis. Black grafts are necrotic. Gentle wound care without debridement is the best treatment for graft necrosis. The necrotic graft will act as a biologic wound dressing, promote dermal healing, and generally avoid contraction. Antibiotics should also be started to minimize the risk of infection.

BUROW'S/REGIONAL GRAFT.

Burow's or regional grafts essentially use the Burow's triangle or dog-ear, often from a partial linear closure, to act as an FTSG (eFig. 243-29.1 in online edition). This utilizes removed skin that might otherwise have been thrown away and eliminates the need for removing tissue from a separate donor site. Because these are often local grafts, the tissue match is generally excellent.[46] Since a circular defect has a much larger surface area than a standard triangle taken in an elliptical closure, the triangle must be designed more like that of an island pedicle with a wider and longer body.

STAGES OF WOUND HEALING

- First 24 hours: plasmatic imbibition or ischemia: the graft affixes to the recipient bed via fibrinous material
- 48–72 hours: anastomosis and proliferation of vessels
- 4–7 days: reestablishment of full circulation

Stress on the wound should be avoided to provide the best results. Overstimulation of the patient may lead to increased blood flow to graft site leading to fluid overload and disruption of vascularity. The patient should be advised not to undergo strenuous activity for at least 1–2 weeks.

COMPOSITE GRAFTS

Composite grafts consist of one or more adjacent tissues, often involving a typical FTSG with underlying cartilage.[47] Small full-thickness defects of the nasal ala and helical rim most commonly require such a graft. Donor sites for composite grafts frequently include the helix and conchal bowl. It is desirable to harvest the graft in a manner that allows the underlying cartilage to extend beyond overlying tissue. This extension allows for the cartilage to insert under the surrounding defect margins. Two small pockets are generally made across from each other at a level below the dermis in the recipient site to accommodate the cartilaginous wings on the composite graft. The cartilage may or may not be sutured, and the remaining FTSG is sutured and secured as described earlier in this section. After being sutured into place, a composite graft with cartilage at its base receives its blood supply from its lateral margins only. Therefore, composite grafts should remain less than 2 cm^2, as a larger graft will not receive sufficient nutrients to allow its central portion to survive.[48]

FREE CARTILAGE GRAFTS

Free cartilage grafts consist of cartilage and perichondrium. This type of graft assists in structural support (e.g., prevent nasal valving) and retention of natural facial contours (e.g., ala and helical rim). Elastic cartilage from the ear, versus hyaline cartilage from the nose, is the best for recontouring. A strip or disc of cartilage is usually harvested through an incision in the postauricular sulcus or conchal bowl. As is done with a composite graft, the strip of cartilage harvested is slightly longer than the size of the defect and the edges are inserted into pockets made under the dermis. The cartilage is sutured lightly into place with absorbable sutures. The site is then typically closed with a flap. Full-thickness skin grafts may be placed over very thin cartilage struts but as the size of the cartilage increases, the vascular supply to the graft becomes increasingly compromised and decreases graft survival. The addition of cartilage helps with structural support such as preventing collapse of the nasal valves which results in disruption of air flow. It also helps retain the patient's original facial contours and prevents concavity and/or contraction of the repair.

SPLIT THICKNESS SKIN GRAFTS

STSGs are composed of epidermis and partial dermis. Because these grafts are much thinner than FTSGs, they have a less rigorous demand for vascular support and have an increased survivability profile. Unfortunately, since they lack the full thickness of dermis and dermal appendageal structures, STSGs appear more like scar tissue than skin; they are depressed, hypopigmented and have a shiny texture. They are used to cover large defects unable to be closed by other methods, to allow better wound bed surveillance, to line tubed pedicle flaps, or to resurface mucosa.[49] STSGs are often harvested from the upper inner arm, thigh, or buttock. If small, STSGs may be harvested with a blade by hand. When they are larger STSGs are harvested with a dermatome, which provides a more precise width and depth. Once the graft is obtained, it is placed in sterile saline on the meshing plate. Meshing is beneficial since it expands the donor tissue, allows wound exudate to drain preventing seroma and hematoma formation, and has been found to increase graft survival. Increased wound contraction and decreased cosmesis, however, are associated with meshing. After harvesting is complete, STSGs are placed over the defect and secured similarly to FTSG. For larger defects, surgical staples are often used to secure the graft.

STSGs size can vary. They are categorized as thin (0.013–0.033 cm), medium (0.033–0.046 cm), or thick

(0.046–0.076 cm). The amount of dermis present determines the chance of survival of the graft on a poor vascular bed. Generally, the thinner the graft, the higher the "take rate" but the poorer cosmesis. The donor site re-epithelializes rapidly and relatively painlessly with the use of bio-occlusive dressings.

The main advantage of an STSG is that it survives even in locations with poor vascularization, such as over bone or cartilage. It also allows for early detection of tumor recurrence. Cosmetically, the final outcome of this graft is suboptimal with absent appendages, poor color match, and frequent wound contracture under the graft. For this reason, second intention healing and skin substitutes are often employed for defects once covered with STSGs. These methods avoid the wound care and generally unsightly appearance of the STSG harvest site.

PUNCH AND PINCH GRAFTS. A subset of STSGs includes punch and pinch grafts. These are useful for accelerating the healing phase of a chronic ulcer. Several grafts are harvesting from a donor site and placed in the wound bed. Instruments used are a 4-mm punch for punch grafts or a scalpel (Weck knife) for pinch grafts. The rate of survival of these grafts is good if the site has meticulous postoperative care; however, the cosmetic outcome is suboptimal due to the variable thickness throughout the wound.

SKIN SUBSTITUTES

Tissue which has been cultured or processed prior to grafting is known as a *skin substitute*. There are a few different types: autologous epidermal, allogenic dermal, and xenogenic and allogenic bilayered.

Epidermal skin substitutes are derived by culturing the patient's own skin. These are good for covering a wound and stimulating the healing process.

Dermal skin substitutes are allografts developed from cadaver skin. They often consist of neonatal foreskin-harvested allogenic fibroblasts with an overlying silicone epidermis. These are helpful in replacing the dermis in a defect and can be covered by a STSG. There are several different types available commercially including Alloderm, Integra, Trancyte, and Dermagraft.

Bilayered skin substitutes are made from allogenic neonatal foreskin-derived fibroblasts and keratinocytes and bovine collagen. They are useful for protection of large wounds where donor tissue is insufficient to cover. Commercially available products include Apligraf and Orcel.

POSTOPERATIVE CARE

Meticulous postoperative wound care is necessary to ensure an optimal outcome. Attention must be made to limit postoperative bleeding of all surgical wounds, particularly flaps and grafts, as hemorrhage or hematoma formation may jeopardize tissue survival and increase the risk of infection. Meticulous intraoperative hemostasis and good postoperative compression dressings are very important in minimizing postoperative bleeding. A pressure dressing should be applied and left intact for 24–48 hours. This dressing includes a layer of ointment applied directly to the wound, a nonstick bandage such as Telfa, gauze for pressure, and surgical tape. Finally, elastic dressing materials, such as Flexinet or Coban, may be helpful for wounds on the scalp or extremities.

For the aforementioned procedures, it is important that the wound be kept clean, moist, and covered until suture removal. This will eliminate desiccation and promote re-epithelialization,[50] reduce bacterial contamination, and aid in hemostasis. Verbal and written instructions regarding home wound care should be reviewed and then provided in writing to the patient. After removal of the pressure dressing, the wound should be cleaned once or twice daily with attention to gently removing any crust and debris that may form. This is followed by a layer of ointment. A bland, nonmedicated ointment, such as petrolatum or Aquaphor is preferred over topical antibiotics such as Neomycin. The use of these topical antibiotics following cutaneous surgery increases the risk of contact dermatitis[51] without imparting a significant reduction in infection rates.[52] The patient should be advised to limit activity for 1 to 2 weeks after surgery, particularly, movement that stretches or adds tension to the wound area and may result in wound dehiscence or a widened scar.

The signs and symptoms of hemorrhage and wound infection should be reviewed as early intervention can reduce serious complications. To better prepare patients, it is helpful to educate him or her about what to expect during normal wound healing. The patient should be provided with the physician's contact information and should be encouraged to call with any questions or concerns.

COMPLICATIONS OF DERMATOLOGIC SURGERY

Early complications of all forms of cutaneous surgery and closure are bleeding, pain, and infection. Bleeding typically occurs in the first 24 hours after surgery and must be addressed promptly. Low flow ooze may be treated by compression. Patients should be instructed to apply direct pressure for at least 20 minutes without peeking to see if it is working. Frank arterial hemorrhage or large hematoma formation will require partial or complete suture removal, evacuation of clot, and exploration of the wound to allow visualization and closure of the bleeding vessel. Patients should be instructed to call if they see an enlarging mass below or around the wound.

Pain is usually manageable with non-narcotic pain relievers such as acetaminophen. Acetaminophen may be administered at the time of surgery and continued for 24 hours to reduce the risk of postoperative discomfort. It is generally easier to get ahead of pain than it is to catch up to it. Patients should be instructed to avoid non-prescribed nonsteroidal anti-inflammatory medication for up to 48 hours postoperatively to reduce bruising and bleeding from platelet dysfunction. While more severe pain may require the

administration of prescription pain medication, it should be investigated to be sure more significant issues such as infection or hematoma are not occurring.

Signs of infection usually will occur within the first week after surgery and include increased pain, erythema, and heat around the wound, purulent and sometimes foul-smelling drainage, and fever. When wound infection is suspected, a culture must be obtained for pathogen identification and antibiotic susceptibility, and treatment with a broad-spectrum antibiotic should be initiated. Common pathogens on skin and mucosal surfaces are Gram-positive cocci, notably staphylococci or, less commonly, streptococci. However, Gram-negative aerobes and anaerobic bacteria contaminate skin in the groin/perineal areas. Gram-negative bacilli may also be cultured from ear and lower leg wounds, particularly in diabetic patients. Methicillin resistant *Staphylococcus aureus* (MRSA) infections are increasing dramatically in frequency and should be vigilantly watched for.[53]

An expected consequence of surgery is the formation of a scar. While the goal of reconstructive surgery is to minimize the appearance of the resultant scar, at times they may widen, or even become hypertrophic. With time, hypertrophic scars tend to flatten and soften. Their course may be hastened with the administration of intralesional steroids and laser treatment. In areas under tension and or motion, such as the upper back and arms over the deltoids, scars may spread or become atrophic. While scar spread may become less noticeable with time as the initial dark pink color fades, the width generally does not change significantly. Erythema and telangiectasia often form around scars during the healing phase and may persist for extended periods of time. Highly vascular areas (rosacea) and those under high tension are more likely to develop persistent erythema and telangiectasia. This can be effectively treated with lasers, such as the pulsed dye laser, KTP, or intense pulsed light.

Spitting sutures or suture granulomas from buried sutures may occur. Placing the buried dermal sutures in the appropriate plane will help minimize the occurrence. If the spitting suture becomes visible it may be trimmed out, but it is unadvisable to aggressively go after these as a scar may result.

In the case of a flap repair, additional complications may be encountered. In the early postoperative period, partial or complete flap necrosis may occur. This may be due to inadequate blood supply from the wound bed, which is more commonly encountered in smokers, or when an underlying hematoma is present. Flap design may also lead to vascular compromise and flap necrosis, as when the pedicle is too narrow to support the mass of the flap, when there is too much torque, or when there is too much tension at the flap's leading edge. Areas of partial necrosis will heal secondarily and may lead to a less appealing scar, which can be revised after wound healing is complete. Later in the postoperative period, a trapdoor deformity may occur in which the center of the flap becomes elevated and the suture line becomes depressed. It may resolve spontaneously over a period of 6–12 months. However, if the trapdoor effect or pin-cushioning persists, it may respond to intralesional steroids, flap elevation with flap thinning, and/or dermabrasion. The trapdoor effect may be prevented with wide undermining around the primary defect, proper thinning of the flap, proper size of the flap, and the use of a geometric shape for the flap.

Complications of grafting include graft failure in the early postoperative period and results from inadequate nutrient supply to the tissue. This is often due to poor vascular health of the wound bed as encountered in smokers or diabetics, inadvertent shearing forces or trauma to the graft, hematoma formation, or infection. Later complications typically are attributed to the cosmetic appearance of the graft, usually related to mismatch of thickness, color, or texture. Contraction may be considerable, particularly with thinner grafts, which may result in the distortion of free margins.

MONITORING AND FOLLOW-UP

If nonabsorbable epidermal sutures are placed, the patient should return for suture removal at the appointed time. If the defect has been left to heal secondarily, the wound should be checked in approximately 4 weeks. The surgical site should then again be evaluated 3 to 4 months postoperatively to ensure wound healing is progressing as expected. Patients who have been treated for malignancy should be counseled regarding proper follow-up for full skin examination to monitor for new or recurrent skin cancers.

Chapter 244 :: Mohs Micrographic Surgery

:: Joseph Alcalay & Ronen Alkalay

BACKGROUND

MOHS MICROGRAPHIC SURGERY AT A GLANCE

- Mohs micrographic surgery (MMS) is a precise method of treating skin cancer that results in the highest cure rate with maximal tissue conservation, cosmesis, and function.
- MMS is indicated for the treatment or basal cell cancer and squamous cell cancer and certain less common skin cancers.
- Specific indications for MMS include location in high-risk anatomic sites, aggressive histology, recurrent tumor, and when there is a need for maximal preservation of tissue.
- Advances in processing and staining techniques and the use of immunostains have increased the speed and accuracy of MMS as a cost-effective means of skin cancer extirpation.

Mohs micrographic surgery (MMS) is a surgical technique developed to excise skin cancer under complete microscopic control. The fresh frozen tissue technique is used, which permits immediate examination of the specimen, and the tissue is oriented in a way to permit evaluation of all surgical margins. This is distinct from the traditional bread loafing technique used to process tissue specimens. A special orientation is combined with a precise mapping technique, which leads to maximal conservation of normal tissue. The technique was developed by Dr. Frederick Mohs approximately 80 years ago using a fixed tissue technique that relied on zinc chloride paste. The original term, *chemosurgery* refers to the use of the tissue fixative which is no longer used. As a result, the term chemosurgery is considered archaic.[1] MMS has been described by various names such as chemosurgery, microscopically controlled excision, and microscopically oriented histographic surgery. The latter is an attempt at creating an acronym to replace the eponymous term *Mohs*.

In the past several decades, the mapping component has been retained but the procedure has been refined using frozen tissue rather than fixed tissue, which has permitted more efficient patient care. The advantages of MMS over conventional excisional surgery include maximum cure rate and optimal preservation of healthy tissue. The latter serves to enhance cosmetic outcome and preserve function where applicable. MMS is now recognized as the standard of care for the treatment of various skin cancers in indicated circumstances. The most common cancers treated by this method are basal cell carcinoma (BCC, 73%) and squamous cell carcinoma (SCC, 23%).[2] A defining characteristic of MMS is that the surgeon acts to interpret the histopathologic specimens. Specifically, the MMS procedure requires a single physician to act in two integrated but separate distinct capacities as surgeon and pathologist. MMS is a highly technical procedure that requires meticulous attention to detail and considerable training and experience to achieve the expected high cure rates.

THE PROCEDURE

Mohs surgery is performed under local anesthesia in the office setting or in an ambulatory center. In unusual cases, where multiple cancers or complex malignancies are to be removed, sedation may be used.[3] Prior to surgery, it is essential to have the patient affirmatively identify the biopsy site as very often the biopsy site may fade due to postbiopsy healing. It has been shown that in 25% of patients, who had prior biopsy, no remnants of tumor were found during MMS. [4] This is consistent with the fact that the inflammatory process may contribute to elimination of residual cancer cells after biopsy. The fundamental elements of MMS are listed in Table 244-1. A complete medical history and list of medications should be documented before surgery is performed. Anticoagulants are not contraindicated and data have shown that they should not be discontinued prior to MMS. [5] Once the patient is properly positioned, it is important to mark the clinical tumor border with a surgical pen. Local anesthesia is then obtained by injection (Fig. 244-1). Marking the clinical borders of the tumor is necessary since the local anesthetic may cause blanching that can obscure the tumor borders. The most commonly used local anesthetic is 1% or

2% lidocaine with 1:100,000–200,000 epinephrine (Fig. 244-2). After the surgical site is gently curetted to determine the clinical extent of the cancer, a specimen is taken using the Mohs technique. (Fig. 244-3). This is considered the first Mohs stage. A thin layer of tissue is excised using a scalpel and incising the skin at a 45° angle. Nicks are made in the surrounding tissue to denote tissue orientation and mapping (Fig. 244-4). In some cases, double nicks can help in the orientation of the tissue.[6] Mapping of the tissue is a crucial step in MMS. The topographic map allows the Mohs surgeon to relate the microscopic findings to the excised tissue and the anatomic reference points at the surgical site (Fig. 244-5) The Mohs map is typically created by drawing freehand, using a template or digitally using computerized software (Fig. 244-6). The tissue is brought to the adjacent laboratory (another key element of the Mohs technique is the presence of a contiguous lab under the supervision of the Mohs surgeon). Color coding of specimens is critical. The Mohs technician or the surgeon marks the borders of the tissue with different colors to allow orientation relative to the Mohs map. Usually two dyes are used such as red and black or black and yellow (Fig. 244-7). One of the dyes is represented on the map as a solid line and the other as a dotted line.

The tissue is then processed by a technician who is specifically trained in the *en face* method of sectioning. The tissue is frozen and is cut horizontally on a microtome. In contrast to traditional paraffin sections, which are cut vertically (bread-loaf sections) the Mohs sections theoretically allows 100% of the tumor margins (depth and periphery) to be examined. Most Mohs surgeons use hematoxylin-eosin stain (83%) and a minority use toluidine blue as the preferred stain. The latter stain helps distinguish basal cell carcinoma from hair follicles by highlighting mucopolysaccharides in the stroma.[7] In between the Mohs stages, the wound is dressed temporarily and the patient waits either in the procedure room or in a dedicated waiting room. Slide preparation takes 20–30 minutes on average. Examination of the slides by the surgeon is then performed in the laboratory. Residual cancer noted microscopically is marked on the Mohs map and the process of excision, mapping,

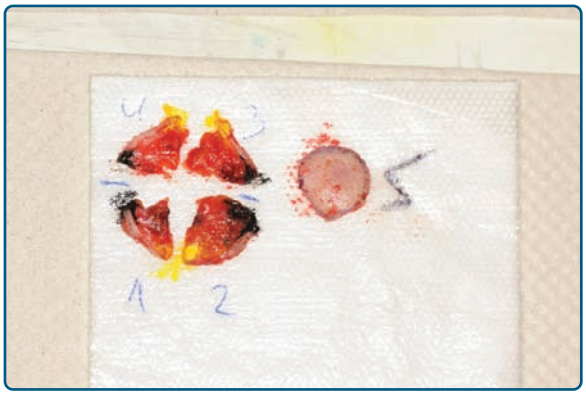

Figure 244-7 Color coding of the tissue in the laboratory.

and processing is repeated until all margins are free of tumor (Figs. 244-8, 244-9). High quality frozen sections are mandatory for the success of MMS[8] Figs. 244-10 and 244-11 illustrate how the Mohs technique ensures complete tumor removal. Once MMS is complete, the wound is evaluated and reconstruction is either performed at that time by the Mohs surgeon or the wound is allowed to heal by second intention. In complex cases, collaboration with other reconstructive surgeons may be indicated. Reconstructive surgery has become an important and integral aspect of the care of the skin cancer patient. The original chemosurgery defects healed by second intention, but the current defects that result from the fresh tissue technique permit primary closures, adjacent tissue transfer, and grafts. As a result, parallel advances in reconstructive surgery have been significant in the evolution of MMS.

INDICATIONS

Currently, the major indications for MMS are based on the anatomic location of the tumor, tumor size, histology, and patient considerations. Mohs surgery is typically used on the head and neck and for difficult or biologically challenging tumors elsewhere.

MOHS SURGERY FOR BASAL CELL CARCINOMA

BCC accounts for approximately 75%–80% of all cases of non-melanoma skin cancer. This tumor has a predilection for the head and neck as it is related to ultraviolet light exposure. Despite an extremely low metastatic rate (0.0028%), BCC can be locally aggressive and cause significant tissue destruction. Of special importance are high-risk BCCs: those in the midfacial location (the so-called H zone which includes the nose, periocular region, lips, ears), recurrent and incompletely excised tumors, BCC with aggressive histological characteristics (sclerosing, basosquamous, infiltrative, and micronodular), BCC with perineural involvement, and BCC in which tumor size exceeds 2 cm. MMS is also very helpful in treating BCC with indistinct clinical borders. The aggressive tumor subtypes tend to be large, have ill-defined borders, and tend to recur when treated with other modalities. MMS has been shown to result in superior cure rates for high-risk BCCs compared with other approaches. Rowe et al found in their meta-analysis a recurrence rate of 10.1% for primary BCCs treated with simple excision, whereas MMS–treated lesions had only a recurrence rate of 1%.[10] Other studies have confirmed that MMS yields the highest cure rate in primary tumors (98.6%–99%) and in recurrent tumors[11,12] In the case of recurrent cancers,

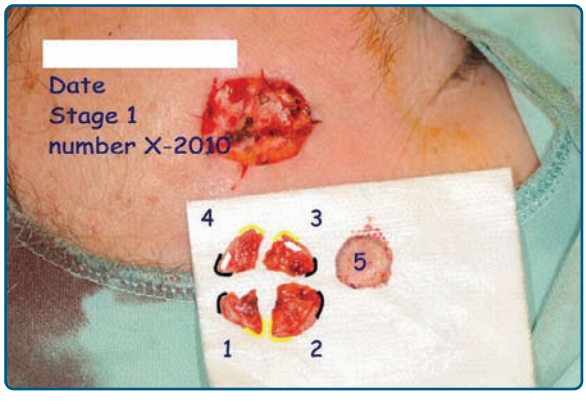

Figure 244-6 Digital image of the Mohs map.

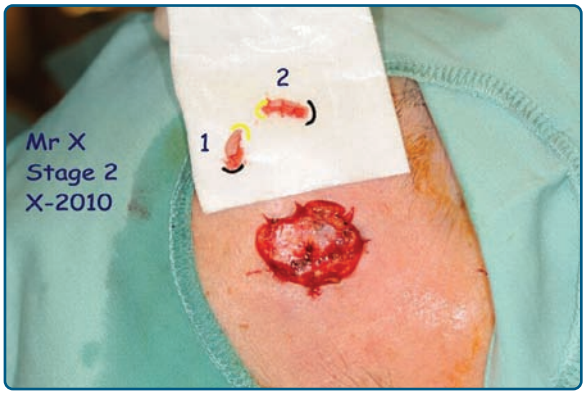

Figure 244-8 A Mohs map of the second stage.

Figure 244-9 Reconstruction by linear closure.

the 5-year recurrence rate of recurrent BCCs was 17% with simple excision and only 4.5% with MMS.[11,13] A recent study in Europe showed that MMS is preferred over surgical excision for the treatment of recurrent facial BCC on the basis of significantly fewer recurrences after MMS than after surgical excision. However, because there was no significant difference in recurrence of primary BCC between treatment groups, treatment with surgical excision is probably sufficient in most cases of routine primary BCC.[14] BCCs located on the ear, nose, eyelids, and lips have higher recurrence rates when treated by simple excision. The reason is believed to be the tendency of the surgeon to conserve as much tissue as possible, thus risking incomplete excision. Some of the aggressive subtypes of BCC (morpheaform, infiltrative) tend to recur in those locations. These aggressive subtypes may spread along scars, perichondrium, periosteum, perineurium, and fascial planes. The advantage of MMS as a tissue sparing technique was demonstrated for higher-risk BCCs requiring multiple stages of MMS.[15] Large BCCs (>2 cm) tend to be more aggressive, and have a higher recurrence rate than smaller cancers. They are usually present for longer duration, allowing the cancer to penetrate the surrounding tissue more extensively. MMS is especially advantageous in this situation. Incompletely excised tumors tend to recur as more aggressive tumors 12%–41% of the time. Recurrent tumors tend to be subtle at first, but when they clinically reappear they can be aggressive, demonstrating extension along deep tissue planes. MMS for recurrent cancer yields the highest cure rates (93%–96%) compared to 80%–83% for other modalities.[14]

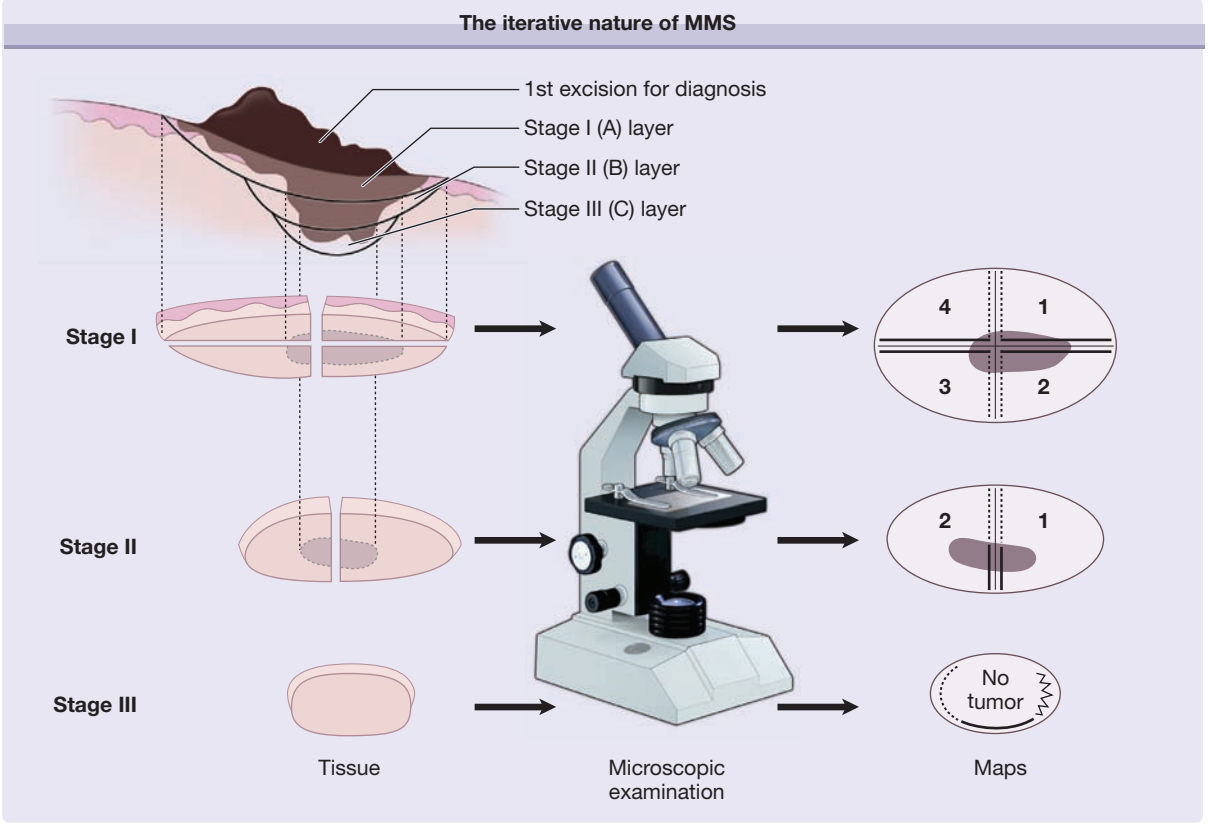

Figure 244-10 This schematic illustrates how the Mohs technique assures complete tumor removal. Obvious cancer (black) is obtained to determine subtype (upper left). Cancer discovered by microscopic examination is outlined by dots in each layer. In Stage I, a layer was removed and divided into four specimens (as viewed from the bottom); after microscopic examination, residual tumor was found only in the central area of all four specimens. In Stage II, a central layer was excised and bisected; after microscopic examination, residual tumor was found only in the center of specimens 1 and 2. In Stage III, another small block specimen was removed; after microscopic examination no residual tumor was found. In this case, the Mohs procedure consisted of three stages of excision and the microscopic examination of seven specimens. (From *Mohs Micrographic Surgery*, 2nd ed., edited by SN Snow and GR Mikhail 2004. The university of Wisconsin Press, with permission.)

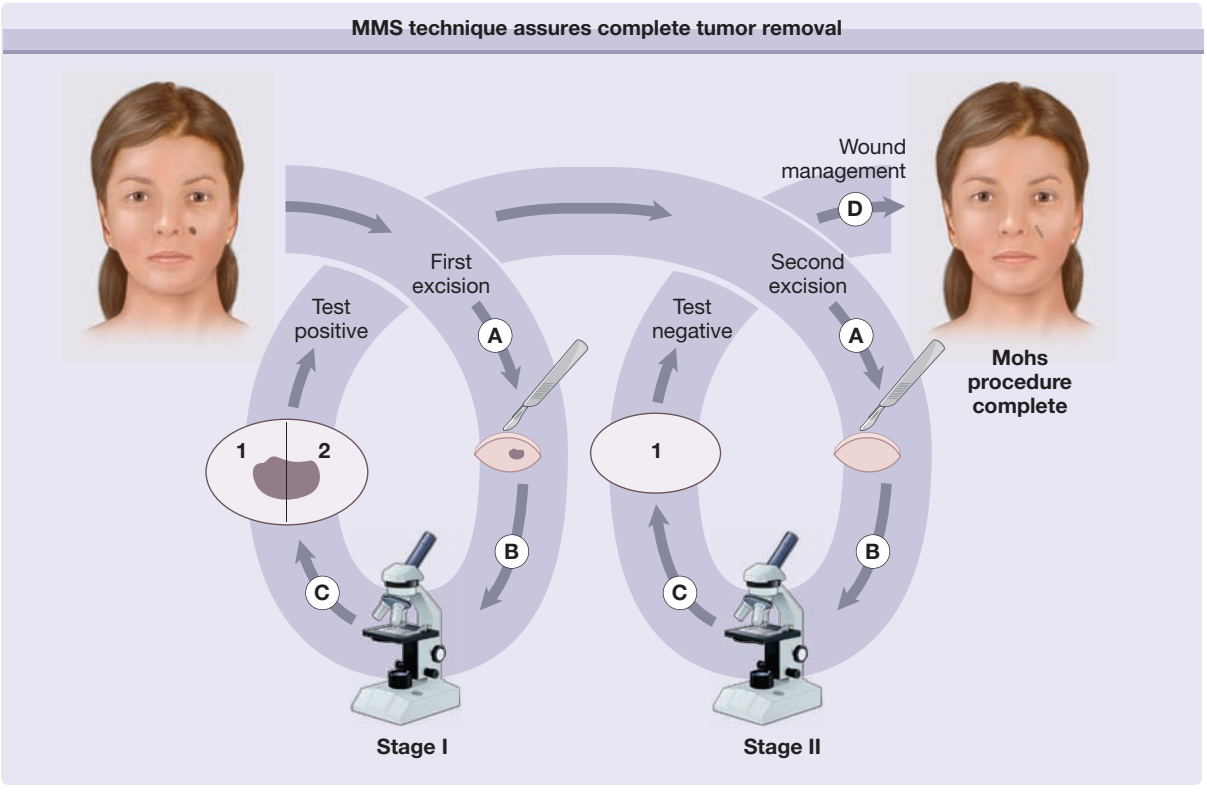

Figure 244-11 This schematic illustrates the cyclic nature of Mohs surgery. The four main components are the excision of a disc of tissue (a), microscopic examination (b), the appropriate marking of the map when residual cancer is found (c), and wound management (d). In Stage A, the tumor was removed, examined with the microscope. Residual tumor (black) was found throughout specimens 1 and 2. In Stage B, a deeper layer was removed and examined microscopically. In the second layer, no remaining cancer could be found. The defect was then allowed to heal by second intention. (From *Mohs Micrographic Surgery*, 2nd ed., edited by SN Snow and GR Mikhail 2004. The university of Wisconsin Press, with permission.)

MOHS SURGERY FOR SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma (SCC) is the second most common skin cancer among whites.[16] More than 200,000 new tumors are estimated to occur in the United States each year, and there is a significant increase in the incidence of SCC around the world.[17] Most cases of primary cutaneous SCC are induced by UV radiation. SCC may also occur on nonexposed skin in the pelvic area including the penis where the cause is usually infection with carcinogenic subtypes of human papilloma virus. Although SCCs and BCCs are treated similarly, they are biologically distinct. SCC metastasizes at a much higher rate and accordingly has a higher mortality rate than BCC even though its metastatic rate remains very low on an absolute basis. Metastases are more common in the setting of chronic scar (37.9%), or certain anatomic locations.[18] The indications for MMS are similar to BCC, but additionally involve identifying and reducing the risk for metastasis. MMS permits tracking SCC along nerves or when the histology is highly infiltrative, thus increasing the chance of complete extirpation. As with BCC, histologic pattern is important in determining the potential aggressiveness. Tumors that are poorly differentiated and/or have perineural involvement have a worse prognosis. Locations such as the ear, penis, lip, and digits, lesions greater than 2 cm, and those occurring in scars carry a higher risk of metastasis and local recurrence. The five-year cure rate for primary SCC of the skin with MMS is 97.4% to 96.9% versus 92% (95%–82%) with simple excision, and 90% for radiation therapy.[19] The difference in cure rate increases with the location such as primary SCC of the lip (97.7% vs. 89.5%) and ear (94.7% vs. 81.3%). For recurrent SCC, the cure rate with MMS is 94.1% to 90% versus 76.7% for simple excision and 65%–50% with radiation therapy. (Tables 244-2 and 244-3). The importance of MMS in the treatment of SCC with perineural invasion has also been documented.[20,21] MMS has also been proven to be effective for treating Bowen disease with a 5-year recurrence rate of approximately 6%.[22] Immunosuppressed patients including organ transplant patients have a disproportionate number of SCCs and also carry a greater risk of more aggressive disease. Recent studies show that SCC is up to 65 times as likely to develop in transplant recipients as in age-matched controls.[23] Increased incidence, younger age at onset, higher incidence of multiple tumors, and increased biologic aggressiveness of SCC in these patients is manifested by an increased risk of local recurrence, regional and distant metastasis, and mortality. MMS is an important treatment option in these high-risk patients to minimize recurrence and mortality risks.[24]

MOHS SURGERY FOR CUTANEOUS MELANOMA

The role of MMS for management of malignant melanoma is highly controversial. Melanoma in situ (MIS), which typically occurs on sun-damaged skin, can be difficult to interpret on frozen section. A review of MMS for melanoma in situ indicated that the recurrence rates for melanoma in situ post-MMS varied from 0%–3.6%.[25] One author claims that MMS for melanoma in situ can maximize the cure rate.[26] At some centers, a modified MMS is used in which a 2- to 3-mm margin is excised beyond the final frozen section margin and submitted for permanent paraffin-embedded sections. These sections are processed in the MMS en-face method so that 100% of the peripheral margins are visualized. In addition, a technique of rush permanent sections has been described.[27] The introduction of immunohistochemistry (IHC) staining may make MMS more reliable as a treatment for MIS. In one study 100% correlation was found between frozen sections stained with MART-1 and paraffin-embedded sections.[28] Many surgeons who do perform Mohs surgery for MIS have begun to use intraoperative IHC to identify melanocytes in frozen sections, and MART-1 is currently the preferred immunostain. S100 and HMB-45 have traditionally been used to identify melanocytes but have variable sensitivity and specificity. Although the processing time of MMS frozen sections is less than with paraffin sections, it is still more labor intensive than traditional hematoxylin and eosin-based frozen sections. The need for more accurate diagnosis of MIS in MMS has led to the development of rapid permanent paraffin-embedded sections (R13) and rapid IHC staining.[29]

MOHS SURGERY FOR DERMATOFIBROSARCOMA PROTUBERANS

Dermatofibrosarcoma protuberans (DFSP) is a rare spindle cell cutaneous tumor with low-grade malignancy. It is a slow growing tumor and, for many years, wide local excision has been the treatment of choice. MMS has become the preferred treatment in most clinical circumstances with recurrence rates as low as 1.3%.[30]

MOHS SURGERY FOR OTHER CUTANEOUS MALIGNANCIES

MMS has been used to treat a wide range of cutaneous malignancies. The consensus indications outlined by the American Academy of Dermatology[31] include verrucous carcinoma, keratoacanthoma, dermatofibrosarcoma protuberans, atypical fibroxanthoma, malignant fibrous histiocytoma, leiomyosarcoma, adenocystic carcinoma of the skin, sebaceous carcinoma, extramammary Paget disease, erythroplasia of Queyrat, oral and central facial paranasal sinus neoplasms, microcystic adnexal carcinoma, apocrine carcinoma of the skin, certain aggressive locally recurrent benign tumors, and Merkel cell carcinoma. All cutaneous malignancies that exhibit a contiguous pattern of radial growth and can be interpreted on frozen section should theoretically be amenable to MMS.

However, less than 2% of the tumors treated with MMS are rare cutaneous malignancies. For this reason, it is important to remember that because a lesion can be treated by MMS does not mean that it should be treated in that way. If the Mohs surgeon does not have experience in reading rare tumors and cannot collaborate with a dermatopathologist, the lesion is best treated in another fashion or by a more experienced Mohs surgeon. The introduction of immunostains in MMS in the last decade has created the opportunity to explore its use in treating other cutaneous tumors.[32]

Microcystic adnexal carcinoma has been shown to have only 5% recurrence rate with MMS.[33] Treatment of primary sebaceous carcinoma of the eyelid with MMS has yielded excellent results.[34] MMS is more effective and superior to standard surgical excision in the treatment of extramammary Paget disease.[35] The effectiveness of MMS in the treatment of dermal spindle cell tumors has also been suggested.[36]

SAFETY, PATIENT SATISFACTION AND COMPLICATIONS

MMS is performed in an office or ambulatory center setting rather than hospital operating rooms. A study performed in almost 4,000 patients that underwent MMS showed that MMS can safely be performed in the office or outpatient hospital setting.[37] Patients treated with MMS have well-established long-term satisfaction.[38]

Chapter 245 :: Nail Surgery

:: Robert Baran

The main objectives of nail surgery are to aid diagnosis by biopsy, to treat infection, to alleviate pain, to remove local tumors, and to ensure the best cosmetic results in acquired and/or hereditary and congenital abnormalities.

PATIENT SELECTION

Providing the patient with an exact illustration of the operation is helpful to give the patient insight into the procedure and its expected outcome. A thorough discussion regarding postoperative morbidity is essential.

RISKS AND PRECAUTIONS

Factors to be considered include the following:

- History of systemic disease
- History of allergies
- Concomitant drug use

Preoperative photographs as well as any taken during surgery may be useful medicolegally. Careful history taking may reveal systemic disease such as diabetes mellitus, blood dyscrasia, vascular disease, vascular collagen disease (scleroderma), allergy, chronic pulmonary disease, or immune impairment. Any of

these may at times be contraindications to surgery or may call for alteration of the technique to be used. Surgery of the nail is not recommended in patients with high-risk conditions. A history of concurrent use of drugs may be relevant, because these drugs may affect anesthesia (e.g., monoamine oxidase inhibitors or phenothiazines), prolong bleeding (e.g., aspirin and anticoagulants), delay healing (e.g., glucocorticoids), or have toxic effects on the nail apparatus (e.g., retinoids). There may be a history of allergy to lidocaine or mepivacaine or to parabens contained in both as a preservative. A knowledge of previous antitetanus immunization is important, because administration of tetanus toxoid may be advisable in association with surgery involving the toenail or traumatic lesions that come into contact with soil.

A magnifying lens may be useful to observe the color, surface, and structure of the periungual tissue and to compare the unaffected contralateral digit. It may be necessary to probe in order to localize pain, to obtain a radiograph to rule out underlying bone involvement, or to ask for ultrasonography and magnetic resonance imaging when a tumor is suspected.

The basic requirements for nail surgery include a detailed knowledge of the anatomy and physiology of the nail apparatus on the part of the surgeon. Full aseptic conditions, regional block anesthesia, and local hemostasis are indispensable.

ANATOMY[1]

(See Chapter. 89)

The nail plate is the permanent product of the nail matrix. Its normal appearance and growth depend on the integrity of the perionychium and the bony phalanx (Fig. 245-1). The nail is a semihard horny plate covering the dorsal aspect of the tip of the digit. The nail is inserted proximally in an invagination that is practically parallel to the upper surface of the skin and laterally in the lateral nail grooves. This pocket-like invagination has a roof, the proximal nail fold, and a floor, the matrix from which the nail is derived. The matrix extends approximately 6 mm under the proximal nail fold, and its distal portion is only visible as the white semicircular lunula. The general shape of the matrix is a crescent, concave in its posteroinferior portion. The lateral horns of this crescent are more developed in the great toe and are located at the coronal plane of the bone. The ventral aspect of the proximal nail fold encompasses both a lower portion, which continues the matrix, and an upper portion (roughly three-quarters of its length), called the *eponychium* (see eFig. 245-1.1 in online edition). The germinal matrix forms the bulk of the nail plate. The proximal element forms the superficial third of the nail plate, whereas the distal element provides its inferior two-thirds. The ventral surface of the proximal nail fold adheres closely to the nail for a short distance and forms a gradually desquamating tissue, the cuticle, made of the stratum corneum of both the dorsal and the ventral sides of the proximal nail fold. The cuticle seals and protects the nail cul-de-sac.

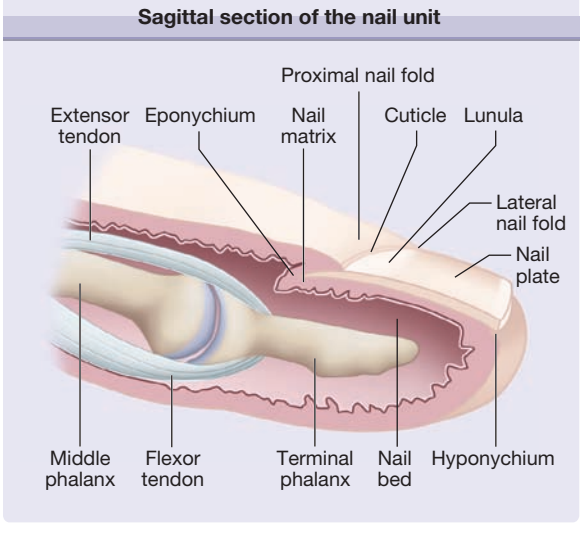

Figure 245-1 Sagittal section of the nail unit.

The nail plate is bordered by the proximal nail fold, which is continuous with the similarly structured lateral nail fold on each side. The nail bed extends from the lunula to the hyponychium. It has parallel, longitudinal rete ridges.

In contrast to the matrix, the nail bed has a firm attachment to the nail plate. Colorless but translucent, this highly vascular connective tissue, containing glomus organs, transmits a pink color through the nail. Avulsion of the overlying nail plate denudes the nail bed.

Distally, adjacent to the nail bed, lies the hyponychium, an extension of the volar epidermis under the nail plate, which marks the point at which the nail separates from the underlying tissue. The distal nail groove, which is convex anteriorly, separates the hyponychium from the fingertip.

The circulation of the nail apparatus is supplied by two digital arteries that course along the digits and give off branches to the distal and proximal arches. The sensory nerves to the distal phalanx of the three middle fingers are derived from fine, oblique, dorsal branches of the volar collateral nerves. Longitudinal branches of the dorsal collateral nerves supply the terminal phalanx of the fifth digit and also the thumb.

Among its multiple functions, the nail provides counterpressure to the pulp that is essential to the tactile sensation involving the fingers and to the prevention of hypertrophy of the nail bed.

INSTRUMENTS AND DRAPING

The instruments used in nail surgery are, in general, the same as those used in cutaneous surgery with the addition of the instruments listed in Box 245-1.

Draping is accomplished by means of a sterile glove on the involved hand. The tip of the glove is cut off on the finger that is to undergo surgery. The remaining open finger of the glove is then rolled back down the digit. This exsanguinates the digit and provides a

BOX 245-1 INSTRUMENTS REQUIRED FOR NAIL SURGERY

- Nail elevators
- Single- or double-pronged skin hooks
- Double-action nail splitter (bone rongeur)
- Clippers, splitting scissors, English nail splitter
- Pointed scissors (Gradle scissors), curved iris scissors
- Small-nosed hemostats
- Disposable biopsy punches
- Penrose drains
- Luer-Lok syringe, 30-gauge needles

tourniquet when it reaches the proximal part of the finger. For toenail surgery, the foot is draped in the usual aseptic manner with sterile towels secured by towel clamps.

ANESTHESIA

Local anesthesia should be administered while the patient is reclining or in a supine position. Lidocaine is widely used because the incidence of allergy to this agent is very low. Because the benefit of epinephrine is still debatable, it is preferable to use 2% lidocaine alone. A tourniquet can provide prolonged hemostasis when a bloodless operative field is required. It has been claimed that using tepid lidocaine minimizes the burning sensation associated with its administration. The use of one part 7.5% bicarbonate with nine parts lidocaine for the same purpose has also been advocated.

Anesthetics are administered via a 30-gauge needle on a Luer-Lok syringe using either a proximal digital block or a distal digital block (wing block) procedure. Other techniques, such as median distal anesthesia or transthecal block, have not replaced the classic routes of anesthesia. Although emergencies related to minor surgery occur rarely, the ready availability of resuscitative equipment and expertise is essential.

PROXIMAL DIGITAL BLOCK

The proximal digital block procedure is less painful than the distal block procedure, but the anesthesia takes 5–10 minutes to become established. The hand is laid down flat, with the fingers spread, so that 1–2 mL of anesthetic can be administered by a dorsal injection, with a thin needle inserted and directed tangentially to the sides of the bony phalanx at the base of the involved finger and as far as the lateral side of the flexor tendon (Fig. 245-2). A tourniquet effect may inadvertently be produced by injecting more than 5 mL of anesthetic and should be avoided. The absence of blood reflux in the syringe should be verified before injection if a nondental syringe is used. When the operation is strictly localized to a lateral region, a block limited to the nerves ipsilateral to the lesion suffices, as in the case of a partial distolateral nail avulsion.

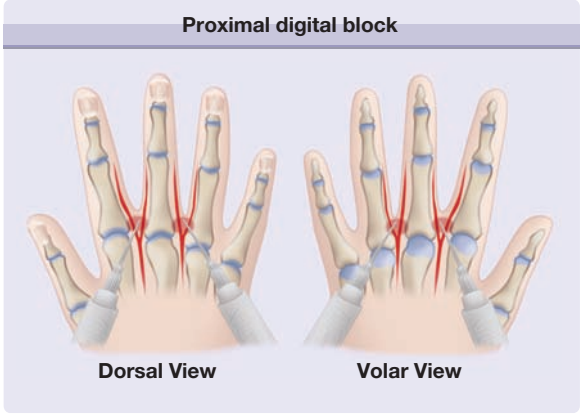

Figure 245-2 Proximal digital block.

DISTAL DIGITAL BLOCK

The distal digital block procedure is more painful than the proximal block procedure, but anesthesia occurs immediately. This method is absolutely contraindicated, however, when bacterial infection in the region is being addressed. The latter requires wrist block or general anesthesia.

For a distal digital block, the needle is inserted just behind the junction of the proximal nail fold and a lateral nail fold and a few tenths of a milliliter of anesthetic is injected, which whitens the region. The injection is continued by aiming the needle toward the pad. One then returns to the initial area to inject the proximal fold transversely. Finally, at the junction of the proximal fold with the lateral fold on the opposite side, one proceeds as described earlier (Fig. 245-3). The anesthesia is almost immediate, and when the procedure is done correctly, injections rarely have to be extended to the distal area of the finger.

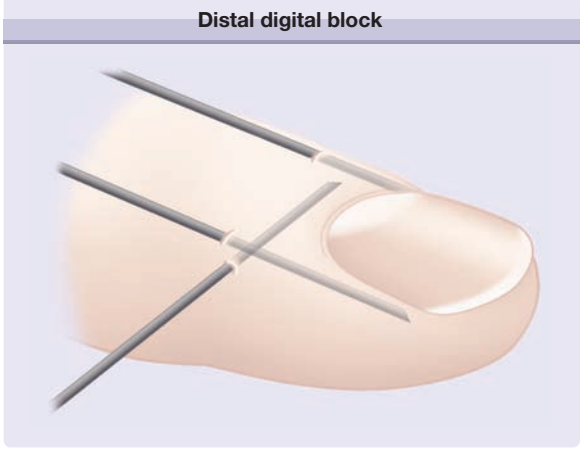

Figure 245-3 Distal digital block.

Figure 245-4 Median distal block.

Median distal administration is relatively simple and quick (Fig. 245-4). The needle is introduced at a 30-degree angle into the middle of the proximal nail fold and advanced distally into the underlying matrix. Anesthetic is injected slowly as the needle pierces first the nail plate, then the matrix, and finally the adjacent nail bed. The nail plate is soft and offers little resistance. Blanching confirms the delivery of anesthetic to the nail matrix and bed. Pain is brief and anesthesia nearly instantaneous. This method is suitable for most procedures performed on the proximal half of the nail unit. It is not suitable for matricectomy or complete nail avulsion.

TRANSTHECAL BLOCK

The flexor tendon sheath may be used as an avenue for introducing anesthetic to the core of the digit. Through centrifugal anesthetic diffusion all four digital nerves are anesthetized rapidly. This technique involves palmar percutaneous injection of 2 mL of lidocaine into the potential space of the flexor tendon sheath at the level of the palmar flexion crease using a 3-mL syringe and a 25-gauge hypodermic needle.

WRIST BLOCK

There are several circumstances under which it is useful to have anesthesia of more than one digit at the same time. A wrist block may be appropriate in the surgical treatment of numerous warts and in the infiltration of more than one finger with triamcinolone in the treatment of nail unit psoriasis. This should be undertaken with the guidance of an experienced clinician.

TOURNIQUETS

For brief intraoperative hemostasis (e.g., nail avulsion, punch biopsy of the nail bed), squeezing the sides of the digits is effective. If a prolonged bloodless field is required, a Penrose drain may be placed around the base of the digit and secured with a hemostat for use as a tourniquet. It is preferable not to leave it on for more than 15–20 minutes. The tourniquet application can be interrupted for a few minutes during longer procedures.

To complement anesthesia and facilitate establishment of a bloodless field, use of an exsanguinating tourniquet is recommended.[1] A wide Penrose drain is wound tightly in loops that overlap in a distal to proximal fashion, with an exposed loose end left distally (eFig. 245-4.1 in online edition). This "milks" the blood from the digit. The loose end is then grasped and the drain unwound, again from distal to proximal, until the nail unit is exposed with the final proximal loop.

DRESSING AND POSTOPERATIVE CARE

At the end of the operation, either the digit is cleansed with sterile 10% hydrogen peroxide solution and sprayed with a colorless disinfectant, or an antiseptic with hemolytic action is applied. The nail area is then covered with an antiseptic or antibiotic ointment on gauze or pads. Dressing must be done in a way that takes into account oozing, pain, and sensitivity. A bulky dressing provides a cushion against local trauma.

Dressings should be changed every other day or daily if there is infection. Several layers of sterile gauze should be kept in place by Micropore (2.5-cm) tape placed first on the dorsal aspect of the finger or toe, then on the ventral aspect, and last on the lateral edges in a U shape (a circular dressing should never be applied in the first week). Finally, use of an X-span tube dressing or Surgitube will give the patient more freedom to use the hand, but care must be taken that dressings do not constrict blood flow. During the first 48 hours the arm must be kept in a sling. Stitches are removed after 7–12 days.

When the feet are treated, daily chlorhexidine baths precede the care just described.

For all operations involving the toes, the patient should wear an appropriate shoe or sandal after the dressing has been applied. The patient should be recumbent for 24–48 hours, with the foot elevated to 30°.

POSTOPERATIVE COMPLICATIONS

BLEEDING

Bleeding is seen after the tourniquet is removed but can be stopped by compressing the lateral edges of the distal interphalangeal joint. In cases of persistent bleeding, 35% aluminium chloride solution or a cellulose application (Gelfoam) should be applied.

PAIN

Pain threshold varies from patient to patient. Postoperative pain can be almost nonexistent if, in the absence of infection, the operation is followed by a periungual injection of 0.6 mL of 0.5% bupivacaine with 0.4 mL of 4 mg/mL dexamethasone. While the dressing is being put in place, the patient must be told what precautions to take. Providing a supply of moderately potent oral analgesics will help the patient feel in control of any pain, even if the patient chooses not to take the tablets. Sometimes postoperative pain may be severe, and it is alleviated by elevating the extremity as much as possible for 2 days. Pulsating pain beginning after 36–48 hours may indicate an infection, which should be treated according to the results of bacterial culture of the organism. Any bulky dressing that is blood stained after 24 hours should be changed.

INFECTION

Prophylactic antibiotic treatment is mandatory for patients with valvular heart disease, including those with a prosthetic valve. Peripheral vascular disease and young age (in childhood, the nail matrix is extremely fragile and behavior is less sanitary) are further indications. If there are ragged surfaces to the nail, which makes thorough preoperative cleaning difficult, antibiotics may prevent wound infection.

Postoperative infection may be caused by preoperative colonization or infection. Culture of preoperative swab specimens will indicate the best choice of drug after initial coverage with a broad-spectrum antibiotic.

Attention to detail is important. Carelessness may result in serious infectious complications in the soft tissue and occasionally in bone. Routine or preoperative nail cleansing softens the nail plate and keeps contamination to a minimum.

MISALIGNED NAIL

Misaligned nail may result from a lateral longitudinal nail biopsy, especially if the routine 3-mm width is exceeded.

RELAPSE

Relapse will depend on the nature of the lesion treated. Warts, ingrown nails, and myxoid cysts can be difficult to eradicate.

RESIDUAL DYSTROPHY

Residual dystrophies are not unusual when surgery involves the proximal area of the matrix.

UNPREDICTABLE COMPLICATIONS

Implantation epidermoid cysts can occur in operation scars. Reflex sympathetic dystrophy after nail biopsy, although exceptional, has been reported.

NAIL AVULSION

The removal of the nail plate can be carried out using distal or proximal approaches. In both techniques, inserting the blunt instrument back and forth between the horny layer of the proximal nail fold and the nail plate loosens the proximal nail fold adherence.

DISTAL APPROACH

In the more commonly used distal approach, a Freer septum elevator or a dental spatula is inserted between the nail plate and nail bed (Fig. 245-5A). The nail is separated from its nail-bed attachment using proximal force applied in anterior-posterior movements so as not to injure the longitudinal ridges of the nail bed. The detachment is completed by firmly pushing the instrument into the posterolateral corners of the nail plate. Then, one of the lateral edges is grasped with a sturdy hemostat, and extracted with an upward and circular movement to accomplish the removal of the nail plate.

PROXIMAL APPROACH

The proximal approach for nail avulsion is advisable when the subungual distal area adheres strongly to the nail plate and when the hyponychium may be injured by the subungual introduction of the spatula. The proximal nail fold is freed as described in Distal Approach. The spatula is then used to reflect the proximal nail fold, and is delicately inserted under the base of the nail plate where adherence is normally weak (see Fig. 245-5B). The instrument is advanced distally

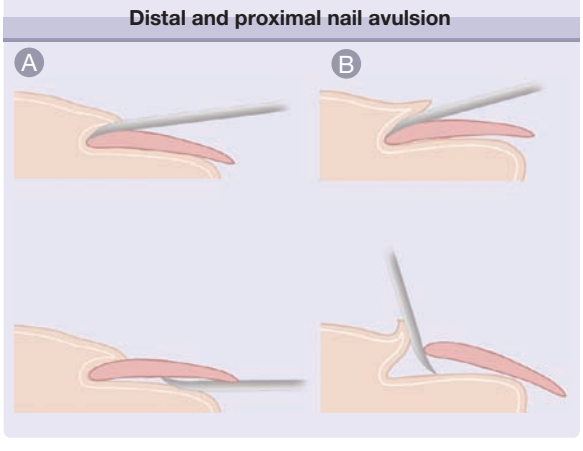

Figure 245-5 A. Distal nail avulsion. **B.** Proximal nail avulsion.

following the natural cleavage plane, and this operation is repeated on the entire width of the subungual region. After the last attachments are freed, the nail plate is easily pulled out.

Total surgical removal should be discouraged, however, because the distal nail bed may shrink and become dislocated dorsally. In addition, the loss of counterpressure produced by the removal of the nail plate allows expansion of the distal soft tissue, and the distal edge of the regrowing nail then embeds itself. In patients at high risk, nonsurgical removal of the nail plate should be considered when necessary. This can be accomplished by applying 40% urea paste directly to the nail after protecting the surrounding skin. Urea acts on the bond between nail keratin and diseased nail plate, sparing only the normal nail tissue.

PARTIAL NAIL AVULSION

The problems that can arise after total nail avulsion may be overcome by partially avulsing the nail. Partial distal avulsion requires only separation of the nail from the distal nail bed. This procedure can be performed under local anesthesia in selected patients, when, for instance, a fungal infection is of limited extent. An affected portion of the nail plate may be removed in one session, even when the disease has reached the deeper regions of the subungual tissue beneath the proximal nail fold. Commonly, an English anvil nail splitter or a double-action bone rongeur is used for this procedure.

Partial surgical section of the lateral and/or medial segment of the nail plate may be sufficient for the treatment of distal lateral subungual onychomycosis. In the toe, this procedure leaves enough normal nail to counteract the upward forces exerted on the distal soft tissue when walking, and this will prevent the appearance of a distal nail wall.

In proximal subungual onychomycosis, removal of the nonadjacent base of the nail plate, cut transversely, leaves the distal portion of the nail in place (Fig. 245-6), which decreases discomfort. Similarly, an acute paronychia that does not respond to appropriate antibiotics within 48 hours should be treated surgically by removing the base of the nail plate.

TRAP DOOR NAIL AVULSION

This technique minimises trauma in nail surgery when accessing the nail bed and matrix. Trap door nail plate avulsion entails separation of all periungual attachments except for that between the dorsum of the nail and the ventral aspect of the proximal nail fold. Both are then reflected in bloc in the manner of a trap door, utilising the same oblique incisions normally made for reflection of the PNF alone.

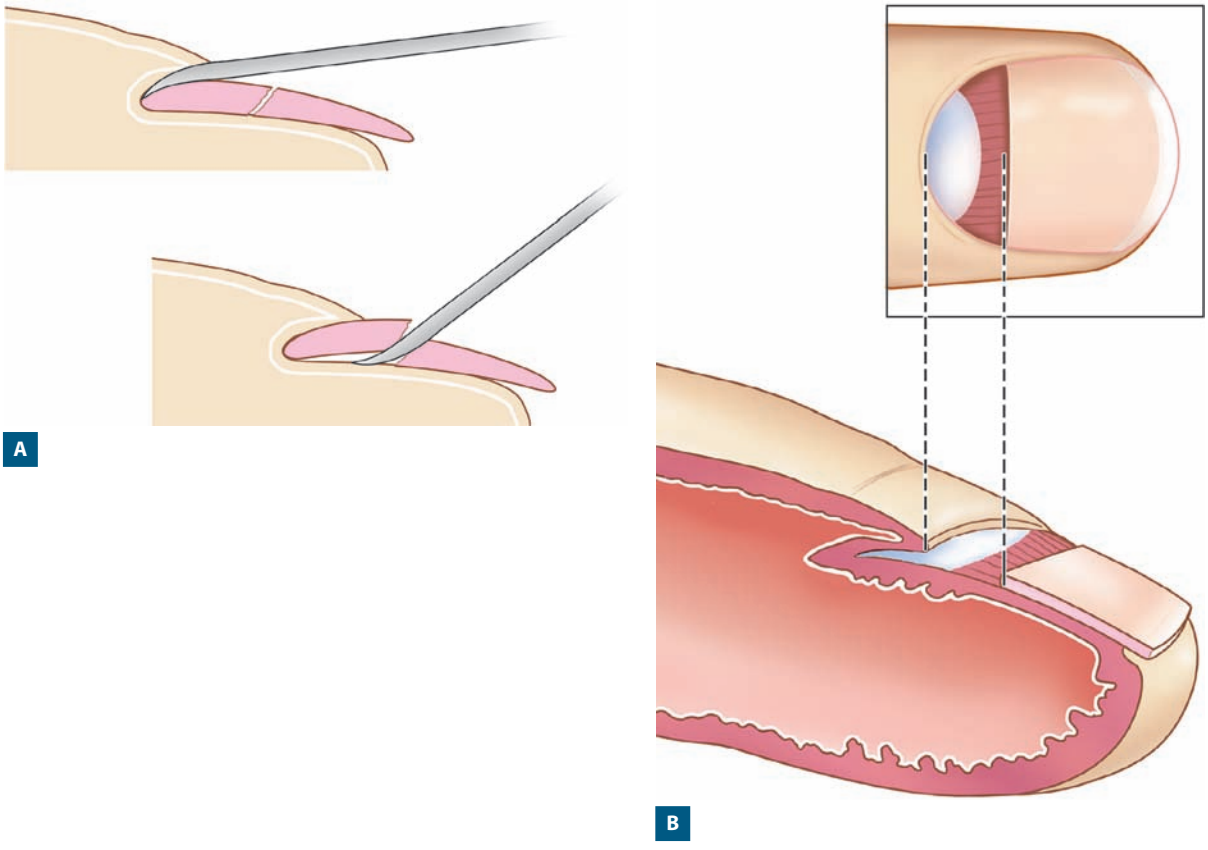

Figure 245-6 **A** and **B.** Technique of removal of the base of the nail plate.

SURGICAL APPROACHES TO THE DIFFERENT TISSUES OF THE NAIL APPARATUS

NAIL MATRIX

When surgery involves the nail matrix, there are three primary approaches, including (1) a reduction in its width or (2) its length for removal of tumors, for instance, by using a cold steel procedure or (3) a 2-to 3-mm punch biopsy. In contrast to these three procedures, complete matricectomy, that is, ablation of the nail-forming tissue, is rarely performed because the nail is permanently lost (eFig. 245-12.1 in online edition).

After reduction of the nail matrix width, one is left with a narrower nail and after reduction of the length, with a diminution in the thickness of the nail. Reduction of the matrix width is a useful and/or necessary procedure in the following major circumstances:

- Need for lateral-longitudinal biopsy
- Lateral nail splitting
- Benign or malignant tumor in the lateral third of the nail apparatus
- Longitudinal melanonychia in a lateral location
- Ingrown nail
- Racquet nail

Reduction of the matrix length is necessary only in limited cases: to obtain a transverse elliptical biopsy specimen, to treat tumors that are 3 mm wide or larger, and to thin thick nails in patients with dystrophic congenital and/or hereditary disorders.[2]

BIOPSY.[3–5] Biopsy of the nail matrix is performed to determine the histopathologic features of a lesion or to clarify an uncertain clinical diagnosis.

A 3-mm punch biopsy may be performed through the nail plate into the matrix. Three millimeters is the maximum size that does not produce serious dystrophy, although even biopsies of this size can cause such effects if carried out in the most proximal portion of the nail matrix. When a punch biopsy is used to sample longitudinal melanonychia of less than 3 mm in width, the circumferential incision is made around the origin of the band, through the nail plate (Fig. 245-7A). This area may be distal enough to be reached by pushing back the cuticle (Fig. 245-7B), but if it is more proximal, the proximal nail fold may have to be reflected using a posterolateral incision. The next step is to remove the proximal third of the nail plate (see Fig. 245-7B and C), while leaving the cylinder of tissue containing the origin of the longitudinal melanonychia still in place. This technique allows the surgeon to inspect the surrounding nail matrix and bed with a magnifying lens to determine whether pigment extends around the punch incision (see Fig. 245-7C and D) and facilitates the removal of the cylinder of biopsy tissue with a Gradle scissors.

For lateral longitudinal biopsy (Fig. 245-8), an elliptical incision may be made on either side of the nail plate and proximal nail fold. For the most part, the incisions parallel the lateral edge of the nail plate. Beginning in the lateral nail groove, the incisions should include a 3- to 4-mm nail segment reaching to the bone. This ensures that a full-thickness fragment of the matrix with its lateral horn is obtained. Slightly curved iris scissors are useful for separating the tissue from the bone. Starting at the tip of the digit, one proceeds proximally while maintaining contact with the bony phalanx. Lateral longitudinal biopsy is the advised procedure when longitudinal melanonychia[3] is located in the lateral part of the nail plate.

For transverse biopsy (Fig. 245-9), two small oblique incisions are made on each side of the proximal nail fold. The fold is then reflected to expose the matrix area. The proximal third of the nail plate is avulsed. Then, the lesion is removed by excising an elliptical or crescent-shaped wedge of tissue with the convex portion of the crescent paralleling the anterior border of the lunula. When longitudinal melanonychia lies within the midportion of the nail plate, the potential for postoperative dystrophy is great, and selection of the optimal biopsy method is difficult (eFig. 245-10.1 in online edition) (Haneke's releasing flap technique derived from Schernberg's releasing flat method). It is important to establish the matrix origin (proximal or distal) of longitudinal melanonychia preoperatively, because the more proximal the origin, the greater the risk of nail dystrophy.[3] The origin of pigmentation may be determined by microscopic examination of Fontana-Masson–stained clippings from the free edge of the nail.

Tangential matrix biopsy (Fig. 245-10) for longitudinal melanonychia is a new technique devised by E. Haneke. Cutting, then reclining the proximal portion of the nail plate (1), after reflecting the proximal nail fold (2), the pigmented lesion is exposed. An incision is made around the lesion, followed by its tangential removal. Finally the proximal nail plate is replaced and the oblique incisions of the proximal nail fold are maintained by micropore. This technique is claimed to give the best cosmetic results.

RACQUET NAIL

SPLIT-NAIL DEFORMITY.[6] The common causes of split-nail deformity include trauma, surgery, lichen planus, and tumors. Split-nail deformity may occur in either the lateral or the medial region. The appropriate surgical technique varies accordingly.

If the split is located within the lateral third of either portion of the nail, especially when it is close to the lateral margin, the best method is the technique recommended for lateral longitudinal nail biopsy, that is, the removal of the lateral portion of the nail with the defect. If the split is located in the middle region of the nail and involves its whole length, the proximal nail fold is carefully freed from the underlying nail plate, obliquely incised at both sides, and reflected to expose the whole matrix area (Fig. 245-11). The nail plate bordering the split is cautiously cut as a rectangular block approximately 1 mm wider than the scar that has to be excised. The nail bed and matrix of the defective tissue

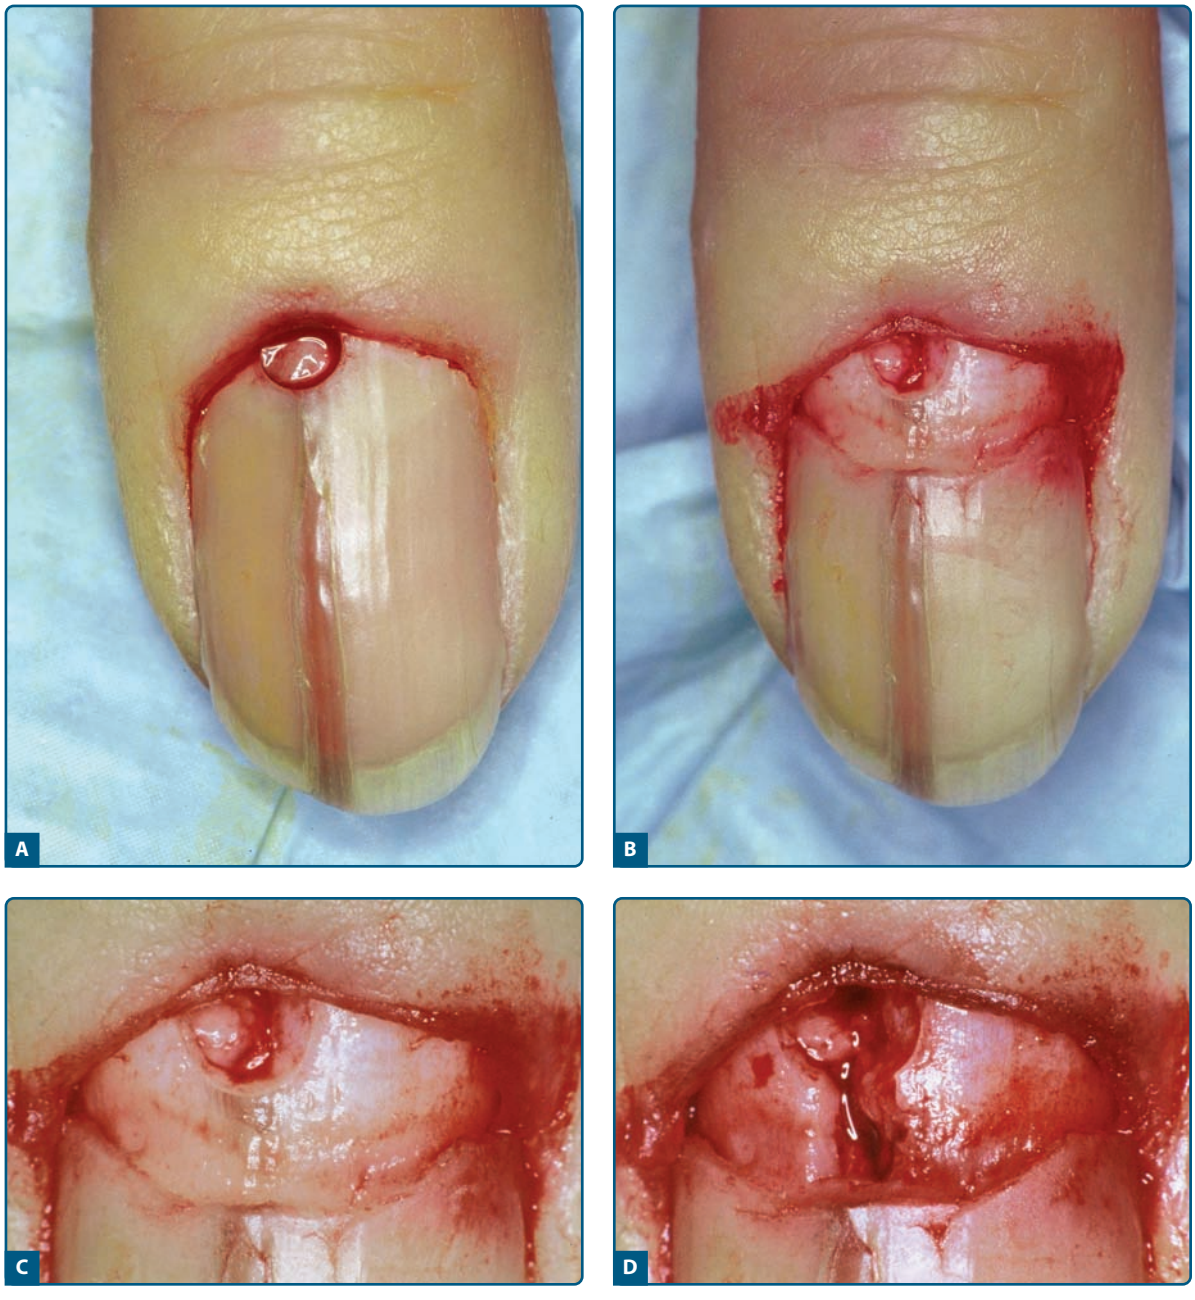

Figure 245-7 **A.** Punch biopsy of longitudinal melanonychia of less 3 mm in width. **B–D.** Removal of the base of the nail plate (**B**) to allow easy removal of the biopsied cylinder of matrix tissue (**C**) and pigment left distally (**D**).

are dissected from the bone to allow an exact approximation of the remaining bed and matrix, which are sutured with 6-0 monofilament absorbable sutures. To prevent the sutures from tearing the tissue, 3-0 sutures are put through the nail plate. When these threads are knotted firmly, the matrix and nail bed are further approximated, which relaxes the 6-0 sutures.

If the scar is too wide to allow primary closure of the defect, relaxing longitudinal incisions along the lateral nail grooves down to the bone usually permit suturing. An alternative approach is the formation of a Schernberg nail bed–matrix flap with an L-shaped incision of the lateral aspect of the finger (eFig. 245-11.1 in online edition).

NAIL ABLATION AND ISOLATED MATRICECTOMY. Nail ablation (eFig. 245-12.1A in online edition) is the definitive removal of the entire nail organ and matricectomy (eFig. 245-12.1B in online edition), the complete extirpation of the nail matrix, which results in permanent nail loss. The principle of nail ablation is the complete removal of the nail unit with hyponychium, nail bed, matrix, and lateral and proximal nail folds. Except for treatment of malignant tumors of the nail apparatus,

Figure 245-8 Lateral longitudinal biopsy of longitudinal melanonychia located within the lateral third of the nail plate.

nail ablation is rarely indicated. It may be necessary in the case of an excessively painful nail treated several times without success, but this should be an exception. Scalpel excision is strongly advocated whenever the surgical specimen needs histopathologic examination. If periungual pigmentation is associated with longitudinal melanonychia or if the latter is wider than 6 mm or the full thickness of the nail is pigmented, a large portion of the matrix would necessarily be involved. Under these circumstances, the underlying disease process is unlikely to be benign. The entire portion of the involved nail apparatus has to be excised en bloc.

The defect from nail ablation (see Fig. 245-12B) may be covered with a free graft (split-thickness, full-thickness, reversed dermal graft), which usually takes on the bone in this particular location. A cross-finger flap is a very useful alternative to a free graft. The use of the skin from the intermediate phalanx of a neighboring finger is more convenient for the patient than skin from the thenar area of the palm.

If only permanent nail matrix removal is necessary, the procedure is less extensive.

In cases in which pathologic examination of the removed tissue is unnecessary, phenol cautery, rather than scalpel excision, is the preferred technique for matricectomy. Most patients return to normal ambulation and activity as early as 1 day after the operation.

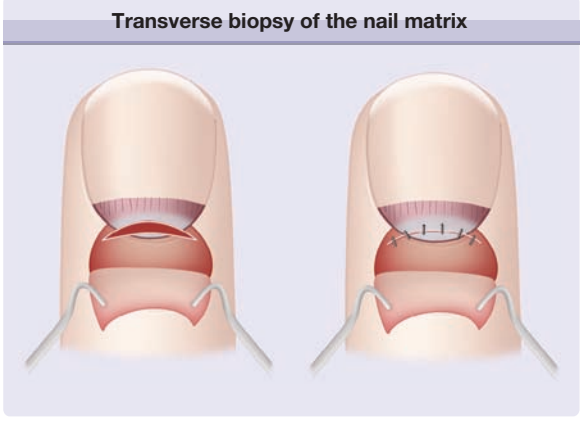

Figure 245-9 Transverse biopsy of the nail matrix.

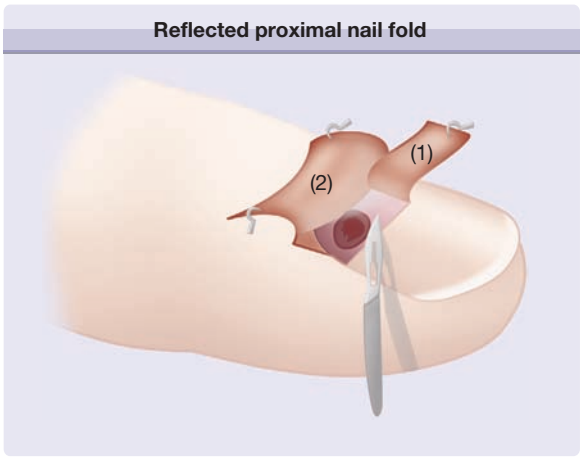

Figure 245-10 Reflected proximal nail fold and removal of the proximal portion of the nail plate exposing the pigmented lesion. Around the latter is made an incision followed by its tangential removal Haneke's matrix tangential biopsy technique.

NAIL BED

Nail-bed surgery is performed for biopsy, removal of tumors, and treatment of nail dystrophies such as onychogryphosis.

BIOPSY. Biopsy (Fig. 245-13) may be useful in any pathologic condition involving the nail bed.

Punch biopsy is done with a 3- or 4-mm diameter punch, which is driven perpendicularly into the nail plate in a circular motion down to the bone. However, it is not always easy to extract the cylinder cut with an area this small. One useful technique is to perforate the nail plate with a 6-mm punch without injuring the underlying tissue (see Fig. 245-13A). The covering nail is then detached by using the tip of the scalpel to remove the disk of nail, and the biopsy is performed easily by using the 4-mm punch to the bone. The tissue can then be released from its tether with fine scissors. It is advisable to replace the 6-mm disk of nail keratin, after cleaning with 10% hydrogen peroxide, to cover the hole. If the

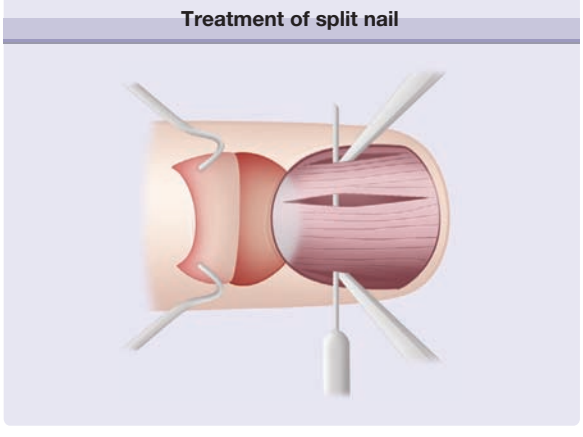

Figure 245-11 Treatment of split nail in the middle region of the nail plate.

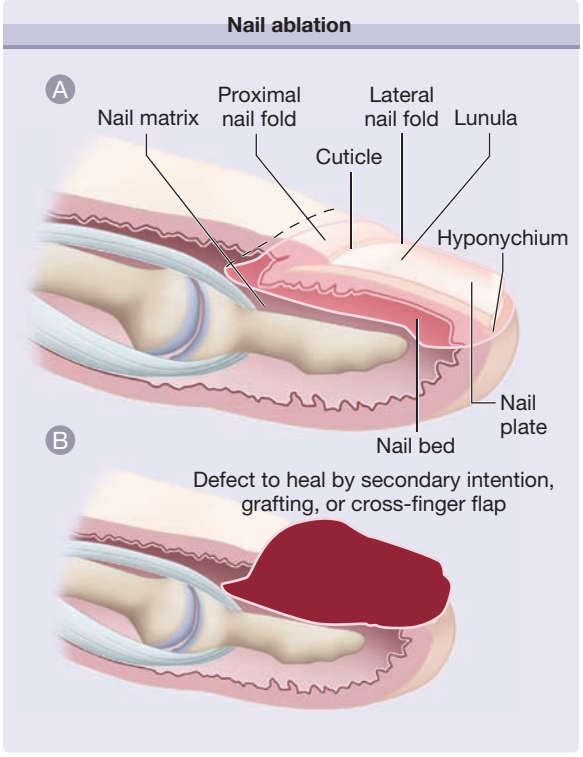

Figure 245-12 Nail ablation. **A.** Area of excision. **B.** Remaining defect.

nail plate is thick, rotating grinders can be used to thin it down and facilitate the transungual biopsy.

If a larger nail bed fragment is needed, fusiform biopsy with a major longitudinal axis can be performed after partial avulsion of the lateral half of the nail (see Fig. 245-13B) or after total avulsion if the fragment is central. After excision, the nail bed is undermined to facilitate reapproximation of both sides. The suture needle is used generously on these fragile subungual tissues. The wound is stitched with 6-0 resorbable thread. It is sometimes useful to make relaxing incisions at the most lateral margins of the nail bed.

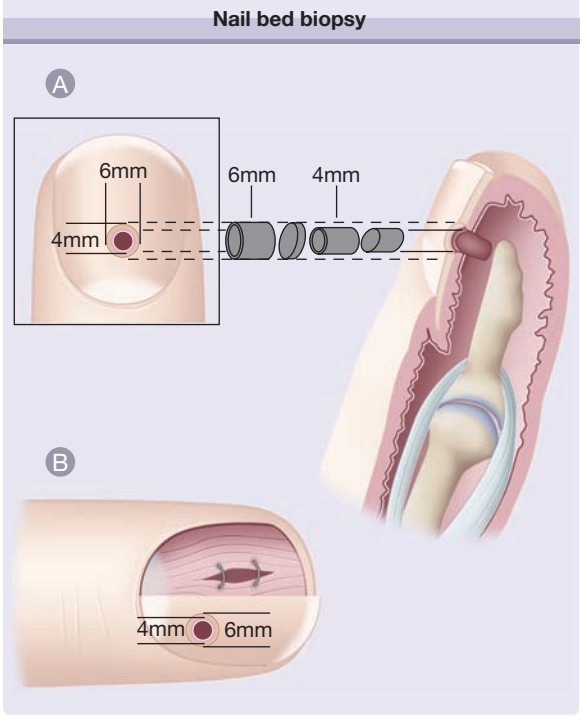

Figure 245-13 Nail bed biopsy. **A.** Punch biopsy. **B.** Fusiform biopsy.

SUBUNGUAL HEMATOMA. In cases of subungual hematoma, acute trauma with severe pain is always remembered by the patient. Depending on the site and intensity of the injury, the hematoma may be visible almost immediately or it may grow out from under the proximal nail fold within a few weeks.

When the hematoma is partial (less than 25% of the visible portion of the nail), it should be drained with a pointed scalpel or by hot paperclip cautery over the center of the dark spot (Fig. 245-14). This will produce relief from pain. Sometimes the nail sloughs as the new nail regenerates beneath the old one.

Small hematomas may be included in the nail, but they cannot be degraded to hemosiderin and results of the Prussian blue test will be negative. Therefore, to demonstrate the nature of the blackish pigment, scrapings are boiled in a small test tube with Hemostix, which gives a positive benzidine result.

A hematoma involving more than 25% of the visible portion of the nail is a sign of significant nail bed injury. A radiograph is mandatory, because the phalanx may be fractured. The nail plate is carefully removed and the hematoma evacuated. Traumatic nail bed laceration or wounds need a surgical approach to avoid delayed complications.

Nail bed lacerations can be sutured after thorough cleaning with antiseptics, using 6-0 resorbable monofilament material. The avulsed nail plate should be put back to cover the wound and then kept in place by suturing to the lateral nail folds or the fingertip.

Nail bed defects larger than 4 mm can be repaired using a split-thickness graft taken either from the nail bed of the same digit or from the nail bed of a great toe.

The torn nail bed should be sutured with 6-0 resorbable thread, and large bites of tissue should be taken

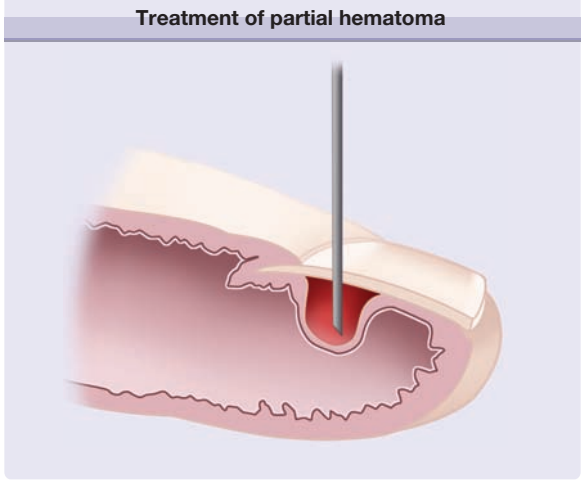

Figure 245-14 Treatment of partial hematoma.

so that the suture material does not pull through when it is tied. The nail plate is cleaned, shortened, and slightly narrowed, and then replaced with sutures into the lateral nail folds. The stitches are left in for 2 weeks.

Chronic hematomas are usually painless and are caused mainly by repeated microtrauma from either ill-fitting footwear or sporting activities. A notch is made with a scalpel blade at the distal and proximal border of the pigmented spot. Observation over a 3-week period will demonstrate whether the nail grows independently of the pigmentation or with it. However, chronic hematoma may resemble subungual melanoma and pose a distressing problem, and nonmigrating hematoma should be ruled out.

PROXIMAL NAIL FOLD

BIOPSY. A 2- to 3-mm punch may be used for biopsy of a tumor. A blister may be completely removed by shave biopsy using half a razor blade (see eFig. 245-14.1 in online edition). Excision of a 3-mm crescent-shaped tissue segment in the proximal region of the lateral nail folds may be helpful in the evaluation of collagen disease.

RECALCITRANT CHRONIC PARONYCHIA. Presence of a foreign body (e.g., hair) under the proximal nail fold is the main cause of recalcitrant chronic paronychia. The disorder manifests as a red swelling that is painless except when pressed, with secondary retraction of the paronychial tissue whose cuticle has disappeared and with recurrent episodes of acute paronychial inflammation.

For crescentic excision, a Freer septum elevator is inserted under the proximal nail fold to protect the matrix and extensor tendon. A No. 15 Bard-Parker blade is used to excise, en bloc, a crescent-shaped full-thickness skin segment, 4 mm at its greatest width, that extends from one lateral nail fold to the other. Use of a beveled incision prevents accidental damage to the proximal nail matrix and the most proximal portion of the proximal nail fold, which is responsible for the normal shine of the nail plate (see eFig. 245-14.2 in online edition).

In patients who experience repeated acute flares associated with chronic paronychia, additional removal of the base of the nail is useful.

TUMORS OF THE PROXIMAL NAIL FOLD. Different techniques can be used to treat tumors of the proximal nail fold, depending on the nature of the tumor, its location, and the length of its long axis.

Crescentic excision is useful for small distal tumors. The crescent should not exceed 4 mm at its greatest width.

Tumors of the proximal nail fold that are situated in a median position and have a longitudinal axis longer than 4–5 mm can be excised with a wedge of proximal nail fold whose base is located at the free margin and whose apex points proximally (Fig. 245-15A). Two relaxing lateral incisions are then made in the proximal nail fold to allow suturing of the wedge-shaped defect after the undersurface of the proximal nail fold has been released from the nail plate (see Fig. 245-15B).

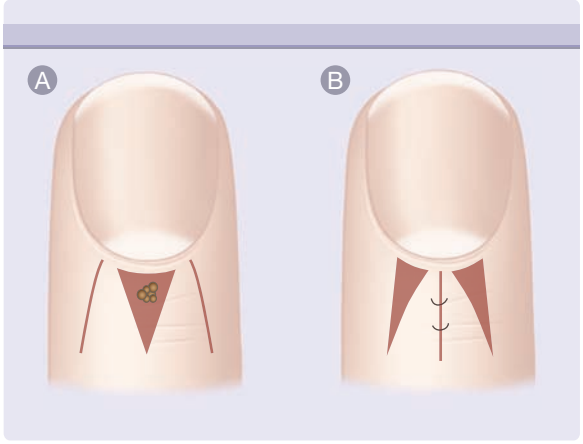

Figure 245-15 **A.** Tumor of the proximal nail fold situated in a median position. **B.** Suturing of the defect after relaxing lateral incisions are made and the proximal nail fold has been released from the nail plate.

The resulting symmetric narrow defects on both sides heal rapidly by secondary intention.

A small tumor on the lateral part of the proximal nail fold may be treated using a wedge-shaped excision (see eFig. 245-15.1 in online edition). Only one lateral relaxing incision is made at the opposite region of the proximal nail fold. To obtain better healing of the secondary defect, which is wider than in the procedure using two relaxing incisions, the surgery may be supplemented by making a relaxing crescent-shaped incision in the proximal nail fold.

A dorsal flap can be raised from the proximal nail fold by using two dorsolateral incisions and a horizontal one proximal to the cuticle. This gives complete exposure of subcutaneous tumors.

RECONSTRUCTION OF THE PROXIMAL NAIL FOLD. Reconstruction of the proximal nail fold may be necessary after any injury (accident, burn, avulsion caused by rapidly rotating belts and sanders, etc.). If the irregular tissue is excised, it is sometimes possible to recreate the distal curve of the proximal nail fold, which may produce a nearly perfect restoration. The proximal nail fold may also be restored by using two long, narrow, V-shaped transposition flaps from the lateral aspects of the terminal phalanx.

LATERAL NAIL FOLD

A 2- to 4-mm punch can remove a tumor of the lateral nail fold (see eFig. 245-15.2 in online edition). Benign tumors may be removed by taking an elliptical wedge of tissue from the lateral nail fold and lateral nail wall. Malignant tumors, such as in Bowen disease, are treated by excision of the whole lateral nail fold or by Mohs micrographic surgery followed by healing by second intention.

INGROWN NAILS. Ingrown nail is a condition that occurs mainly in the great toe. It is created by impingement of the nail plate into the dermal tissue distally or

into the distolateral nail groove. Irrespective of the initial cause, the condition finally presents with a nail bed that is too narrow for its nail plate. Logical treatment is therefore aimed at correcting this disparity.

Distal Toenail Embedding. Surgical avulsion or the loss of the toenail from trauma, such as tennis toe, may initiate the pathology. The distal subungual tissues released from the physiologic counterpressure of the nail plate become hypertrophic, and the newly formed nail plate abuts this distal wall. To treat the condition, a crescentic wedge-shaped excision is made around the distal phalanx (see eFig. 245-15.3 in online edition). The wedge should be 4 mm at its greatest width and must be dissected from the bone. The defect is closed with 5-0 monofilament sutures, which should be removed after 12–14 days.

Retronychia. Retronychia represents proximal regrowth of the nail that occurs when the nail embeds backwards into the proximal nail fold. Sonography is a useful tool to diagnose easily this condition. Nail-plate avulsion with supplementary medical management is curative.

Juvenile (Subcutaneous) Ingrown Nails. Juvenile or subcutaneous embedded nail is the most common type of ingrown nail. The nail is usually embedded medially, but both sides are often affected. In an effort to relieve the pain, the patient often tries to cut off the offending corner under the inflamed and swollen soft tissue. The remaining portion gives rise to a nail spicule piercing the epithelium of the lateral nail groove, which produces secondary infection and excessive granulation tissue.

Treatment at the early stage must be conservative but demands a high degree of patient compliance. The foot is soaked in warm water with povidone-iodine soap; then, under local anesthesia, the nail spicule is removed and a wisp of cotton wool is placed between the nail and the lateral nail groove. It should be moistened repeatedly with a disinfectant.

For definitive cure, surgical excision or, better, chemical suppression of the lateral horn of the nail matrix permanently narrows the nail. The lateral fifth of the nail plate is freed with a nail elevator from the proximal nail fold and the subungual tissues. It is then cut longitudinally with an English nail splitter or nail-splitting scissors and extracted using a sturdy hemostat. The lateral matrix horn is cauterized with a freshly made solution of liquefied phenol (88% solution) (see eFig. 245-15.4 in online edition). Above all, a bloodless field is needed, because blood inactivates phenol. Hemostasis is therefore accomplished with a tourniquet, and the blood is carefully cleaned from the space under the proximal nail fold using sterile gauze. The surrounding skin is protected with petroleum jelly. The phenol is rubbed onto the matrix epithelium for 3 minutes with a cotton-tipped swab that is changed two or three times. Postoperative pain is minimal because phenol has a local anesthetic action and is antiseptic. The matrix epithelium is sloughed off, and oozing is usual for 2–6 weeks. Daily warm foot baths with povidone-iodine soap accelerate healing.

Besides phenol and sodium hydroxide, 100% trichloracetic acid has been performed for partial matricectomy. The wound almost always heals within 2 weeks without prolonged exsudative discharge. Pain is mild and transient.

Pincer Nail.[7] Overcurvature of the nails may affect the great toe alone or all the digits. This condition may be so painful that even contact with a bedsheet becomes unbearable.

When the condition is mild, the nail brace technique aims at correcting the inward distortion of the nail by maintaining continuous tension on the nail plate. A stainless steel wire brace is fitted to the nail plate. A series of adjustments adapted to the gradual decrease of curvature is made over a period of 6 months and results in a painless correction of the pincer nail. Because the underlying bone pathology remains untreated, however, relapse is usual. Therefore, the definitive cure—the use of phenol cautery on the lateral matrix horns—is undoubtedly the simplest effective treatment modality.

Hypertrophy of the Lateral Nail Fold. Hypertrophic lateral nail folds are usually the result of long-standing ingrown nails. Inflammation may range from the subclinical to the severe. For treatment, approximately one-fifth of the nail digging into the lateral nail fold is removed. Then an elliptical wedge of tissue is taken from the lateral nail wall of the toe, down to the bone (see eFig. 245-15.5 in online edition). Suturing of the defect pulls the lateral nail fold away from the offending lateral nail edge. In severe cases, this procedure may be combined with phenol cautery of the lateral horn of the matrix. In contrast to adult-acquired hypertrophy of the lateral nail fold, congenital lateral hypertrophic lips disappear progressively and spontaneously within 12 months.

Congenital Malalignment of the Great Toenail.[8] In congenital malalignment of the nail of the great toe, typically the nail is malaligned laterally, with transverse furrows on a thick brownish or greenish nail. In 50% of cases, this condition corrects itself without therapy before the age of 10. If the appearance is extreme, surgery diminishes the risk of permanent dystrophy.

Treatment requires rotation of a bulky nail unit flap, including the entire nail, nail bed, and matrix (see eFig. 245-15.6 in online edition). This demands creation of an external Burow's triangle. An eccentric crescent-shaped excision is made to undermine the nail unit, with the maximum width located on the internal side of the foot, corresponding to the side to which the nail needs to be redirected. This crescent ends on each side 3–4 mm behind the most proximal part of the proximal nail fold. The nail bed and the matrix are then undermined and lifted until the fibers of the extensor tendon are visible on its bony insertion, and the dorsal expansion of the lateral ligament of the distal interphalangeal joint is cut.

Suturing the edges of the excised triangle together reduces the loss of cutaneous substance. The nail unit is rotated inwardly, because the maximum cutaneous resection is mostly distal and medial.

Chapter 246 :: Cryosurgery and Electrosurgery

:: Justin J. Vujevich & Leonard H. Goldberg

CRYOSURGERY, CRYOBIOLOGY, AND CROYGENS

Cryosurgery refers to the use of extreme cold to destroy cells of abnormal or diseased tissue. The earliest use of a cold refrigerant in medicine is attributed to White, a New York dermatologist, in 1899.[1,2] Using a cotton-tipped applicator dipped into liquefied air, he successfully treated warts, nevi, and precancerous and cancerous lesions. In 1907, Whitehouse, another New York dermatologist, reported the utilization of the spray method in the cryosurgical treatment of skin cancers.[3]

Cryobiology refers to the study of the effects of subzero temperature on living systems. Tissue destruction from cryotherapy results from direct cell injury, vascular stasis, and the local inflammatory response.

Rapid freezing of cells causes intracellular ice crystal formation with the disruption of electrolytes and pH changes, whereas slow freezing causes extracellular ice formation and less cell damage. Therefore, tissue effects and cell death are most readily achieved when tissue is frozen rapidly.[4]

During thawing, recrystallization occurs when ice crystals fuse to form large crystals that disrupt cell membranes. As the ice melts further, the extracellular environment becomes hypotonic, causing water to infuse into sells a cell lysis.[5] The longer the thawing time, the greater damage to the cells because of increased solute effect and greater recrystallization.[5]

After freezing, stasis within the vasculature occurs. This loss of circulation and resultant anoxia is a major mechanism of injury from cryosurgery. As the tissue thaws over 0°C (32°F), a brief hyperemic response ensues, with resultant edema and inflammation.

Liquid nitrogen is the cryogen of choice in dermatology. It is easy to store and use, environmentally friendly, nonflammable, inexpensive, and at –195.8°C (–320.4°F), has the lowest temperature of all the common cryogens, causing rapid freeze of treated tissue.

Other available cryogens include fluorinated hydrocarbons, solid carbon dioxide, and nitrous oxide (Table 246-1). Fluorinated hydrocarbons are used as topical sprays to provide temporary anesthesia before the removal of skin lesions or the administration of vaccinations. Cryogen spray cooling is also used to reduce the pain of laser surgery and eliminate overheating of the epidermis.[6]

TABLE 246-1
Cryogens Used in Cryosurgery

Agent	Boiling Point (°C/°F)
Freon	–40.8/–41.4
Solid CO_2	–79.0/–110.2
Nitrous oxide	–89.5/–129.1
Liquid nitrogen	–195.8/–320.4

PATIENT SELECTION AND CONSIDERATIONS FOR CRYOSURGERY

Cryosurgery is a destructive modality used to treat benign and malignant skin neoplasms. Several factors, including lesion type, size, depth, border, location, and patient skin type, should be considered when cryosurgery is a treatment choice.

Absolute contraindications to cryosurgery include lesions that require histopathology for diagnosis and recurrent nonmelanoma skin cancers. Relative contraindications to cryosurgery include patients with cold urticaria, abnormal cold intolerance, cryoglobulinemia or cryofibrinogenemia, or tumors with indistinct borders or darkly pigmented melanotic features.

RISKS AND PRECAUTIONS

Precautions should be undertaken when:

- Treating lesions overlying nerves, such as the postauricular nerve on the neck or digital nerves on medial and lateral fingers and toes. Damage may result in regional paresthesia or motor dysfunction.
- Treating sites prone to scarring with retraction, such as the eyelids, mucosa, nasal ala, and auditory canal.
- Treating patients with darkly pigmented skin, may result in hypopigmentation at treated sites.

PATIENT POSITIONING

Patients may be seated or lying on a examination table at a angle but the spray canister should be held upright. Tilting the canister sideways will result in the sudden release of vapor from the canister.

EQUIPMENT

- Cryogen storage container
- Cryogen
- Cryosurgical spray unit

ANESTHESIA

For the majority of patients, anesthesia is not used prior to a cryosurgical procedure. However,

cryosurgery is painful, especially in children. 1% lidocaine with 1:100,000 epinephrine may be locally injected prior to treatment. For longer cryosurgery treatment times, such as treatment of skin neoplasms (up to 30 seconds), local anesthesia is mandatory. Topical anesthesia can be applied approximately 1 hour prior to the procedure to minimize pain. A single-center, double blinded, randomized placebo-controlled, parallel-group trail comparing a lidocaine/prilocaine 5% cream applied 1 hour prior to cryosurgery for warts, however, did not demonstrate a statistically significant difference in pain during the procedure.[7] For longer cryosurgery treatment times, such as treatment for skin neoplasms (up to 30 seconds), 1% lidocaine with 1:100,000 epinephrine can be locally injected prior to treatment.

TECHNIQUES FOR CRYOSURGERY

Table 246-2 lists targets of cryosurgery with associated cell death temperatures. Melanocytes are the most sensitive to cryosurgery, with cell destruction at –4°C to –7°C (24.8°F–19.4°F).[8] Depigmentation may occur, especially in darkly pigmented individuals. Keratinocytes require longer freezing to –20°C to –30°C until cell death and are more resistant to cooling effects. Fibroblasts are the most resistant to freezing and do not undergo cell death until –30°C to –35°C (–22°F to –31°F). A temperature of –50°C to –60°C (–58°F to –76°F) is needed for destruction of malignant lesions, whereas lesser degrees of freezing are needed for benign lesions.

There are several cryosurgical techniques that can be used in treating skin lesions. The open spray method is most frequently used. This method uses a handheld cryosurgical unit with fingertip trigger (eFig. 246-0.1 in online edition). Spray tips with varying-sized apertures are attached to the unit, emitting a stream of liquid nitrogen toward the lesion from a distance of 1–2 cm. A new model has been released, which measures the temperature on the skin surface.[9]

Although freeze times vary for lesion types, an intermittent spray in a solid, circular, or paintbrush pattern is normally used. Longer spray times are required for thicker, keratotic lesions or malignant lesions; shorter times are required for thinner, atrophic, or benign lesions. The intermittent spray helps localize treatment to the lesion with a small freeze halo, thus minimizing collateral normal tissue damage. This is particularly important when treating lesions around the orbital, nasal, auricular, genital, or periungual regions.

As the lesion is treated, a lateral freeze spreads beyond the margins of the lesion. The measurement of the surface radius of the freeze is equal to the central depth of the freeze into the skin.[5] Temperature gradients exist within the freeze, with colder temperatures in the middle and warmer temperatures toward the periphery. In general, superficial lesions should have a clinical freeze margin of 2–3 mm, and malignant or deeper lesions should have a clinical freeze margin of 5 mm to ensure successful treatment.

The closed technique uses a copper cryoprobe that is attached to the cryosurgical unit. Once the metal probe is pressed against a lesion on the skin, the trigger of the unit is squeezed, and liquid nitrogen leaves the unit through a conduit line that maintains it in a closed system. This technique is useful for treating small, well-circumscribed lesions or lesions found in confined locations.

Similarly, a metal, cone-sized chamber can be attached to the cryosurgical unit and held in contact with the lesion. This allows liquid nitrogen spray to enter the cone and rapidly freeze the lesion. Another cone-apparatus option includes holding an otoscope cover tip against the lesion with one hand while freezing with the cryosurgical unit in the other hand. Treatment times using the cone method should be decreased because the final temperature at the orifice of the cone is obtained faster, when compared with an open spray.

If a cryospray unit is not available, the dipstick technique can be used. First, a small amount of liquid nitrogen is poured into a polystyrene cup or other insulated container. Cotton-tipped swabs are placed tip-down in the container and cooled. Using firm pressure, the cotton-tips are placed against the lesion until a 2- to 3-mm halo forms around the treated lesion. This method is useful where surrounding tissue must be spared, such as periorbital, mucosal, nail, and genital regions.

Alternatively, tissue forceps can be placed in the container and allowed to cool. This method is useful for treating filiform lesions such as verrucae and skin tags. The metal forceps cool rapidly, so gloves should be worn while holding the forceps to prevent freeze injury to the practitioner's fingers.

TABLE 246-2
Tissue Target Cell Death Temperatures

Cell	Temperature (°C/°F)
Melanocytes	–4 to –7 (24.8 to 19.4)
Keratinocytes	–20 to –30 (–4 to –22)
Fibroblasts	–30 to –35 (–22 to –31)

OUTCOMES ASSESSMENT FOR COMMON BENIGN LESIONS

SEBORRHEIC KERATOSIS

The spray technique is an effective modality for treating this common lesion. Although longer freeze times of 10–15 seconds with a 1- to 2-mm halo are required for these raised growths, too aggressive freezing may result in scarring or hyperpigmentation. For cosmetic purposes and to prevent pigmentation changes, a lighter freeze followed by curettage may be preferential. Forewarn patients that a second

Figure 246-1 Warts on hand treated with liquid nitrogen.

treatment may be required, especially for thicker seborrheic keratoses.

VERRUCAE

Warts are a common problem, with a high prevalence in the population.[10] Although cryosurgery for warts has sustained a common practice in dermatology, varying techniques have been offered with regard to freezing method, number of freeze-thaw cycles, and frequency of treatment sessions. Cryosurgery using the spray technique is probably the most common method due to its quick, convenient use and ease of obtaining a freeze halo around the lesion (Fig. 246-1). The cotton-tip applicator technique is cheaper and may be less frightening to the patient, particularly children. Care must be undertaken not to cross contaminate the liquid nitrogen by reintroducing the cotton-tip applicator into a common flask.

Combination therapy with cryosurgery has also been advocated to treat verrucae. Berth-Jones and Huchinson[11] demonstrated a 52% cure rate at 3 months with the combination of cryotherapy, keratolytic wart paint, and paring. The authors also noted that paring the wart before cryotherapy improved the cure rates for plantar warts, but not hand warts.

SOLAR LENTIGO

As shown in Table 246-2, pigmented cells are highly susceptible to freezing. Therefore, these lesions require a shorter freeze time of 3–5 seconds with minimal halo. For darker-skinned individuals, care must be taken not to induce hypopigmentation at treatment sites. Therefore, a test site in a cosmetically less noticeable region may be performed first before treating multiple lesions on sun-exposed areas. In addition, sunscreen with ultraviolet A and ultraviolet protection should be advocated post-treatment.

KELOIDS AND HYPERTROPHIC SCARS

Treatment of keloids and hypertrophic scars is frequently unsatisfactory. Cryosurgery is a less common but effective means of treating these recalcitrant lesions. Freeze times of 30 seconds are required over 1-month interval sessions until flattening is achieved. Zouboulis et al reported a prospective study of 93 keloids and hypertrophic scars treated with 30-second freeze times over one to three sessions.[12] Improved responses were seen in patients treated with three or more sessions (79%), compared with subjects treated once or twice (33%).

DERMATOFIBROMA

Treatment time may be 60 seconds due to the fibrotic nature of the lesion and the need to treat cells located in the deep dermis. A retrospective study of 393 dermatofibromas treated with cryosurgery reported 65% clearance of a visible and palpable lesion.[13]

SEBACEOUS HYPERPLASIA

These benign lesions may be a cosmetic concern for patients. Freeze times of 5–10 seconds are required, using the cryoprobe technique with the probe applied directly into the central punctum of the lesion. Patients must be advised that retreatment is frequently necessary.

OUTCOMES ASSESSMENT FOR PREMALIGNANT LESIONS

ACTINIC KERATOSIS

Cryosurgery is an effective modality for the treatment of actinic keratoses (AKs). The open spray technique, using a single freeze-thaw cycle of 8–10 seconds, is the treatment of choice (Fig. 246-2). Hypertrophic AKs

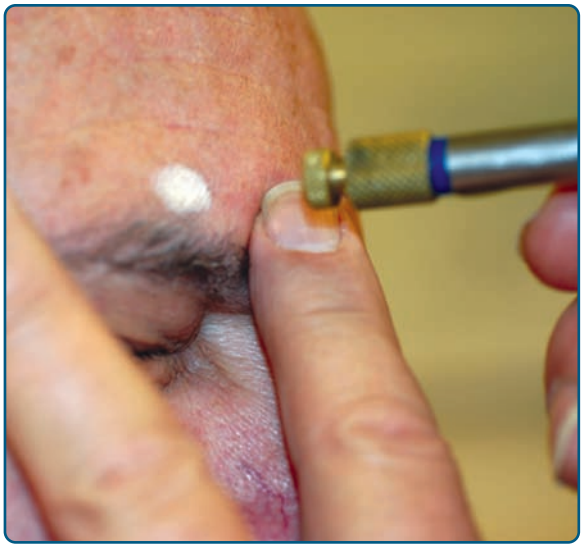

Figure 246-2 Actinic keratosis on forehead treated with liquid nitrogen.

require longer freeze times while atrophic AKs and AKs on thin-skinned regions require shorter freeze times. A 1- to 2-mm freeze margin around the lesion is adequate. For thicker lesions, pretreatment of emollients or curetting may shorten freezing times.

Although cryosurgery is widely utilized in dermatology for treatment of AKs, there are few well-designed studies assessing cure rates. Lubritz and Smolewski[14] treated 1,018 AKs on 70 patients with cryosurgery with 20–45 seconds thaw times. At 1-year post-treatment, they reported a cure rate of 99%.

Another prospective, multicenter study of 421 AKs over 5 mm in diameter on the face and scalp demonstrated a complete response of 39% with a 5-second freeze, 69% for a 5- to 20-second freeze, and 83% for a 20 second freeze.[15]

Goldberg et al treated a number of AKs with monitoring of the skin surface temperature, and achieved a 100% cure rate after 6 weeks.

In patients with diffuse actinic damage, extensive cryosurgery or cryopeeling, may be useful. Chiarello[16] reported cryopeeling was twice as effective as 5-fluorouracil in treating AKs, and preventing squamous cell carcinomas at 1–3 years postoperatively.

MALIGNANT LESIONS

Cryosurgery appears useful in well-defined lesions for situations where surgery is less favorable, either for technical or cosmetic reasons, or when the patient prefers this treatment option. The goal of cryosurgery is to cure the patient by destroying the lesion in a single treatment. The margins of destruction of the lesion cannot be assessed using cryosurgery of malignant tumors.

BOWEN DISEASE

Ahmed et al[17] treated 26 BDs using 3-mm clinical margins and spray technique with two 5- to 10-second freeze-thaw cycles. After 2 years, 50% of the lesions had recurred. The average healing time was 46 days, with lesions on the lower leg taking longer to heal (90 days). Although the cure rate using cryosurgery for BD was low in this study, the authors did use a lower freeze time to minimize side effects postprocedure.

BASAL CELL CARCINOMA

Several studies have reported treating basal cell carcinomas (BCCs) with cryosurgery with cure rates ranging between 95% and 99%.[18–20] Although excellent cure rates have been claimed, few studies have demonstrated histologically that the BCC is no longer present post-treatment. Furthermore, there are no good studies comparing cryosurgery with other known treatment modalities, such as Mohs micrographic surgery, excision with clinical margins, and electrodesiccation and curettage.

Postsurgical cosmetic appearance is a concern to patients. Kokoszka and Scheinfeld[21] reported good cosmetic results in their review of the literature. Thissen et al,[22] however, compared the cosmetic results of surgical excision compared with cryosurgery for BCCs of the head and neck and concluded that cosmetic results after excision are better than after cryosurgery.

SQUAMOUS CELL CARCINOMA

Similar cure rates to BCCs are evident when treating squamous cell carcinomas (SCCs) with cryosurgery. In a study of 563 primary SCCs, of which most were between 0.5 and 1.2 cm in diameter, Graham and Clark[23] reported a cure rate of 97.3%. Treatment technique with cryosurgery for SCCs is the same as for BCCs.

LENTIGO MALIGNA

With proper patient selection, cryosurgery can be an effective treatment option for lentigo maligna (LM) due to the sensitivity of melanocytes to cold. With the aid of a Wood's lamp, a clinical margin of 5 mm is drawn around the visible borders of the lesion. The lesion is subsequently treated with a double freeze-thaw cycle of 30–60 seconds each cycle. Because atypical melanocytes may extend along the length of the hair follicles, treatment must freeze the tissue to this depth.

Stevenson and Ahmed[24] reviewed cure rates from more than 200 LMs treated with cryotherapy, with an overall recurrence rate of less than 9%. However, the recurrence rates in these studies ranged from 0%–50%.

Advantages of cryotherapy for LM include its efficiency and avoidance of large surgical scars. One major disadvantage of cryosurgery is the inability to assess whether the lesion has been completely destroyed. In addition, because no tissue is obtained for definitive confirmation of cancer removal, the chance exists that recurrent melanoma may develop and that it may be invasive. Overlying scars may conceal the cancer.

COMPLICATIONS

PAIN

In addition to pain during freezing, patients will experience some discomfort several hours posttreatment. Typically, pain is controlled with acetaminophen. Lesions such as periungual warts, digital lesions, or mucous membrane lesions may require stronger analgesics due to intense swelling and throbbing.

BLEEDING

Patients on anticoagulant therapy should be warned of bruising due to tissue necrosis. If painful hemorrhagic bullae form, they may be drained with an 18-gauge needle inserted into the lateral blister skin.

Care should be undertaken not to remove the surface of the bullae, as this tissue acts as a natural wound dressing.

PIGMENTATION CHANGES

Hypo- or hyperpigmentation is the most disconcerting complication postcryosurgery. As previously described, pigmented cells are sensitive at temperatures of –4°C to –7°C (24.8°F–19.4°F). Although pigmentation changes are usually transient, prolonged freezing greater than 30 seconds may result in permanent pigment loss. Topical steroids, glycolic acids, retinoids, and hydroquinone may aid in reducing the incidence of hypopigmentation.

NERVE DAMAGE

Treatment of lesions overlying nerves, such as the postauricular nerve on the neck or digital nerves on medial and lateral fingers and toes, may result in regional paresthesia or motor dysfunction. Digital neuropathy occurring postcryosurgery of digital warts has been reported.[25]

SCARRING

Fibroblasts are the most resistant to freezing and do not undergo cell death until –30°C to –35°C. Therefore, most benign and premalignant lesions treated with cryotherapy heal with little scarring. Scars due to second intention may occur after malignancies treated with cryosurgery.

ALOPECIA

Freeze times longer than 20 seconds may result in alopecia. This is especially the case in treating malignant lesions.

MONITORING/FOLLOW-UP

Benign and premalignant lesion sites typically heal in 1–2 weeks, with malignant lesion sites requiring 3–4 weeks of healing. Clinically suspicious actinic keratoses not responsive to cryosurgery should be biopsied to rule out invasive Squamous Cell Carcinoma.

PATIENT INSTRUCTIONS

Patients should be given simple verbal and written wound care instructions post-treatment. Edema, vesicles, bullae, and weeping should be expected from treated areas within 24 hours post-treatment. Treated sites may be rinsed with soap and water and patted dry with a towel daily. If actively weeping, the wound site may be bandaged.

ELECTROSURGERY

Electrosurgery is a technique that uses the transmission of electricity to cut tissue, destroy tissue, and cauterize vessels. Variations in current wavelength result in different biologic effects on tissue. For cutaneous procedures, electrosurgery can be categorized into six different treatment modalities: (1) electrofulguration, (2) electrodesiccation, (3) electrocoagulation, (4) electrosection, (5) electrocautery, and (6) electrolysis.

MODALITIES OF ELECTROSURGERY

ELECTROFULGURATION

Electrofulguration uses a damped sine wave, high-voltage, low-amperage alternating current to generate a spark from a monoterminal electrode to the tissue via the air. There is no contact between the electrode and the tissue. This modality is the least tissue damaging of all of the high-frequency electrosurgery techniques, resulting in rapid tissue healing. Most of the tissue damage is superficial, primarily involving the epidermis.

ELECTRODESICCATION

Electrodesiccation uses a damped sine wave, high-voltage, low-amperage alternating current to generate a current from direct contact of a monoterminal electrode to the tissue. Superficial tissue damage occurs as heat is transferred to tissue, causing cell death. The extent of tissue damage is directly related to electrode contact time with the skin. Although skin injury is greater with electrodesiccation compared to electrofulguration, most of the tissue damage remains superficial.

ELECTROCOAGULATION

Electrocoagulation uses a moderately damped sine wave, low-voltage, high-amperage alternating current to generate a current from direct contact of a biterminal electrode to the tissue. Tissue damage is deeper than with electrofulguration and electrodesiccation, providing tissue coagulation through the generation of heat in the tissue.

Another distinguishing feature of electrocoagulation is the involvement of the patient within the circuit. This allows the use of a lower voltage and higher amperage to generate more coagulation.

ELECTROSECTION

Electrosection uses an undamped or slightly damped sine wave, low-voltage, high-amperage alternating current to cut tissue with minimal peripheral heat

damage. The "Bovie" knife incorporates a blended undamped and damped sine wave that provides both cutting and coagulation at the same time.

ELECTROCAUTERY

Electrocautery uses a heating filament tip connected to a low-voltage, high-amperage direct current, usually a battery. Heat is transferred from the filament to the target tissue, causing protein denaturation and tissue coagulation. There is no electric current transfer to the target tissue, and the patient is not part of the circuit loop.

Electrocautery is most used for patients with pacemakers or implantable cardiac defibrillators (ICDs) who are high-risk candidates for receiving electrosurgery. In addition, because patients are not part of the circuit loop, electrocautery is useful for nonconductive tissue areas of the body, such as the cartilage, bone, and nails.

ELECTROLYSIS

Electrolysis uses low-voltage, low-amperage direct current from a negative electrode to the positive electrode. The negative electrode is applied to the target tissue where electrons are released. The electrons interact with the tissue to produce sodium hydroxide and hydrogen gas resulting in tissue liquefaction. Acids are produced at the positive electrode resulting in tissue coagulation. The main use of electrolysis is for hair removal.

PATIENT SELECTION

When taking preoperative history for surgery, patients should be asked if they have a cardiac pacemaker or ICD. High-frequency electrosurgery may interfere with their function or damage the pacemaker or defibrillator, resulting in patient morbidity or mortality.

Patients commonly present for cutaneous surgery with either a cardiac pacemaker or an ICD. Although technologic advances, such as titanium shielding, have provided safeguards against electromagnetic interference (EMI), electrosurgical devices may cause these cardiac devices to malfunction.

Fixed-rate pacemakers are not influenced by EMI from electrosurgery.

ICDs deliver an electrical response to an abnormal ventricular rhythm. Some ICDs have a combination of a pacemaker and defibrillator to respond to both bradycardia and tachycardia. EMIs from electrosurgical devices may mimic a cardiac arrhythmia and cause the unit to discharge.

RISKS AND PRECAUTIONS

Recommendations have been published for the preoperative and intraoperative management of patients with pacemakers and ICDs during dermatologic surgery.[26–31] Patients should be asked when scheduling surgery if they have one of these devices. If present, a preoperative evaluation by the patient's cardiologist should be arranged before the surgical procedure. For management of patients with pacemakers or ICDs undergoing surgical procedures, consider the following recommendations:

- Provide continuous electrocardiography monitoring throughout the procedure.
- Have advance cardiac life support (ACLS) staff and crash-cart equipment available.
- Place the dispersing electrode in a location that directs the current pathway away from the cardiac device.
- Use a bipolar forcep device to maintain the electrical circuit between the forcep tips.
- Use minimal power and short electrosurgical bursts of 5 seconds or less.
- Consider using a disposable heat cautery device.
- Do not discharge the electrosurgical electrode on the skin directly over the pacemaker power source.

PATIENT POSITIONING

Patients should be supine or prone on the examination table. The dispersing electrode (grounding pad) should be placed in a location that directs the current pathway away from the cardiac device (usually the right lower leg). If a pedal is used, it should be placed near the surgeon's feet.

EQUIPMENT

Electrosurgical equipment uses either direct or alternating current. In direct current, electrons flow in one direction, while in alternating current, electron flow reverses direction. With the exception of electrocautery or electrolysis, electrosurgical units used in dermatologic procedures have high-frequency alternating current.

The terms *monopolar* and *bipolar* refer to the number of tissue-containing tips at the end of a surgical electrode. Monopolar denotes one tip, and bipolar denotes two tips. *Monoterminal* refers to the use of a treatment electrode without an indifferent or dispersing electrode. *Biterminal* refers to the use of both treatment and indifferent electrodes.

ANESTHESIA

During electrosurgery, local anesthesia such as lidocaine with epinephrine is required for patient comfort.

TECHNIQUE

HEMOSTASIS

The most common application of electrosurgery is its use in maintaining hemostasis in the operative field.

Figure 246-3 Electrodesiccation of bleeding vessel during Mohs micrographic surgery.

Different techniques of electrosurgery can be used based on the type of electrosurgical unit used during surgical procedures. Coagulation can be achieved using electrofulguration electrodesiccation or electrocoagulation by direct application of the electrode to the bleeding vessel. This provides conduction of heat to the vessel, resulting in tissue coagulation (Fig. 246-3).

Alternatively, vessels can be grasped by a forcep or hemostat, followed by application of the active electrode. When electrical current is placed against the metal instrument, heat is transferred from the electrode through the metal tip to the vessel. This technique is best used when the surgical field cannot be visualized due to bleeding (Fig. 246-4).

ELECTROSURGERY OF BENIGN LESIONS

Electrodesiccation is an effective treatment modality for papular or plaque-like tumors of the epidermis, such as seborrheic keratoses, verrucae, dermatosis papulosis nigra, molluscum, or flat warts. First, the area around the lesion is anesthetized with lidocaine-containing epinephrine. Then, the lesion is touched with the low-power electrode until a gray, superficial charred layer involves the entire lesion. The charred tissue is removed from the treated lesion by wiping with a sterile gauze or curetting. The process is repeated until the lesion is removed at the level of the surrounding skin. This method results in minimal bleeding and scarring because just the epidermal components are removed.

ELECTRODESICCATION AND CURETTAGE OF MALIGNANT LESIONS

Curettage and electrodesiccation (C+D) is a commonly used treatment option for BCCs and SCCs. Certain tumor characteristics, however, should be present to ensure high cure rates and acceptable cosmetic outcome. Tumors should be primary, have distinct clinical borders, be located on sites of low recurrence such as the trunk, extremities, or non-"H"-zone regions of the face (see Chapters 114 and 115), have a superficial or nodular histologic subtype, and have a diameter of <1 cm on the face and <2 cm on the trunk and extremities. In addition, C+D is a viable treatment option for patients with high morbidity cofactors that make surgical excision too risky or patients who cannot make regular follow-up visits.

Tumors not acceptable for C+D include those with indistinct borders, tumors on the "H"-zone of the face, tumors with an aggressive histologic pattern, tumors with high metastatic potential, and tumors that require histologic diagnosis. For patients with cardiac pacemakers or ICDs, electrocautery may be substituted for electrodesiccation.

The tumor outline should be marked, and lidocaine with epinephrine should be injected to provide adequate local anesthesia (Fig. 246-5). With firm counterpressure, the lesion is then curetted in a checkerboard pattern until the clinical appearance of the lesion is

Figure 246-4 Electrocurrent applied to forcep to cauterize bleeding vessel during Mohs micrographic surgery.

Figure 246-5 Clinical outline of skin tumor before curettage and electrodesiccation.

Figure 246-6 Curettage of skin tumor during curettage and electrodesiccation procedure.

removed (Fig. 246-6). This is followed by electrodesiccation on high power of the base and periphery of the lesion (Fig. 246-7). This C+D procedure is repeated up to two more times until a resultant atrophic defect without clinical evidence of residual tumor is achieved. Some advocate the inclusion of a 2- to 4-mm rim of clinically normal skin during the C+D procedure, and individual variations of the protocol are established. If curettage of the BCC extends into subcutis, then an extensive invasion of a BCC has occurred, and excision should be performed.

The advantages of treatment with C+D include time efficiency, ease of surgical technique, and minimal post-treatment morbidity. Disadvantages of treating with C+D include nonconfirmation of histologic tumor clearance, practitioner-dependent efficacy, and potentially long (3- to 4-week) healing times via second-intention healing. Furthermore, the cosmetic result may show hypopigmentation, atrophy, persistent erythema, and hypertrophic scarring.

Figure 246-7 Electrodesiccation of skin tumor during curettage and electrodesiccation procedure.

OUTCOMES ASSESSMENT

The 5-year cure rates for C+D have been reported to be 74%–100% for BCCs[32–42] and 96%–100% for SCCs.[32] Although some authors have reported that 20%–40% of tumors remain immediately post-C+D, the 5-year cure rates demonstrate an additional factor may be contributing to the destruction of the treated malignancy. Some authors have speculated that the inflammatory response or a specific antitumor humoral response following electrosurgery may be responsible for the low recurrence rate.[43,44]

C+D in combination with other topical treatments may have a synergistic effect in tumor clearance. In a double-blinded, placebo-controlled pilot study by Spencer,[45] ten BCCs were treated with C+D and ten patients were treated with C+D followed by 1 month of daily topically applied imiquinod cream. The author reported a substantially reduced frequency of residual BCC and improved cosmetic appearance in the C+D/imiquinod group compared with the C+D alone group. Another study by Wu et al[46] reported excellent efficacy and cosmetic results for nodular BCCs of the trunk and limbs treated with curettage (no electrodessication) followed by daily topical application of imiquinod cream for 6–10 weeks. In that study, 32 of 34 (94%) lesions demonstrated no residual histological evidence of tumor.

COMPLICATIONS

Although electrosurgery is safe, the surgeon must recognize several dangers while using this technique.

BURNS

There are several situations in which burns may occur with electrosurgery. Thermal injury can occur if there is inadequate contact between the patient and the dispersing electrode plate, when there is inadvertent contact between the dispersing electrode and the patient or surgeon, and if the patient or surgeon may "ground" him- or herself by touching a metal component of the table. Metal jewelry near the electrosurgical site should also be removed.

FIRE

Electrosurgical current will ignite flammable substances like alcohol. When prepping the patient before electrosurgery, nonflammable disinfectants such as iodine or chlorhexidine should be used. If an alcohol-based disinfectant is used, the surgical area must be allowed to dry for at least 90 seconds prior to electrosurgery. In addition, electrosurgery should not be used near the presence of nasal cannulas, masks, or endotracheal anesthesia

administering oxygen. Finally, care should be taken not to ignite paper surgical drapes in the surgical field.

CHANNELING

High-frequency electrosurgical current can be conducted along neurovascular bundles, causing pain and tissue damage distant to the local electrosurgical site. Using low-current settings or bipolar forceps may minimize this.

INFECTION AND MUTAGENICITY

A plume of smoke is generated during electrosurgery. This traveling plume has been shown to contain carbonized tissue and blood, airborne particles, and various chemicals and gases. In addition, smoke created from treating lesions such as warts may contain infectious material, such as bacteria and viruses that may transmit infection.

No known long-term risk for neoplasia or infection is known. The Occupational Safety and Health Administration recommends that surgical smoke be removed and properly filtered by a smoke evacuation system as close to the surgical site as possible.[47] Furthermore, protective equipment, such as face shields and respiratory masks, should be worn during electrosurgery.

COMPLICATIONS WITH PACEMAKERS/ICDS

Complications resulting from using electrosurgery for cutaneous surgery in patients with pacemakers or ICDs are uncommon. Matzke et al published a 3-year retrospective review of 173 patients with pacemakers and 13 patients with ICDs undergoing dermatologic surgery and reported no documented complications from electrosurgery.[48] El-Gamal et al reported a rate of 0.8 cases per 100 years of surgical practice from 166 completed surveys from members of the American College of Mohs Surgery and Cutaneous Oncology.[49] In this study, the types of interference reported were skipped beats, reprograming of a pacemaker, firing of an ICD, asystole, bradycardia, and depletion of pacemaker battery life.

MONITORING/FOLLOW-UP

For all treatment groups, wound areas should be covered with a pressure bandage consisting of a topical petroleum product directly on the wound, an overlying nonstick bandage, and firmly applied gauze with adhesive tape.

PATIENT INSTRUCTIONS

After 24–48 hours, the pressure bandage is removed, and the wound site is cleaned with tap water or saline gently rinsing over the wound. Petroleum jelly and bandage is changed daily after rinsing, for 3–4 weeks or until healed.

Chapter 247 :: Surgical Complications

:: Richard G. Bennett

SURGICAL COMPLICATIONS AT A GLANCE

- Complications in dermatologic surgery are relatively uncommon.
- Complications are best avoided by
  - Obtaining patient history of medications, prior bleeding episodes, allergies, and prior surgeries.
  - Observing asepsis during procedure.
  - Gentle handling of tissue.
  - Complete cessation of bleeding at time of surgery.
  - Good wound care by patient after surgery.

Surgical complications are unexpected problems that arise in association with an operation. Although the surgeon is always vigilant to minimize complications, adverse outcomes will inevitably occur. This chapter focuses on preventing, identifying, and treating common complications seen with skin surgery. One recently discussed method to minimize complications is the use of a surgical checklist similar to one used by airplane pilots.[1]

COMPLICATIONS AT THE TIME OF SURGERY

Most complications that occur on the day of surgery involve the patient's underlying medical problems, reactions to administered anesthetics, and bleeding. Allergy, hypersensitivity, or toxic reactions to local anesthetics and fainting with or without seizure can also occur.

PATIENT'S MEDICAL PROBLEMS

Before surgery, it is important to obtain a medical history and perform a physical examination. The level of physical examination is commensurate with the extensiveness of the surgery that is planned. For example, a small cyst excision would only require a cursory physical exam (i.e., general appearance) and vital signs, whereas an extensive liposuction procedure using a large volume of tumescent anesthesia would require a full physical examination and diagnostic testing, if indicated.

The patient's medical history, including allergies, medications, and past surgeries, is important to obtain. Medications such as anticoagulants, pain medications, and certain herbs can affect bleeding at the time of surgery (Table 247-1).[2,3] Excessive bleeding with prior surgeries, especially if requiring transfusions, can be associated with a prolonged bleeding time. It is important to determine if the patient has a cardiac pacemaker, defibrillator, or any other implantable medical devices. Also, if the patient has an artificial heart valve or a rheumatic heart valve, preoperative antibiotics will be required.

Some of the common problems associated with skin surgery include fainting, seizures, and diaphoresis. Fainting is almost always a vasovagal reaction, and the best treatment is to position the patient in the Trendelenburg position. Seizures sometimes occur with the vasovagal reaction and are short lived. Usually, when patients faint, there is a history of fainting episodes, pointing out the importance of inquiring about this in the medical history. Diaphoresis may occur associated with a vasovagal reaction, angina, or hypoglycemia.

Certain equipment is necessary to address emergencies. A "crash cart" includes a heart monitor with defibrillator and common medications to manage

  - Ibuprofen
  - Ketoprofen
  - Naproxen

emergencies. Oxygen tanks with appropriate masks or nasal cannulas should be ready for use and checked regularly. In addition, a blood pressure cuff, heart rate monitor, and pulse oximeter should be available. Although we now live in a "911" culture, the operating physician is still responsible for handling medical problems, and the dermatologic surgeon should be certified in basic or advanced cardiac life support. Furthermore, ancillary staff should be similarly certified and know their role in emergency situations.

ANESTHESIA-RELATED COMPLICATIONS

Because almost all cutaneous surgery performed by dermatologists is done with local anesthetic, this section only discusses local anesthetic complications. Fortunately, problems with local anesthetics are extremely rare. Thus, physicians have been lulled into a false sense of security. Allergy to lidocaine is rare if it happens at all; generally, the allergy is to the paraben preservative.[4]

Problems with local anesthetic toxicity are most often related to the total dosage and the addition of epinephrine (see Chapter 242). The total dosage (for a 70-kg patient) should not exceed 500 mg of lidocaine if epinephrine is used and 200 mg if epinephrine is not used.[5] Alternative anesthetics such as bupivacaine have a different recommended total dosage. The initial sign of lidocaine toxicity is tongue and circumoral numbness. If this occurs, oxygen should be administered and an intravenous line established.

The addition of epinephrine to local anesthetics is commonplace. However, epinephrine can cause an increase in heart rate, increased contractility of heart muscle, and vasoconstriction. This phenomenon often occurs with inadvertent direct injection into a blood vessel or it could represent a hypersensitivity reaction especially if the patient is hyperthyroid. Epinephrine should be given cautiously in patients with severe hypertension or cardiac arrhythmias. In these situations, epinephrine, which is present in prepackaged anesthetic in a dilution of 1:100,000, can be diluted further to 1:200,000 or less without decreasing hemostasis. If patients have a history of sensitivity to epinephrine, it is best to use lidocaine without epinephrine. However, in the absence of epinephrine, the anesthetic duration and level of anesthesia will decrease, and the onset time will increase. Also, the absence of epinephrine in local anesthetic can contribute to increased intraoperative bleeding.

Anesthetic containing epinephrine should not be injected into the digits. Although there is some controversy about this, a patient with unknown diabetes may be at high risk for tissue necrosis. Anesthetic containing epinephrine may be injected into the nose, earlobes, and penis; however, it maybe preferable to do a pudendal nerve block in the latter site.

BLEEDING

During and after surgery, a cardinal goal is to minimize blood loss. A medical history helps identify medical problems that might promote bleeding, such as thrombocytopenia, coagulopathy, or hypertension. Several medications inhibit platelet function (see Table 247-1). Anticoagulants should be specifically queried. Extensive intake of garlic, ginkgo, vitamin E, and some other herbs can promote bleeding. During surgery, meticulous hemostasis will help minimize postoperative bleeding.

One medication with specific importance in dermatologic surgery is warfarin (Coumadin). Patients on warfarin should not discontinue this medication before cutaneous surgery. In some patients who stop and start warfarin, the blood becomes hypercoagulable, which may lead to blood clots or strokes.[6] Aspirin, on the other hand, is generally safe to stop 10–14 days before surgery, unless the patient has had a history of strokes or transient ischemic attacks.[7]

COMPLICATIONS IN THE IMMEDIATE POSTOPERATIVE PERIOD

Some specific complications occur from the day of surgery until approximately 1–2 weeks later. It is important to give the patient a way to immediately contact the physician in case complications arise, and it is prudent to call the patient the day after surgery to inquire how he or she is doing.

INFECTION

Wound infection can occasionally sterile occur despite every effort to adhere to appropriate surgical technique. Three types of infection occur most commonly with cutaneous surgery: (1) *Streptococcus pyogenes*, (2) *Staphylococcus aureus*, and (3) *Mycobacterium* (especially *M. fortuitum* and *M. chelonei*).[8,9] Generally, all three are quite different in clinical presentation and timing. *Streptococcus* occurs early, within 24–48 hours of surgery, and appears as a spreading, painful erythema. *Staphylococcus* infection appears at 2–5 days after surgery and is usually associated with pus formation. Finally, *Mycobacterium* infection appears 2–4 weeks after surgery.[8] Clinically, it appears as ulcerating papules or nodules that will not heal or that repeatedly heal and break down.

Recently a particular form of *S. aureus* resistant to methicillin, so-called *methicillin-resistant S. aureus* (MRSA), has appeared in an increasing number of wounds.[10] It is therefore important to culture wounds that appear infected so that the proper antibiotic can be selected. Antibiotics that generally work well against methicillin-resistant *S. aureus* are doxycycline and trimethoprim-sulfamethoxazole.

The risk of infection with MRSA is increased fourfold if a patient is a nasal carrier of MRSA.[11] This fact has led to physicians in plastic surgery, orthopedics, and cardiac surgery now recommending use of mupirocin ointment in the nasal vestibule prior to surgery.[12] However, in one study, MRSA was resistant to mupirocin 12% of the time.[13]

Infections with herpes simplex or herpes zoster are rare after cutaneous surgery. One exception to this is the development of herpes infection after whole-face dermabrasion or laser resurfacing. With these procedures, an antiviral medication, such as acyclovir, valacyclovir, or famciclovir, should be started before surgery, especially in those patients who have a history of herpes simplex infections (see Chapter 193).

CONTACT DERMATITIS

Allergic reactions can occur to antibiotic ointments used in routine wound care to keep wounds moist. The patient most often has a contact allergy to neomycin or bacitracin.[14] Although bright-red, poorly marginated erythema appears around the operative site with the antibiotic allergy (Fig. 247-1), the diagnosis is usually obvious because the patient will complain of marked pruritus. This symptom is in contrast to that of an infection where the patient complains mainly of pain and pruritus is minimal or absent. Allergic reactions to bandage materials such as Telfa and Micropore paper tape are extremely rare.

Contact dermatitis can also occur to disinfectant surgical solutions (e.g., chlorhexidine) used to clear the skin prior to surgery.[15]

PAIN

Significant pain is rarely present after cutaneous surgery. Patients should take plain acetaminophen for uncomplicated pain. Occasionally, if the surgery is extensive, acetaminophen with codeine or hydrocodone may be used. On rare occasions, stronger narcotics may be necessary.

BLEEDING AND HEMATOMA FORMATION

After suturing a wound, roll a cotton-tipped applicator over the wound with pressure to express any trapped blood and then place a secure pressure dressing on the wound. The less residual blood in the wound, the faster healing will occur.

Occasionally, patients will continue to bleed from their wound, whether sutured or open. If the patient is on warfarin, an international normalized ratio should be checked. If the patient has unexplained, continuous bleeding, he or she should be evaluated for a coagulopathy.

Occasionally, a large collection of blood may occur under a sutured wound (Fig. 247-2A). This may be more common in men and those with hypertension.[16] If this occurs within a few hours of surgery to up to 24 hours postoperatively, it is best to unsuture the wound, locate the source of bleeding (see Fig. 247-2B), and obtain hemostasis. Almost always, an artery is found that is pumping blood; it is advisable to ligate it and then resuture the wound (see Fig. 247-2C). If the patient returns after a few days with a large fluctuant hematoma, aspirate the wound using a large bore needle or, if available, a blunt microliposuction canula. It is not usually necessary to remove the sutures at that point, as the hematoma will probably not reform. However, if the hematoma does reform, it may become necessary to remove the sutures, locate the bleeder, excise the wound edges, and resuture the wound.

Figure 247-1 Contact dermatitis to Polysporin® ointment near skin flap.

NECROSIS

If the blood supply is inadequate, tissue death can occur. This phenomenon can occur with a skin flap or skin graft (Fig. 247-3); it rarely occurs with a side-to-side wound repair but may develop if an extremely tight pressure dressing is applied. Inadequate blood supply can occur due to factors intrinsic to the wound itself such as hematoma or factors extrinsic to the wound such as the patient's medical condition or local tissue problems.

Intrinsic factors causing tissue necrosis include excess wound tension, infection, and hematoma formation. For a skin graft, excessive thickness may inhibit vascularization. A skin flap may necrose if the base is too small or the flap is too thin or kinked (see Chapter 243).

Extrinsic factors that can lead to tissue necrosis include local tissue considerations such as poor blood supply due to anatomy, prior radiation, or prior surgery. Other extrinsic factors are systemic diseases such as diabetes, medications, or malnutrition. Smoking may also cause tissue necrosis, probably as a result of decreased blood flow due to nicotine. The smoking effect appears to be dose related: patients who smoke one pack per day do not have an increased likelihood of necrosis, whereas those smoking two packs per day do.[17]

DEHISCENCE

Despite careful wound apposition and suturing, wound edges can pull apart. Often, this dehiscence occurs due to excess tension on the wound edges, but it may result from suture breakage or unraveling. To

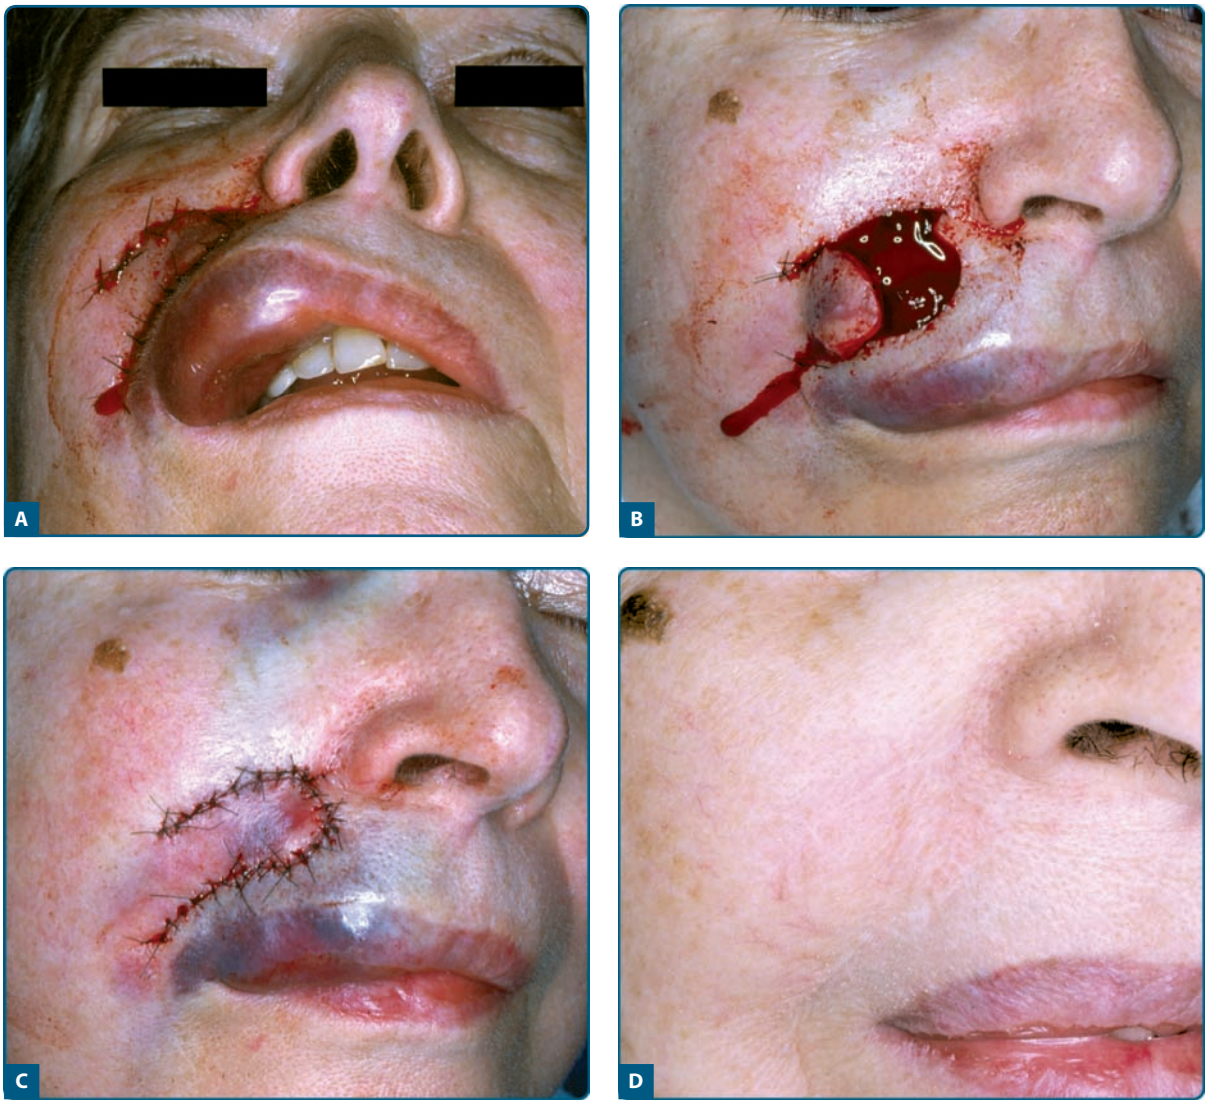

Figure 247-2 **A.** Swelling of right upper lip 2 hours after skin flap. **B.** Flap unsutured, exposing blood coagulated below. Arteriole bleeder found and tied off. **C.** Flap immediately resutured. **D.** Healed flap 3 months later.

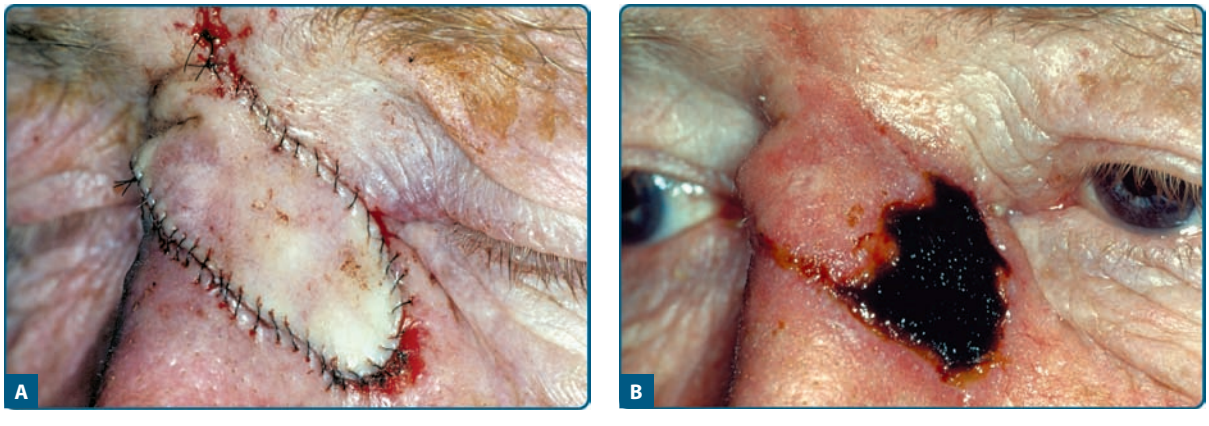

Figure 247-3 **A.** Flap from glabella to left dorsal nose. **B.** Necrosis in flap 1 week postoperatively.

prevent dehiscence, vertical mattress sutures are quite useful because they provide an increase in tensile strength earlier than do interrupted sutures. This phenomenon is especially true for thin skin or skin with abundant large sebaceous glands (e.g., the nose).

If the dehiscence occurs within a day of suturing, the wound can be resutured without freshening the wound edges. If the dehiscence occurs more than 48 hours after the initial surgery, the wound edges should be freshened by excising 1 mm of normal skin before resuturing the wound.

In the presence of infection, necrosis, or extreme wound edge tension, it may be best not to immediately resuture a dehisced wound but, rather, allow the wound to heal by granulation.

Dehiscence can also occur after suture removal. To prevent this problem, percutaneous sutures may be left in place for more than 7 days. In wounds under tension, such as on the back, or in locations where wound healing is slow (i.e., the leg), sutures may remain for up to 2 to 3 weeks. Another approach to a wound under tension is to remove a fraction of the sutures at 7 days and the balance several days later. To further help prevent dehiscence, apply a glue (Mastisol®) and Steri-Strips™ across the wound immediately after suture removal. The patient is instructed to keep the wound dry so the Steri-Strips™ will stay in place for about 1 week after placement. In some anatomic locations (e.g., scalp, bearded areas in men), Steri-Strips™ placement will not work well because of hair.

COMPLICATIONS IN THE DISTANT POSTOPERATIVE PERIOD

After sutures have been removed, the wound continues to heal. Patients may be followed up to 1 year postoperatively to address any problems that might arise.

MILIA OR KERATINOUS CYSTS

Occasionally, during surgery, small pieces of epidermis may be buried or a follicle may be transected by the suture needle. When this happens, a milial cyst may occur adjacent to the suture line. It is easily removed with a comedone expressor after a needle incision. Larger cysts can occasionally grow, associated with scars. However, one should be wary if a cyst appears where a skin cancer was excised; the "cyst" may indeed prove to be a skin cancer on pathologic examination.

SUTURE TRACK MARKS

Suture track marks can occur due to suture material cutting into tissue (Fig. 247-4A). These scars can be minimized by using polypropylene suture material, which stretches, rather than nylon suture, which does not. Also, when suturing, the surgeon should be careful not to tie knots too tightly or pull on the suture too

Figure 247-4 **A.** Suture track marks around forehead scar. **B.** Dermabrasion of scar at 5 weeks after being sutured. **C.** Healed scar 2 months later. Suture track marks have disappeared.

Figure 247-5 Keloid of earlobe and posterior auricular sulcus. Patient underwent an ear pinning procedure.

tightly when tying or cutting. If caught early, within 1 or 2 months, dermabrasion works well to eliminate suture track marks (see Fig. 247-4B and C).[18]

Other methods to avoid suture track marks include use of the over-and-over running suture that distributes tension along the wound length and the buried intradermal (running intradermal subcuticular) suture.

HYPERTROPHIC SCAR

Occasionally, scars will become elevated and stay within the boundaries of the wound. This is known as a *hypertrophic scar* in contrast to a *keloid scar* that grows beyond the boundaries of a wound (Fig. 247-5; Table 247-2; see Chapter 66). Both keloids and hypertrophic scars are treated by pressure massage; they also respond well to intralesional triamcinolone acetonide 10 mg/cc (Fig. 247-6A and B). Other useful methods that have been reported to improve keloids include excision, intralesional 5-fluorouracil or interferon-α, cryosurgery, and radiotherapy.

Scar lines may also appear lumpy due to buried sutures. Usually this lumpiness disappears in 2–3 months as sutures absorb.

Patients occasionally ask about various commercially available products to use for scar improvement. Some of these products contain silicone or polyurethane foam. It may be that the use of these products improves scars by increasing the moisture of the scar or by the constant application of pressure. Similar improvement may be seen by using paper tape on wounds for 3 months after surgery.[19]

DEPRESSED OR FURROW-LIKE SCARS

A depressed or furrow-like scar is common in skin with an abundance of sebaceous glands. In this circumstance, wound edges often cannot be held together without tearing. With tearing of the skin, varying degrees of wound separation occur that result in depressed scars. To correct this problem, the depressed scar is excised, and the wound edges are undermined and resutured. At the time of resuturing, use of several buried sutures and vertical mattress sutures will even up and tightly oppose the wound edges, minimizing recurrence of the depressed scar. The vertical mattress suture grasps more tissue laterally than does a simple interrupted suture. Thus, there is less chance for sutures to tear through tissue. It is also important when working in very sebaceous skin to use suture no finer than 5-0.

SPREAD SCARS

Scar spreading occurs with tension on wound edges. Sometimes, this tension is unavoidable due to anatomic considerations, such as on the chest or upper back. Sometimes spread scars occur where there is great tension on the wound edges that exceeds the holding

TABLE 247-2
Comparison of Hypertrophic Scar and Keloid

	Hypertrophic Scar	Keloid
Incidence	Common	Uncommon
Race	All	Usually dark skin
Injury	Yes	Sometimes
Location	Anywhere, especially perpendicular to maximal skin tension lines	Earlobes, trunk, rare on central face
Growth	Within scar line	Beyond scar line
Resolution	Usually	No
Recurs with excision	Usually no	Usually yes

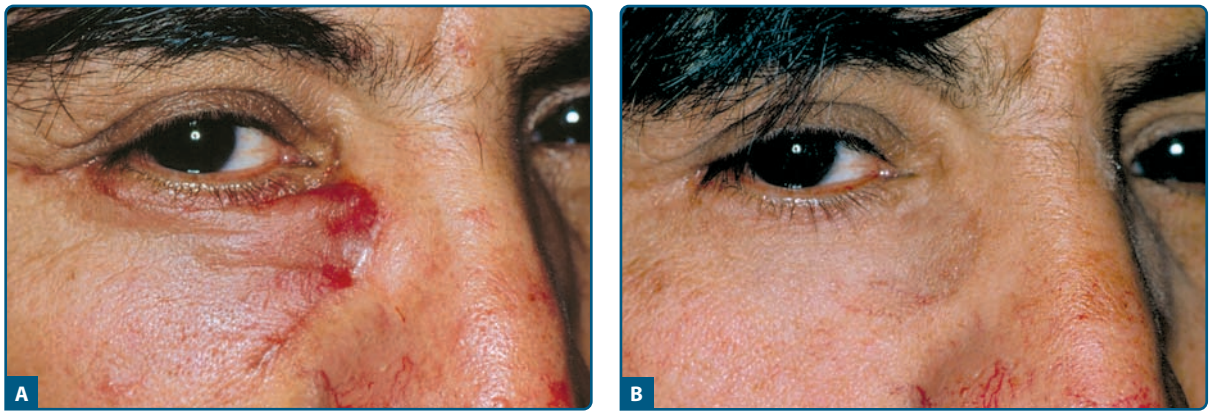

Figure 247-6 **A.** Hypertrophic flap on right nose and cheek. Injected with triamcinolone acetonide, 10 mg/cc. **B.** Flap 2 months later.

power of the sutures or the healing wound edges after suture removal. Stretching of scars is quite common on the scalp, trunk, and extremities. It is prudent to explain this phenomenon to the patient in advance.

BURIED SUTURE EXTRUSION

Buried dissolvable sutures may occasionally extrude through the wound edges about 3–4 weeks after placement. This problem is very common. Usually pulling or cutting the extruding suture out will help the wound edges heal faster.

TELANGIECTASIA

The appearance of fine red vessels adjacent to a suture line or on top of a flap or graft can be quite noticeable. This is a normal occurrence, and the vessels usually fade with time; thus, we encourage patients to wait about 6 months after surgery before treating these vessels. Vascular ablating lasers (e.g., the 585- to 595-nm pulsed dye laser and the 532-nm potassium-titanyl-phosphate laser) generally do an excellent job of eliminating the vessels (see Chapter 252).

ERYTHEMA

All sutured wounds are at first erythematous, but generally with time (3–12 months), the erythema fades. Occasionally, however, the redness does not fade. Like telangiectasias, persistent redness is treated with vascular lasers (see Chapter 252). Telangiectasias and redness may be more common in women, especially those on estrogenic medication, than in men.

HYPOPIGMENTATION

As redness fades, all scars become hypopigmented to some extent. The hypopigmentation may be very noticeable if surrounded by erythema, especially in those patients with a ruddy complexion or rosacea. Generally, nothing is done with hypopigmented scars, as the problem will recur if excised. However, if the hypopigmented area is relatively enhanced by surrounding erythema, laser treatment of the adjacent redness may make the hypopigmentation less noticeable.

Occasionally, full-thickness skin grafts become hypopigmented. This pigmentation problem often occurs because the skin graft is excessively thinned before placement. One way to rectify the color in this circumstance is to tattoo the graft to match the surrounding skin color.

HYPERPIGMENTATION

Scars rarely become darkly pigmented, but, occasionally, this can occur. Most often hyperpigmentation appears in individuals with darker complexions and brown eyes. Patients with this type of complexion should be advised to keep their scars out of direct sunlight and to wear a sunscreen that protects against ultraviolet A.

ANESTHESIA

Loss of sensation in the area of surgery is very common, especially with flaps and grafts. Almost always, the sensation returns slowly over 3–18 months, depending on the location and size of the surgery.

Loss of sensation in a few anatomic locations is worthy of special mention. If one operates on the forehead and transects the supraorbital nerve, all sensation superiorly, up to the top of the scalp, will be lost. However, usually, the patient regains most of the sensation slowly over 6 months to 2 years. On the lateral neck, if the great auricular nerve is severed, loss of sensation will occur to most of the lower anterior ear. Unfortunately, in this location, the anesthesia will be permanent.

MOTOR LOSS

(See Chapter 242)

Chapter 248 :: Mechanisms of Wound Repair, Wound Healing, and Wound Dressing

:: Vincent Falanga & Satori Iwamoto

WOUND REPAIR AT A GLANCE

- Acute and chronic wounds are different but overlap.
- In acute wounds, there is an orderly progression from injury to coagulation, inflammation, proliferation, cell migration, and tissue modeling.
- In the initial phases, a wide range of growth factors, including platelet-derived growth factor and transforming growth factor-β1, play an important role. In the proliferation/migration and modeling phases, tissue matrix metalloproteinases (MMPs), integrins, basic fibroblast growth factor, and endothelial growth factor are critical. MMP-1, MMP-9, and MMP-10 are essential for remodeling.
- Moist wounds heal faster, and a variety of wound dressings are now available to fit this requirement. They include transparent films, hydrocolloids, foams, alginates, gels, and collagen-based products.
- Chronic wounds are different from acute wounds in that the one-way relationship between the different phases is lost. Chronic wounds are the complex result of ischemia, pressure, and infection; healing is highly dependent on these factors.
- Wound healing of skin grafts is also different, as it is completely dependent on revascularization, be it true neovascularization or inosculation.

INTRODUCTION

The terms "wound healing", "wound repair", or "tissue repair" are often used interchangeably, but actually "healing" and "repair" point to different sets of events and outcomes. First of all, before any distinction is made, one must recognize the rather obvious fact that "healing" and "repair" are not confined to the skin, but can encompass any organ system. Technically, wound healing is a term that should be used only in the context of true regeneration, when the original architecture and structure of an organ or anatomic part is completely restored to the way it was before injury. More primitive animals, such as small amphibians and reptiles, are still capable of this type of regeneration. However, as animals became larger and more complex during evolution, true regeneration was no longer possible. The human fetus is still largely capable of regeneration (especially in the early stages) but, in adults and with the possible exception of the liver (probably a compensatory enlargement and not regeneration), true regeneration does not take place. Rather, man and other higher vertebrates heal by a process of repair (wound repair or tissue repair), whereby the eventual outcome is not true anatomic restoration but a functional compromise. Still, because of well established terms and the published literature, even within our discussion here, we may at times use "healing" and "repair" interchangeably; we will be more specific when truly referring to the process of tissue regeneration.

There are probably evolutionary reasons for why repair occurs in higher vertebrates compared to true healing or regeneration. Teleologically and from an evolutionary standpoint, the process of repair for higher animals needed to be rapid, economical from an energy standpoint, and allow for the immediate survival of the organism. However, by necessity, repair leads to a rapid solution to injury and thus to

scarring. Another important consideration is that most of the mechanisms of wound repair that have evolved are aimed at addressing acute tissue injury and not chronic conditions. Again from an evolutionary standpoint, humans were not meant to develop degenerative diseases or live long enough to develop arterial, venous and pressure ulcers, or neuropathic ulcers from diabetes. Therefore, humans are quite unprepared for these types of chronic wounds, and there are no specific mechanisms that have evolved to deal with them in a truly effective way.[1–3] It should be noted that the extent of injury and its depth are important considerations. Thus, shallow wounds (i.e., shave biopsies) that retain skin appendages (hair follicles, sweat glands, etc.) in the wound bed have the capacity to heal from the "inside", since keratinocytes associated with those skin appendages are still present. On the other hand, full-thickness wounds (punch biopsies are a good example) have to rely on keratinocyte migration and proliferation from the edges (Fig. 248-1). Not surprisingly, full-thickness wounds are associated with delayed healing and more scarring.[2] Some animal models, particularly those in which certain genes are overexpressed or knocked-out, are providing greater understanding of the role of certain proteins and mediators.[4–7] Impaired healing is found in mice with combined deficiency of molecules critical in inflammation (E- and P-selectins), and in mice without plasminogen, uPA and tPA (double knock-out), fibroblasts growth factor-2 (basic FGF or bFGF), or inducible nitric oxide (iNOS). On the other hand, impaired or delayed healing occurs in transgenic mice overexpressing some tissue metalloproteinases (MMP-1) and antisense to CD44, the receptor for hyaluronic acid. Some induced mutations lead to accelerated healing, as reported with Smad-3 or skn-1a knock-out mice.[8] In the future, it may be possible to use these clues to stimulate the healing process in humans.

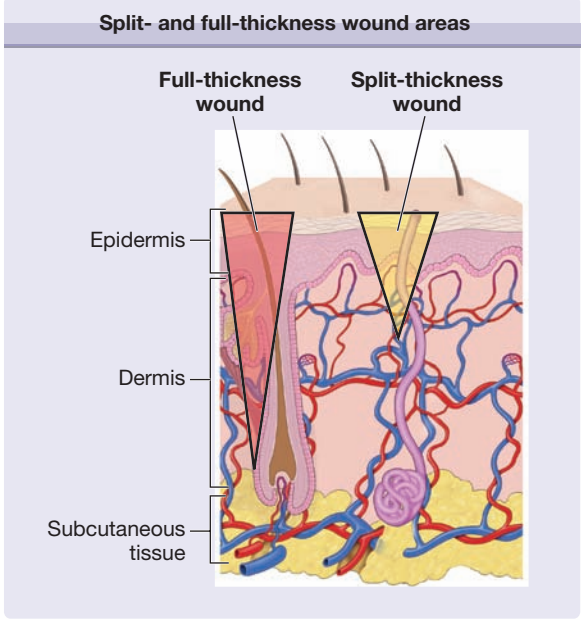

Figure 248-1 Diagrammatic representation of the skin, with two inverted triangles representing either a split- or full-thickness wound. Extending the injury below the reservoir of keratinocytes present in skin appendages (full-thickness wound) removes the ability for the keratinocytes to populate the defect from within the wound bed; healing has to occur from the wound edges and, moreover, more scarring takes place.

PHASES OF WOUND HEALING

In general, there are four recognized phases that characterize the cutaneous repair process: (1) coagulation, (2) inflammatory phase, (3) proliferative and migratory phase (tissue formation), and (4) remodeling phase. The coagulation and inflammatory phases ore sometimes grouped together, so great is the overlap of mediators that are released. In a diagrammatic form, Fig. 248-2 illustrates these phases of healing in sequence, while Fig. 248-3 shows specific events that take place during the different phases. We will discuss these phases and identify the main components and events that characterize them. The cell types primarily involved in wound healing have been regarded to be the platelets, neutrophils and macrophages, fibroblasts, endothelial cells, epithelial cells. More recently, increasing importance is accumulating for the role of lymphocytes, either directly or indirectly.[9] However, it should be noted that breaking down the overall process of wound repair into these seemingly defined phases is artificial, as they overlap considerably.[2,3] Another consideration is that the occurrence and hypothesis of these phases of wound healing has been determined in laboratory animal experiments; it is assumed that the same processes are involved in human tissue repair.

COAGULATION AND INFLAMMATORY PHASES

Although we have shown these as separate phases, the degree of overlap is such that it is appropriate to discuss them together. These early phases begin immediately after an acute injury. Disruption of blood vessels leads to local release of blood cells and blood borne elements resulting in clot formation. While the blood clot within the vessel lumen provides hemostasis, the clot within the injury site acts as a provisional matrix for cell migration,[10] further formation of new extracellular matrix (ECM),[11] and a reservoir for cytokines and growth factors.[12] The initial component of this phase is dominated by the platelet, which directs clotting of the fresh wound by the intrinsic and extrinsic pathways. Platelets also release a number of chemotactic factors that attract other platelets, leukocytes, and fibroblasts to the site of injury. Leukocytes are slowed down within the blood stream through the expression of selectins, which, coupled with integrins, bring inflammatory white cells into the wound.[5] These cells have multiple roles, including debridement of necrotic material and bacteria, as well as the production of certain critical cytokines. A case in point is the production of connective tissue growth factor (CTGF) by inflammatory cells

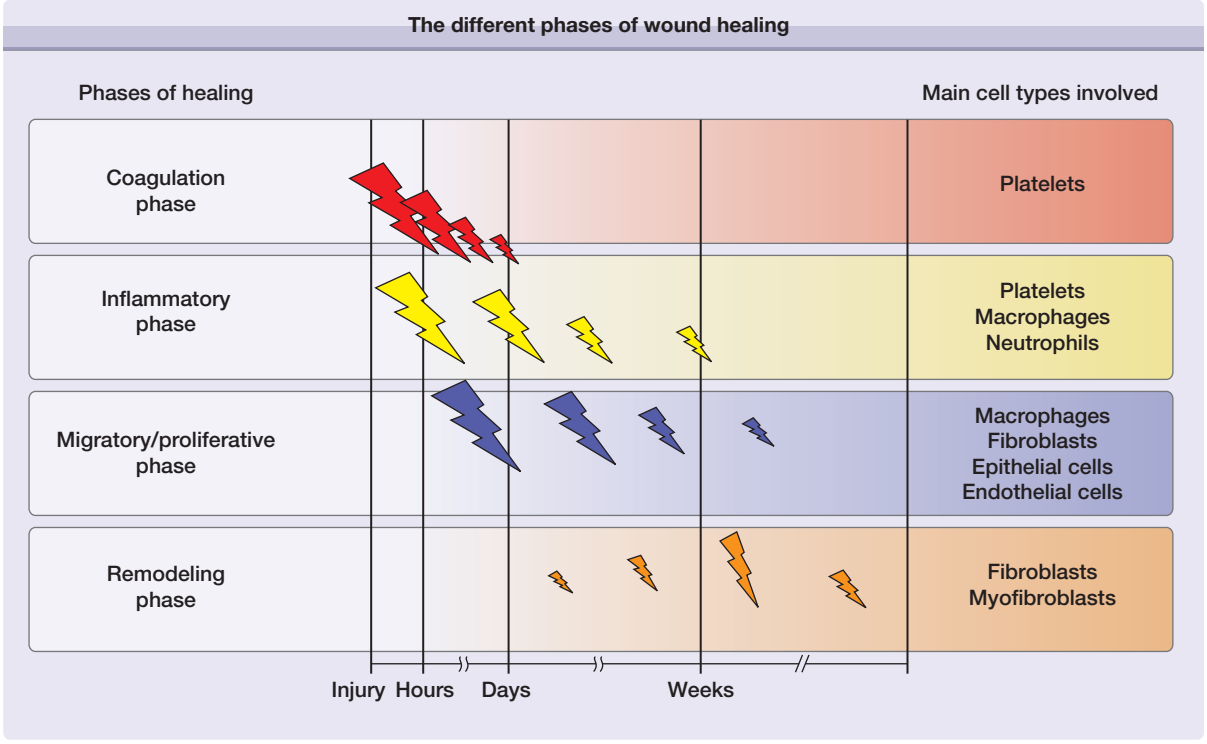

Figure 248-2 Schematic representation of the different phases of wound healing.

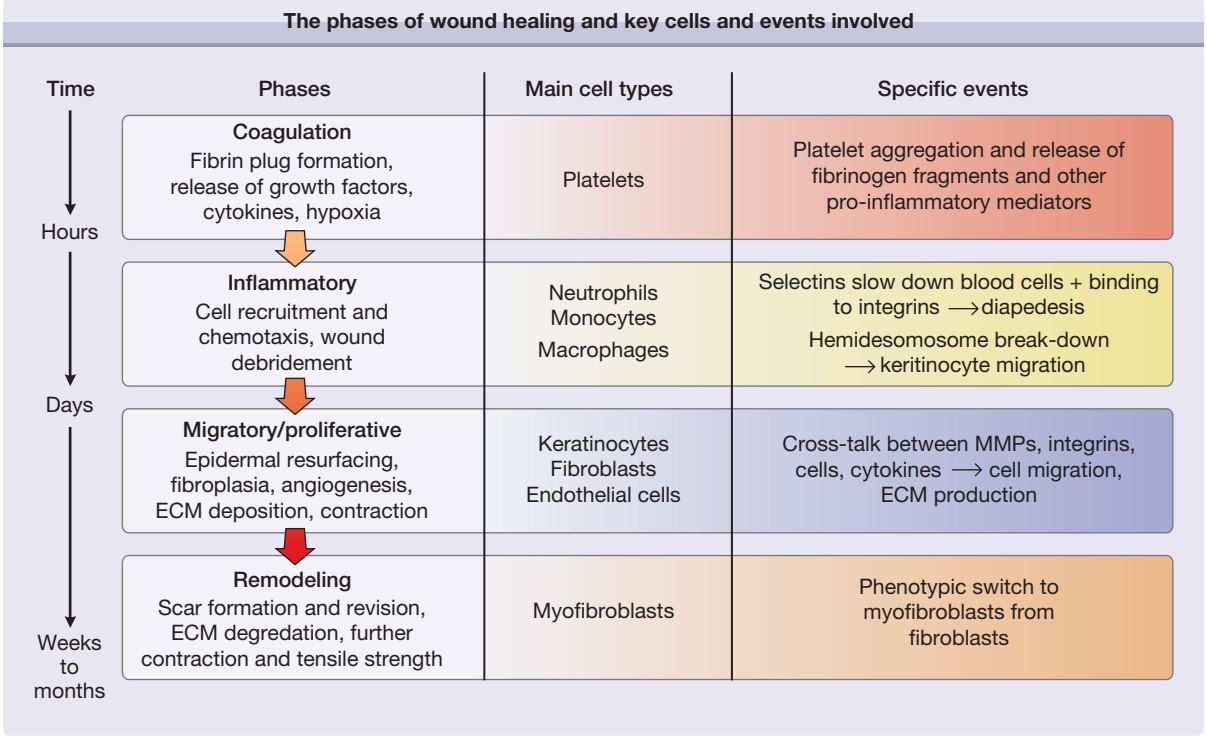

Figure 248-3 The phases of wound healing, and key cells and events involved. (Redrawn from Falanga V: Wound healing and its impairment in the diabetic foot. *Lancet* **366**:1736–43, 2005)

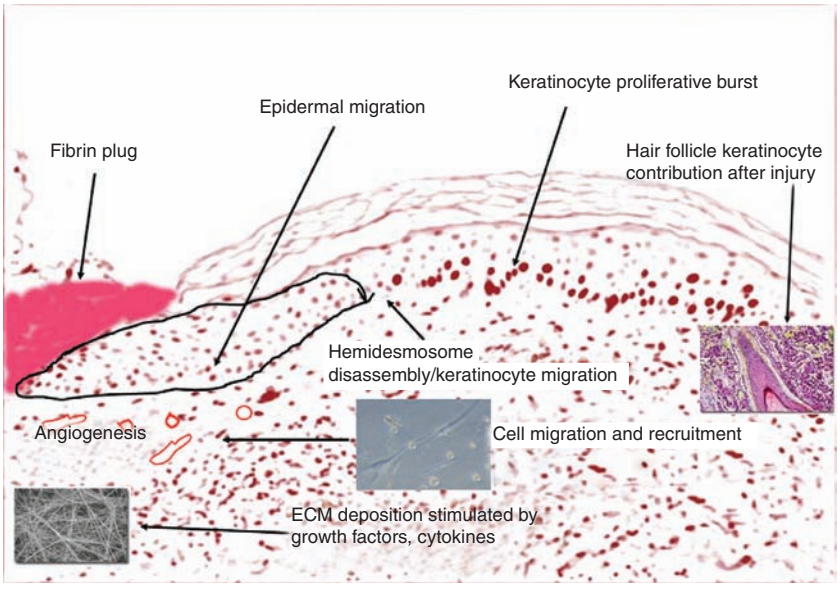

Figure 248-4 Schematic representation, using a modified photomicrograph section, of the events taking place shortly after injury, including formation of a fibrin plug, epidermal migration, and ECM deposition.

and expressed in wounds.[13] After the first few days, the neutrophils are removed by macrophages.

Fig. 248-4 is a diagrammatic representation, using a tissue section, of the events that take place after injury. The fibrin plug resulting from the initial injury provides a temporary wound coverage and consists of platelets embedded within a complex meshwork of mainly polymerized fibrinogen (fibrin), fibronectin, vitronectin, and thrombospondin.[3,14] Cross-linking of fibrin by Factor XIII also appears to be critical, and there is evidence that the function and probably migration of keratinocytes is impaired by uncross-linked fibrin.[15] As they immediately aggregate, platelets release a wide range of growth factors, including platelet-derived growth factor (PDGF) and transforming growth factor-β1 (TGF-β1). In fact, platelets are the main storage site for the TGF-β1 isoform. The acute injury environment, with its hypoxia, proteases, and low pH, contributes to the activation of these growth factors.[2] The principal mediators themselves produce others from their fragmentation or polymerization. A classic example is the chemotactic fibrinopeptides A and B, which are produced from the action of thrombin on fibrinogen.[15,16] Another example is the formation of bradykinins, as well as C3a and C5a, which are activated by Hageman factor.[17]

As the inflammatory component of this early phase continues, within 24–48 hours after injury, monocytes replace neutrophils and become the predominant leukocyte. Monocytes are attracted to the injury site by some of the same chemoattractants responsible for recruitment of neutrophils, such as kallikren, fibrinopeptides, and fibrin degradation products.[18] Other, more specific chemoattractants then take over in recruiting monocytes, and they include fragments of collagen, fibronectin, elastin, and TGF-β1. Monocytes undergo a phenotypic change to tissue macrophages and, unlike neutrophils, they are critical for the progression of wound healing.[19,20] Macrophages phagocytose and kill bacteria, and scavenge tissue debris.[21] They also release several growth factors, including PDGF, fibroblast growth factor (FGF), TGF-β, thereby stimulating migration and proliferation of fibroblasts, as well as production and modulation of extracellular matrix. The macrophage is generally regarded as the master cell in wound healing.[22] However, this is an oversimplification, as it is important to consider that what may delay or impair healing is not so much the presence or absence of inflammation and certain cells but, rather, an inappropriate inflammatory response.[17] For example, there is evidence that healing may occur in the absence of an inflammatory infiltrate.[23,24] Conversely, experiments in mice constitutively expressing the chemotactic cytokine IP-10 show that an intense inflammatory infiltrate can impair neovascularization and the formation of appropriate granulation tissue.[25] Therefore, the true role of inflammation in tissue repair remains somewhat controversial from an experimental point of view.[26,27] From the clinical standpoint, one observes that in certain cutaneous wounds, such as pemphigus or pyoderma gangrenosum, downregulation of inflammation with the use of corticosteroids is effective. Possibly, modulation and "correction" of the inflammatory response by corticosteroids may be helpful in these selected clinical entities.[28]

PROLIFERATION/MIGRATION AND REMODELING PHASES

Fig. 248-4 illustrates a representation of the fibrin plug in place and certain events that occur in the next two phases of healing, the proliferative/migratory and remodeling phases. As inflammation has already played its major role early on after injury, the most important event in cutaneous wound healing now

becomes reepithelialization. This critical event is not based on keratinocytes alone, because there is a high interdependence between keratinocyte movement through the provisional fibrin matrix, recruitment of fibroblasts and endothelial cells, and extracellular matrix formation (Figs. 248-2 and 248-3). Tissue matrix metalloproteinases (MMPs) and other enzymes (tPA and uPA) are critical to the movement of cells through provisional structural matrix components, as well as for freeing the keratinocytes at the edge of the wound from their hemidesmosomal and desmosomal attachments. Another critical set of molecules that help guide this migratory components are the integrins.[29,30] The integrins, consisting of at least 24 αβ heterodimers (18 α and 8 β subunits), are transmembrane cell surface receptors that bind the extracellular matrix (ECM) to cytoskeletal structures.[31] The integrin profile is very dynamic during the repair process. For example, dermal fibroblasts undergo a switch from α2 to α3 and α5 integrin subunits. As another example, endothelial cells cannot respond to angiogenic stimuli without the expression of αvβ5 integrin. Certain polypeptide growth factors are absolutely essential to angiogenesis, including basic fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF).[3,31] Table 248-1 shows some of the main cytokines and growth factors shown to play a role in the repair process. One must realize that such tables are oversimplifications of very complex biologic properties of these polypeptides. Only the main effects are noted, and it must be borne in mind that the actions of growth factors are often context specific and not the same in every biological situation.

Evidence points to low oxygen tension as an important early stimulus for fibroblast (and endothelial cell) activation. Fibroblast replication and longevity are enhanced in hypoxia,[32] and low oxygen tension stimulates clonal expansion of dermal fibroblasts seeded as single cells.[33] Moreover, the synthesis of a number of growth factors is enhanced in hypoxic cells. Macrophages secrete an angiogenic substance only when they are exposed to low oxygen tension. This reversible effect was observed at an oxygen tension of 15–20 mm Hg.[34] TGF-β1 transcription and peptide synthesis are enhanced in cultures of human dermal fibroblasts exposed to a similar level of hypoxia.[35] In addition, hypoxia upregulates the synthesis of endothelin-1,[36] PDGF B chain,[37] and VEGF[38] in endothelial cells. It appears that, at least in some cases, the effect of hypoxic conditions is mediated by hypoxic inducible factor-1 (HIF-1), a DNA binding complex shown to contain at least two basic helix-loop-helix PAS-domain proteins.[39]

The importance of the hemidesmosome and desmosome is well known for many dermatological diseases where specific defects in their overall structural integrity are present (i.e., pemphigus, bullous pemphigoid, epidermolysis bullosa, etc.). Now, however, during the healing process and for keratinocyte migration to occur, there is a need to break down these complex structures anchoring the basal keratinocytes to the basement membrane and neighboring keratinocytes. This breaking down process is just as complex as the structure itself, and involves interactions between MMPs, integrins, growth factors, and structural proteins. In the normal resting state, laminin-5 is bound to α6β4 integrin, the latter linking the intracellular keratin filaments of keratinocytes to the basement membrane. In large part due to the interactions of integrins (including their phosphorylations status) with the ECM and receptor clustering on the surface of keratinocytes, there are important morphological changes (such as lamellipodia formation) that are required for keratinocyte locomotion.[3,40–42] Molecular GTPases switches (Rho, Rac, Cdc42) are involved. Partially as a result of phosphorylation of the α6β4 integrin, α3β1

TABLE 248-1

Partial List of Growth Factors and Cytokines in the Context of Wound Repair and Their Roles in Some Cellular Functions and Matrix Production

Responses	EGF	FGF	GMCSF	IL-1	PDGF	TGF-β1	VEGF	CTGF	IGF
Fibroblast proliferation	+	+		+	++	+		+	+
Keratinocyte proliferation	+	+		+		–			+
Angiogenesis	+	+	+	+	+	+	++		
Matrix formation		+			++	++		++	+
Inflammatory cell migration/ chemotaxis			++	+		+			

EGF = epidermal growth factor; FGF = fibroblast growth factor; GMCSF = granulocyte-macrophage colony-stimulating factor; HGF = hepatocyte growth Factor; IL-1 = interleukin-1; IGF-1 = insulin growth factor-1; PDGF = platelet-derived growth factor; TGF-β1 = transforming growth factor-β1, VEGF = vascular endothelial growth factor, CTGF = connective tissue growth factor.
Blank cell: no definite response
+ = definite but mild response
++ = definite and marked response

integrin promotes lamellipodia formation and keratinocyte locomotion. It has often been stated that migration of keratinocytes is key to resurfacing of the wound and that in fact such resurfacing is not dependent on proliferation.[3] Overall, one must add, epithelial-mesenchymal transition (EMT), also important in cancer and epithelial adhesion and gain of mesenchymal features, empowers the epithalial cells to migrate in a way that is reminiscent of the embryonic stage. Recently, this process was reconstituted in vitro by exposure of epithelial cells to tumor necrosis factor-α (TNF-α), which led to the expression of vimentin, FSP1, and MMPs. The TNF-α mediated EMT may be secondary to bone morphogenetic proteins (BMP).[43]

In addition to the critical role of migration, keratinocytes do proliferate within the first hours after injury, and this is certainly more evident when the gap or size of the defect cannot be bridged temporarily with cell movement alone and is dependent on the cells beyond.[2,3] By a week after injury, the repair process is well underway. Cytokines and growth factors (EGF, PDGF, TGF-β, FGFs, VEGF), matrix components, and MMPs continue to play an active role. In addition to the growth factors themselves, signaling proteins are critical. For example, certain kinases (MAPK) are activated in basal and suprabasal keratinocytes by further action of integrins or the release of interleukin (IL)-1α. Ion fluxes, including calcium levels and entry into the cells, are also critical to the overall process of keratinocyte migration and skin resurfacing.[44] There is evidence that, in addition to lamellipodia extension, wound edge suprabasal keratinocytes may "leap-frog" over the basal cells near the wound. However, this system may not be very efficient, certainly not to the extent of the purse-string mechanism occurring in fetal healing and corneal healing, which is accompanied by other important differences in matrix deposition and growth factor profile.[5,45] Wound contraction, rather than epithelialization, is common in major injuries, including burns. It is also the preferred mode of repair in many animal species, such as rodents. In experiments using knockout mice, MMP-13 has been implicated in keratinocyte migration, angiogenesis, and contraction, while the role of MMP-9 appears critical in keratinocyte migration.[46]

The remodeling of the ECM, as well as the movement of cells, is highly dependent on MMPs and serine proteases.[47] A very important component of this dependence on MMPs is the MMPs-driven degradation of ECM and the resultant exposure of selective bioactive ECM segments that influence cell behavior, including migration and proliferation.[47] The remodeling phase begins 5–7 days after injury.[11] Upregulation of tPA and uPA are important for keratinocyte migration, which may depend on cross-talk and interactions between α3β1, keratinocytes, and collagen. These events lead to the induction of MMP-1 (collagenase-1 or interstitial collagenase), important in keratinocyte migration and epithelialization.[11] MMP-9 plays a fundamental role in "cutting" Type IV and type VII collagen, which are essential components of the basement membrane and anchoring fibrils, and it also promotes inflammation and neutrophil migration. MMP-10 (stromelysin) breaks down other noncollagenous ECM components and facilitates migration.[2,11,14,48] Other mediators, such as thymosin-β, have been found to upregulate MMPs during wound repair.[49] Of critical importance during the remodeling process is the phenotypic switch in certain cell subpopulations from fibroblasts to myofibroblasts.[2,50] Therefore, while the early process of healing relies heavily on matrix accumulation, which in turn facilitates cell migration, there is now a need to dampen the ECM formation and degrade it to a level that at least approximates the preinjury state. However, the remodeling phase is more than a breakdown of excess macromolecules formed during the proliferative phase of wound healing. Cells within the wound are returned to a stable phenotype, extracellular matrix material is altered (i.e., collagen type III to type I), and the granulation tissue that was so exuberant during the early phases of wound healing disappears.[2,3]

Over the last several years, considerable attention has turned to the role of stem cells from the follicular and interfollicular epidermis in wound healing. Using murine models, it has been reported that, at least after injury, cells from the hair-follicle bulge are recruited to the epidermis and migrate to the center of the wound.[51] In subsequent studies, it has been shown that hair follicles form de novo after wounding and that epidermal cells in the wound assume a hair follicle stem cell phenotype. Some of these findings may be dependent on Wnt signaling.[52]

EXTRACELLULAR MATRIX (ECM)

In wound healing, the extracellular matrix (ECM) comprises four main components:[47] (1) structural proteins (i.e., collagen, elastin); (2) multidomain adhesive glycoproteins (i.e., fibronectin, vitronectin, laminin); (3) matricellular proteins, including secreted protein acidic and rich in cysteine (SPARC), thrombospondin 1 and 2, tenascins, osteopontin; and (4) glycosaminoglycans (GAG), including hyaluronic acid and proteoglycans, that is, syndecans, perlecan (such as chondroitin sulfate and heparan sulfate). The glycosaminoglycan (GAG) hyaluronic acid (hyaluronan) is a particularly abundant component of the provisional matrix, and one whose deposition needs to be modified during the remodeling process. GAGs are often around other ECM proteins, including collagen and elastin.[47] High levels of hyaluronic acid and fine reticular collagen are present in the early embryo, where they are thought to offer less resistance to cell migration.[53] Indeed, embryonic wound repair is characterized by a hyaluronic acid–rich environment, thought to be at least in part responsible for the "scarless" healing of embryonic wounds. Fibroblasts from early granulation tissue produce large amounts of hyaluronic acid, and proliferating cells express CD44, which is the receptor for this GAG molecule.[54,55] Besides the issue of offering less resistance to cell movement, hyaluronic acid may stimulate cell motility by altering cell-matrix adhesion. One example of this is that hyaluronic acid weakens the adhesion of heparan sulfate and fibronectin.[56] Perhaps more importantly from a physical/spatial

standpoint is that hyaluronic acid creates a highly hydrated structure leading to tissue swelling and interstitial spaces, and thus an environment more conducive to cell movement.[2,57] The effects of hyaluronic acid are also regulated by growth factors and cytokines. Upregulation of the hyaluronic acid expression and its receptors (for example RHAAMM) by TGF-β1 stimulates fibroblast motility.[58] Eventually, as remodeling occurs, hyaluronic acid is degraded by hyaluronidase and replaced by sulfated proteoglycans, which contribute a stronger structural role in late granulation tissue formation and in scars, while being less able to stimulate cellular movement. Two major proteoglycans, chondroitin-4-sulfate and dermatan sulfate, are produced by mature scar fibroblasts.

Three main classes of collagens are present normally in connective tissue: (1) fibrillar collagens (types I, III, and V), (2) basement membrane collagen (type IV), and (3) other interstitial collagens (types VI, VII, and VIII). These are examples of the different types of collagen present in skin. Importantly, however, the fibrillar collagens serve as the major structural collagens in all connective tissues.[2,57,59] During the initial phases of wound repair, it appears that the wound tends to recapitulate the processes involved in embryogenesis.[45] Thus, granulation tissue is initially comprised of large amounts of type III collagen, which is a minor component of adult dermis and indeed is present in larger amounts in fetal wound repair. During the phase of remodeling, type III collagen is gradually replaced by Type I collagen. Type I collagen replacement is associated with increased tensile strength of the scar. However, the final tensile strength of a scar is only about 70% of that of preinjured skin.[3,57] The process of converting the collagen content of the dermis from type III to type I collagen is controlled by interactions involving synthesis of new collagen with breakdown of old collagen.[14] Key to this process of conversion are matrix metalloproteinases (MMPs) and, specifically, the collagenases.

Matrix-degrading metalloproteinases (MMP) are proenzymes that need to be activated, and are considered to be the physiologic mediators of matrix degradation.[48] The prototypic MMP is interstitial collagenase, but over 20 such enzymes (zinc-dependent endopeptidases) have been described.[11] We have already mentioned these critical proteinases in the context of keratinocyte migration, but it is important to go over them in more detail. Five groups of these enzymes have been identified: (1) collagenases, (2) gelatinases, (3) stromelysins/matrilysins, (4) membrane-type MMPs, and (5) other types. Table 248-2 is a summary of certain MMPs that have a prominent effect in wound healing, and which supplements this discussion. The collagenases include interstitial collagenase (fibroblast collagenase, MMP-1), which acts on collagens I, II, III, VII, and X. Collagen type II is a particularly good substrate for MMP-1. Another important member of the collagenase class is neutrophil collagenase (MMP-1),

TABLE 248-2
Some MMPs That Have a Well-Established Functional Effect on Wound Healing

Effect	Common Names	Corresponding MMP Designation	Some Specific Effects
Keratinocyte Proliferation and Migration	Collagenase 1 Gelatinase A Stromolysin 2 Matrilysin-1 Epilysin	MMP-1 MMP-2 MMP-10 MMP-7 MMP-28	Increased migration
Endothelial cell (EC) migration	Collagenase 3 Gelatinase A MT1-MMP	MMP-13 MMP-2 MMP-14	Increases (EC) migration Needed for angiogenesis Needed for angiogenesis
Cell migration	Stromolysin 1 Stromolysin 2 Matrilysin-2	MMP-3 MMP-10 MMP-26	Required for excisional wounds
Inflammation	Collagenase 2 Gelatinase A Gelatinase B Matrilysin-1	MMP-8 MMP-2 MMP-9 MMP-7	Anti-inflammatory Anti-inflammatory Promotes inflammation
Neutrophil Migration	Gelatinase B MT6-MMP	MMP-9 MMP-25	Increases neutrophil migration
Apoptosis	Collagenase 2 MT1-MMP MT2-MMP MT6-MMP	MMP-8 MMP-14 MMP-15 MMP-25	Prevents apoptosis Antiapoptotic

MMP = matrix metalloprotease; MT = membrane type.

which also degrades type II and III collagens but is particularly active against type I collagen. Gelatinases break down denatured collagen (gelatin). Among the most important gelatinases are gelatinase A (MMP-2), which breaks down gelatins, collagen IV, and elastin. Another key gelatinase is gelatinase B (MMP-9), which is produced by many cell types, including macrophases, neutrophils, and keratinocytes. Stromelysins have a relatively broad substrate specificity. Both stromelysin 1 (MMP-3) and 2 (MMP-10) act on proteoglycans, fibronectin, laminin, gelatins, and collagens III, IV, and IX. Another member of the stromelysin family, matrilysin (MMP-7) degrades mainly fibronectin, gelatins, and elastin. A member of the MMPs family is epilysin (MMP-28), which appears to be produced by proliferating keratinocytes distal to the wound edge. It may be needed to restructure the basement membrane.[3,48,57] Deficiency of MMP-7 (matrilysin-1), which regulates inflammation, epithelialization, and inhibits apoptosis, is reported to lead to the most severe wound healing defect associated with MMPs.[11]

MOIST WOUND HEALING AND THE REPAIR PROCESS

One of the most important clinical observations of the last several decades is the realization that wounds kept moist re-epithelialize faster.[60–63] The evidence for this is best for acute wounds. However, even in chronic wounds, the moisture-retentive dressings that have been developed to create moist wound conditions do lead to a number of desirable outcomes, such as pain control, painless autolytic debridement, and stimulation of granulation tissue.[63–66] There have been fears that keeping the wound moist will cause infection, but this fear is unfounded.[67–69] Nevertheless, occlusion of the wound is still contraindicated in the presence of infection. There are a variety of wound dressings available to the clinician and which fit the particular clinical situation.[65,66,70,63] The main types of dressings include transparent films, hydrocolloids, foams, gels, alginates, and the relatively new collagen products (Table 248-3). In determining the most appropriate dressing for a particular wound, the clinician must take into consideration the need for absorption of excessive exudate (foams and alginates), whether the wound is too dry and needs additional moisture (gels or hydrogel materials) and whether the wound and its epithelial edges can tolerate the often subtle but serious trauma that comes from removal of adhesive dressings such as films. Thin contact layers, consisting of different polymeric materials with perforations, allow wound fluid to escape and are useful in preventing tissue injury upon dressing changes by minimizing removal of the primary dressing in direct contact with the wound.

The exact mechanisms by which moist wound conditions facilitate keratinocyte migration are unknown.[2,66,70] A number of explanations, some supported by experimental work, have been proposed and appear plausible. Intuitively, a dry wound bed and the presence of a scab

TABLE 248-3
Representative Types of Wound Dressings and Their Properties

Products and Properties	Other Advantages	Disadvantages	Other Indications
Absorb exudate			
ALGINATES	Hemostatic, nonadherent, fewer dressing changes	Require secondary dressings; foul-smelling gel	Highly exudative wounds, partial- or full-thickness wounds, postoperative wounds
FOAMS	Conforms to body contours, applicable to many wounds	Opaque, require secondary dresssings, may adhere to the wound	Partial-thickness exudative wounds, pressure relief. May be used in many uncertain clinical situations
HYDROFIBERS	Soft, interacts with exudate to form gel	May be opaque and require secondary dressings, sometimes difficult to remove	Deep wounds, packing
Keep moisture level			
FILMS	Transparent, partial bacterial barrier, adherent	Adheres to fragile periwound skin; can cause fluid accumulation	Donor sites, superficial burns, partial-thickness wounds with minimal exudate
HYDROCOLLOIDS	Fibrinolytic, enhance angiogenesis, barrier to bacterial and physical agents	Opaque, foul smelling after interaction with exudate; generally highly adherent	Partial- or full-thickness wounds, pressure ulcers
Increase moisture levels			
HYDROGELS	Donate water to a dry wound, nonadherent	May require secondary dressings	Especially painful wounds, postlaser surgery, chemical peels, contact dermatitis, partial- or full-thickness wounds

or crust may render keratinocyte migration more difficult. Some have proposed that the electrical gradient is altered in a beneficial way when wounds are occluded and kept from getting dry. Certainly, there is considerable amount of work indicating that electrical currents can indeed affect the healing process.[71–73] Retention of growth factors and cytokines in the wound bed has been proposed as yet another explanation for how moisture retentive dressings work. The wound fluid taken from acute wounds has been shown in vitro to stimulate the proliferation of a number of cell types, including fibroblasts and endothelial cells.[74] Conversely, there is work indicating that the opposite is true for wound fluid harvested from chronic nonhealing wounds.[75] Whether this difference in the wound fluid characteristics helps explain the greater effect of moist wound healing on keratinocyte migration in acute wounds remains unknown. Indeed, another view has been to remove the wound fluid from chronic wounds, which can be accomplished with certain devices consisting of a film dressing applied to the wound and connected to a source of negative pressure.[76]

WOUND HEALING OF SKIN GRAFTS

The biology of acute wound healing has direct clinical application to dermatologic surgery. For example, reconstructions following Mohs micrographic surgery routinely involve the four main forms of acute wound healing that include secondary intention healing, side to side closure, cutaneous flaps, and skin grafts. Secondary intention healing is a variation of acute wound healing in which the wound is left to heal on its own. The biology of this process is characterized by all of the usual steps of wound healing but differs in the predominance of the inflammatory reaction and granulation tissue, as well as that of wound contraction.[77] Side to side and flap closures are examples of primary intention healing and follow all of the phases of wound healing described previously.

The healing of a skin graft, however, is quite different from what was described earlier with acute injury. One distinguishing feature of a skin graft is the complete dependence of the graft on the recipient wound bed for revascularization,[78–80] a feature that requires several unique physiological events. On the basis of histological studies, graft healing has classically been divided into three identifiable phases: (1) imbibition, (2) inosculation, and (3) neovascularization.[81]

IMBIBITION PHASE

As in conventional acute wound healing, the immediate event is the formation of a fibrin clot at the graft interface,[82] an event that is also accompanied by infiltration of leukocytes from the recipient to the graft.[83] What distinguishes a skin graft from a conventional wound is the diffusion of plasma from the recipient site into the overlying skin graft, resulting in a weight increase of the graft of up to 40% within the first day.[84] This net diffusion of the plasma into the graft was termed *imbibition*, and its significance had initially been thought to be limited to keeping the graft moist and the graft vessels patent.[84,85] Other investigators had hypothesized that imbibition also played a role in providing nutrition to the graft,[86,87] but support for this nutritional role was only demonstrated years later, when bromodeoxyuridine was shown to incorporate into skin graft cells after systemic injection in a mouse model.[88]

The imbibition phase ends as the venous and lymphatic drainage is reestablished, with a concomitant reduction in the weight of the graft.[84] In a rabbit graft model, lymphatic drainage of contrast material has been shown to begin slowly on day 2 and to improve until day 12, with histologically visible anastomoses of the graft and recipient lymphatic vessels by day 4.[89] A fundamental biological issue of skin graft healing has been to determine the relative contributions of the graft and the recipient tissues to vasculature of the graft, a more precise understanding of which has been achieved by recent molecular biological approaches.

REVASCULARIZATION PHASES OF INOSCULATION AND NEOVASCULARIZATION

Inosculation was originally proposed as the anastomoses of graft blood vessels with the recipient-derived vessels, and neovascularization as the ingrowth of new blood vessels from the recipient wound bed into the graft. The early histological studies had suggested that the graft maintained its own vasculature after grafting,[90,91] in support of the idea of inosculation. However, others felt that histological studies could not distinguish graft (or donor-derived) from recipient-derived vessels. Lambert concluded that at least during the first several days, the vessels of a skin graft were donor-derived[92] based on combined histology and radiographic methods. Using a human tissue–engineered skin equivalent with a network of endothelialized vessels,[93] Auger and his group demonstrated a significantly increased speed of vascularization by inosculation compared to the rate of vascularization of the nonendothelialized skin equivalent,[94] highlighting the higher efficiency of inosculation over that of neovascularization.

More precise dissection of the relative roles of graft and recipient in the creation of the final vasculature had to await molecular biologic methods to distinguish graft cells from recipient cells. Specific in-situ hybridization and immunolabeling were used to distinguish graft from recipient in studies of human split thickness skin grafted onto nude mice. It was found that the recipient endothelial cells grew into the preexisting donor capillary tubes, decisively supporting the process of immediate inosculation.[95] Most recently, transgenic mice were used to distinguish donor-derived from recipient-derived vascular growth to reveal an even more precise picture. Capla and colleagues showed regression of the graft vessels starting

at day 3, with simultaneous vessel ingrowth from the recipient primarily into the graft's preexisting vascular framework, resulting in inosculation by day 7.[96] Presumably, neovascularization without anastomosing with the graft's vascular framework is not the predominant event. Using a mouse bone marrow transplant model, the same investigative group further showed that bone marrow-derived endothelial progenitor cells contributed 20% of the recipient-derived endothelial growth within the graft.[96]

OTHER PROCESSES IN SKIN GRAFTS

As with the blood vessels, there have been analogous issues about the relative contributions of graft and recipient tissue for the final reinnervation of the graft.[97] In a porcine graft model, there was a suggestion based purely on histological studies that recipient nerves enter the graft and follow the course of the graft tissue's preexisting neurolemmal sheaths.[98] In another study, human skin was grafted onto nude mice in which the graft structures could be distinguished from recipient tissue using species-specific antibodies. In that report, neurites from the recipient were shown to grow into the graft but did not appear to connect with preexisting donor graft nerve trunks.[95] Using histochemical labeling of cholinesterases, other studies had suggested that the reinnervation of the graft also involved chemotactic attraction of growing neurites to adnexal structures.[99]

Much of the remainder of skin graft healing involves events in common with the normal wound healing process. Infiltration by fibroblasts in the graft occurs 3 to 5 days after grafting, followed by a progressive increase in both graft and recipient fibroblasts within the graft.[95] Full-thickness skin grafts are thought to reduce wound contraction compared to the significant contraction found in secondary intention healing, with one study suggesting that a graft in the exact size of the original defect minimizes this contraction.[100] Hyperpigmentation can be an occasional undesirable side effect of grafting, and histological changes of melanocytes have been observed after grafting.[101] It has been proposed that skin grafts, in a fashion similar to that of cultured autografts, may also stimulate wound healing of the recipient site, especially after prewounding of the donor site from which the grafts were harvested.[102,103] In further support of this hypothesis, expression of keratinocyte Ki-67 and β-1 integrin after grafting has been noted, in addition to the production of stimulatory growth factors and cytokines. This may imply an additional phase of graft healing.[104]

Finally, the mechanisms of contraction of the actual graft are unclear; however, a working model proposes that keratinocytes and myofibroblasts separately contract the graft in two phases. During the initial phase, which occurs during the first two days, epidermal cells contract the graft in a purse string fashion.[105] The initial epidermally mediated contraction is followed, starting at 3–5 days, by a longer contractive phase mediated by myofibroblasts (which have differentiated from fibroblasts).[106] The contraction phases have been modeled in vitro using collagen gels[106] and tissue engineered skin.[107] Among the findings from in-vitro studies is that TGF-β does not drive graft contraction as it does hypertrophic scarring.[108]

CHRONIC WOUNDS AND IMPAIRED HEALING

The previous discussion has focused on cutaneous wound repair after acute injury. It must be recognized, however, that the applicability of those events and processes is limited when it comes to chronic wounds, such as in diabetes, venous, and arterial insufficiency, and in a variety of situations complicated by inflammatory processes and faulty host response. The linear and one-way relationship between the different phases of wound repair is lost in chronic wounds (Fig. 248-5).

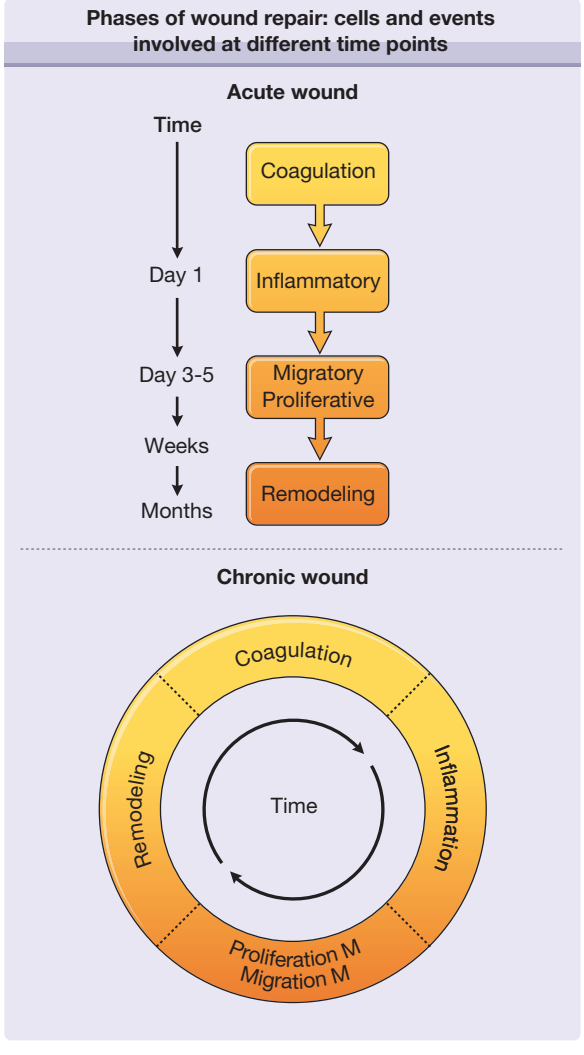

Figure 248-5 Schematic representation of the different phases of wound repair, the cells and events involved at different time points. The left side of the diagram shows the linear progression observed with the healing of acute wounds. The right side is an attempt to show that chronic wounds are in disarray, and that the linear progression is lost.

There is no specific orderly sequence, and parts of the chronic wound may be in different phases at different times. Acute wounds, such as those created by surgery or by trauma, have a predictable time-frame for healing and generally heal quite readily. However, chronic wounds display what has been called a "failure to heal" or impaired healing. A number of observations have been made with regard to chronic wounds, and hypotheses have been proposed for impaired healing. It must be noted that it has proven difficult to study chronic wounds from a pathophysiological standpoint. A major drawback has been the unavailability of animal models that truly display impaired healing.

Some chronic wounds are the complex result of ischemia, pressure, and infection. A case in point for this pathophysiological triad is the diabetic ulcer.[3] There is still considerable controversy whether hyperglycemia itself plays a pathophysiological role in the development of diabetic ulcers, although neutrophil function is impaired and thus the propensity to infection is enhanced in the diabetic state.[3] Importantly, the notion of "small vessel disease" in diabetes has been more properly evaluated and shown not to be an obstructive phenomenon, but rather a more physiological one.[109] This being the case, revascularization of the diabetic foot is now viewed as the right approach in the presence of large vessel disease and good run-off circulation. Perhaps the best example of truly impaired healing, not related to undue pressure and poor arterial supply, is venous ulceration. The underlying abnormality in the development of venous ulcers is *venous hypertension*, which refers to the inability of venous pressure in the foot to decrease in response to exercise.[110] There have been several hypotheses proposed for how venous hypertension then results in venous ulceration or the development of lipodermatosclerosis. Some of these hypotheses have emphasized the accumulation of fibrin around dermal blood vessels and defects in fibrinolytic activity. Another hypothesis has centered on damage to the microvascular endothelial cells, which then results in leakage of fibrinogen and dermal pericapillary fibrin cuffs. The leakage of macromolecules from the blood vessels into the dermis in venous disease is substantial, prompting other investigators to propose that such molecules can trap growth factors and other important components and render them unavailable to the healing process or the maintenance of tissue integrity.[111–115] There is evidence that growth factors in chronic wounds are bound to and trapped by macromolecules leaking into the dermis, such as albumin, fibrinogen, α-2-macroglobulin. The latter molecule is a scavenger for growth factors, including PDGF.[114,115]

We have earlier discussed at some length the critical importance of MMPs in cutaneous wound repair, particularly in the context of keratinocyte migration. However, in chronic wounds, MMPs may contribute to the overall failure to heal. For example, in venous ulcers and other types of chronic wounds, the wound fluid contains excessive amounts of metalloproteinases, which break down the extracellular matrix and, most likely, cytokines and growth factors.[116,117]

It should also be recognized that tissues around chronic wounds are not normal, and indeed they are altered by the primary pathogenic mechanisms or in the face of inability to heal readily. Clinically, the best example of this is the intense fibrosis surrounding venous ulcers, which is termed lipodermatosclerosis.[118] Once lipodermatosclerosis becomes established, it can lead to ulcers, and becomes the site of ulcer recurrence. Indeed, venous ulcers surrounded by lipodermatosclerosis are much more difficult to heal. The reason for these observations may lie in an increasing body of evidence suggesting that the cellular makeup of wounds that do not heal is altered. Thus far, most likely because of the ease with which they are grown and studied in culture, the best evidence is with wound fibroblasts. We now know that ulcer fibroblasts are senescent,[119] and unresponsive to certain selected cytokines and growth factors.[120–122] For example, it has been shown that venous ulcer fibroblasts are unresponsive to the action of transforming growth factor-β1 (TGF-β1)[120,121] and platelet-derived growth factor (PDGF)[122] The unresponsiveness of venous ulcer fibroblasts to TGF-β1 may be due to decreased expression of type II TGF-β receptors. This receptor abnormality also leads to decreased phosphorylation of key TGF-β signaling proteins, including Smad2, Smad3, and MAPK.[121,123] The synthetic program of cells in diabetic ulcers may also be altered, so that such chronic wounds are said to be "stuck" in a certain phase of the repair process.[124] A close relationship has been reported between some of these abnormalities and the inability to heal.[119]

BASIC STANDARDS OF CARE

Arterial ulcers need vascular reconstruction; anything less is a temporary measure and ultimately leads to amputation. The latter may be the only option in inoperable patients. Arterial ulcers that are necrotic and stable with an overlying eschar should probably not be disturbed unless a vascular reconstructive plan is in place.[3] Leg elevation and limb compression are the fundamental therapy for venous ulcers. Contact dermatitis is extremely common in patients with venous disease and, therefore, avoidance of topical agents is required in many patients.[125] Pentoxifylline has been tested in several large randomized trials for its ability to accelerate the healing of venous ulcers. The results have varied, and it may be that a high dose of pentoxifylline, at 800 mg three times a day, is more effective than the usual dose of 400 mg three times a day.[126] Whether the use of pentoxifylline should be considered standard therapy for venous ulcers is unclear at the moment. The anabolic steroid stanozolol has been effective in diminishing the induration of lipodermatosclerosis, which is the fibrotic component of venous ulcers, and in the acute and painful phase of lipodermatosclerosis, when compression bandages and stockings are too painful to use.[127] However, this agent is no longer available; danazol may be a useful substitute (V. Falanga, unpublished). For now, the only known medical approach for decreasing recurrence of venous

ulcers seems to be graded elastic stockings, with a pressure at the ankle in the range of 40 mm Hg. Stockings should be considered a lifelong therapy to help prevent ulcer recurrence and the other manifestations of venous disease.

The triad of neuropathy, ischemia, and trauma is the main pathophysiological underpinning for the development and recurrence of foot ulcerations in patients with diabetes.[3] Measures addressing these components will accelerate healing. Glucose control and optimal management of other systemic complications of diabetes, including renal failure, are an important aspect of therapy for diabetic foot ulcers. From a local wound care standpoint, off-loading is critical and is the main standard of care for neuropathic ulcers. Patients with diabetic ulcers due to vascular insufficiency or with ulcers that are mixed in etiology, that is, having both a neuropathy and surgical compromise, need to be referred immediately for vascular studies and surgical consultation.[3]

Aggressive surgical debridement of the necrotic tissue and the callus surrounding the ulceration has recently become part of standard care in the management of diabetic ulcers.[128] The callus probably provides additional pressure and perpetuates the ulceration. As with neuropathic diabetic ulcers, off-loading is the standard of care for pressure (decubitus) ulcers. Turning and shifting the position of the patient every 2 hours is said to be effective but actually is not proven to be so.

SURGICAL APPROACHES TO CHRONIC WOUNDS

In the management of venous ulcers, surgical therapy may be considered in the absence of deep vein obstruction and when significant superficial or perforator incompetence is documented. Recently, considerable promise has come from less invasive ligation of perforators using subfascial endoscopic perforator surgery (SEPS). This approach, sometimes combined with or followed by more definitive procedures, such as the removal of the long saphenous vein (Linton procedure), may be effective in healing the ulcers.[129] However, it is yet unclear whether this type of therapy prevents ulcer recurrence.

The realization a few years ago that the concept of an occlusive microangiopathy in diabetic ulcers is incorrect brought about a fundamental change in how revascularization of the diabetic foot is viewed; it has now become common practice to revascularize the diabetic limb.[109,130] Therefore, standard vascular surgical techniques are applicable to diabetic patients as long as there are adequate distal vessels. Vascular reconstruction may need to be combined with limited digital, ray, or forefoot amputation. Ostectomy procedures can alleviate pressure from bony prominences in selected cases.

Ostectomy can also be useful in the management of pressure ulcers, to broaden bony prominences. In the appropriately selected patient, random or musculocutaneous flaps are indicated.

OTHER THERAPIES FOR IMPAIRED HEALING

Growth factors are polypeptides with a variety of potent effects on cell proliferation and synthetic capacity (Table 248-1). To date, the only growth factor that has proven clinically effective is topically applied platelet-derived growth factor (PDGF). The PDGF-BB isomer, becaplermin, is approved by the FDA for the treatment of diabetic neuropathic foot ulcers. Several clinical trials have tested the effectiveness of becaplermin gel (30 μg/g) in diabetic foot ulcers.[128,131] The results showed an incidence of wound closure of up to 48% compared to 33% for the control group. Becaplermin must only be used when combined with optimal wound bed preparation and elimination of other factors that impair healing.

In the last decade, a number of tissue engineering products have become available for clinical use.[132,133] Two main types of bioengineered skin have been tested and proven to be effective in venous and diabetic neuropathic foot ulcers. One construct, approved for use in diabetic neuropathic ulcers, is comprised of neonatal foreskin fibroblasts in an absorbable suture material.[134] The other type of construct, approved for use in both venous[135,136] and diabetic neuropathic foot ulcers,[137] is bilayered and consists of both fibroblasts and keratinocytes from neonatal foreskin. The exact mechanism of action of bioengineered skin is unknown, but there is no prolonged engraftment of cells.[138] In clinical trials, both constructs were applied repeatedly to the wound, in order to stimulate healing. However, in clinical practice, it appears that a more limited number of applications is required. As with the use of becaplermin, optimal preparation of the wound bed is required for these constructs to be effective. Moreover, there is evidence that bioengineered skin is only helpful in ulcers that are of long duration and have not responded to conventional therapy.[136] However, the field of tissue engineering is extensive, making use of viable or nonviable cells and matrix constructs, which can be dermal, epidermal, and dermal–epidermal (bilayered).

Even more recently, stem cell therapy of difficult to heal wounds is becoming a reality and is considered a great promise in the field of regenerative medicine, including cutaneous wound healing.[139] We have discussed the possible role of stem cells generated from hair follicles.[51,52] However, in addition to the still controversial use of human embryonic stem cells, the hope is that the recently achieved reprograming of adult differentiated cells (i.e., skin fibroblasts) into induced pluripotential stem cells (iPS) would lead to the possibility of either accelerating the repair process or true regeneration. The iPS have been generated from adult differentiated cells for the most part through the use of key transcription factors "cocktails". For the most part, though the field is rapidly evolving, two different combinations of transcription factors were originally used: (1) (NANOG, OCT3, SOX2, LIN28)[140] and (2) (OCT3/4, SOX2, KLF4, AND c-MYC). Many if not all of the characteristics of embryonic stem cells are present with iPS cells, but we keep learning more about the consistency or lack thereof of iPS and how to control differentiation.[141] An exciting new development is the use

of very small embryonic-like stem cells (VSELs), which are present in adults and are pluripotential.

While rapid developments are occurring with the use of embryonic stem cells and iPS cells, extensive progress is also being made with the use of adult multipotent stem cells, that is, from bone marrow. We can only address representative studies here. Most studies of adult stem cell therapy of human wounds have used cultured bone marrow–derived mesenchymal stem cells (MSCs).[142] In pilot studies, clearly defined MSCs have been used successfully in the treatment of nonhealing chronic wounds and in acute wounds resulting from Mohs micrographic surgery defects not amenable to reconstruction.[143] In that study, the MSCs were applied to the wounds using a novel fibrin spray delivery method. The improvement of wounds with adult stem cells may be due to either integration of the stem cells or by their paracrine effects.[144]

PREDICTING WOUND CLOSURE

Several recent studies have now placed us in the position to predict from simple observation and in the first 3–4 weeks of therapy whether a wound will heal in a timely fashion. The methods used to predict wound closure range from simple measurements of wound size (width and length) and change in wound area, to computerized planimetric analysis and assessment of migration of the wound edge.[145] In a study of 56,488 wounds, it was shown that a percent change in area of approximately 30% at 4 weeks could predict wound closure with a sensitivity of 0.67, a specificity of 0.69, and had a positive and negative predictive value of 0.80 and 0.52, respectively.[146] In even more practical terms, the appearance of the wound edge is important, so that steep edges imply no progress of the wound, while in healing wounds the edges become less steep and begin to migrate toward the center. The ability to predict closure is very important. By four weeks, the clinician should be able to make a determination of whether the present therapy should be continued or whether a change is required, including a complete reassessment of the clinical situation. The prognostic value of the healing rate by 4 weeks of therapy has been confirmed by additional investigators.[147]

CONCLUSIONS

Characterizing the events occurring after tissue injury and their overlaps represents a rather daunting task. Yet, over the last several decades, the orderly progression from injury to inflammation and coagulation, to the development of a provisional matrix, to the formation of granulation tissue and to tissue remodeling, has been elucidated to a high degree. Although somewhat artificial, the different phases of wound repair described here are the platform on which more knowledge can be built. Much still needs to be learned, but the framework is there for understanding tissue repair and for developing ways to accelerate it. Indeed, due to breakthrough in science and technology, progress has been exponential in the last few years. Today, we are in the position of using smart dressings and stem cells. With the use of cultured adult stem cells or even iPS cells or VSELs that are pluripotent, we can aim for skin regeneration and not simply for tissue repair. There are still challenges, in terms of improving traditional dressings, smart biological dressings, bioengineered skin, stem cell therapy; we will need continued and increased understanding of the science involved. It is also possible that lessons learned from failure to heal, as in chronic wounds, will provide valuable lessons for the general principles of surgical and acute wound healing.

Chapter 249 :: Treatment for Varicose and Telangiectatic Leg Veins

:: Robert A. Weiss & Margaret A. Weiss

TREATMENT FOR VARICOSE AND TELANGIECTATIC LEG VEINS AT A GLANCE

- 53% of patients over 50 years of age show some venous reverse flow.
- Pregnancy, body mass, age, and family history can all affect incidence of venous reflux.
- Sclerotherapy and laser are main cosmetic treatments for spider veins.
- For larger varicose veins, sclerotherapy, phlebectomy, endovenous occlusion by radiofrequency or laser are standard approaches.

INTRODUCTION

Bulging varicose veins and unsightly "roadmap" telangiectatic webs affect millions of patients around the world. The incidence is highest in Caucasian patients in which telangiectasias comprise the most common of all cosmetic complaints. This is borne out by epidemiologic surveys in which leg telangiectasia are reported in 70% of women.[1] These same 24 city studies of thousands of patients indicate that 53% of the population over 50 years of age show some venous reverse flow.[1] Women are at least 4 times more likely than men to develop telangiectasia, while males have double the risk of developing large varicose veins.[2] Women aged over 50 years are five times more likely than women aged 29 or less to develop large varicose veins. Pregnancy increases the risk of varicose vein development by a factor of 1.5× to 3× and is associated with higher risks following three pregnancies.[1,3,4] Increased body mass index correlates with a higher risk of reverse flow or reflux which leads to pain, swelling and abnormalities of the saphenous system.[5,6] A positive familial history of disease is well known to increase the risk for varicose veins. Varicose veins may cause significant morbidity including chronic stasis dermatitis, ankle edema, spontaneous bleeding, superficial thrombophlebitis, recurrent cellulitis, lipodermatosclerosis and skin ulceration on the ankle and foot.

The incidence of varicose veins increases with each decade of life. Increased incidence has led to increased demand for treatment of varicose and telangiectatic veins as the average age of the US population grows. While 41% of women in the fifth decade have varicose veins, this number rises to 72% in the seventh decade.[7] Statistics for men are similar with 24% incidence in the fourth decade, increasing to 43% by the seventh decade. Six million workdays per year may be lost in the United States due to complications of varicose veins, although this number is being affected by endovenous ablation techniques.[8] Treatment is now much less complicated as an outpatient procedure avoiding dreaded stripping. As such noninvasive treatments are more frequently utilized so that lost workdays may actually be decreasing, although these statistics do not exist.

The main techniques employed in the dermatologist's office for treatment of cosmetic spider veins are sclerotherapy and lasers. For larger varicose veins, dermatologic surgeons employ sclerotherapy (with or without Duplex ultrasound guidance), ambulatory phlebectomy, and endovenous ablation by radiofrequency or laser. *Sclerotherapy*, which is defined as the intravascular introduction of a sclerosing substance, is the most frequently utilized procedure. We recommend that the term be changed to "endovascular chemoablation" which more accurately describes the procedure, although sclerotherapy is so entrenched that this will be unlikely to occur.

Sclerotherapy gained acceptance in the United States as a highly effective treatment during the early 1990s as it can be utilized for veins of all sizes.[9] With the addition of foaming the sclerosant, utility has been expanded further.[10] Sclerotherapy is also an important adjunctive therapy to surgical techniques such as ambulatory phlebectomy for saphenous tributaries[11,12] and endovenous ablation of refluxing saphenous veins.[13,14] Knowledge of venous anatomy and physiology, principles of venous insufficiency, methods of diagnosing venous abnormality, uses and actions of sclerosing solutions and proper use of compression are essential elements of successful venous therapy.

HISTORICAL ASPECTS

Primitive stripping and cauterization were practiced by Celsus, while ligation was mentioned by Antillus (30 AD). In the second century AD, Galen proposed tearing out the veins with hooks, a precursor to the modern day technique of ambulatory phlebectomy originated by Swiss dermatologist Robert Muller in the late 1960s.

A crude concept of sclerotherapy appeared in 1682, as Zollikofer described injection of acid into a vein to create a thrombus. By the late 1700s, the critical role of saphenofemoral reflux in the pathogenesis of varicose veins had been recognized by a Swiss surgeon, Rima. Reports of use of absolute alcohol as a sclerosing agent appeared from 1835–1840. In 1851, Pravaz attempted

sclerotherapy with ferric chloride using his new invention, the hypodermic syringe.

The foundation of modern sclerotherapy can be traced to World War I when Linser and Sicard both noticed the sclerosing effect of intravenous injections used to treat syphilis which often resulted in vein sclerosis. Tournay greatly refined the sclerotherapy technique in Europe. It was not until 1946, when a safe sclerosant, Sotradecol (sodium tetradecyl sulfate) had been tested and described that sclerotherapy began to be seriously studied in the United states.[15]

Another key to success and acceptance of the treatment of varicose veins by sclerotherapy was the addition of compression. Sigg and Orbach in the 1950s and Fegan in the 1960s emphasized the importance of combining external compression immediately following injections. Starting in the 1980s, Duffy promoted the technique among dermatologists and advocated the use of polidocanol (POL) and hypertonic saline as safe and effective sclerosing solutions.[16] In March 1999, the first endovenous obliteration technique utilizing radiofrequency was cleared by the US Food and Drugs Administration (FDA). Dermatologic surgeons were instrumental in developing this technique.[14,17,18] Goldman's first American textbook of sclerotherapy integrated the world's phlebology literature, introduced new sclerosing solutions and validated dermatology's claim to expertise in vein treatment.[19] Several additional textbooks by dermatologic surgeons have firmly established phlebology within the domain of dermatology.[20,21] The newest development in sclerotherapy has been the FDA approval of polidocanol (Asclera, Merz Aesthetics/Bioform, San Mateo, CA) in late spring of 2010. The advantages of this solution are discussed later.

PATIENT SELECTION—VENOUS ANATOMY AND PHYSIOLOGY, SYMPTOMS, AND CONTRAINDICATIONS

The venous system is comprised of a primary deep venous compartment and superficial compartment with thousands of small veins (perforating veins) connecting the two systems. The deep compartment, "the muscle pump," normally acts as a conduit for 85%–90% of venous return from the leg. During contraction of the calf muscles, the valves of the perforating veins and associated superficial veins close, allowing blood to flow only proximally at high pressures through the deep system. This generates primary propulsive force returning venous blood to the heart (Fig. 249-1).

The superficial venous system consists of three primary territories: (1) great saphenous vein (GSV) (2) small saphenous vein (SSV) and (3) subdermic lateral venous system (LVS) (Fig. 249-2). Comprising the three major patterns are multiple collateral veins (accessory) and multiple tributary veins emptying into all 3 major superficial systems of the GSV, SSV and LVS. The

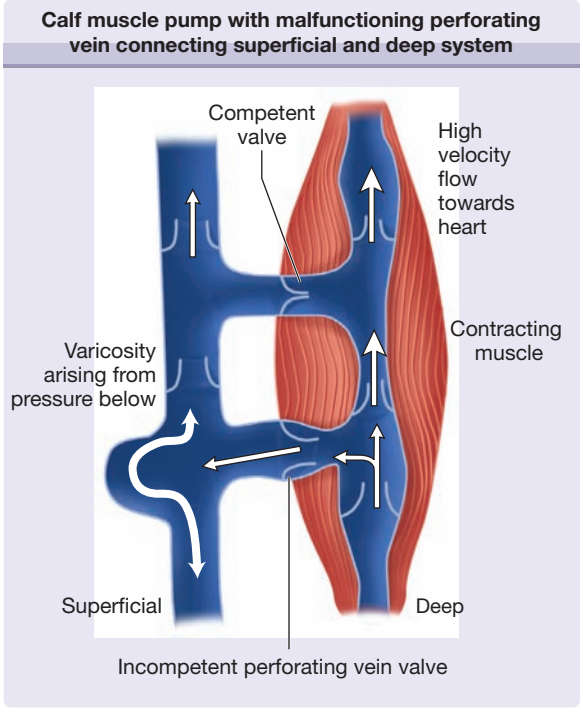

Figure 249-1 Schematic of the calf muscle pump with malfunctioning perforating vein connecting the superficial and deep system. High pressures are generated when the gastrocnemius muscle contracts to pump blood proximally. A malfunctioning valve is shown diverting pressure to the skin surface. Competent valve directs flow proximally.

points of connection (perforating veins) between the superficial and the deep system play important roles as these are sites through which reflux or reverse flow often develops (Fig. 249-3). Due to gravitational hydrostatic pressure, sequential retrograde breakdown of venous valve function often follows a leak at one point leading to propagation of a varicosity. Increased diameter between valve leaflets with failure to oppose properly caused by genetically weak venous wall or venous valve structure may initiate these events. Calf muscle pump pressure plus gravitational hydrostatic forces are transmitted directly via the incompetent perforating vein or communicating veins to the surface veins. Venous hypertension may reach levels higher than systolic arterial blood pressure in the cutaneous venules with the patient erect. Transmission of pressure may result in venular dilatation over a wide area of skin including the formation of telangiectatic webs and more serious consequences such as ulceration.[22] This leads to a number of symptoms with heaviness, fatigue, and aching of the legs.[23]

When present in significant quantity, the volume of blood sequestered and stagnant in reticular veins and associated telangiectatic webs (particularly of the lateral venous system) may cause enough distention to produce symptoms.[24] Symptoms are relieved by the wearing of support hose or with rest and elevation of the legs. Prolonged standing or sitting without calf muscle contraction worsens symptoms. The size of

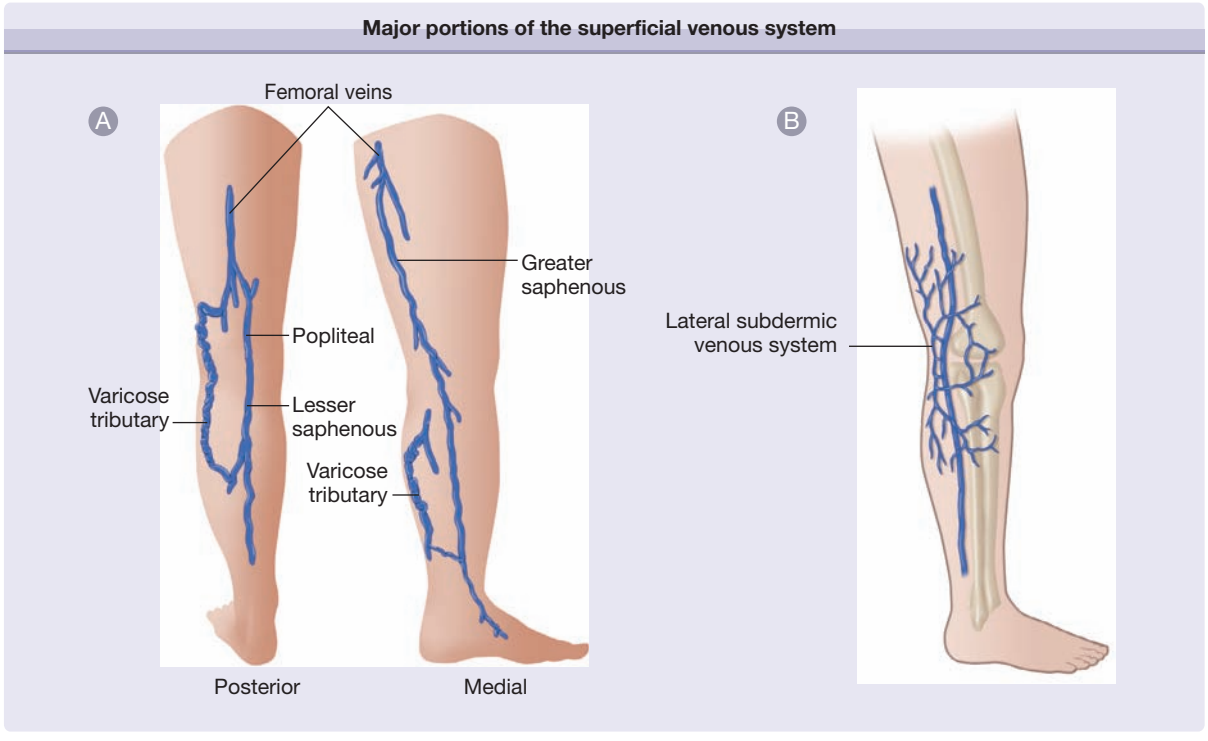

Figure 249-2 Schematic of the major portions of the superficial venous system. **A.** Greater saphenous vein and lesser saphenous vein. **B.** Subdermic lateral venous system. When varicosities or telangiectatic webs are present within the distribution of these saphenous veins, the source of pressure must be elucidated. The lateral venous system is the most common source of telangiectasias.

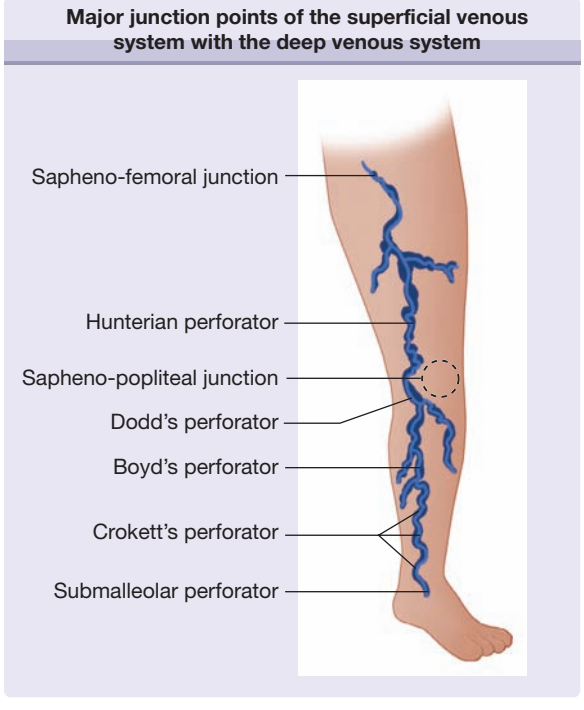

Figure 249-3 Diagram indicating major junctions points of the superficial venous system with the deep venous system. Larger surface varicose veins may originate from any of these points.

the vessels causing moderately severe symptoms may be as small as 1–2 mm in diameter. Sclerotherapy has been reported to yield an 85% reduction in these symptoms as well as superb cosmetic results.[24]

CONTRAINDICATIONS TO TREATMENT OF SPIDER VEINS

(Table 249-1)

Vein treatment and, in particular, foam sclerotherapy may be performed safely and effectively in virtually all types of veins, except when reflux exists at the saphenofemoral junction. Since the goal of sclerotherapy is to eliminate reflux at its origin, the goal of noninvasive diagnostic evaluation is to uncover primary sources of high reverse flow pressure. A high rate of recurrence for sclerotherapy is commonly seen when reflux originates at the major saphenous junctions. The techniques of endovenous ablation by radiofrequency or laser are the means by which reflux occurring at the termination point of the saphenous veins is now treated. Five-year data indicates that these techniques are as effective as the old surgical techniques of ligation and stripping to eliminate saphenous veins.[25] Our experience at ten years show that these techniques are superior to older surgical techniques. Recent studies show high recurrence rates (30%–50%) following ligation and stripping.[26] Archaic and invasive stripping techniques are no longer recommended for primary treatment of saphenous reflux.

TABLE 249-1

Indications and Contraindications for Sclerotherapy

Indications	Contraindications
Pain	Reflux at saphenofemoral or sahenopopliteal junction[a]
Major tributaries of greater and lesser saphenous veins	Nonambulatory patient
Major perforator reflux	Obesity
Lateral venous system varicosities	Deep venous thrombosis
Cosmetic	Known allergy to sclerosing agent Arterial obstruction Pregnancy

[a]Relative contraindication, success has been reported under the right conditions, proper sclerosing solutions (not available in the US) and/or the use of Duplex-guided sclerotherapy.

Endovenous ablation techniques have been embraced due to the high degree of safety and efficacy, without morbidity and downtime of general anesthesia and invasive technique required by stripping.[27]

Venous treatment is contraindicated in a bedridden patient since ambulation is important for minimizing risks of thrombosis. Similarly, patients under general anesthesia for nonrelated procedures should not undergo simultaneous sclerotherapy. Severely restricted arterial flow to the legs necessitates postponement of vein treatment. A history of deep venous thrombosis (DVT) or previous trauma to the leg (e.g., auto accident) should preclude sclerotherapy until adequately evaluated by Duplex ultrasound. Previous urticaria or suspected allergy to a sclerosing agent should serve as a relative contraindication to use of that particular sclerosing agent.

Pregnancy should be considered a contraindication during the first and second trimester, although extremely painful or bleeding, varices may be treated in the last trimester by endovenous ablation techniques. Treatment is typically postponed since varicosities and telangiectasias may resolve spontaneously 1–6 months postpartum.

Obesity should be considered a relative contraindication since maintaining adequate external compression is difficult. Sclerotherapy of larger varicosities should be postponed until weight reduction is achieved. During hot summer months, heat-induced vasodilatation and inability to comply with wearing of compression hose may also require postponement of treatment.

TREATMENT TECHNIQUES

PRETREATMENT EVALUATION

Physical examination is performed by viewing the patient's legs in a 360° rotation. Palpation is performed along the saphenous vein distributions to rule out early large axial varicosities which cannot be seen. Based on the history and physical examination, noninvasive diagnostic vascular tests are performed as necessary.[28] Those patients with a family history of large varicose veins are more likely to have early axial (saphenous) reflux even when presenting with telangiectasias alone.[11] Previous venous surgery warrants further testing before treatment.

Once the patient is judged to be a candidate for vein treatment, informed consent is obtained. Any veins visible or palpable suggestive of saphenous system involvement should be minimally evaluated by handheld Doppler ultrasound, which is equivalent to using an enhanced "stethoscope" to hear vein flow. It is generally recommended to supplement Doppler with Duplex ultrasound as this method of visualization of venous anatomy is more reliable and more prevalent. For Doppler to generate or augment an audible signal of flow, a maneuver such as manual compression of the calf must be performed by the examiner. When compression is released, gravitational hydrostatic pressure causes reverse flow to cease within 0.5–1 second when valves are competent, but a long flow sound is audible when valves are incompetent.

The most essential part of the Doppler examination is the examination of the saphenofemoral junction below the inguinal fold just medial to the femoral arterial signal. During a Valsalva maneuver, a continuous and pronounced reflux signal is a reliable sign of valvular insufficiency. An equivocal result may require a duplex ultrasound examination for a definitive answer. Methods of complete Doppler examination are detailed in other texts.[11]

The gold standard of noninvasive examination of the venous system is duplex ultrasound. This allows direct visualization of the veins and identification of flow through venous valves. An image is created by an array of Doppler transducers, which are switched on and off sequentially. The Duplex examination is often used to uncover hidden sources of reflux prior to beginning any method of treatment or delineate reflux sources when patients experience poor results from sclerotherapy. The declining price and increasing portability of Duplex ultrasound is rapidly making this examination the standard and reducing Doppler ultrasound to a relic of the past.

SCLEROTHERAPY OR ENDOVENOUS CHEMOABLATION SOLUTIONS

Sclerosing solutions have been classified into groups based on chemical structure and effect: hyperosmotic, detergent, and corrosive agents (chemical toxins—salts, alcohols, and acid or alkaline solutions). Commonly employed sclerosing solutions are summarized in Table 249-2.

HYPERTONIC SALINE. Although approved by the FDA only for use as an abortifacient, it is still commonly used in the United States in spite of its shortcomings. Used at a concentration of 23.4% (HS), a theoretical

TABLE 249-2
Comparison of Commonly Employed Sclerosing Agents

Sclerosing Solution	Category	Advantages	Disadvantages	Vessels Treated	Concentrations
Sodium tetradecyl sulfate (Sotradecol)	Detergent	FDA approved Painless—unless injected extravascularly	May cause breakdown rarely—rare allergic reaction	All sizes	0.1%–0.2% telangiectasias 0.2%–0.5% reticular 0.5–1.0% varicose 1.0–3.0% axial varicose
Polidocanol	Detergent	Painless Low ulceration risk at low concentrations—low skin toxicity	Not FDA cleared until 2010 Rare allergic reaction	Small to medium	0.25–0.5% telangiectasias 0.5%–1.0% reticular 1.0%–3.0% varicose
Hypertonic saline	Hyperosmolar	Low risk of allergic reactions	Ulcerogenic Painful to inject	Small	23.4%–11.7% telangiectasias 23.4% reticular
Hypertonic saline + dextrose (Sclerodex)	Hyperosmolar	Low risk of allergic reaction Mild stinging Low ulcerogenic potential	Not FDA approved Relatively weak sclerosant	Small	Undiluted–telangiectasias Undiluted–reticular
Sodium morrhuate (Scleromate)	Detergent	FDA approved	Allergic reactions highest	Small	Undiluted–telangiectasias Undiluted–reticular
Chromated glycerine (glycerine with 6% chromium salt (Scleremo)	Chemical irritant	Low skin ulcer potential	Not FDA approved Very weak sclerosant	Smallest	Undiluted to strength–telangiectasias
Glycerine – plain	Chemical irritant/ hyperosmolat	Painless, low-risk or allergic reaction, decreased risks of pigmentation and matting	FDA approved for reduction of cerebral edema	smallest	50%–72%
Polyiodinated iodine (Varigloban)	Chemical irritant	Highly corrosive—allows treatment of largest veins	Not FDA approved Avoid in iodine allergic patients painful to inject	Largest	1%–2% for up to 5mm veins 2%–6% for the largest veins

advantage of HS is its total lack of allergenicity when unadulterated. HS has been commonly used in various concentrations from 10% to 30%, with occasional addition of heparin, procaine, or lidocaine. Additional agents typically provide no benefit. Therefore, HS is used either unadulterated or diluted to 11.7% with sterile water for smaller telangiectasias.[29]

With hypertonic solutions, damage of tissue adjacent to injection sites may easily occur. Skin necrosis may be produced by extravasation at the injection site, particularly when injecting very close to the skin surface. Injection of hyaluronidase into sites of extravasation may significantly reduce the risks of skin necrosis with HS.[30] The pain of injection with risks of ulceration of this solution, makes it highly undesirable for modern vein treatment. We strongly recommend against the use of HS, especially with newer safer and less painful sclerosing agents approved by the US FDA.

HYPERTONIC SALINE AND DEXTROSE

(HSD) (*Sclerodex*, Omega Laboratories Ltd, Montreal, Canada). HSD is a viscous mixture of dextrose 250 mg/mL, sodium chloride 100 mg/mL, propylene glycol 100 mg/mL, and phenethyl alcohol 8 mg/mL. HSD is a relatively weak sclerosant for local treatment of small vessels, with a total volume of injection not to exceed 10 mL per visit with 0.1–1.0 mL per injection site. HSD is marketed predominately in Canada. Although a slight burning sensation occurs, pain is far less than with HS.

POLIDOCANOL

(Asclera™, Merz Aesthetics, Bioform, San Mateo, CA/Aethoxysklerol, Kreussler & Co, Wiesbaden-Biebrich, West Germany). The detergent-based POL, a urethane compound, was originally developed as an anesthetic, but was found to have the property of sclerosing small diameter vessels after intradermal injection. POL contains hydroxypolyethoxydodecane dissolved in distilled water with 5% ethanol as a stabilizer. First used as a sclerosing agent in the late 1960s in Germany, POL is popular worldwide for smaller vessels due to painless injection and lowest incidence of cutaneous necrosis with intradermal injection. Lower concentrations of POL were initially suspected to have a lower incidence of hyperpigmentation than HS or STS, but recent clinical trials indicate a significant percentage of hyperpigmentation occurs.[31] Asclera was recently approved by the FDA and now represents a safe, virtually painless sclerosing solution available to US dermatologists. The European data indicates safe utilization for over 30 years with recent studies adding to the safety and efficacy data.[32,33]

SODIUM TETRADECYL SULFATE. Sodium tetradecyl sulfate (STS) (Sotradecol™, Bioniche Pharmaceutical, Bioniche Pharma USA LLC, Lake Forest, IL; Fibrovein, S.T.D. Pharmaceuticals, United Kingdom) is an anionic surfactant which occurs as a white, waxy solid which must be carefully purified for sterile injection. It is a highly effective sclerosing agent used worldwide. Approved for use in the United States since 1946, it has been popular with vascular surgeons since the 1960s and first described for use in telangiectasias in the 1970s. A relatively high incidence of postsclerosis pigmentation was reported at inappropriately high doses (1% STS). More appropriate concentrations for superficial telangiectasias are 0.1%–0.2%. Other concentrations are 0.2%–0.5% in reticular veins or small varicosities (1–3 mm diameter), and 0.5% to 3% in larger varicosities related to major sites of valvular reflux. When foamed, this is used in half the concentrations listed above. In repeated studies, both POL and STS are found to be roughly equivalent.[34] More data will be available as widespread use of POL becomes routine in the United States with the official approval of polidocanol as Asclera.

SODIUM MORRHUATE

(Scleromate™, Palisades Pharmaceuticals, Inc., Tenafly, NJ, USA). Sodium morrhuate is a 5% solution of the salts of saturated and unsaturated fatty acids in cod liver oil. Approximately 10% of its fatty acid composition is unknown and use is limited by reports of fatalities secondary to anaphylaxis.[19] Although sodium morrhuate is approved by the FDA for the sclerosis of varicose veins, use in treatment of telangiectasias is not common due to the caustic qualities with potential for cutaneous necrosis and higher risks of allergy. This agent is reserved primarily for sclerosis of esophageal varices. We recommend not using this agent for leg veins.

CHEMICAL IRRITANTS. The chemical irritants include polyiodinated iodine (very caustic) and chromated glycerine (very weak) and are believed to have a direct toxic effect on the endothelium. After injection of polyiodinated iodine salt, the endothelium near the site of injection is destroyed within seconds. The corrosive action is limited due to rapid inactivation by blood proteins. At the sites of endothelial destruction, the chemical can penetrate further and diffuse into deeper layers of the vessel wall causing further destruction. These agents are not cleared by the US FDA.

Recently glycerine (nonchromated) has been rediscovered a valuable sclerosant for telangiectasias. Glycerine (50%–72%) has a low incidence of side effects and minimizes telangiectatic matting and pigmentation. At lower concentration, glycerine may share properties with hypertonic agents rather than having a pure toxic effect. The exact mechanism of action is still being investigated.

SCLEROTHERAPY TECHNIQUE

A basic principle of treatment is to begin at the largest (reflux sources) and progress to the smallest varicosities and then finally to telangiectasias. When present without larger varicosities, telangiectasias are approached by combined injection of visibly connected reticular veins, venulectases, and telangiectatic webs or networks. Reticular veins are treated only after all sources of reflux from major varicosities have been treated by sclerotherapy and/or surgery. When no clear feeder vessel is seen or identified by Doppler, transillumination (Veinlite, 3Gen, Dana Point, CA, USA) is another method, which may be used to identify the "feeding" reticular vein. (Fig. 249-4). When unable to locate an associated reticular vein, then the point at which the telangiectasias begin to branch out is the site at which to begin injection. Injection of telangiectasias is simultaneously performed with injection of reticular veins in the hopes of decreasing the number of treatments.[35]

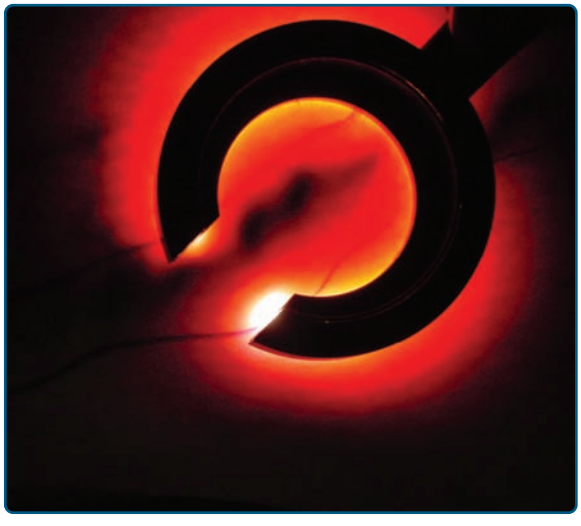

Figure 249-4 Transillumination of a reticular vein. The reticular vein shows up as a dark curvilinear object against a light background.

TABLE 249-3
Sclerotherapy Tray

- Cotton balls soaked with 70% isopropyl alcohol
- Protective gloves
- 3-cc disposable syringes
- 30-g disposable transparent hub needles
- Cotton balls or STD pads for compression
- Transpore and/or paper tape
- 2% nitroglycerine paste (for prolonged blanching or extravasation)

Sclerosing solutions:

1. Sodium tetradecyl sulfate (ranging concentrations 0.1%–0.5%)
2. Hypertonic saline (11.7–23.4%)
3. Hypertonic saline (10%) and dextrose (25%) (may be mixed by local pharmacy)
4. Polidocanol (0.5%–1%)
5. 3-way stopcock to foam solutions (1:4-sclerosant:air)

The injection method for telangiectasia is basically as previously described by Goldman, Weiss, and Duffy.[16,20,36] The sclerotherapy tray is prepared with the necessary equipment (Table 249-3). A 30-gauge needle, bent to an angle of 10°–30° with the bevel up, is placed on the skin so that the needle is parallel to the skin surface. A 3-cc syringe filled with 1.5–2 cc of solution is held between the index and middle fingers while the fourth and fifth finger support the syringe against the leg in a fixed position facilitating accurate penetration of the vessel. The nondominant hand is used to stretch the skin around the needle and may offer additional support for the syringe (Fig. 249-5). Magnifying lenses or operating loops on the order of 1.5× to 3× may help cannulation of the smallest telangiectasias.

The initial treatment of telangiectatic webs begins with lowest possible concentration that will cause a telangiectasia to sclerose over a period of 1–6 months postinjection. This typically is 0.1% sodium tetradecyl sulfate or 0.2% polidocanol. The approval of polidocanol has increased our use of this solution in addition to use of 50% to 72% glycerine in water. Both of these solutions have seen increasing use in our practice of sclerotherapy. When ineffective sclerosis occurs judged at a subsequent visit, the concentration but *not* the volume per site of sclerosing solution is increased. Post-treatment compression consists of graduated 20–30 mm Hg or 30–40 mm Hg support hose for 2 weeks for larger veins and OTC 15 mm Hg compression for smaller veins. Treatment intervals vary but allowing 4–8 weeks between treatments helps minimize the number of necessary sessions. Typical results are shown in Fig. 249-6.

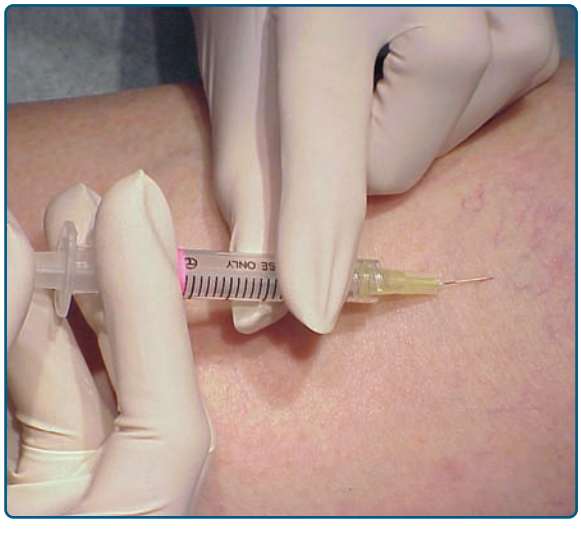

Figure 249-5 Position of the hands for sclerotherapy. While the dominant hand holds the syringe and creates a platform with the fifth digit, the nondominant hand stretches the skin and acts as a support for the needle hub so that fine changes in position are permitted.

FOAM SCLEROTHERAPY

Foam sclerotherapy has become a standard of treatment for veins larger than 1 mm as foam completely fills and displaces the blood in the vein. The microbubbles of foam allow maximal contact with the highest concentration of the sclerosant thereby resulting in maximal endothelial cell injury and subsequent fibrosis of the vein wall. This results in more effective sclerotherapy which leads to less treatment sessions. Less total amount of solution is required with foam. This has the additional benefit of decreasing systemic toxicity. An additional advantage of foam is that Duplex-guided sclerotherapy becomes more precise as the foam is very echogenic and easily visualized on ultrasound.

The most utilized technique for foam sclerotherapy is the Tessari technique.[37] A luer to luer connector is utilized. One syringe is filled with air and one syringe is filled with a detergent type of sclerosant. The optimal ratio of solution to air is 1:4. The contents of the syringes are shifted back and forth quickly approximately 10–20 times and the turbulent flow generates the foam. (Fig. 249-7) The foamed solution should be used immediately since it degrades within 60–90 seconds. The nature of the foam allows for the same therapeutic effect with approximately half the concentration of sclerosant. For instance, one can substitute 0.1% STS foam for 0.2% STS liquid or 0.25% polidocanol foam for 0.5% liquid. Lower concentrations are used for all size veins. Foamed solution should only be used for varicosities, perforating veins, reticular veins, and larger telangiectasias (1.0–2 mm). Smaller telangiectasia run the risk of increased pigmentation and matting as more inflammation occurs with the relatively increased concentration interacting with the vein wall.[38] Liquid sclerosants such as 0.5% POL are recommended for telangiectasias.

SIDE EFFECTS AND COMPLICATIONS OF SCLEROTHERAPY

POSTSCLEROTHERAPY HYPERPIGMENTATION. Postsclerosis pigmentation is defined as the appearance of increased visible pigmentation along

Figure 249-6 Typical results following sclerotherapy. **A.** Large varicose vein treated twice with 0.5% STS. **B.** Excellent clinical results at 15 month follow-up.

the course of a treated vein of any size. Initially, perivascular hemosiderin deposition, and not increased melanin production, causes this appearance[39]; however, over time, the hemosiderin is replaced by melanin. The incidence of pigmentation is related to dilution and type of sclerosing agent as well as diameter of treated vessel.[40] Pigmentation incidence ranges from 11%–30% using HS,[24] 11%–30% with POL[16,41] and up to 30% with

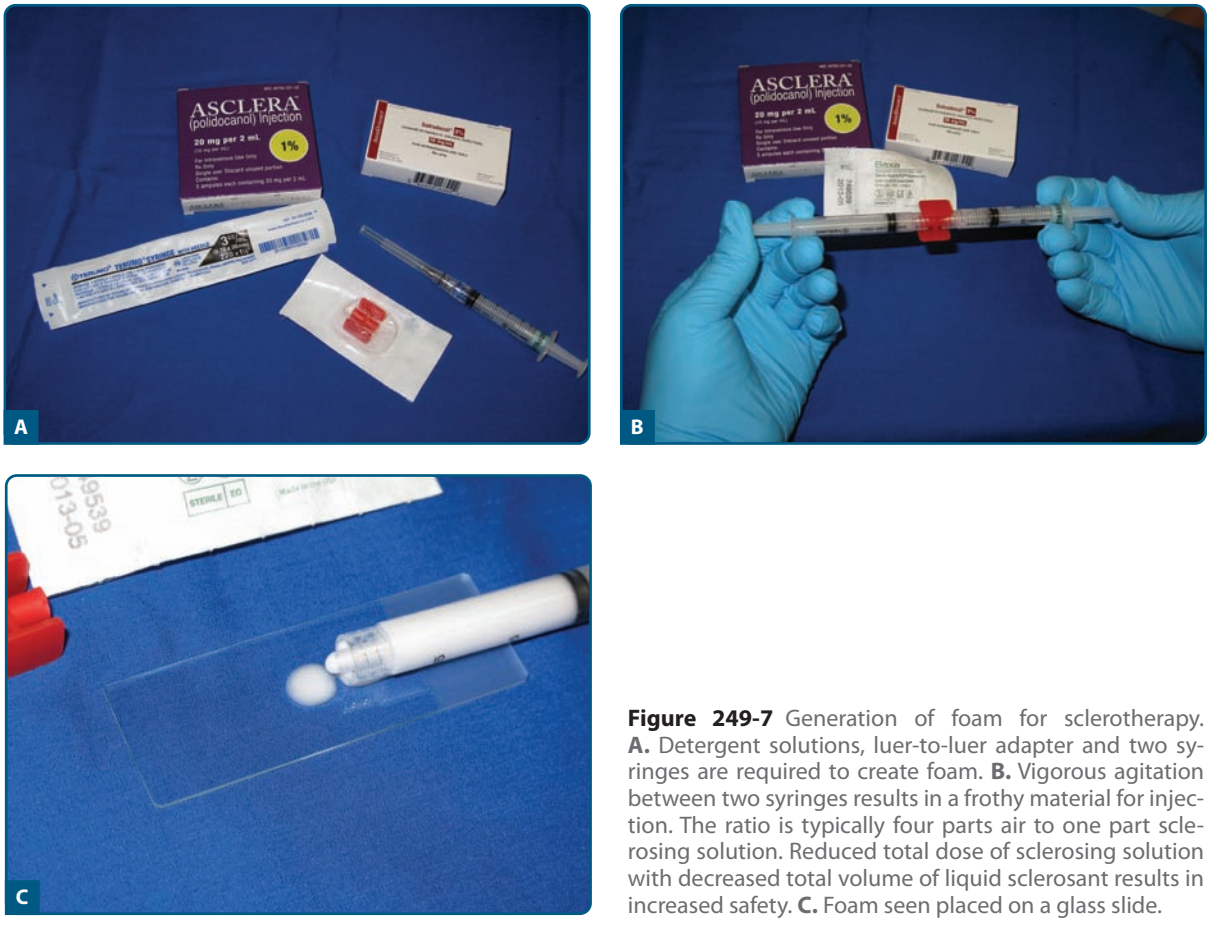

Figure 249-7 Generation of foam for sclerotherapy. **A.** Detergent solutions, luer-to-luer adapter and two syringes are required to create foam. **B.** Vigorous agitation between two syringes results in a frothy material for injection. The ratio is typically four parts air to one part sclerosing solution. Reduced total dose of sclerosing solution with decreased total volume of liquid sclerosant results in increased safety. **C.** Foam seen placed on a glass slide.

STS. The incidence of pigmentation may be reduced in varicose veins by expressing the dark, viscous blood thought to be a liquefied coagulum or intravascular hematoma, which may accumulate 1–4 weeks following sclerotherapy.

Pigmentation clears in 70% within 6 months but rarely persists for greater than a year.[40] Attempts to hasten resolution of pigmentation have been mostly unsuccessful as the pigment is dermal hemosiderin and not epidermal melanin. Bleaching agents, exfoliants such as trichloroacetic acid or phenol, cryotherapy, various lasers and intense pulsed light have achieved limited success.[42,43] The Q-switched ruby laser has been found to be the most consistently effective for treatment of postsclerosis pigmentation.[44]

TELANGIECTATIC MATTING. Telangiectatic matting is defined as the appearance of groups of new, fine (<0.2 mm diameter) telangiectasias surrounding or replacing a previously treated area in a blush-like manner. A retrospective analysis of over 2,000 patients reports an incidence of 16% in patients treated with HS and POL.[45] Resolution usually occurs spontaneously within a 3–12 month period with 70%–80% spontaneous resolution within the first 6 months.[46]

Matting may also occur as a result of trauma to the leg, in association with pregnancy or hormonal therapy or in scars around previous sites of surgical stripping. Predisposing factors include predilection for certain areas of the leg, such as the medial lower thigh, obesity, hormonal therapy with estrogen, family history, and a longer history of telangiectasias.[45] The relative risk factor for development of telangiectatic matting is 3.17 times greater for female patients taking hormonal supplements.[47] Successful treatment of matting can be performed with long pulsed dye laser (LPDL) using pulse durations of 6–20 msec.[48] The use of enhanced visualization with a cross-polarized light source (Syris Scientific, LLC, Grey, MA) has been found to assist injection of sclerosing solution into telangiectatic matting. Treatment is often not required since matting will resolve spontaneously except when sustained by a source of reflux superiorly.

CUTANEOUS NECROSIS/ULCERATION. Cutaneous ulceration may occur with all sclerosing solutions in spite of the most skilled technique. Unavoidably, a tiny amount of sclerosing solution may be left along the needle tract as the needle is withdrawn. Sclerosing solution may also leak out into the skin through the small puncture sites of vessel cannulation. The varicose vein may have a fragile, thin wall, with the injection causing rapid injury leading to sudden unexpected rupture with perivascular accumulation of sclerosant. Additionally, injection may inadvertently occur into a small arteriole associated with telangiectatic varicosities with resultant necrosis and ulceration.

When the dermatologic surgeon recognizes that extravasation has occurred, the risk for necrosis can be minimized by injecting normal saline in a ratio of 10:1 over sclerosant into the extravasation site. Extensive massage of small subcutaneous blebs to spread the trapped sclerosing agent as quickly as possible will minimize prolonged blanching of the area. We have found that application of topical 2% nitroglycerine paste applied immediately to the suspected extravasation site greatly reduces the risks of necrosis but will not always prevent it.

SUPERFICIAL THROMBOPHLEBITIS. This complication is most commonly mistaken for the normal nodular fibrosis (endosclerosis) that occurs with proper sclerotherapy. After sclerotherapy, a *nontender,* nonpigmented, nonerythematous fibrotic cord may normally be palpable along the course of a treated 4- to 8-mm vein. This frequent finding is due to a liquefied intravascular hematoma with surrounding vein wall sclerosis and is not a thrombosis. In contrast, superficial thrombophlebitis is characterized clinically by a very tender, indurated, linear erythematous swelling. Incidence of superficial thrombophlebitis is quite variable estimated at 1%–0.01% following sclerotherapy,[49] although a recent report indicates that the incidence is higher than previously suspected.[50] Treatment consists of leg elevation and/or compression and regular administration of aspirin or other nonsteroidal anti-inflammatory drugs. Extension of superficial thrombophlebitis into the deep system is extremely rare.

PULMONARY EMBOLISM. Pulmonary emboli probably occur from extension of a superficial thrombus into the deep venous system. Evidence of extension from superficial thrombus to deep thrombophlebitis should be treated promptly by anticoagulation. The incidence of pulmonary embolism has been associated with injection of large quantities of sclerosant at a single site. The incidence is extremely low with less than 1 case in 50,000.

ARTERIAL INJECTION. This dreaded medical emergency is fortunately extremely rare. Classic warning signs include immediate intense pain far beyond the normal discomfort at the initiation of injection, although leakage of sclerosant into the arterial circulation may present in an atypical fashion. Continuous intense burning pain with immediate bone white cutaneous blanching over an area of several square centimeters is the usual initial sign. Progression to a sharply demarcated cyanosis within minutes is typical for arterial injection. Emergency treatment involves immediate application of ice, attempts to flush the inadvertently injected artery with normal saline and/or heparin, injection of 3% procaine to inactivate STS and vascular surgery consultation for intravenous anticoagulation. Rarely arterial injection may not be accompanied by any pain or cutaneous signs. This is not widely known. Atypical or nonclassic cases of arterial injection in which signs or symptoms are not seen for up to 24 hours are suspected to arise from A-V malformations.[51] Arterial injection may lead to wide areas of skin necrosis and damage to subcutaneous tissue and muscle, which take months to heal. Typically a malpractice lawsuit will be initiated, although the cause can rarely be pinpointed and is often not a result of negligent injection.

MODERN MINIMAL SURGICAL APPROACHES FOR VARICOSE VEINS

ENDOVENOUS ABLATION/OCCLUSION TECHNIQUES

Endovenous ablation techniques were first developed by dermatologic surgeons.[14,13] When it has been determined by ultrasound that the originating point of reverse flow or reflux is the great saphenous vein (GSV) or small saphenous vein (SSV), endovenous radiofrequency or laser techniques are utilized. Ligation and stripping are antiquated techniques that should no longer be utilized. When saphenous system reflux is present, the endovenous occlusion techniques must be performed prior to treatment of visible and associated varicosities, reticular veins, or telangiectasias. Without elimination of reflux, a patient will be doomed to recurrence after recurrence following local treatment.

RADIOFREQUENCY

The efficacy for radiofrequency (RF) elimination of reflux is 90% at 2 years and 80% at 5 years.[17,25] Our unpublished experience is presently 90% at 10 years with supplemental foam sclerotherapy at follow-up visits. RF endovenous ablation involves the placement of an RF catheter within the varicose vein through a small puncture or incision. The catheter is threaded up to the saphenofemoral junction typically under duplex ultrasound guidance. Critical to the safety and success of the technique is placement of tumescent local anesthesia, which involves first infiltrating the tissue under the skin including thigh muscles to push the saphenous vein further away from the skin and then creating a space between the fascia and the saphenous vein so as to hydro-dissect the vein away from structures such as nerves and arteries. Tumescent anesthesia was developed and perfected by dermatologic surgeons. Once a hydrodissection has been performed with high volume, low concentration of local anesthetic (0.1% lidocaine), or tumescent anesthesia, energy is applied as the catheter is slowly withdrawn. This results in heat directly applied to the vein wall via a computer controlled thermocouple feedback loop. This results in a collagen shrinkage accompanied by complete vein wall occlusion. The newest system is designated ClosureFast and can seal the vein in under 5 minutes.

LASER (HEMOGLOBIN PREDOMINANT ABSORPTION—810, 940, AND 980 nm)

Endovenous laser treatment is similar to RF in that energy which ultimately releases heat in order to produce endothelial and vein wall shrinkage with subsequent fibrosis. The target for lasers with 810-, 940-, and 980-nm wavelengths is intravascular red blood cell absorption of laser energy. These techniques are highly dependent on correct placement of tumescent local anesthesia so as to protect surrounding nerves from injury. Direct thermal effects on the vein wall without the presence of blood probably do not occur. The extent of thermal injury to tissue is very much dependent on the amount and duration of heat to which the tissue is exposed, which for these lasers is dependent on multiple factors including the presence of blood in the lumen, rate of pullback, and amount of tumescent anesthesia placed around the vein. One in-vitro study model showed that thermal gas production by laser heating of blood in a 6-mm tube results in 6 mm of thermal damage.[52,53] Histologic examination of one excised vein demonstrated thermal damage along the entire treated vein with evidence of perforations at the point of laser application described as "explosive-like" photodisruption of the vein wall. This produced the homogeneous thrombotic occlusion of the vessel. Formation of bubbling blood is the proposed mechanism of action for heating surrounding tissue.[53] We have found superheating of blood during these procedures to a maximum of approximately 1,200°C.[18]

These endovenous lasers have short-term efficacy of 90% occlusion over the first year, but the rate decreases with time.[54,55] In addition, most patients experience major degrees of postoperative ecchymosis and discomfort. Saphenous nerve injury, skin burns, and deep venous thrombosis have occurred due to the high temperatures of blood heating from these wavelengths, although the overall safety and efficacy record is better than for stripping.[56–58]

LASER (WATER PREDOMINANT ABSORPTION—1,320, 1,440, AND 1,470 nm)

A variation of the endovenous laser, 1,320 nm, was developed by dermatologic surgeons in 2003 in an attempt to bypass the problems associated with laser wavelength absorption of hemoglobin. Tissue water is the target and the presence or absence of red blood cells within the vessels is unimportant. For more controlled release of laser energy, it is coupled with an automatic pull-back device variable from 0.5–1 mm/s. The penetration of the 1.32-μm wavelength is unique with far less heat and risks than with the hemoglobin absorbing wavelengths.

Endovenous ablation appears best accomplished not by hemoglobin heating but by heating water within collagen in the vein wall as a target. Proebstle et al demonstrated a statistically reduced rate of postoperative pain accompanied by a higher initial success rate using 1,320 nm versus 940 nm.[59] Our own experience reflects this, with a reduction in pain and bruising of 80% when switching from 810 nm endovenous to 1,320 nm endovenous. Having treated over 500 greater saphenous veins with 1,320 nm, our incidence of mild pain is 5%. No significant pain interfering with walking has been observed as observed with 50% of 810-nm treatment. A clinical example of varicose veins

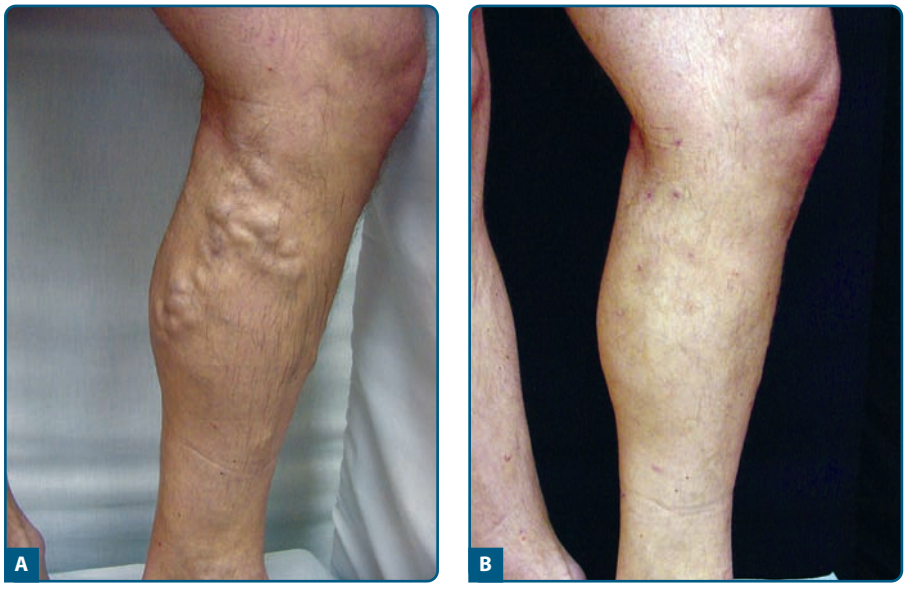

Figure 249-8 Endovenous ablation of the great saphenous vein (GSV) results in the improvement of associated varicosities. Adjunctive ambulatory phlebectomy was performed during the endovenous procedure.

resulting from reflux at the saphenofemoral junction is shown in Fig. 249-8. Recent data indicates that the 1,440-nm or 1,470-nm wavelengths may also be effective.[60] but data is preliminary and there is no comparison data on efficacy between the different water predominant wavelengths.

AMBULATORY PHLEBECTOMY. This technique, originally described by Robert Muller and further refined by another Swiss dermatologist (Albert-Adrien Ramelet) involves the use of tiny incisions through which the varicose vein is removed by a small hook.[61,62] This safe, outpatient local anesthesia technique allows removal of almost any varicose vein except the saphenofemoral or saphenopopliteal junction, which are treated initially by endovenous ablation techniques. Areas or veins that are resistant to foam sclerotherapy are particularly indicated for ambulatory phlebectomy (Fig. 249-9). Risks minimized compared with sclerotherapy are deep venous thrombosis, postsclerotherapy pigmentation, skin necrosis, and superficial phlebitis. In many cases larger varicose veins coexist with smaller reticular veins and associated telangiectatic webs. It is reasonable to treat larger varicose veins

Figure 249-9 Ambulatory phlebectomy of a large truncal varicose vein. **A.** Marked just prior to surgery. **B.** Clinical results with complete disappearance at 6 weeks. Bruising usually lasts no longer than 2 weeks.

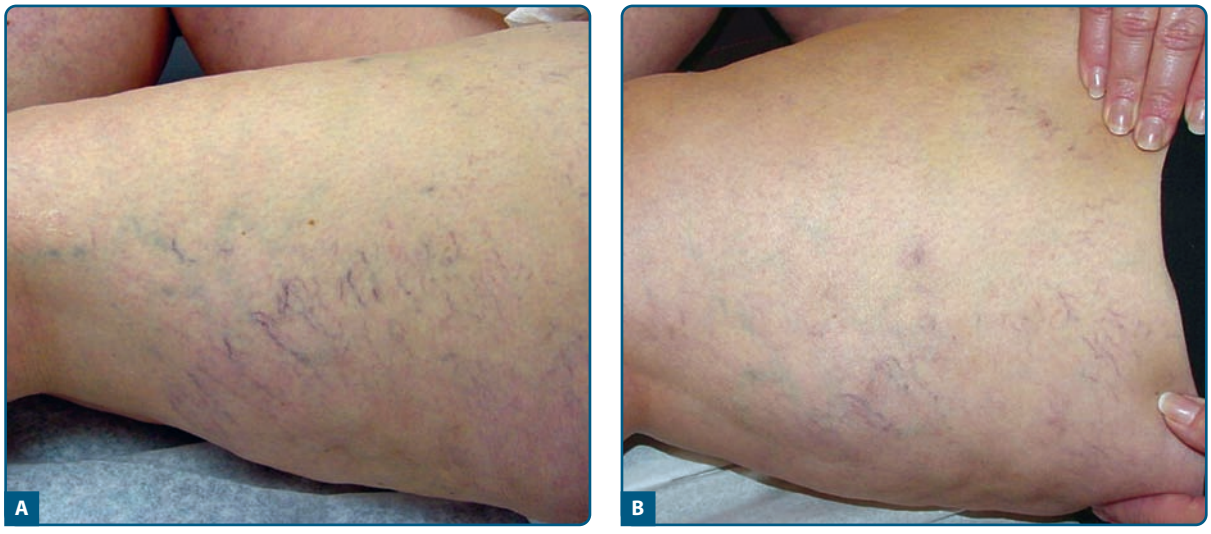

Figure 249-10 Clinical results with treatment of reticular veins with sclerotherapy and telangiectasias with 1,064 nm laser (CoolTouch Varia™, CoolTouch Corp, Roseville, CA). Sclerosant used was 0.25% foamed POL and laser parameters were 150 J/cm2, 3 mm spot, 20 msec pulse duration. **A.** Before and **B.** 3 months after treatment. Treatment parameters are single 16-ms pulse, 6-mm spot size, 120 J/cm^2.

by various surgical techniques and follow up with sclerotherapy of the remaining reticular networks.

Lasers and Light Sources. New trends for improved results with lasers and light sources for spider veins include longer wavelengths, larger spot sizes and cooling to protect the skin (Fig. 249-10). The first report of 1,064-nm Nd:YAG laser indicated that 75% improvement was possible after a single treatment at 3 months.[63] These findings were confirmed and mechanism of action explained as heat-induced vessel damage and subsequent fibrosis.[64] Recent reports also indicate effectiveness of 940-nm diode laser.[65] Shorter wavelengths used in the past, like pulsed dye laser, have limited utility on leg veins although many devices are now being adapted to longer pulse durations up to 40-ms. In our practice, the vast majority of laser treatments are performed using 1,064-nm Nd:YAG in the millisecond domain on isolated telangiectasias, sclerotherapy-resistant telangiectasias, ankle telangiectasias and suspected A-V malformations. Even associated reticular veins with telangiectasias can be treated with 1,064 nm, however, the larger the vein, the more painful the treatment due to increased absorption of infrared energy.[66]

Cosmetic Dermatology

Chapter 250 :: Cosmetics and Skin Care in Dermatology

:: Leslie Baumann

COSMETICS AND SKIN CARE IN DERMATOLOGY AT A GLANCE

- Nonmedical skin care and cosmetic use of over-the-counter products represent a major growth area among consumers.
- Understanding variations in skin types using a new system of classification facilitates patient selection of over-the-counter products.
- Cosmetics and skin-care products can be a source of a range of adverse reactions including irritation and allergy.

According to recent data, the US sales of skin-care cosmeceuticals (cosmetics with attributed biologic effects) range between $3.5 and $6.4 billion, with forecasts of steady continued growth despite the global recession.[1–3] A plethora of skin-care products are currently available to account for this substantial sales volume. The range of products and their associated claims is so extensive and complex that physicians and consumers are often confused about their indications and effectiveness. One approach to understanding these many options is to consider how the products are used to treat specific skin types.

For the purposes of choosing the most appropriate cosmetics and other skin-care products, facial skin can be grouped into four main categories that in practice represent up to 16 skin types: dry (D) or oily (O), sensitive (S) or resistant (R), pigmented (P) or nonpigmented (N), and wrinkled (W) or unwrinkled [or "tight" (T)]. These "skin types" are not static and can be affected by a range of intrinsic and extrinsic factors such as environment, aging, and disease. The key to proper skin-care recommendations is to take all four parameters into consideration. The various permutations of the four skin-type parameters yield 16 possible skin types. For example, a person may have dry, sensitive, pigmented, wrinkled skin, and her needs would significantly differ from someone with oily, sensitive, pigmented, and wrinkled skin.

This chapter discusses the basic science and defining characteristics of the four parameters. Certain extrinsic or intrinsic factors, such as a move to a different climate, a change in stress levels, pregnancy, menopause, and other stressors, can result in a skin type change. The Baumann Skin Type Indicator, a questionnaire developed to determine skin type, is helpful in assessing skin type initially and again after major life events.[4]

SKIN HYDRATION

OILY VERSUS DRY

Xerosis or "dry skin" describes skin that is characterized by dull color (usually gray white), rough texture, and an elevated number of ridges.[5] The etiology of this common condition is multifactorial. The most significant factor in the development of xerosis is the role of the *stratum corneum (SC)* and its capacity to maintain skin hydration. Rawlings et al showed that patients with dry skin have a perturbation in the lipid bilayer of the SC, which is associated with increased fatty acid and decreased ceramide levels.[6] Defects or deficiencies in this barrier layer of the skin cause a spike in water evaporation, known as transepidermal water loss (TEWL). This leads to abnormal desquamation of corneocytes[7]because desmosomes remain intact at higher levels of the SC, and desmoglein I levels remain elevated in the superficial SC of individuals with dry skin as compared to controls. This occurs because the enzymes necessary for desmosome digestion are impaired when the water level is insufficient, which leads to abnormal desquamation resulting in visible "clumps" of keratinocytes that cause the skin to appear rough and dry.[8] Recent studies suggest that both the initial cohesion and the ultimate desquamation of corneocytes from the SC surface may be orchestrated by localized changes in pH, which selectively activate different classes of extracellular proteases in a pH-dependent fashion.[9] Impairment of the lipid bilayer of the SC can be caused by various exogenous factors such as ultraviolet (UV) radiation,

detergents, acetone, chlorine and prolonged water immersion.

The SC is composed of three primary groups of compounds: (1) ceramides, (2) fatty acids, and (3) cholesterol. When present in the proper amount and balance, these components help protect the skin and keep it watertight (see Fig. 250-1). When the barrier is impaired, however, the skin is rendered dry, because of the inability to retain water, and sensitive, because of increased vulnerability to extrinsic elements. Several other factors play a causative role in dry skin.

Natural moisturizing factor (NMF), derived from the breakdown of the protein filaggrin, is integral in maintaining water within skin cells. Filaggrin provides structural support and strength in the lower layers of the SC. It is broken down in higher levels (stratum compactum) of the SC by a still-uncharacterized, cytosolic protease into free amino acids, including histidine, glutamine (glutamic acid), and arginine.[10] These osmotically active amino acids remain inside the keratinocyte and avidly bind to water. The pace at which filaggrin is broken down into NMF is thought to be regulated by aspartate protease (cathepsin), which initiates this cascade and determines the amount of NMF that is present.[11] Interestingly, this putative aspartate protease (cathepsin) is regulated by changes in external humidity. In other words, in low-humidity environments, the pace of NMF production increases. This acclimation process typically occurs over the course of several days[12] and cannot yet be regulated artificially via products or procedures.

Hyaluronic acid (HA), which can bind 1,000 times its weight in water, is another substance found in the skin that may help it retain and maintain water. HA is produced mainly by fibroblasts and keratinocytes in the skin, and has an estimated turnover rate of 2–4.5 days in mammalians.[13] HA is localized not only in the dermis but also in the epidermal intercellular spaces, especially the middle spinous layer, but not in the SC or stratum granulosum.[14] Aged skin, which is less plump than youthful skin, is characterized by decreased levels of HA. The role of HA in skin hydration is not clear, and HA does not penetrate the skin upon topical application[15]; however, this has not stopped many companies from putting HA in topical skin-care products and claiming efficacy.

Bricks and mortar structure of the epidermis

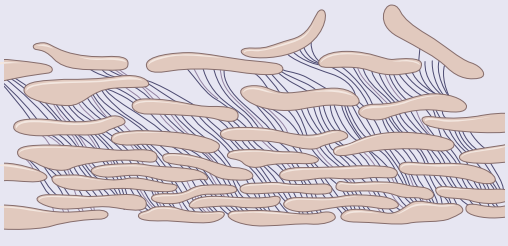

Figure 250-1 Bricks and mortar structure of the epidermis.

Aquaporin-3 (AQP3) is a member of a family of homologous aquaporin water channels that facilitate fluid transport. Other aquaporins in this family are well known to contribute to water transport in kidney and lung epithelia. AQP3 is a member of a subclass of aquaporins called aquaglyceroporins, which transport not only water but also glycerol and possibly other small solutes. AQP3 was recently found to be expressed at the plasma membrane of epidermal keratinocytes in human skin[16] (eFig. 250-1.1 in online edition). There is evidence for a high concentration of solutes (Na^+, K^+, and Cl^-) and a low concentration of water (13%–35%)[17] in the superficial SC, producing in the steady-state gradients of both solutes and water from the skin surface to the viable epidermal keratinocytes.[18,19] Although transepithelial fluid transporting properties have been studied extensively in kidney and lung epithelia, the molecular mechanisms of fluid transport across epidermal keratinocyte layers remain poorly understood, as is the relationship between keratinocyte fluid transport and SC hydration. It has been proposed that AQP3[16] might facilitate transepidermal water permeability to protect the SC against desiccation by evaporative water loss from the skin surface and/or dissipate water gradients in the epidermal keratinocyte cell layer. Water permeability of human epidermal keratinocytes was inhibited by mercurials and low pH, consistent with the involvement of AQP3.[16] A study[20] looking at skin phenotype in transgenic mice lacking AQP3 showed significantly reduced water and glycerol permeability in AQP3 null mice proving that AQP3 is functional as a plasma membrane water/glycerol transporter in the epidermis. Conductance measurements showed remarkably reduced SC water content in AQP3 null mice in most areas of the skin. However, epidermal cell water permeability is probably not a major determinant of SC hydration because water movement across AQP3 is very slow compared with other tissues.[21] Pharmacologic manipulation of AQP3 may be used in the future to treat skin disorders of excess and decreased hydration. At this time, only *Ajuga turkestanica* extract has been shown to play a role in regulating AQP3.[22] *Ajuga turkestanica* is found as an ingredient in a high-end line of skin-care products.

Sebum production may also be a factor in the pathogenesis of xerosis. The oily secretion of the sebaceous glands contains wax esters, sterol esters, cholesterol, di- and triglycerides, and squalene,[23] and is thought to confer protection to the skin from environmental influences and, when production is decreased, play a part in dry skin.[24] Because sebaceous-gland-impoverished skin, such as that in prepubertal children, exhibits normal basal barrier function,[25] it has been assumed that sebum does not influence epidermal permeability barrier function. Furthermore, when sebaceous glands are involuted pharmacologically with supraphysiologic doses of isotretinoin,[26,27] both barrier function and SC lamellar membranes remain unaltered.[28] Although sebum levels may not influence barrier function, sebum may still play a role in dry skin types, especially dry, resistant types that exhibit dry skin but not increased skin sensitivity. Lipids from modified sebaceous glands in the eye, called *meibomian glands*, help

prevent dry eyes by preventing tear evaporation[29,30]; therefore, it makes intuitive sense that sebum-derived fats form a lipid film over the skin surface, preventing TEWL. Credence is given to this theory by a study that examined permeability barrier homeostasis and SC hydration in asebia J1 mice that demonstrate sebaceous gland hypoplasia.[31] Normal barrier function was found in these sebum-deficient mice and can be explained by the unaltered levels of the three key barrier lipids, ceramides, free sterols, and free fatty acids, as well as the persistence of normal SC extracellular membranes. However, the mice were found to have decreased SC hydration. These results show that an intact intercellular membrane bilayer system, although sufficient for permeability barrier homeostasis, does not always suffice for normal SC hydration. Interestingly, the researchers found that topically applied glycerol returned the SC to normal hydration levels. In normal skin, sebaceous gland-derived triglycerides are hydrolyzed to glycerol prior to delivery to the skin surface. Replacing this glycerol in sebum-deficient skin may be a way to decrease skin dryness in sebum-deficient individuals. Glycerol has also been shown to be effective in accelerating barrier recovery.[32]

Patients rarely complain about decreased sebum production. However, it seems certain that sebum production plays a role in dry skin. For example, prepubertal children (>2 years and <9 years) commonly display eczematous patches (pityriasis alba) on the face and trunk that disappear coincidentally with the onset of sebaceous gland activation. Conversely, increased sebum production, which results in oily skin that can lead to acne, is a common complaint. It is well understood that an age-related change is seen in sebaceous gland activity, with levels typically low during childhood, rising in the mid-to-late teens, and generally remaining stable for decades until trailing off in the seventh and eighth decades as endogenous androgen production declines.[33] The level of sebum production is also influenced by diet, stress, hormone production, and, to a degree, by genetics. In a study of 20 pairs each of identical and nonidentical like-sex twins, the identical twins exhibited essentially the same sebum excretion rates, with significantly divergent acne severity, whereas the nonidentical twins differed significantly according to both parameters, implying both the genetic influence of sebum and the mediation of exogenous factors in lesion development.[34]

SKIN CARE FOR THE O–D PARAMETER

In the context of the oily–dry parameter, ideal skin is typically characterized by an intact SC with an intact barrier, sufficient NMF levels, normal levels of HA, normal expression of AQP3, and balanced sebum secretion. In skin that falls on the oily side of the spectrum, increased sebum secretion is usually the culprit. This may or may not be accompanied by acne. If acne is a concern, then the patient would also fall into the sensitive skin category and would be labeled as an oily-sensitive skin type. The skin-care treatments would focus on decreasing sebum with retinoids, decreasing skin bacteria with antibiotics, benzoyl peroxide or other antimicrobials, and adding anti-inflammatory ingredients. If acne is absent, the individual would be labeled as an oily-resistant skin type. Skin care would focus only on decreasing sebum production unless other parameters such as dyspigmentation and wrinkling are also factors. Oral ketoconazole[35] and oral retinoids[36] have been shown to decrease sebum secretion, but this has not been shown with topical agents. Sebum-absorbing polymers and talcs are also useful for camouflaging unwanted sebum in people with oily-resistant skin.

In skin that falls on the dry side of the continuum, one must decide which factors are contributing to the dry skin. Clues can be derived by looking at the other skin parameters. If a patient has dry and sensitive skin, it is likely that the skin barrier is impaired and care should be taken to use products that repair the skin barrier, such as those that contain fatty acids, cholesterol, ceramides and glycerol. If the skin is photodamaged and wrinkled as a result, decreased HA likely plays a role. Topically applied HA is not absorbed, so using skin-care products with HA is not helpful; however, studies have suggested that glucosamine supplements may contribute to an increase in HA levels.[37] One small single-blind study showed improvement of wrinkles but no change in skin hydration so the role of glucosamine is unclear.[38] Dry skin that endures ongoing sun exposure likely suffers from an impaired skin barrier and decreased levels of NMF. At this time, there are no products that increase NMF, so skin care should focus on repairing the skin barrier and providing adequate sun protection.

All patients with dry skin are advised to avoid harsh foaming detergents that remove hydrating lipids and NMF from the skin. These detergents are found in laundry and dish cleansers in addition to body and facial cleansers. All dry skin patients should also abstain from taking protracted baths, particularly in hot or chlorinated water. In addition, people with very dry skin are advised to use humidifiers in low-humidity environments and apply moisturizers two to three times a day and after bathing.

In addition to targeting the causes of dry skin, there are many moisturizers on the market that help hydrate the skin in a more basic or generic manner. These products can be categorized as occlusives, humectants, or emollients (Table 250-1).

OCCLUSIVES

Occlusives coat the SC to retard TEWL. An occlusive provides an emollient effect as well as decreases TEWL. The best occlusive ingredients currently available are petrolatum and mineral oil. Petrolatum, for example, has a water vapor loss resistance 170 times that of olive oil.[39] However, petrolatum has a greasy feeling that may make agents containing it cosmetically unacceptable to many patients. Other commonly used occlusive ingredients include paraffin, squalene, dimethicone, soybean oil, grapeseed oil, propylene glycol, lanolin,

TABLE 250-1
Types of Ingredients in Moisturizers for Topical Skin Care

Barrier Repair
- Ceramides
- Cholesterol
- Fatty acids

Occlusives
- Petrolatum[a]
- Mineral oil[a]
- Paraffin
- Squalene
- Dimethicone
- Soybean oil
- Grapeseed oil
- Propylene glycol
- Lanolin[a]
- Beeswax

Humectants
- α-Hydroxy acids
- Glycerin
- Hyaluronic acid
- Propylene glycol
- Sodium hyaluronate
- Sorbitol
- Sugars
- Urea

[a]Also confer emollient effects

and beeswax.[40] These agents are only effective while present on the skin; once removed, the TEWL returns to the previous level. Interestingly, it is not desirable to decrease TEWL by more than 40% because maceration with increased levels of bacteria can result.[41] Therefore, occlusives are usually combined with humectant ingredients.

HUMECTANTS

Humectants are water-soluble materials with high water absorption capabilities. They are able to attract water from the atmosphere (if atmospheric humidity is greater than 80%) and from the underlying epidermis. Although humectants may draw water from the environment to help hydrate the skin, in low-humidity conditions they may absorb water from the deeper epidermis and dermis resulting in increased skin dryness.[42] For this reason, they are more effective when combined with occlusives. Humectants are also popular additives to cosmetic moisturizers because they prevent product evaporation and thickening, which increases the shelf-life of products. Some humectants have bacteriostatic activity as well.[43] Humectants draw water into the skin, causing a slight swelling of the SC that gives the perception of smoother skin with fewer wrinkles. Examples of commonly used humectants include glycerin, sorbitol, sodium hyaluronate, urea, propylene glycol, alpha hydroxy acids, and sugars.

EMOLLIENTS

These are substances added to cosmetics to soften and smooth the skin. They function by filling the spaces between desquamating corneocytes to create a smooth surface.[44] Emollients provide increased cohesion causing a flattening of the curled edges of the individual corneocytes.[45] This leads to a smoother surface with less friction and greater light refraction. Many emollients function as humectants and occlusive moisturizers as well. Lanolin, mineral oil, and petrolatum are examples of occlusive ingredients that also confer an emollient effect.

SKIN SENSITIVITY AND COSMETIC INTOLERANCE SYNDROME

SENSITIVE VERSUS RESISTANT

Sensitive skin is much more challenging to describe than resistant skin. The latter is characterized by a strong SC that confers potent cutaneous protection, shielding the skin from allergens and irritating substances. As the term implies, resistant skin rarely exhibits erythema (unless overexposed to the sun) or acne (unless it is so affected due to stress or hormonal fluctuations). People with resistant skin can use most skincare products without fear of developing an adverse reaction such as a rash, acne, or a stinging sensation. The disadvantages of such skin include an inability to detect different effects among cosmetic products and, more important, having too high a threshold for penetration, so that few products are likely to cross the SC and impart beneficial changes.

The concept and presentation of sensitive skin is much more complex. Data from the early 1990s suggested that more than 40% of people presenting to a dermatologist reported having sensitive skin.[46] In fact, in a recent epidemiological study of 1,039 people not selected based on sensitive skin-related criteria, questionnaire results indicated that 68.4% of the study population stated that their skin was sensitive to some degree, 77.3% claimed sensitive facial skin, 60.7% claimed sensitive body skin, and 56.3% claimed sensitive genital skin.[47] Healthy women of child-bearing age comprise the majority of people that complain about this type of skin. With increasing age, the incidence of sensitive skin appears to decline. There are numerous cosmetic products available that are marketed for sensitive skin. However, sensitive skin itself is a relatively complex dermatologic phenomenon.

Cosmetic intolerance syndrome is not a single entity but rather a symptom complex of multiple exogenous and endogenous factors and represents an extreme of the continuum of patients who complain of sensitive skin. The syndrome is an uncommon clinical phenomenon in which patients complain bitterly of facial burning and discomfort associated with application of most skin-care products. Their skin may show overt inflammatory changes, or symptoms may be subjective only. These patients seriously challenge the diagnostic skills

and even empathy of practitioners because the severity of symptoms does not match objective signs of disease. Many patients affected with this syndrome have tried numerous cosmetics and topical medications.

Fisher[48] coined the term *status cosmeticus* for the condition in which patients no longer tolerate the use of any facial cosmetic product. Some of these patients initially experience subjective or objective irritation in response to use of cosmetics and become intolerant to many other topical agents during the evolution of this disorder. Other patients have occult allergic contact dermatitis, allergic photocontact dermatitis, contact urticarial reaction, or a combination of these conditions. In such patients, causal agents can be documented by careful clinical review and patch testing.

Strictly observing a prolonged program of eliminating cosmetics is an important therapeutic intervention. Some patients are able to return gradually to using other cosmetics after 6–12 months. Subsequent additions to the skin-care regimen can be made one at a time every 2 weeks. For the final regimen, the number of cosmetics and frequency of their use should remain limited.

Other patients experience facial burning continuously, without showing objective signs. Cotterill[49] described these patients as having "dermatologic nondisease." Many of these patients have a disturbed body image or body dysmorphic disorder—that is, they complain of physical defects that lack objective evidence. Many are depressed and need psychiatric help, which they frequently reject.

Sensitive skin covers the same range of pathophysiology as cosmetic intolerance syndrome, but it is generally less severe. Most of these consumers manifest sensory skin irritation.

Indeed, there are four very distinct variations of sensitive skin: (1) acne type (prone to developing acne, black heads, or white heads); (2) rosacea type (featuring a tendency toward recurrent flushing, facial redness, and experiencing hot sensations); (3) stinging type (predilection to stinging or burning sensations); and (4) allergic type (more likely to exhibit erythema, pruritus, and skin flaking).

Each of these subtypes of sensitive skin presents a unique challenge to the practitioner regarding appropriate treatment and recommendations regarding over-the-counter cosmetic skin-care products. The common process among these four subtypes is inflammation. Therefore, treatments for any kind of sensitive skin should focus on reducing and eliminating inflammation. Treatment can be further complicated when a patient displays a proclivity toward more than one sensitive skin subtype.

ACNE TYPE

Definitive data on the prevalence of acne in the United States or worldwide are challenging to collect, but acne is generally considered the most pervasive skin condition in the United States. An overwhelming majority of these patients, roughly 70%–80%, are adolescents and young adults between 11 and 25 years old.[50] (Fig. 250-2.) Adult women manifesting a hormonal component to their acne comprise most of the remainder of acne sufferers. There are three primary factors in the pathogenesis of acne: (1) elevated sebum production (which falls into the oily skin type); (2) clogged pores, characterized by dead skin cells inside the hair follicles adhering more than in those without acne (increased sebum production may also play a role in causing these skin cells to clump); and (3) the presence of the bacteria *Propionibacterium acnes*. Although acne can be a dynamic condition with various causal pathways or contributing factors, the essential pathognomonic feature is that increased amounts of sebum cause dead skin cells in the hair follicles to adhere, thereby clogging the follicle and creating a papule or pustule. *P. acnes* then migrate into the hair follicle, attacking the collected sebum and dead skin cells. This stimulates the release of cytokines and other inflammatory factors that engender the inflammatory response with the clinical correlates of redness and pus.

Figure 250-2 Sensitive skin types often suffer from acne. Salicylic acid and benzoyl peroxide are over-the-counter options in these patients.

Some skin and hair care cosmetics cause acneiform eruptions. *Acnegenicity* encompasses both *comedogenicity*, which refers to follicular keratin impaction,[51] and papulopustular formation. The time course for the appearance of facial papulopustules and comedones is different: papulopustules may appear in just a few days, whereas the appearance of comedones is delayed. Considerable confusion derives from the testing techniques: for example, isopropyl myristate in concentrations as low as 10% in petrolatum rapidly induces comedones in the rabbit ear but yields papulopustules in humans. Even common emulsifiers such as sodium lauryl sulfate produce pustules in a dose-related manner. The mechanisms appear to be related in spite of varied morphology. The European Union's ban on animal testing of final products, which took effect in March 2009, will result in stronger reliance on human testing, whether this takes the form of use tests or application of a cosmetic under occlusion to the back for 4 weeks and subsequent cyanoacrylate or cationic polymer biopsies (to identify microcomedones), or both.

In 1996, the clinical significance of cosmetics in precipitating postadolescent acne in women was called

Figure 250-3 Rosacea patients fall into the sensitive skin type category and should be treated with anti-inflammatory ingredients.

into question by one of the authors of the original paper on "acne cosmetica."[52,53] Consequently, it is best to advise female acne patients to keep their cosmetic regimen simple and gentle, using products from manufacturers who test for acnegenicity.

ROSACEA TYPE

Typically afflicting adults between 25 and 60 years of age, rosacea affects tens of millions of Americans. Like acne, this condition is characterized by facial redness, flushing, and papules, but is also distinguished by the formation of prominent telangiectasias (see Fig. 250-3). Topical skin care for rosacea is primarily geared toward preventing exacerbation of the condition, and using anti-inflammatory ingredients to decrease inflammation. Ingredients with anti-inflammatory activity include feverfew, sulfur, zinc, sulfacetamide, quadrinone, niacinamide, licorice extract, cucumber extract, aloe vera, colloidal oatmeal, and chamomile (Table 250-2).

STINGING TYPE

Burning, stinging, or itching caused by application of a cosmetic or topical medicament without detectable visible or microscopic change is termed *sensory irritation*. The afferent limb of this reaction is carried by C nerve fibers that are present throughout the dermis and viable epidermis. The stinging occurs on the face within an hour of application in susceptible individuals. In a segment of the population, this sensory response is caused by many ingredients at dosages that do not produce clinical objective irritation.

TABLE 250-2
Anti-Inflammatory Products for Topical Skin Care (Over-the-Counter)

- Licorice extract
- Licochalcone
- Quadrinone
- Cucumber
- Aloe vera
- Chamomile
- Colloidal oatmeal
- Arnica
- Feverfew (has anti-inflammatory and antioxidant capabilities)
- Niacinamide (also known as nicotinamide)
- Salicylic acid
- Zinc
- Witch hazel

Nonallergic stinging is a phenomenon that a discrete subset of people experience in response to certain triggers. Some patients may indeed be more sensitive than others and are referred to as "stingers" by dermatologists. Stingers do not have a higher incidence of atopy or dry skin, but do report frequent adverse reactions to cosmetics. Strontium nitrate and chloride inhibit sensory irritation caused by α-hydroxy acids, ascorbic acid, and aluminum salts.[54] These blockers are incorporated into skin-care products such as those containing α-hydroxy acids.

Several tests have been devised to identify stingers or the stinging propensity. The lactic acid stinging test is a widely accepted standard method for evaluating individuals who report invisible and subjective cutaneous irritation. In an early study, Frosch and Kligman applied 5% lactic acid to subjects' nasolabial folds during profuse sweating, which resulted in 20% of participants reporting an unpleasant sensation.[55] In a similar study in which lactic acid (10%) was applied to nasolabial folds, Seidenari et al observed that individuals with "sensitive skin" experienced a much stronger stinging sensation than those in the healthy control group.[56] The stinging sensation is not necessarily associated with erythema as many patients feel stinging without experiencing redness or irritation.[57] However, patients with rosacea distinguished by facial flushing are more susceptible to stinging from lactic acid exposure. It is recommended that patients with the stinging subtype of sensitive skin avoid products that contain the following ingredients: α-hydroxy acids (particularly glycolic acid), benzoic acid, bronopol, cinnamic acid compounds, Dowicel 200, formaldehyde, lactic acid, propylene glycol, quaternary ammonium compounds, sodium lauryl sulfate, sorbic acid, urea, or vitamin C.

ALLERGIC TYPE

According to the findings of a 2004 epidemiologic survey in the United Kingdom, over the course of a year, 23% of women and 13.8% of men experience an adverse reaction to a personal care product (e.g., deodorants

and perfumes, skin-care products, hair-care products, and nail cosmetics).[58] To identify allergies to cosmetic ingredients patch testing can be performed. Various studies reveal that approximately 10% of patch-tested dermatologic patients are allergic to at least one ingredient common in cosmetic products.[58] Approximately 80% of reactions occur in patients aged 20–60 years, with the majority seen most often in women.[59] Fragrances and preservatives are the most common allergens. Individuals who use several skin-care products with a commensurately high number of ingredients are more likely to develop allergies to ingredients, simply due to such overexposure. Patients with an impaired SC, manifested by xerosis (the dry skin type), are likely to have an increased incidence of allergic reactions to allergens placed on the skin.[60]

SKIN IRRITATION AND ALLERGY DUE TO COSMETICS AND SKIN-CARE PRODUCTS

Skin irritation is defined as localized inflammation that is not mediated through the immune system and is caused by endogenous and environmental factors. Hair straighteners, permanents, and depilatories can cause *acute reactions* if directions for their safe use are not strictly followed. Cleansers are frequently responsible for causing *irritant dermatitis*. Moisturizers or emollient creams, in which water and oleaginous materials are blended, contain surfactants and emulsifiers that are often mild irritants. When these cosmetics are applied to the face or to dry or eczematous skin, where the SC is a less efficient barrier, *irritant reactions* may result. Morphologic features include scaling, which may rapidly clear with avoidance of exposure but become erythematous with recurrent dosing and may evolve into chronic irritant dermatitis. Some cosmetics produce irritation only after repeated application; this phenomenon is termed *cumulative irritation*. Friction, injury, and *mechanical irritation* can be caused by popular cosmetics containing granules or by devices (e.g., synthetic sponges) used to exfoliate the skin (Table 250-3).

TABLE 250-3
Diagnosis and Treatment of Patients Whose Skin Is Intolerant to Cosmetics

Examine every cosmetic and skin-care product
Administer patch and photopatch tests to rule out occult allergic and photoallergic dermatitis
Test for contact urticaria
Do careful repeat open application testing (ROAT)
Treat endogenous inflammatory disease
Limit skin-care to:
Water washing without soap or detergent
Lip cosmetics as desired, if lips are clear
Eye cosmetics as desired, if eyelids are asymptomatic
Face powder
Glycerin and rose water as a moisturizer, if necessary
Avoiding other cosmetics for 6–12 months

Sensitive bioengineering techniques used to evaluate the pathophysiology of irritation include TEWL, skin impedance, conductance resistance, and blood flow velocity.[61] By using predictive testing in animals and humans, manufacturers can recognize strong or moderate irritant ingredients or products. In premarket testing, mild irritants are more difficult to detect and quantify.

Bergamot oil (5-methoxypsoralen) is a *phototoxic* fragrance ingredient that was used in cosmetics but has been removed. As interest in "natural" ingredients increases,[62] new phototoxins may be inadvertently introduced that could provoke serious consequences if they are not recognized clinically.

NATURAL AND ORGANIC PRODUCTS AND SKIN IRRITATION

A product labeled "natural" is not necessarily organic. It may contain aloe, vitamin E, or other natural ingredients, but also chemicals intended to act as preservatives or to improve texture. Only products that are truly organic are legally permitted to include the Organic Seal. In organic farming of food crops or those intended for topical products, farmers do not use synthetic pesticides, hormones, genetically modified crops, or chemical products. Nevertheless, adverse reactions to organic as well as natural ingredients can occur. For example, coconut oil, a popular organic ingredient, can cause acne. Also, it is worth noting that because producers of topical products were not able to label their products as organic until August 2005, there have not been sufficient clinical research trials on the organic products on the market.

Allergies can develop in response to the use of many essential oils and botanicals. Many natural and organic brands contain certain fragrances and essential oils that can cause dermatitis. For example, strong essential oils like peppermint or rosemary can irritate or inflame sensitive skin. Chamomile, which is generally considered a gentle and soothing herb, can provoke allergies in some individuals, particularly those allergic also to wheat. In addition, a "perfume mix" is included in various conventional as well as some natural products to mask the odor of other ingredients. These perfume mix ingredients are rarely listed on the product label because each company uses its own proprietary blend. A perfume mix sufficient to elicit an allergic response can be present in a product listed as 95% organic.

ORGANIC PRODUCTS BY SKIN TYPE

For a patient with nonpigmented skin, an organic body lotion containing whole soy oil is likely suitable. However, that same product could activate the proclivity for melasma and other hyperpigmentation in a patient with pigmented skin. In this case, a nonorganic product would be more appropriate because only fractionated soy (also known as "active soy"), which is not organic, removes the pigment-inducing estrogenic components of soy, thus allowing this patient to derive the benefits

of soy. Another example of factoring organic products into the identification of proper skin-care selections based on skin type might include a patient with dry, wrinkled skin who would benefit from using green tea formulations, of which several options are organic. A patient who strictly uses organic products (e.g., food, clothes) but who has oily, wrinkle-prone skin, however, would cutaneously benefit from using retinoids, even though they are not organic.

OTHER SKIN REACTIONS DUE TO COSMETICS

CONTACT URTICARIA SYNDROME

Contact urticaria syndrome typically consists of a wheal-and-flare response developing within 30–60 minutes after the skin is exposed to certain agents. Symptoms range from the mildest manifestations (e.g., itching, tingling, burning, and erythema) to the most severe (e.g., anaphylaxis and death). Diagnosis of immediate contact urticaria is based on a thorough medical history (including notation of burn, sting, or itch resulting from skin contact; urticaria; or respiratory symptoms) and skin testing using suspected substances.[63]

Contact urticaria syndrome is divided into two subtypes—nonimmunologic and immunologic—based on proposed pathophysiologic mechanisms.[64] Nonimmunologic contact urticaria, the most common form, occurs in the absence of previous exposure and remains localized, causing no systemic symptoms. Typically, the strength of the reaction varies by ingredient concentration and location of use. The mechanism is not completely delineated. Benzoic acid, cinnamic acid, and cinnamal are commonly used in cosmetics and are potent substances capable of eliciting this response.

Immunologic contact urticaria is an immediate type I allergic reaction that occurs in sensitized individuals and is induced more frequently in atopic individuals. The eliciting chemicals react with specific IgE molecules on mast cell membranes. Localized urticaria can extend beyond the site of contact, or may be accompanied by other symptoms such as rhinitis, conjunctivitis, asthma, and anaphylaxis. In this manner, methylparaben, ethylparaben, henna, and ammonium persulfate have been associated with systemic reactions.[65]

DELAYED HYPERSENSITIVITY REACTIONS

Adverse reactions to cosmetics constitute a small but significant portion of contact dermatitis cases treated by dermatologists. In a study conducted by the North American Contact Dermatitis Group, patch testing showed contact dermatitis related to cosmetics in 5% of more than 13,000 patients evaluated.[66] These figures underestimate the total number of cases, because most mild reactions are not investigated by dermatologists. In the North American Contact Dermatitis Group study, 59% of the cosmetic-induced reactions occurred on the face and 79% were seen in women, but a relation to cosmetics was suspected by the dermatologist or patient initially in fewer than half the cases. Diagnosis of allergic contact dermatitis is based on a compatible history and examination supported by results of patch testing. Most cosmetics are not strong irritants and closed patch testing can be applied in the usual manner; however, notable exceptions exist. Weakly positive reactions should be confirmed by medical history, test repetition, and patch testing of ingredients. Ingredient testing is a problem in the United States because of the limited number of chemicals available on the thin-layer rapid use epicutaneous (TRUE) test screening tray. It is important to recognize which of these allergens are found in cosmetics. Cosmetic Industry on Call[67] provides information for contacting manufacturers who may provide ingredients for patch testing. De Groot et al[68] provide reference information on chemical concentrations and vehicles to use in testing cosmetic ingredients.

The provocative use test, also called the *repeat open application test*,[69] is a practical way to screen for allergy to cosmetics, including fragrances[70] or to confirm the clinical significance of weak positive reactions. The cosmetic is applied twice daily for up to 4 weeks to an approximately 5-cm area on the flexor surface of the forearm near the cubital fossa.

Most photoallergic ingredients in cosmetics are sunscreening agents or fragrances. To test for photoallergy, the patch site is exposed to between 5 and 10 J of UVA 24 hours after application; after 48 hours, the photo patch site is compared with a nonirradiated site similarly patch tested.

Most allergic reactions to cosmetics are caused by fragrances, preservatives, and a small number of miscellaneous ingredients. Familiarity with these allergens will enable clinicians to diagnose many of these cases accurately (Table 250-3).

SKIN REACTIONS DUE TO FRAGRANCES

Fragrance allergy is common, affecting approximately 1% of the general population; dermatitis may develop on the face, neck, hands, and axillae, or it may be generalized.[71] Fragrances also represent several of the 15 most frequently positive allergens as identified by the North American Contact Dermatitis Group.[72] In fact, fragrances consistently placed among the top 10 contact dermatitis allergens, represent the second most common allergen family (behind nickel) associated with allergic contact dermatitis, and are the most often cited cause of such reactions to cosmetic products.[73]

Fragrances are ubiquitous: in addition to cosmetics and toiletries, they are added to household goods or cleansers in the workplace, and some are used as flavorings. Paradoxically, "unscented" cosmetics may contain a masking fragrance. A new method of promoting fragrances is to claim that scents have mood-altering effects—so-called aromatherapy. Inevitably, troublesome sensitization has occurred in consumers

who have doused themselves and their surroundings with fragrance. Since 1966, toxicologic information related to fragrance ingredients has been assembled and assessed by the industry-sponsored Research Institute for Fragrance Materials.[74] Based on this information, the International Fragrance Association publishes guidelines that industry members generally agree to follow.

Photosensitization (see Chapter 92) occurred more commonly before methyl coumarin and musk ambrette were eliminated from fragrances. Sensitization to musk ambrette left an extensive legacy of so-called persistent light eruptions. Because fragrance allergy is not frequently suspected by either the patient or the physician, patch testing is an important tool for reaching this diagnosis. Balsam of Peru, cinnamal, fragrance mix (now known as Fragrance Mix I), and colophony are recognized markers for fragrance allergy on patch-test screening series. Fragrance Mix I (marketed by Hermal and by Chemotechnique and also marketed in the TRUE test) contains eight ingredients: (1) eugenol, (2) isoeugenol, (3) oak moss absolute, (4) geraniol, (5) cinnamal, (6) α-amyl cinnamic aldehyde, (7) hydroxycitronellal, and (8) cinnamic alcohol. In an international study of 165 patients with probable fragrance allergy, the fragrance mix detected 86% of positive reactions. The addition of ylang-ylang oil, narcissus oil, sandalwood oil, and balsam of Peru raised this rate to 96%. Ethnic and geographic distinctions exist; for instance, Japanese patients tested were more frequently reactive to benzyl salicylate. Such racial differences were highlighted by the epidemic of bizarre facial hyperpigmentation seen in Japanese women in the 1960s and 1970s caused by allergy to fragrances and coaltar dyes used in some cosmetics; elimination of these allergens solved the problem.

Fragrance Mix II [Hydroxyisohexyl 3-cyclohexene carboxaldehyde (Lyral), citral, farnesol, coumarin, citronellol, and α-hexyl cinnamal] was introduced during the early part of the new millennium after 1,701 consecutive patients in 6 European countries were patch-tested to evaluate 14 frequently used chemicals.[75–77] Allergy to fragrance can be tested by using the repeat open application test for up to 4 weeks. Balsams, cinnamic alcohol, cinnamaldehyde, benzyl alcohol, and benzaldehyde are among the fragrance ingredients that can evoke contact urticaria not detected by closed patch testing. It is also important to note that fragrance-based chemicals are sometimes included in products labeled as "fragrance-free" if incorporated for an indication other than as a fragrance.[73]

SKIN REACTIONS DUE TO PRESERVATIVES

Preservatives are added to prevent contamination of cosmetics by microorganisms, which degrade the product or cause infection in consumers; but the term *preservative* may encompass agents that prevent degradation induced by oxidation or UV light. Approximately 60 chemicals are commonly used as preservatives in cosmetics. Preservatives may consist of a single ingredient or a mixture of ingredients (e.g., Euxyl 400 is a mixture of methyldibromoglutaronitrile and phenoxyethanol). Use of specific preservatives varies among American, European, and Asian markets; consequently, the incidence of allergic reactions to individual agents also varies. Adverse reactions have prompted development of preservative-free cosmetics. Strategies for developing such products include modification of the manufacturing and packaging processes as well as use of botanicals that have antimicrobial activity. The increasing complexity of cosmetics and their vehicles makes this goal even more difficult to achieve.

Paraben esters, the most widely used group of preservatives in cosmetics[78] and used in most skin-care formulations,[79] are effective against fungi and Gram-positive (but not Gram-negative) bacteria. Parabens rarely sensitize but may do so when applied to eczematous skin. Sensitized patients frequently tolerate parabens in cosmetics applied to normal skin.

Propylene glycol, a popular solvent and humectant, has antimicrobial properties but is used in some "preservative-free" cosmetics. A review of the literature and observations in patch-tested patients suggest that propylene glycol is a mild irritant that only occasionally sensitizes.[80]

Formaldehyde and formaldehyde releasers are widely used preservatives.[81] Formaldehyde is formulated in wash-off products such as shampoos. Quaternium-15, imidazolidinyl urea, diazolidinyl urea, DMDM hydantoin, and 3-bromo-2-nitropropane-1,3-diol are commonly used preservatives that release formaldehyde. They may sensitize themselves or cause reactions secondary to formaldehyde release in formaldehyde-sensitive patients, and cross-reactions in the group are reported. The tolerance of products containing preservatives to which patients are sensitive is modified by the site of application and their degree of sensitivity. For example, some formaldehyde-sensitive individuals can tolerate low levels of formaldehyde releasers on normal skin.

A mixture of methyldibromoglutaronitrile and phenoxyethanol (Euxyl 400) used initially in Europe has gained popularity and is being reported more frequently as an allergen.[82,83] Butylated hydroxyanisole, butylated hydroxytoluene, tocopherol, propyl gallate, and t-butyl hydroquinone used as antioxidants are sometimes reported as allergens. Other ingredients reported frequently as allergens in cosmetics include paraphenylenediamine, toluene sulfonamide/formaldehyde resin (tolysamide/formaldehyde resin), acrylates, lanolin, glyceryl thioglycolate, and UV light–absorbing agents (Table 250-4).

SKIN PIGMENTATION

purposes of describing a skin type to a patient and assisting the individual in selecting appropriate skin-care products, the focus should be on the pigmentary changes that can be improved with skin-care products rather than surgery. For example, skin-care products can be used to prevent or treat conditions such as melasma, solar lentigos, and ephelides. Patients with these concerns would be called pigmented types (see Fig. 250-4).

Skin pigment (melanin) is produced by melanocytes, which transfer the pigment via melanosomes to keratinocytes. Melanin is derived from the enzymatic breakdown of tyrosine by tyrosinase into 3,4-dihydroxyphenylalanine, which yields two forms of melanin (eumelanin and pheomelanin).[84] In darker-skinned people, melanocytes produce more melanin; the melanosomes are larger to accommodate this greater supply of pigment and, thus, are broken down at a slower rate than in lighter-skinned people.[85] Two primary mechanisms can be employed to impede the development of skin pigmentation: (1) inhibiting tyrosinase, which prevents melanin formation, and (6) preventing melanosome transfer into keratinocytes. Tyrosinase inhibitors include vitamin C, hydroquinone, kojic acid, arbutin, mulberry extract, and licorice extract (Table 250-5).

Small proteins present in soy, such as soybean trypsin inhibitor and Bowman-Birk inhibitor, have been suggested to inhibit skin pigmentation. These soy proteins were found not only to have depigmenting activity, but also to prevent UV-induced pigmentation both in vitro and in vivo.[86] According to Paine et al,[86] these soy proteins exert their effect via the inhibition of the cleavage of protease-activated receptor 2. Protease-activated receptor 2 is a seven transmembrane G-protein coupled receptor that is activated by a serine protease cleavage. It is expressed in keratinocytes, but not in melanocytes. By inhibiting this cleavage, soybean trypsin inhibitor and Bowman-Birk inhibitor are believed to affect melanosome transfer into keratinocytes, and thus, pigmentation. Niacinamide, a derivative of vitamin B_3, has also been shown to inhibit melanosome movement from melanocytes to keratinocytes.[87]

Figure 250-4 This patient has a pigmented skin type and would require lightening ingredients in skin-care products.

UV RADIATION AND SKIN COLOR

Melanogenesis results from the exposure of skin to UV radiation and serves as the skin's major defense against further UV damage. Melanocyte cells increase the production of melanin, melanoctye transfer from melanosomes to keratinoctyes is increased,[88] and this process manifests in exogenous skin darkening. Sun avoidance is the most effective method of preventing pigmentary changes, thus broad-spectrum sunscreens are an important component of any skin-care regimen geared toward reducing hyperpigmentation.

SKIN AGING

WRINKLED VERUS TIGHT

Aging of the skin is a complex phenomenon reflecting natural intrinsic and extrinsic processes. Intrinsic aging is a function of individual heredity and results

from the passage of time. This process is, of course, inevitable and beyond voluntary control.

Telomeres, specialized chromosomal components, play a central role in cellular aging: they shorten or diminish with age, so telomeric loss or erosion has become an important measure of aging, a veritable internal aging clock.[89] The enzyme telomerase stabilizes or lengthens telomeres; it is expressed in about 90% of all tumors but absent in many somatic tissues.[89] Interestingly, one of the few regenerative tissues to express telomerase is the epidermis.[90] In fact, recent evidence suggests that telomerase acts against excessive telomere loss in human epidermis throughout the life-long regeneration process.[91] At this time, no skin-care products target telomerase because not enough is known about the safety of extending telomere length.

Exogenous factors, such as smoking, poor nutrition, and sun exposure, are at the root of extrinsic aging. This process is not inevitable and reflects premature skin aging. In fact, 80% of facial aging is believed to be due to solar exposure.[92] Exposure to UV irradiation, by dint of its damaging effect on DNA and its acceleration of telomere shortening, can also be said to influence intrinsic aging. In addition, UV exposure results in skin damage through several mechanisms including sunburn cell formation, creation of thymine dimers, collagenase production, and provoking an inflammatory response. Signaling through p53 following telomere disruption is also a common feature observed in aging as well as photodamage.[93] Although much remains to be learned about the mechanisms through which UV irradiation unleashes a chain of cascading health effects, photoaging, photocarcinogenesis, and photoimmunosuppression are well known results of UV exposure.[94] Nevertheless, a recent paper suggests that the melanogenesis and photoaging induced by UV exposure is also associated with telomere-based DNA damage signaling that may actually represent a cancer-avoidance protective response.[95]

The most obvious manifestation of aging skin is the development of rhytides. Wrinkles are caused by changes in the dermis. Although consumers spend millions of dollars on "antiaging" skin-care products, few skin-care product ingredients can penetrate far enough into the dermis to affect deep wrinkles. The dermatologic focus of antiaging skin care should be to prevent the formation of rhytides in the first place.[96] To this end, the goal is to halt the degradation of the three main structural components of the skin—collagen, elastin, and HA—all of which are known to be diminished in aged skin. Because inflammation can contribute to the breakdown of these key skin constituents, one focus must be to reduce inflammation. Antioxidants protect the skin from free radicals through several mechanisms that are just beginning to be elucidated. Free radicals can act directly on growth factor and cytokine receptors in keratinocytes and dermal cells, leading to skin inflammation. Growth factors and cytokines certainly play a role in skin aging, but their exact mechanisms of action in this context are not well understood. It is apparent that they function together in a complex process requiring many types of growth factors and cytokines.[97] The direct effects of free radicals on the aging process are better understood. Kang et al. have shown that free radical activation of the mitogen-activated protein kinase pathways results in production of collagenase, which leads to degradation of collagen.[98] Blocking this pathway with antioxidants is thought to prevent photoaging by preventing the production of collagenase. Research supporting this theory was performed on human skin by Kang. In this study, he showed that when human skin was pretreated with the antioxidants genistein and N-acetyl cysteine, the UV induction of the cJun-driven enzyme collagenase was blocked. Many antioxidants are available in skin-care products including vitamins C and E, ferulic acid, coenzyme Q10, green tea, pycnogenol, silymarin, and idebenone.

PREVENTION IS THE BEST MEDICINE

Most antiaging products and procedures are geared to salvage collagen, elastin, and HA. However, products containing collagen, elastin, or HA are ineffective; they cannot effectively penetrate the epidermis. While there are no products that can replenish these important skin structures, there are some products that stimulate production of these components. Collagen synthesis has been shown to be increased through the use of retinoids,[99] vitamin C,[100] and copper peptide. Retinoids have also been demonstrated in animal models to increase production of HA[101] and elastin.[102] Oral vitamin C is also believed to have the capacity to increase collagen synthesis[103] and, again, glucosamine supplementation may augment HA levels.[37]

Some new products on the market employ electrical currents to stimulate fibroblasts to produce collagen and elastin. This technology utilizes copper and zinc to create a 10 mV current that is postulated to result in increased collagen and elastin synthesis. Notably, elastin is more complicated than collagen. Collagen is released from fibroblasts in a final triple helix stage, while elastin is excreted as tropoelastin, which represents unbound units of elastin in an immature form. These tropoelastin elements must bind a microfibrillar backbone to form mature elastin. New unpublished proprietary data suggest that dill weed can increase the binding of tropoelastin to microfibrillin while blackberry extract may increase the production of tropoelastin. Although these data are new, it is certain that elastin will be an important topic in the skin-care world in the coming year.

In the future, it is likely that the potential of electric current, growth factors, cytokines, telomerase and/or telomeres will be harnessed through advances including tissue engineering and gene therapy.[102,105] In the meantime, avoiding exposure to the sun, cigarette smoke, and pollution, as well as using sunscreen, taking oral antioxidant supplements or topical antioxidant formulations, and eating a diet high in fruits and vegetables can help reduce or prevent skin aging. Regularly using prescription retinoids can also help treat and prevent unwanted wrinkles.

TABLE 250-6
Baumann Skin Type Determined by the BSTI

	Oily, Pigmented	Oily, Nonpigmented	Dry, Pigmented	Dry, Nonpigmented
Wrinkled, Sensitive	OSPW	OSNW	DSPW	DSNW
Tight, Sensitive	OSPT	OSNT	DSPT	DSNT
Wrinkled, Resistant	ORPW	ORNW	DRPW	DRNW
Tight, Resistant	ORPT	ORNT	DRPT	DRNT

BSTI = Baumann skin type indicator; D = dry; N = nonpigmented; O = oily; P = pigmented; R = resistant; S = sensitive; T = tight; W = wrinkled.

COMBINATIONS OF TYPES

The four skin parameters can be combined to form 16 skin types (Table 250-6). Using this typing system will help consumers focus on their problem areas. For example, a person with oily, sensitive, nonpigmented, wrinkled skin would use products with retinoids and antioxidants whereas an individual with dry, sensitive, nonpigmented, tight skin would use products with barrier repair ingredients. Certain skin problems are more typically associated with particular skin combinations: pigmented, wrinkled skin is more likely exhibited by a person with a significant history of sun exposure manifested by wrinkles and solar lentigos. Eczema is more often observed in dry, sensitive skin types. Acne is most common among oily, sensitive types. Oily, sensitive, nonpigmented, wrinkled types with lighter skin are most prone to develop rosacea. Light skin is more common among nonpigmented, wrinkled types; dark skin is more common among pigmented, tight types.

CONCLUSION

For the purposes of optimal treatment and cosmetic selection, a classification of skin types that defines four different polarities is suggested: (1) dry or oily; (2) sensitive or resistant; (3) pigmented or nonpigmented; and (4) wrinkled or unwrinkled. Characterizing a patient's skin based on all the permutations and combinations of these skin types can facilitate treatment by physicians and help patients select the most appropriate over-the-counter skin formulations.

Chapter 251 :: Ablative Lasers, Chemical Peels, and Dermabrasion

:: Elizabeth L. Tanzi & Tina S. Alster

SKIN RESURFACING AT A GLANCE

- Several approaches are available for the treatment of photodamage, rhytides, and scarring.
- Popular treatment options include fully ablative and fractional ablative laser skin resurfacing and chemical peels.
- Selection of the appropriate technique requires that patient factors as well as the risks and benefits of the procedure be weighed.

Years of damaging ultraviolet light exposure manifest clinically as a sallow complexion with roughened skin surface texture and variable degrees of dyspigmentation, wrinkling, and laxity.[1,2] Other cutaneous insults such as scars from acne, trauma, or surgery also affect the appearance of the skin. Histologically, these extrinsic aging and traumatic effects are usually limited to the epidermis and upper papillary dermis and, thus, amenable to treatment with a variety of ablative and nonablative lasers, chemical peeling agents, and dermabrasion. The armamentarium of lasers and chemical peeling agents available to treat cutaneous photodamage, and textural irregularities is larger than ever. The most appropriate treatment technique is dependent on the severity of the photodamage or scarring, the expertise of the dermasurgeon, and the expectations and lifestyle of the individual patient.

ABLATIVE LASER SKIN RESURFACING

For years, fully ablative laser skin resurfacing (LSR) with the carbon dioxide laser (CO_2) was the gold standard in skin resurfacing. Developed in the mid-1990s, traditional multipass ablative LSR with a CO_2 laser demonstrated excellent efficacy for the treatment of rhytides, photodamage, and scars.[3–6] However, popularity of the procedure waned due to the extended postoperative recovery required, the inability to treat nonracial areas, and the significant risk of side effects and complications including persistent erythema, permanent hypopigmentation, and scarring.[7,8]

To mitigate the problems associated with traditional ablative LSR, nonablative laser devices were subsequently introduced.[9–30] The 532-nm-potassium titanyl phosphate (KTP),[18,19] 585- to 595-nm pulsed dye,[11,12] 1,064- and 1,320-nm Neodymium:yttrium-aluminum-garnet (Nd:YAG),[17–21] and 1,450-nm diode lasers,[9,10,25,26] and a 550- to 1,200-nm intense pulsed light device (IPL)[12–15] were developed to stimulate dermal neocollagenesis without epidermal injury or significant recovery. Each of these systems demonstrated histologic changes in dermal collagen, a series of treatments often yielded limited clinical improvement. Nonablative LSR is described in detail in Chapter 252.

A novel concept in skin resurfacing, termed fractional photothermolysis, was developed by Manstein and colleagues in 2004.[31] Fractional photothermolysis involves the creation of microscopic thermal wounds regularly interspersed within areas of nontreated skin. The intact nontreated skin forms bridges between the microscopic treatment zones (MTZ), thereby leading to rapid healing. The wound healing response differs from fully ablative techniques because the epidermal tissue that is spared between the thermal zones contains viable transient amplifying cells that are capable of rapid re-epithelialization.

Fractional photothermolysis devices include a 1,550-nm erbium-doped fiber, 1,540-nm erbium glass, and 1,320-nm or 1,440-nm Nd:YAG laser.[32–37] Their midinfrared wavelengths target water-containing tissue to effect photocoagulation of narrow columns of skin at depths of 200–500 µm at intervals of 200–300 µm. Histologic evaluation of skin immediately after treatment reveals thermal injury sharply confined to these narrow columns extending from the epidermis to the mid-dermis. Microscopic epidermal necrotic debris (MEND) exfoliate within days, producing a bronzed appearance to the skin. Since the stratum corneum has a low water content, it remains intact immediately after treatment. Although there is gradual exfoliation of the epidermis with resultant improvement in superficial dyspigmentation, these devices are considered nonablative due to the lack of significant epidermal disruption after treatment. As such, nonablative fractional laser resurfacing procedures offer patients a treatment option with little postoperative recovery. However, a series of treatments is required for the best results and, to date, nonablative fractional LSR demonstrates only modest improvement of severe photodamage, laxity, and rhytides compared to ablative LSR.[38–41]

A continued desire for superior clinical results while maintaining a manageable recovery and side effect profile gave rise to the combination of ablative laser devices that adhere to the concept of fractional photothermolysis. Ablative fractional resurfacing (AFR) with either a CO_2 or erbium:YAG (Er:YAG) laser ablates a fraction of both the epidermis and dermis allowing rapid re-epithelialization with a favorable side-effect profile. Pedicles of thermally induced dermal coagulation extend to far greater depths than those delivered by nonablative fractional devices, thereby inducing greater tissue contraction and neocollagenesis. Due to

the less invasive nature of AFR, nonfacial areas such as the neck, chest, and dorsal hands can be safely treated. In addition, the fractional characteristics of treatment reduces recovery time, postoperative discomfort, side effects, and complications associated with traditional multipass ablative LSR.[43]

PATIENT SELECTION

The ideal patient for ablative cutaneous laser resurfacing has a fair complexion [skin phototype (SPT) I or II], rhytides, other signs of photodamage, or atrophic scars that are amenable to treatment, and realistic expectations of the treatment.[3] Adequate preoperative patient evaluation and education are essential to optimize the clinical outcome (Table 251-1). Proper patient selection is paramount because ablative LSR can be complicated by a prolonged postoperative recovery, pigmentary alterations, or unexpected scarring. The patient's emotional ability to tolerate an extended convalescence is an important factor in determining the most appropriate choice of laser. Although CO_2 or modulated Er:YAG LSR produces the most dramatic clinical results, some patients may be unable to tolerate the intensive recovery period that is required. For patients who acquiesce to a moderate amount of recovery, AFR may be a more appropriate choice as intense erythema and serosanguinous drainage are evident for 2–3 days, followed by complete reepithialization and diminution of erythema by day 6 or 7 compared to fully ablative LSR in which re-epithelialization and intense erythema extends to 5–7 days and several weeks, respectively. For patients either unable or unwilling to tolerate more than 1 or 2 days of postoperative healing, a nonablative laser procedure may be a more suitable choice (see Chapter 252).

Currently, no consensus exists among laser experts regarding the most appropriate preoperative regimen for ablative LSR patients. The use of topical retinoic acid compounds, hydroquinone bleaching agents, or α-hydroxy acids for several weeks before ablative cutaneous resurfacing has been touted by some as a means of speeding recovery and decreasing the incidence of postinflammatory hyperpigmentation; however, others have shown that these preparations do little to affect postoperative pigmentation, in particular.[44] Topical tretinoin enhances penetration of chemicals through the skin and has been shown to accelerate postoperative re-epithelialization after dermabrasion or deep chemical peels.[45] Because ablative laser–induced wounds are intrinsically different from those created by physically destructive methods, laser skin penetration is not typically affected by the topical application of any of these medications.[46]

Due to the moist, de-epithelialized state of ablative laser–resurfaced skin and the possibility of bacterial contamination and overgrowth, many laser surgeons advocate oral antibiotic prophylaxis. This practice remains controversial, due to the findings of a controlled study that demonstrated no significant change in post–laser resurfacing infection rate in patients treated with prophylactic antibiotics.[47]

EQUIPMENT

CARBON DIOXIDE LASER. The first system developed for cutaneous laser resurfacing was the CO_2 laser, which was approved by the US Food and Drug Administration (FDA) in 1996. The earliest systems were continuous-wave CO_2 lasers, which were effective for gross lesional destruction; however, these systems could not reliably ablate fine layers of tissue

TABLE 251-1
Ablative Laser Skin Resurfacing: Patient Selection, Risks and Precautions

- Are the lesions amenable to ablative laser skin resurfacing? All suspicious lesions require biopsy before treatment.
- Has the patient ever had the areas treated before? Ablative laser resurfacing can unmask hypopigmentation or fibrosis produced by prior dermabrasion, cryosurgery, or phenol peels. Patients with prior lower blepharoplasties using an external approach are at greater risk of ectropion formation after infraorbital ablative skin resurfacing.
- What is the patient's skin phototype? Patients with lighter skin tones (skin phototype I or II) have a lower incidence of postoperative hyperpigmentation than patients with darker skin tones after ablative laser skin resurfacing.
- Does the patient have a history of herpes labialis? All patients should be treated with prophylactic antiviral medication before ablative laser skin resurfacing in the perioral region, because reactivation and/or dissemination of prior herpes simplex infection can occur. The de-epithelialized skin is also particularly susceptible to primary inoculation by herpes simplex virus.
- Does the patient have an immunologic deficiency or autoimmune disease? Intact immunologic function and collagen repair mechanisms are necessary to optimize the tissue healing response due to the prolonged recovery associated with ablative resurfacing.
- Is the patient taking any medications that are contraindicated? Concomitant isotretinoin use could potentially lead to an increased risk of postoperative hypertrophic scar formation due to its detrimental effect on wound healing and collagenesis. A safe interval between the use of oral retinoids and ablative laser skin resurfacing is difficult to determine; however, most advocate a delay in treatment for at least 6 months after discontinuation of the drug.
- Does the patient have a tendency to form hypertrophic scars or keloids? Patients with a propensity to scar will be at greater risk of scar formation after laser skin resurfacing, independent of the laser's selectivity and the operator's expertise.
- Does the patient have realistic expectations of the procedure and will he or she adhere to postoperative instructions? Those who cannot physically or emotionally tolerate the prolonged postoperative course should be dissuaded from pursuing ablative laser skin resurfacing procedures.

because of their prolonged tissue-dwell times which were responsible for unacceptably high rates of scarring and dyspigmentation.[48–52] With the subsequent development of high-energy pulsed lasers, it became possible to safely apply higher energy densities with exposure times that were shorter than the thermal relaxation time of water-containing tissue, thereby lowering the risk of thermal injury to surrounding nontargeted tissue.[3,4,53]

Two of the first high-energy pulsed-laser systems developed were the Ultra-Pulse 5,000 and SilkTouch lasers (Lumenis Corp., Yokeam, Israel). The UltraPulse emits individual CO_2 pulses (ranging from 600 µs to 1 ms) with peak energy densities of 500 mJ, whereas the SilkTouch is a continuous-wave CO_2 system with a microprocessor scanner that continuously moves the laser beam so that light does not dwell on any one area for more than 1 ms. The peak fluences delivered per pulse or scan range from 4–5 J/cm^2, which are the energy densities necessary for complete tissue vaporization.[5,6,50,54] Studies with these and other pulsed and scanned CO_2 laser systems have shown that after a typical skin resurfacing procedure, water-containing tissue is vaporized to a depth of approximately 20–60 µm, which produces a zone of thermal damage ranging from 20–150 µm.[6,50,55–57]

ERBIUM:YTTRIUM-ALUMINUM-GARNET LASER. The short-pulsed Er:YAG laser was introduced as an alternative to the CO_2 laser for skin resurfacing in an attempt to minimize the recovery period and limit side effects while maintaining clinical benefit. The Er:YAG laser is a more precise ablative tool than is the CO_2 laser and emits 2,940-nm light that corresponds to the 3,000-nm absorption peak of water. The absorption coefficient of Er:YAG light is 12,800 cm^{-1} (compared with 800 cm^{-1} for that of the CO_2 laser), which makes it 12–18 times more efficiently absorbed by water-containing tissue than CO_2 laser energy.[58] The pulse duration (mean, 250 µs) is also much shorter than that of the CO_2 laser, thereby resulting in decreased thermal diffusion, less effective hemostasis, and increased intraoperative bleeding that often hampers deeper dermal treatment. In addition, because of limited thermal skin injury, the amount of collagen contraction is also reduced with Er:YAG treatment compared with that observed to CO_2 laser irradiation.[5,59]

The Er:YAG laser's efficient rate of absorption, short exposure duration, and direct relationship between fluence delivered and amount of tissue ablated leads to 2–4 µm of tissue vaporization per Joule per square centimeter, which produces a shallow level of tissue ablation. Much narrower zones of thermal necrosis, averaging only 20–50 µm, are therefore produced.[58,60–62]

Conditions amenable to short-pulsed Er:YAG laser resurfacing include superficial epidermal or dermal lesions, mild photodamage, and subtle dyspigmentation. The major advantage of short-pulsed Er:YAG laser treatment is the shorter recovery period after therapy. Re-epithelialization is completed within an average of 5.5 days, compared with 8.5 days for multipass CO_2 procedures.[60–62] Postoperative pain and duration of erythema are reduced after short-pulsed Er:YAG laser resurfacing, with postoperative erythema resolving within 3–4 weeks. Because there is less thermal injury and trauma to the skin, the risk of pigmentary disturbance is also decreased, which makes the short-pulsed Er:YAG laser a good alternative in treating patients with darker skin phototypes.[3,63] The major disadvantages of the short-pulsed Er:YAG laser are its limited ability to effect significant collagen shrinkage and its failure to induce new and continued collagen formation postoperatively.[3,60,64] Because of this, the final clinical result is often less impressive than that produced by CO_2 laser skin resurfacing for deeper rhytides.

Through the natural progression of technology, modulated Er:YAG lasers systems were developed to improve hemostasis and increase the amount of collagen remodeling produced.[65] The Er:YAG–CO_2 hybrid laser system delivers both ablative Er:YAG and coagulative CO_2 laser pulses. The Er:YAG component generates fluences of up to 28 J/cm^2 with a 350-µs pulse duration, and excellent hemostasis is provided by the CO_2 component, which can be programed to deliver 1- to 100-ms pulses at 1–10 W of power. Zones of thermal necrosis measuring as much as 50 µm have been observed depending on the treatment parameters used, and significant increase in collagen thickness has been noted 3 months after four passes with a device using this hybrid technology.[66] Another modulated Er:YAG device is a dual-mode Er:YAG laser that emits a combination of short (200- to 300-µs) pulses and long coagulative pulses to achieve tissue ablation depths of up to 200 µm per pass.[65,66] The desired depth of ablation and coagulation can be programed through a touch-screen control panel. Several investigators have studied the histologic effects of dual-mode Er:YAG laser resurfacing and found a close correlation between the programed and actual measured depths of ablation.[67,68] The actual zones of thermal injury correlate well with the first-pass parameters, with decreasing coagulative efficiency on subsequent passes. The variable-pulsed Er:YAG laser system delivers pulse durations ranging from 500 µs to 10 ms. Shorter pulse durations are used for tissue ablation and longer pulses are used to effect coagulation and zones of thermal injury as with the CO_2 laser.[69–71]

ABLATIVE FRACTIONAL LASERS

Since the introduction of the first fractional laser in 2004, numerous devices have been developed to apply the concept of fractional photothermolysis.[72] Initially, ablative fractional treatments were simply traditional CO_2 or Er:YAG lasers with software modifications to deliver smaller spot sizes and lower density scans. With advances in technology, there are currently a wide range of fractional ablative lasers that incorporate either a 10,600-nm CO_2, 2,940-nm Er:YAG or 2,790-nm yttrium scandium-gallium-garnet (YSGG) wavelength. Differences in depth of ablation and coagulation, variation in available spot size and shape, application of energy (stamped vs. rolling), and ergonomics of the handpiece distinguish one laser from the other. Little difference in overall clinical improvement has been demonstrated using several different fractional ablative resurfacing lasers[73]; however, further investigation is necessary to

elucidate the most appropriate treatment parameters and subsequently maximize clinical outcomes for each individual device.

ANESTHESIA

Most ablative laser resurfacing is performed as an outpatient procedure in an ambulatory surgery facility. Regional laser skin resurfacing (perioral or periorbital) can be performed with local anesthesia with no additional analgesia. Full-face LSR often requires additional analgesia, including one or more of the following: oral sedation, nerve blocks, tumescent anesthesia, topical anesthetic creams, and intravenous (IV) sedation. Topical anesthesia protocols have been outlined using either lidocaine cream application for several hours before LSR to enhance tissue hydration and anesthetic penetration[74] or a cream-based formulation that dries to a flexible membrane, which is peeled away from the skin before laser irradiation.[75]

Despite their obvious advantages, these topical regimens are frequently more time consuming and less uniformly effective. For this reason, deeper forms of anesthesia for full-face ablative laser procedures is often used, including regional nerve blockade and IV sedation to provide more complete anxiolysis, amnesia, and sedation.[76] If IV sedation or general anesthesia is used, special precautions must be taken in the presence of oxygen. High-powered lasers have been reported to be the source of operating room fires, so care must be taken to eliminate exposure to flammable objects. A smoke evacuator also must be used to avoid inhalation of the laser plume.

TECHNIQUE

CARBON DIOXIDE LASER SKIN RESURFACING.

The objective of ablative LSR is to vaporize tissue to the level of the papillary dermis. Limiting the depth of penetration decreases the risk of scarring and permanent pigmentary alteration. When choosing treatment parameters, several factors should be given consideration, including anatomic site to be resurfaced, the skin phototype of the patient, and previous skin treatments delivered.[5,77] In general, thinner skin (e.g., periorbital) requires fewer laser passes and laser resurfacing of nonfacial skin (e.g., neck, chest) should be avoided due to the relative paucity of pilosebaceous units in these areas.[77] To reduce the risk of excessive thermal injury during multipass procedures, partially desiccated tissue should be removed manually with wet gauze after each laser pass to expose the underlying dermis.[78]

The depth of ablation is directly correlated with the number of passes performed and usually is restricted to the epidermis and upper papillary dermis.[79] However, stacking laser pulses by treating an area with multiple passes in rapid succession or by using a high-overlap setting on a scanning device leads to excessive thermal injury to the skin with subsequent increased risk of scarring.[7,78] An ablative plateau is reached which results in less effective tissue ablation and increased tissue heating. This effect is most likely caused by reduced tissue water content after initial desiccation, thereby diminishing selective energy absorption.[78] The avoidance of pulse stacking and incomplete removal of partially desiccated tissue is paramount to prevention of excessive thermal accumulation with the use of any laser system.

In an attempt to address many of the difficulties associated with multipass CO_2 LSR, refinements in surgical technique have been developed. A minimally traumatic single-pass CO_2 laser resurfacing procedure has been described that results in faster re-epithelialization and a more improved side effect profile than have been reported with the multiple-pass technique.[80] Partially desiccated tissue is not removed (as is standard with multipass procedures); rather, the lased skin is left intact to serve as a biologic wound dressing. Additional laser passes can then be applied focally only in areas of more extensive involvement to limit unnecessary thermal and mechanical trauma to less involved skin. Subsequent reports have substantiated the improved side effect profile of this less aggressive procedure.[81–83]

ERBIUM:YTTRIUM-ALUMINUM-GARNET LASER SKIN RESURFACING.

The short-pulsed Er:YAG laser fluences used most often range from 5–15 J/cm^2, depending on the degree of photodamage and anatomic location. On irradiation, laser-induced ejection of desiccated tissue from the target site produces a distinctive popping sound. Thermal energy is confined to the selected tissue, with minimal collateral thermal damage. Because little tissue necrosis is produced with each pass of the laser, manual removal of desiccated tissue is often unnecessary. The ablation depth with the short-pulsed Er:YAG laser does not diminish with successive passes because the amount of thermal necrosis is nominal. It takes three to four times as many passes with the short-pulsed Er:YAG laser to achieve similar depths of penetration as with one pass of the CO_2 laser at typical treatment parameter settings.[3,5] To ablate the entire epidermis with the short-pulsed Er:YAG laser using a fluence of 5 J/cm^2, at least two or three passes must be performed, which increases the possibility of uneven tissue penetration. Treatment of deeper dermal lesions or areas of the face with extensive photodamage and dermal elastosis may require up to 9 or 10 passes of the short-pulsed Er:YAG laser, whereas the CO_2 laser would effect similar levels of tissue ablation in 2 or 3 passes.[6,50,58]

Pinpoint bleeding caused by inadequate hemostasis and tissue color change after multiple short-pulse Er:YAG passes can impede adequate clinical assessment of wound depth. Irradiated areas whiten immediately after treatment and then quickly fade. These factors render it more difficult to determine treatment endpoints and, thus, require extensive knowledge of laser-tissue interaction on the part of the operator. Modified Er:YAG ablative laser resurfacing provides better hemostasis and visualization of the treatment area because of the added thermal effects on the tissue.[84]

ABLATIVE FRACTIONAL RESURFACING

After appropriate informed consent, eye protection, and sedation are employed, ablative fractional laser skin resurfacing is best performed in a sequential fashion adhering to cosmetic units. Meticulous technique with placement of nonoverlapping rows will minimize bulk heating during treatment. Additional passes are delivered perpendicular to the previous pass until a desired number of passes has been reached. Optimal settings will vary depending upon the laser device used and the severity of the condition being treated. Average settings for a common fractional CO_2 laser (*Repair*, Solta Medical Inc., Hayward, CA) range 40–70 mJ with a coverage density of 30% to 50%. Treatment of the periocular and neck skin require a decrease in both fluence and coverage density. Although patient satisfaction and clinical results may improve with the use of higher fluences, increased adverse events such as pain, erythema, and postoperative dyspigmentation are more often observed when higher treatment densities are applied.[85] Ablative fractional lasers generally require only one treatment to achieve patient satisfaction; however, reappraisal of photodamage, rhytides, or scarring can be performed 6–12 months postoperatively to assess if additional treatments are clinically warranted.

OUTCOMES ASSESSMENT

The clinical and histologic benefits of cutaneous laser resurfacing are numerous. With the CO_2 laser, most studies have shown at least a 50% improvement over baseline in overall skin tone and wrinkle severity (Fig. 251-1).[4,86–90] The greatest advantages associated with CO_2 laser skin resurfacing are the excellent tissue contraction, hemostasis, prolonged neocollagenesis, and collagen remodeling that result. Histologic examination of laser-treated skin demonstrates replacement of epidermal cellular atypia and dysplasia with normal, healthy epidermal cells from adjacent follicular adnexal structures.[50,56] The most profound effects occur in the papillary dermis, where coagulation of disorganized masses of actinically induced elastotic material are replaced with normal compact collagen bundles arranged in parallel to the skin's surface.[91,92] Immediately after CO_2 laser treatment, a normal inflammatory response is initiated, with granulation tissue formation, neovascularization, and increased production of macrophages and fibroblasts.[56]

Persistent collagen shrinkage and dermal remodeling are responsible for much of the continued clinical benefits observed after CO_2 laser resurfacing and are influenced by several factors.[92,93] Thermal effects of laser irradiation of skin produce collagen fiber contraction at temperatures ranging from 55°C–62°C (131°F–143.6°F) through disruption of interpeptide bonds, which results in a conformational change to the collagen's basic triple-helical structure.[94,95] The collagen molecule is thereby shortened to approximately one-third of its normal length. Collagen fibers with laser-induced shrinkage may act as the contracted scaffold for neocollagenesis, which leads to subsequent production of the newly shortened form. In turn, fibroblasts that migrate into laser wounds after resurfacing may upregulate the expression of immune-modulating factors that serve to enhance continued collagen shrinkage.[96]

Because modulated Er:YAG lasers were developed to produce a greater thermal effect and tissue contraction than did their short-pulsed predecessors, investigators compared collagen tightening induced by the CO_2 laser with that of the CO_2–Er:YAG hybrid laser system.[69] Intraoperative contraction of approximately 43% was produced after three passes of the CO_2 laser, compared with 12% contraction after Er:YAG irradiation. At 4 weeks; however, the CO_2 laser– and Er:YAG laser–treated sites were contracted to the same degree which highlights the different mechanisms of tissue tightening observed after laser treatment. Immediate

Figure 251-1 Facial photodamage and rhytides before (**A**) and several months after (**B**) ablative CO_2 laser skin resurfacing.

Figure 251-2 Facial photodamage and rhytides before (**A**) and 6 months after (**B**) fractional ablative CO_2 laser skin resurfacing.

thermal-induced collagen tightening was the predominant response seen after CO_2 irradiation, whereas modulated Er:YAG laser resurfacing did not produce immediate intraoperative contraction, but instead induced slow collagen tightening.[65,69]

Fractional ablative lasers have been used to successfully treat facial and nonfacial photodamage and a variety of scars, including atrophic, hypertrophic, hypopigmented, and traumatic scars.[43,73,97–100] (Figs. 251-2 and 251-3) Improvement in post-CO_2 laser-induced hypopigmentation, residua from infantile hemangioma, and actinic cheilitis has also been reported.[42,43] Others suggest a supportive role for fractional ablative lasers during Q-switched laser tattoo removal.[101]

Clinical improvement of photodamage and rhytides following AFR has been demonstrated in several published studies. A 2,940-nm Er:YAG fractional device was used to treat 28 patients with photodamaged skin. Two months after a single treatment, 75% of patients rated the results as good to excellent with improvement lasting 6–9 months.[102] Another study using a fractional CO_2 laser on 32 patients demonstrated more than 50% improvement in wrinkles, epidermal pigment, and solar elastosis 6 months after one treatment session.[97] In a pilot study of 12 patients, 51% to 75% improvement of photodamage and acne scars after two successive fractional CO_2 laser treatments was reported.[103]

Ablative fractional laser skin resurfacing has been used to improve skin topography in both atrophic and hypertrophic scars. In a study of 15 patients with SPT I-IV and moderate-to-severe atrophic scarring, an average of 66.8% improvement in scar depth after 2–3 fractional CO_2 laser treatments was achieved.[98] Good clinical improvement in 23 of 25 subjects with moderate-to-severe atrophic scarring who received up to 3 treatments with a fractional CO_2 laser was demonstrated in yet another published report.[99] Sustained improvement of atrophic scars and an overall improvement of clinical appearance including pigmentation and rhytides was noted. Quantitative volumetric improvement of nonacne atrophic traumatic or surgical scars has also been reported. Twenty-two atrophic scars received three fractional CO_2 laser treatments with image analysis at 6 months demonstrating clinical and volumetric improvement as evidenced by

Figure 251-3 Atrophic scars before **(A)** and 6 months after (**B**) fractional ablative CO_2 laser skin resurfacing.

mean reduction of scar volume and depth by 38% and 36%, respectively.[100]

SIDE EFFECTS AND COMPLICATIONS

Side effects associated with CO_2 laser skin resurfacing vary and are related to the expertise of the operator, the body area treated, and the skin phototype of the patient (Table 251-2). Certain tissue reactions, such as erythema and edema, are expected in the immediate postoperative period and are not considered adverse events. Erythema can be intense and may persist for several months after the procedure. The degree of erythema correlates directly with the depth of ablation and the number of laser passes performed.[3,104] It may also be aggravated by underlying rosacea or dermatitis. Postoperative erythema resolves spontaneously but can be reduced with the application of topical ascorbic acid, which may serve to decrease the degree of inflammation.[105,106] It should not be used for at least 4 weeks after the procedure to avoid irritation. Likewise, other topical agents such as retinoic acid derivatives, glycolic acid, fragrance- or chemical-containing cosmetics, and sunscreens should be strictly avoided in the early postoperative period until substantial healing has occurred.[104]

Mild side effects of LSR include milia formation and acne exacerbation, which may be caused by the postoperative use of occlusive dressings and ointments particularly in patients who are acne prone.[7,77,104,107] Milia and acne usually resolve spontaneously as healing progresses and the application of thick emollient creams and occlusive dressings ceases. Oral antibiotics may be prescribed for acne flares that do not respond to topical preparations.[90,104,107] Contact dermatitis, either irritant or allergic, can also develop from various topical medications, soaps, and moisturizers used postoperatively. Most of these reactions are irritant in nature due to decreased barrier function of the newly resurfaced skin.[104,108]

TABLE 251-2
Side Effects and Complications of Ablative Laser Skin Resurfacing

- Expected side effects
  - Erythema
  - Edema
  - Pruritus
- Complications
  - Mild
    - Prolonged erythema
    - Milia
    - Acne
    - Contact dermatitis
  - Moderate
    - Infection (bacterial, viral, fungal)
    - Dyspigmentation
  - Severe
    - Hypopigmentation
    - Hypertrophic scarring
    - Ectropion

Wound infections associated with ablative laser resurfacing include *Staphylococcus* and *Pseudomonas* infections and cutaneous candidiasis and should be treated aggressively with an appropriate systemic antibiotic or antifungal agent.[109] The most common infectious complication is a reactivation of labial herpes simplex virus (HSV) infection, most likely caused by thermal tissue injury and epidermal disruption produced by the laser.[7,104] All patients undergoing full-face or perioral ablative resurfacing should receive antiviral prophylaxis even if they report no history of HSV infection. After CO_2 resurfacing, approximately 7% of patients develop a localized or disseminated form of HSV infection.[104] These infections develop within the first postoperative week and can present as erosions without intact vesicles because of the denuded condition of newly lased skin. Even with appropriate prophylaxis, a herpetic outbreak can occur in upward of 10% of patients and must be treated aggressively.[5] Oral antiviral agents such as acyclovir, famciclovir, and valacyclovir are effective agents against HSV infection, although IV therapy may be required in severe (disseminated) cases. Patients should begin prophylaxis by the day of surgery and continue it for 7–10 days postoperatively.[8]

Hyperpigmentation is one of the more common side effects of cutaneous laser resurfacing and occurs to some degree in all patients with darker skin tones.[96,109] The reaction is transient, but its resolution can be hastened with the postoperative use of a variety of topical agents, including hydroquinone and retinoic, azelaic, kojic, and glycolic acid. Regular sunscreen use is also important during the healing process to prevent further skin darkening. Postoperative hypopigmentation is often not observed for several months and is particularly difficult because of its tendency to be intractable to treatment. The use of an excimer laser or topical photochemotherapy to stimulate repigmentation has proven successful in some patients.[110,111] Others report improvement of hypopigmentation after the use of a nonablative, 1,550-nm fractional resurfacing laser.[112]

The most severe complications associated with ablative cutaneous laser resurfacing are hypertrophic scars and ectropion formation.[79,96] Although the risk of scarring has been significantly reduced with the newer pulsed systems, inadvertent pulse stacking or scan overlapping as well as incomplete removal of desiccated tissue between laser passes can cause excessive thermal injury that could increase the development of fibrosis. Focal areas of bright erythema with pruritus, particularly along the mandible, may signal impending scar formation.[8,38] Potent topical corticosteroid preparations should be applied to decrease the inflammatory response. A pulsed dye laser also can be used to improve the appearance and symptoms of laser-induced burn scars.[113]

Ectropion of the lower eyelid after periorbital laser skin resurfacing is rarely seen but, if encountered, usually requires surgical correction.[77] It is more likely to occur in patients who have had previous lower blepharoplasty or other surgical manipulation of the periorbital region. Preoperative examination is essential to determine eyelid laxity and skin elasticity. If the

infraorbital skin does not return briskly to its normal resting position after a manual downward pull (snap test), then ablative laser resurfacing near the lower eyelid margin should be avoided. In general, lower fluences and fewer laser passes should be applied in the periorbital area to decrease the risk of lid eversion.

Side effects and complications after Er:YAG laser resurfacing are similar to those observed after CO_2 laser skin resurfacing, but they differ in duration, incidence, and severity.[114,115] Although greater postoperative erythema is seen after modulated Er:YAG laser treatment than is usually produced with a short-pulsed Er:YAG system, the side effect profile and recovery period after modulated Er:YAG laser skin resurfacing remain more favorable than after multipass CO_2 laser treatment. In an extended evaluation of 50 patients, investigators reported complete re-epithelialization in an average of 5 days after dual-mode Er:YAG laser skin resurfacing, with only three patients experiencing prolonged erythema beyond 4 weeks.[66] In a split-face comparison of 16 patients after pulsed CO_2 and variable-pulsed Er:YAG laser skin resurfacing, other investigators reported decreased erythema, less edema, and faster healing on the Er:YAG laser–treated facial half.[71]

Postinflammatory hyperpigmentation is not uncommon after any cutaneous laser resurfacing procedure. Although hyperpigmentation after modulated Er:YAG laser skin resurfacing (mean duration, 10.4 weeks) can last longer than after treatment with a short-pulsed Er:YAG laser, it is not as persistent as that observed after multiple-pass CO_2 laser resurfacing (mean duration, 16 weeks).[66] However, when the most current ablative LSR techniques are compared (single-pass CO_2 versus multiple-pass, long-pulsed Er:YAG), postoperative healing times and complication profiles are comparable, even in patients with darker skin phototypes. In a retrospective review and analysis of 100 consecutively treated patients, investigators found that average time to re-epithelialization was 5.5 days with single-pass CO_2 and 5.1 days with long-pulsed Er:YAG laser resurfacing.[83] Postoperative erythema was observed in all patients, lasting an averaging 4.5 weeks after single-pass CO_2 and 3.6 weeks after long-pulsed Er:YAG laser treatment. Hyperpigmentation was seen in 46% of patients treated with a single pass of the CO_2 laser and 42% of patients treated with the long-pulsed Er:YAG laser (average duration, 12.7 weeks and 11.4 weeks, respectively).

The main advantage of ablative fractional lasers when compared with fully ablative LSR techniques is the excellent side effect profile and low incidence of complications.[7,9,43,104] Postoperative recovery is more favorable and predictable after AFR treatment with pinpoint bleeding and serosanguinous discharge resolved within 24–48 hours. Intense erythema and crusting are typical for 3–6 days postoperatively. Moderate erythema lasts days to weeks which stands in sharp contradistinction to the months of erythema often experienced with traditional multipass ablative laser skin resurfacing. The intensity and duration of erythema may be slower to resolve in patients with SPT I-II and those receiving more aggressive AFR treatments. Particular care must be taken in anatomic sites with a relative paucity of pilosebaceous units such as the eyelids, neck, and chest as excessive thermal injury with subsequent hypertrophic scarring has been reported. With proper technique; however, excellent clinical results can be achieved with an exceedingly low risk of scarring and hypopigmentation.[43]

POSTOPERATIVE CARE AND PATIENT INSTRUCTIONS

Proper wound care during the immediate postoperative period is vital to the successful recovery of ablative laser–resurfaced skin. During the re-epithelialization process, an open or closed wound treatment technique can be prescribed. Partial-thickness cutaneous wounds heal more efficiently and with a reduced risk of scarring when maintained in a moist environment because the presence of a dry crust or scab impedes keratinocyte migration.[116] Although there is consensus on this principle among laser surgeons, disagreement exists regarding the optimal dressing for the laser-ablated wound. The "open" technique involves frequent application of thick healing ointment to the de-epithelialized skin surface, whereas occlusive or semiocclusive dressings are placed directly on the lased skin in the "closed" technique. Although the open technique facilitates wound visualization, the closed technique requires less patient involvement and may also decrease postoperative pain. Proposed advantages of closed dressings include increased patient comfort, decreased erythema and edema, increased rate of re-epithelialization, and decreased patient involvement in wound management[116,117] however, additional expense and a higher risk of infection have been associated with their use.[107,109]

In addition to postoperative wound care, ice pack application and the administration of anti-inflammatory medications should be prescribed. Furthermore, pain medication during the first few postoperative days is particularly important for patients undergoing fully ablative laser skin resurfacing. Although pinpoint bleeding, serosanguinous drainage, and edema can be significant during the first 24–36 hours after AFR, minimal (if any) discomfort is present.

CHEMICAL PEEL

The controlled application of one or more exfoliating agents to the skin is a highly efficient and versatile way to improve photodamaged skin. Chemical peels create a more compact stratum corneum associated with a

TABLE 251-3
Chemical Peel Classification

Type	Depth of Penetration
Superficial	Epidermis to upper papillary dermis
Medium	Papillary dermis to upper reticular dermis
Deep	Midreticular dermis

- 70% Glycolic acid and 35% TCA
- 88% Phenol

thicker epidermis and more uniform distribution of melanin.[118] The level of injury and the depth of penetration into the skin determine the classification as a superficial, medium, or deep chemical peel (Table 251-3). Although superficial peeling agents aimed at removing all or part of the epidermis are useful for superficial dyspigmentation, acne, and solar lentigines, they have minimal effect on rhytides and require multiple treatments for the best clinical results (Table 251-4). More complete skin rejuvenation requires the application of a medium or deep chemoexfoliant.[118,119]

MEDIUM-DEPTH PEELS

Medium-depth chemical peels are defined as those causing injury to the skin at or through the papillary dermis (Table 251-5).[118–121] Trichloroacetic acid (TCA) at concentrations of 35%–50% is the classic agent in this category. Because 50% TCA may produce an unpredictable response with subsequent hypopigmentation and scarring, the combination of a superficial peeling agent such as Jessner solution or glycolic acid before the application of 35% TCA is advocated to achieve more consistent results with an increased margin of safety (Fig. 251-4).[122–125]

The Jessner solution–TCA peel is performed after thorough cleansing of the treatment area with soap followed by degreasing with an alcohol and acetone solution. Jessner solution (Table 251-6) is applied in one or two coats to achieve a pale, uniform frost. The TCA is then applied evenly over the skin surface. Those portions of the face with a high concentration of sebaceous glands (T-zone) may receive additional acid in a second application. The observed white frost indicates protein denaturation of keratin and completion of the chemical peel reaction. Cool water compresses and emollient creams are then applied for symptomatic relief. Postoperatively, erythema, edema, and desquamation are expected, with increased severity of side effects noted at the higher acid concentrations and greater number of applications.

DEEP CHEMICAL PEELS

Phenol is a keratocoagulant that is the only deep peeling agent widely used. Application of phenol, as described by Baker and Gordon in the 1960s, causes wounding that penetrates to the midreticular dermis.[126–128] Baker-Gordon formula (Table 251-7) should be freshly prepared and stirred continuously before and during the procedure to ensure even application of the solution. For a full-face phenol peel, regional nerve blocks in combination with analgesics such as propofol (Diprivan) and anxiolytics such as midazolam can be used. Because phenol is partially detoxified in the liver and excreted by the kidney, hydration with lactated

Figure 251-4 Facial dyspigmentation before (**A**) and 6 months after (**B**) treatment with a 30% trichloroacetic acid peel.

TABLE 251-6
Jessner Solution

- Lactic acid 14 g
- Salicylic acid 14 g
- Resorcinol 14 g
- Ethanol 95% in quantity sufficient to yield 100 mL

Ringer solution before and during the treatment is warranted to limit toxicity. Furthermore, because phenol is cardiotoxic, close patient monitoring is necessary during and after the procedure.[129]

After degreasing the skin with hexachlorophene (Septisol), fresh Baker solution is applied systematically over aesthetic units using cotton-tipped applicators. Sufficient time (10–15 minutes) should elapse between treatment of different regions in order to minimize excessive absorption which can lead to systemic toxicity. The solution can be feathered beyond the margins of the treated areas to reduce the line of demarcation between treated and untreated skin.

Postoperatively, an open wound care technique has been favored over a closed dressing due to the lower risk of infection and scarring and speedier re-epithelialization.[129] Petrolatum is applied liberally to the wound until re-epithelialization is complete, usually within 7–10 days.

SIDE EFFECTS AND COMPLICATIONS

The risk of side effects and complications (Table 251-8) increases proportionately with the depth of the chemical peeling agent. Superficial peels are associated with the lowest risk of adverse reactions, whereas medium-depth peels can cause dyspigmentation and, rarely, scarring. Phenol peels are further associated with hepatic, renal, and cardiac toxicity.[129]

DERMABRASION

Modern techniques for dermabrasion were initially described by Paul Kurtin in 1953.[130] Dermabrasion involves the mechanical removal of the epidermis and dermis in a controlled fashion. Indications for treatment include rhytides, facial scars, rhinophyma, epidermal nevi, syringoma, and many other benign skin conditions.[131–134] Dermabrasion is highly operator dependent and the practitioner must have extensive knowledge and experience to obtain excellent results while maintaining high levels of safety. The use of dermabrasion, except for spot treatment of specific lesions or scars, has been largely supplanted by treatment with a variety of ablative lasers.

Before dermabrasion is performed, a thorough patient consultation and evaluation is necessary to identify abnormal scarring tendency, prior treatments to the area, drug allergies, clotting or pigmentary disorders, and koebnerizing skin conditions. Preoperative antiviral prophylaxis is warranted for perioral or full-face procedures.[132,133] Although isotretinoin use within 6–12 months is traditionally considered an absolute contraindication to dermabrasion.[135] Bagatin et al described normal re-epithelialization with no evidence of abnormal wound healing in 7 patients on concomitant isotretinoin who received dermabrasion on a small test area.[136] The recommendation to delay dermabrasion for 6–12 months after oral isotretinoin use is, thus, in question.

Dermabrasion is performed using a wire brush or diamond fraise powered by a hand engine.[131–134] Fraises are available in multiple sizes, shapes, and degrees of coarseness. Pear-shaped fraises and cones are most often used around the nose and oral commissure, whereas wheels are used over flat, broad skin surfaces.[133] In general, diamond fraises offer a greater margin of safety than does the wire brush type, which removes a greater amount of tissue (Fig. 251-5).

The form of anesthesia used for dermabrasion varies depending on the surgeon, the area to be dermabraded, the desired depth of treatment, and the patient's pain tolerance. The use of liquid refrigerants can be problematic because of their potential for excessive skin injury; however, cryoanesthesia has the advantage of providing a firm surface on which to treat. Tumescent anesthesia with 0.05%–0.1% lidocaine solution (with or without the concomitant use of nerve blocks and oral anxiolytics) is an effective form of anesthesia for full-face dermabrasion. A volume of 250–350 mL is typically adequate for the full face.[133]

Dermabrasion is performed in the operating room under strict universal precautions due to the risk of aerosolization of viral particles. The area to be dermabraded is stabilized manually without distortion of the normal skin contour. Some operators use an aerosol refrigerant to stiffen the skin surface to enhance depth control. The device is pulled rather than pushed over

Figure 251-5 **A.** Perioral rhytides before wire brush dermabrasion. **B.** Improved perioral rhytides 6 months after the procedure.

the cutaneous surface, which itself is positioned parallel to the floor. The dermabrasion is performed to the desired depth by closely monitoring the skin surface appearance. Decreased skin pigmentation is observed on epidermal removal, followed by punctate, pinpoint bleeding when the papillary dermis has been reached. The level of the reticular dermis is signaled by a whitish yellow appearance with fewer blood vessels. The goal of dermabrasion is to penetrate to the level of the dermis while avoiding the lower dermis and subcutaneous layer to reduce the risk of scarring. Feathering at the margins of the treatment area can soften the transition between treated and untreated skin.

On completion of a full-face dermabrasion, a dilute lidocaine and epinephrine solution can be used topically to soothe the treated area and improve hemostasis. The use of various biologic and nonbiologic sterile dressings has been advocated, but the choice is determined by the preference of the surgeon.[137] Depending on the total area and depth of dermabrasion, re-epithelialization is typically complete within 7–10 days. Meticulous wound care and close observation during the period of re-epithelialization permits the early detection of and intervention for such potential complications as herpetic, bacterial, and fungal infections. Side effects and complications after dermabrasion are similar to those seen after an ablative laser skin resurfacing procedure (see Table 251-2); however, the incidence of permanent hypopigmentation is markedly higher after dermabrasion (20%–30%) than after ablative laser treatment.

Chapter 252 :: Cosmetic Applications of Nonablative Lasers and Other Light Devices

:: Elliot T. Weiss, Anne M. Chapas, & Roy G. Geronemus

COSMETIC APPLICATIONS OF NONABLATIVE LASERS AND OTHER LIGHT DEVICES AT A GLANCE

- A wide range of lasers and other light devices can be used to treat skin problems of cosmetic concern.
- Photorejuvenation can be achieved with nonablative devices and fractional nonablative devices.
- Vascular and pigmented lesions benefit from treatment with lasers capable of selective photothermolysis.
- Patient selection and patient expectation are critical for optimum outcome.
- All safety precautions must be followed during treatment.

Over the last 40 years, the explosive advancement of laser technology has revolutionized the treatment of numerous skin conditions. The principle of selective photothermolysis set forth in 1983 by Anderson and Parrish[1] has formed the basis for the development of lasers that selectively target and destroy tissues containing water, hemoglobin, and pigment. Lasers exhibiting such selective action were first applied to improve various potentially disfiguring medical conditions such as port-wine stains, hemangiomas, and pigmented birthmarks. More recently, these same principles have been implemented in an effort to improve the cosmetic appearance of normal and aging skin. The principle of fractional photothermolysis (FP) set fort by Manstein and Anderson[2] has further revolutionized nonablative and ablative resurfacing by improving safety and shortening patient recovery times. Because laser treatments target all aspects of photoaging, from ameliorating the appearance of fine and deep rhytides to softening skin texture and improving pigmentation and skin laxity, they are becoming an indispensable tool in the armamentarium of the cosmetic dermatologist. A thorough understanding of the benefits and limitations of each laser technique and the expectations and lifestyle of the individual patient allow the practitioner to achieve the most satisfying cosmetic results.

NONABLATIVE SKIN REJUVENATION

Skin rejuvenation by laser was originally performed with devices that resulted in the destruction or ablation of the epidermis and elements of the dermis. The demand for less invasive procedures with shorter recovery times than those of traditional ablative laser resurfacing has led to the development of nonablative laser surgery. Many of these systems emit light in the infrared portion of the electromagnetic spectrum (1,000–1,500 nm), which is absorbed by water in deeper tissues while leaving the epidermis intact. This type of dermal wounding stimulates new collagen and elastin formation, which can improve the appearance of skin with mild-to-moderate photodamage. In general, the results are not comparable to those achieved with ablative lasers, but many patients are willing to accept more modest clinical improvements in exchange for fewer side effects and shorter recovery times. The advent of fractional nonablative laser technology has enabled the delivery of higher energy fluences to treat a fraction of the skin surface. This technology generally allows more effective and safer treatments for photoaging compared to traditional nonablative lasers.

PATIENT SELECTION

Proper patient selection is the key to successful nonablative laser resurfacing (see Chapter 251 for ablative laser procedures). Patients with realistic expectations who have mildly to moderately photodamaged skin are the best candidates for nonablative procedures. Results from nonablative laser treatments are generally gradual and progressive, with textural irregularities and pigment irregularities improving more than rhytides. Patients who seek immediate dramatic results are likely to be disappointed with the overall clinical outcome. The practitioner must distinguish and educate patients on the difference between static and dynamic rhytides. Static rhytides in general respond more favorably and completely to laser therapy whereas dynamic rhytides are best addressed with appropriate injection of available botulinum toxin preparations.

RISKS AND PRECAUTIONS

As with ablative laser resurfacing, the heat produced by nonablative systems can reactivate prior herpes simplex infections (Table 252-1). Patients with a strong history of herpes labialis should receive prophylactic oral antiviral

TABLE 252-1
Nonablative Resurfacing: Risks and Precautions

- Contraindicated in patient with prior isotretinoin treatment
- May lead to postinflammatory hyperpigmentation
- May cause reactivation of herpes simplex virus infection

medication before treatment. Although nonablative laser procedures have an extremely low risk of scarring, these risks are increased in patients who have received isotretinoin in the previous year. Therefore, these patients should not undergo nonablative resurfacing. Patients with darker skin phototypes may develop a temporary postinflammatory hyperpigmentation after nonablative laser treatment. In order to ensure a safe treatment and to minimize the risk of adverse reactions, practitioners must use appropriate energy settings and correct treatment techniques to avoid bulk heating (heat accumulation) and injury to the treatment area.

PATIENT POSITIONING

Nonablative laser resurfacing can be performed in the physician's office, with both the patient and clinical personnel wearing proper eye protection.

EQUIPMENT

Several visible-light lasers have been developed to target discrete chromophores to stimulate dermal remodeling (Table 252-2). One of the first approaches to photorejuvenation used pulsed dye lasers (PDL) emitting light at wavelengths of either 585 nm or 595 nm. The ability of PDL treatment to improve the appearance of hypertrophic scars, striae distensae, and acne scars suggests that PDL treatment stimulates new collagen formation. A small clinical study confirmed that a single treatment with a PDL (585 nm, 450 ms) induced clinical improvement in 75%–90% of mild-to-moderate rhytides and 40% of moderate-to-severe rhytides.[3] Longer-wavelength lasers such as the 1,064-nm Q-switched neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, the 1,320-nm Nd:YAG laser, the 1,450-nm diode laser, and 1,540-nm erbium:glass laser have also been shown to induce dermal remodeling. Multiple treatments are necessary at 2- to 4-week intervals. The effects are often gradual due to ongoing collagen formation, which may occur up to 6 months after the last treatment.

TABLE 252-2
Nonablative Resurfacing: Equipment

- Visible-light lasers: 585 nm, 595 nm, long-pulse 1,064-nm neodymium:yttrium-aluminum-garnet, 1320 nm, 1,450 nm, 1,540-nm, 1,550-nm erbium:glass, 1,927-nm, fractional photothermolysis
- Intense pulsed light devices
- Radiofrequency devices (monopolar, bipolar, fractionated)
- Focused ultrasound devices

Treatment with intense pulsed light (IPL) devices, which emit a broad, continuous spectrum of light from 515 nm to 1,200 nm, has been shown to successfully rejuvenate photodamaged skin. Filters can be placed over the beam to eliminate the shorter wavelengths, which target hemoglobin and melanin, depending on the clinical application. Studies have shown that IPL treatment produces substantial clinical improvement in the dyspigmentation and telangiectasias that are associated with photoaging but only mild improvement in rhytides.[4]

In contrast to visible-light lasers creating large sheets of thermal damage, the lasers used for fractional photothermolysis are mid-infrared (1,440 nm, 1,540 nm, 1,550 nm, 1,927 nm) devices that create columns of thermal injury to various depths into the dermis, similar to pixels in a digital photograph.[5] The epidermis rapidly heals around these columns of thermal damage, which stimulate progressive collagen remodeling. Treatments are generally scheduled at 3- to 4-week intervals for a total of 3 to 6 sessions. Photodamage of the face, neck, chest, and hands; acne scars (Fig. 252-1); striae distensae (Fig. 252-2); and melasma have all been shown to respond to fractional photothermolysis.

Several nonablative devices that deliver energy deep into the dermis have been shown to cause skin tightening. The direct application of infrared light, with pretreatment and post-treatment contact cooling of the skin, has been shown to heat deep collagen to the point of contraction. In appropriate patients, this contraction results in a visible tightening of redundant skin. Skin tightening can also be achieved by the use of monopolar and bipolar radiofrequency devices generating electric current, which produces heat through resistance in the dermis. Periorbital rhytides and middle and lower face laxity generally require 1 to 3 treatments at 4-week intervals, with tightening noted 1–3 months after the last treatment[6] (Fig. 252-3). A new infrared device that emits light at 1,100–1,800 nm in multisecond cycles has also been shown to induce skin contraction. Focused ultrasound has recently been incorporated into a device designed to generate dermal and subcutaneous heating with subsequent neocollagenesis in treated skin. Selective cryolipolysis is utilized by a novel noninvasive device to cool and selectively treat localized subcutaneous fat deposits.

ANESTHESIA

Nonablative laser procedures are generally more easily tolerated than ablative procedures. The degree and type of anesthesia required depends on the patient's pain tolerance and the amount of heat energy generated by the device. A topical anesthetic such as lidocaine or a eutectic mixture of lidocaine and prilocaine applied 1 hour before the procedure is usually sufficient. Forced-air cooling can also make the procedure more tolerable. Higher-energy procedures such as fractional photothermolysis occasionally require

Figure 252-1 Acne scarring treated with fractional photothermolysis. **A.** Before treatment. **B.** After treatment.

nerve blocks, oral or intramuscular analgesics, and anxiolytics.

TECHNIQUE

Nonablative visible-light laser systems require different treatment parameters depending on the skin type and condition to be treated. To protect the epidermis, all of these devices are used in conjunction with a contact cooling handpiece or cryogen spray delivered several milliseconds before the laser pulse. IPL devices are used with various filters and at different energy levels depending on the desired treatment effect. A transparent water-based gel is used to protect the epidermis. Fractional photothermolysis is performed in the presence of forced-air cooling. Various density and energy settings are used depending on the indication and clinical endpoint desired.

Finally, tightening procedures are performed by holding the handpiece in firm contact with the treated skin. Several investigators have shown that multiple passes using radiofrequency at relatively low-to-medium energies are effective and more tolerable for patients than high-energy treatments.

OUTCOMES ASSESSMENT

Because nonablative laser treatments stimulate collagen remodeling over several months, objective clinical improvements after a series of treatments may take weeks or months to be achieved. Reassurance by the physician as well as the use of pretreatment

Figure 252-2 Striae distensae treated with fractional photothermolysis. **A.** Before treatment. **B.** Three months after treatment.

photographs may help patients to better appreciate their progress. Setting realistic goals and targeting the aspects of photoaging that are important to the patient will also yield a more favorable outcome and enhance patient satisfaction.

COMPLICATIONS

Nonablative laser surgery is not without risks, but side effects are much milder than with ablative laser treatment. Depending on the treatment, patients may have erythema and edema, which resolves in hours to days. Rarely are treatments associated with blistering, transient hyperpigmentation, or scarring. In some cases, post-treatment hyperpigmentation has been caused by excessive use of cryogen spray but has resolved with topical bleaching agents. IPL treatment of tanned skin or darker skin phototypes should be used cautiously due to the increased risk of adverse events including blistering, hypopigmentation, and scarring. To avoid reactivation of latent herpes simplex virus (HSV) infections with fractional resurfacing, appropriate oral antiviral prophylaxis should be considered for all patients regardless of reported HSV status.

PATIENT INSTRUCTIONS

Because the epidermis remains intact after nonablative laser procedures, minimal postoperative care is required. Ice can be applied to decrease erythema and

swelling, and occasionally systemic glucocorticoids may be required.

TREATMENT OF VASCULAR LESIONS

A wide range of vascular lesions are amenable to safe and effective treatment by a class of lasers that take advantage of the principle of selective photothermolysis (see also Chapter 239).

PATIENT SELECTION

Vascular lesions can be a significant cosmetic concern for some patients and are generally amenable to laser treatment. Telangiectasias are small, superficial cutaneous blood vessels often appearing on the nose, cheeks, and chin in fair-skinned individuals as a result of actinic damage or rosacea. Other causes of telangiectasias include collagen vascular disease, genetic disorders, hormonal disorders, primary cutaneous disease, and radiation dermatitis. Telangiectasias are often associated with facial erythema, which can manifest as a flushing or blushing disorder. Various laser treatments can target this background erythema in addition to treating the discrete vascular lesions.

Other types of vascular lesions, including cherry and spider hemangiomas, venous lakes, and angiokeratomas, may respond to vascular laser treatment (Fig. 252-4). Poikiloderma of Civatte, which manifests as a combination of telangiectasia, irregular pigmentation, and atrophic changes in fair-skinned individuals with actinic damage, can also be treated with vascular lasers. Extreme caution must be used when treating this condition, because overly aggressive treatment can worsen the atrophy and hypopigmentation.

In addition to improving vascular lesions, vascular laser treatments can improve the appearance of hypertrophic scars and keloids. Vascular lasers not only reduce the erythema by eliminating the underlying dilated microvasculature in a scar, they can also reduce the height of the scar and improve the skin surface texture. Multiple treatment sessions are required, and the treatment can be augmented by intralesional injections of corticosteroid with 5-fluourouracil. Newly formed atrophic scars, such as striae rubra, can sometimes be greatly improved with vascular laser treatment, whereas older lesions are less responsive.

TABLE 252-3
Treatment of Vascular Lesions: Associated Risks

- Postinflammatory hyperpigmentation
- Postinflammatory hypopigmentation
- Atrophic scarring
- Hypertrophic scarring

RISKS AND PRECAUTIONS

Laser treatment of vascular lesions is relatively safe but not without risks (Table 252-3). Higher-energy treatments or treatments with overlapping passes can result in atrophic or hypertrophic scarring. Alterations in pigmentation may result due to the concomitant absorption of 532-nm light by epidermal melanin. Patients with tans or darker skin types must be treated with caution to avoid pigmentary changes.

PATIENT POSITIONING

Most cosmetic vascular laser treatments are performed in the office. The patient's eyes are protected with laser surgery goggles or with intraocular metal eye shields if treatment around the eye is required. All clinical personnel must wear laser surgery glasses that specifically absorb the wavelength of light used in the treatment. Flammable gases and other materials must not be present, because vascular lasers are capable of igniting fires.

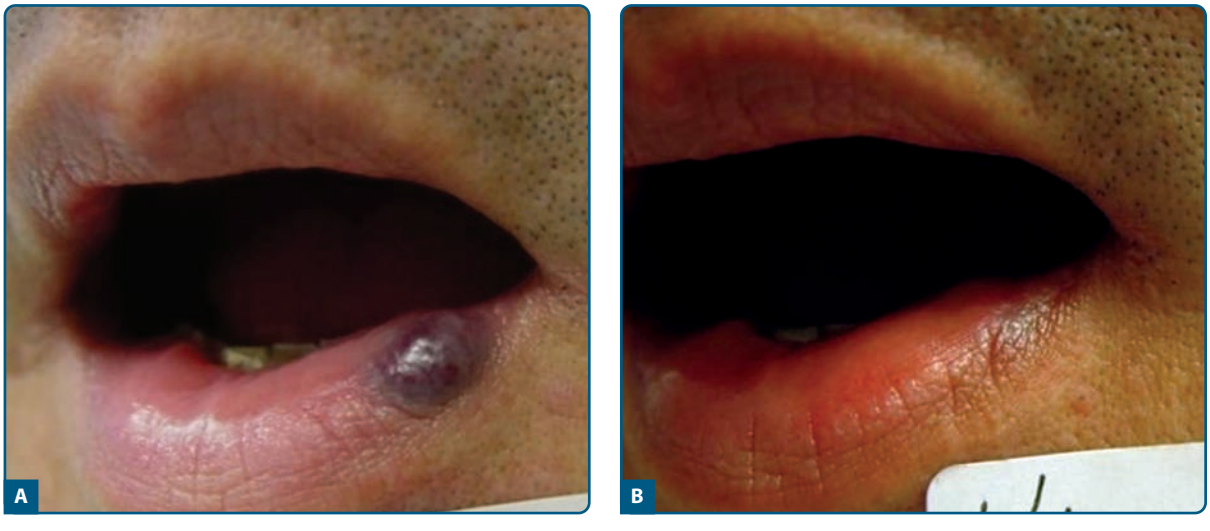

Figure 252-4 Venous lake treated with a potassium-titanyl-phosphate laser. **A.** Before treatment. **B.** After treatment.

EQUIPMENT

Vascular lesions were one of the first targets of treatment with early lasers. These early lasers, such as the argon laser (488 nm, 514 nm), argon-pumped tunable laser (488–638 nm), copper and bromide lasers (578 nm), potassium-titanyl-phosphate (KTP) laser (532 nm), and krypton laser (568 nm), emitted continuous energy that was absorbed by oxyhemoglobin in cutaneous blood vessels (Chapter 239). Their use was limited because the continuous thermal energy often resulted in scarring and pigmentary alterations. The development of pulsed lasers in the 1980s allowed for more precise targeting of the oxyhemoglobin-containing vessels with less thermal and mechanical injury of surrounding tissues (Table 252-4). It is believed that pulsed energy delivered with short pulse widths causes intravascular cavitation, vessel wall fragmentation, and hemorrhage, whereas pulsed energy delivered over longer intervals causes intravascular coagulation and collagen contraction within the vessel wall and surrounding tissue. To reduce epidermal damage, all vascular lasers use an epidermal cooling system, with a cryogen spray or contact cooling.

The flashlamp-pumped PDL uses a high-power flashlamp to excite an organic dye (rhodamine) and produces a pulse of yellow light that is absorbed by oxyhemoglobin. The newer PDLs can deliver a variety of fluences over variable pulse durations (0.45–40 ms) to effectively treat many cosmetic conditions (see also Chapter 239). These PDLs can deliver high-energy, shorter pulses of light to treat striae distensae rubra, keloids, CVM, and infantile hemangioma. Purpura often results at these settings but resolves within 1–2 weeks. However, the device is most useful in treating facial erythema and facial telangiectasias at longer pulse durations that do not lead to purpura, which is a barrier to treatment for some patients.

The long-pulse, frequency-doubled Nd:YAG-KTP lasers emit a green 532-nm light that can also improve telangiectasias with minimal purpura. The current KTP lasers deliver energy with pulse durations of 1–100 ms through a fiberoptic handpiece with contact cooling. Although the 532-nm light is strongly absorbed by hemoglobin, the laser has a limited depth of penetration, which makes it useful for treatment of superficial facial vessels. Because melanin also absorbs 532-nm light, this laser should be used with caution in patients with darker skin phototypes.

Long-pulsed infrared lasers such as the alexandrite (755 nm), diode (800 nm), and Nd:YAG (1,064 nm) lasers allow deeper penetration into the skin, but their light is absorbed less specifically by hemoglobin than is the light of other vascular lasers (see also Chapter 239). There is still enough absorption, however, to treat superficial and deep reticular veins (up to 3 mm in diameter) in patients with a variety of skin types. More recently, multiplex lasers have been developed that sequentially deliver a PDL (595-nm) pulse followed by an Nd:YAG (1,064-nm) pulse at precise intervals. It is theorized that the first PDL pulse induces blood clot formation and methemoglobin conversion, which allows for greater absorption of the Nd:YAG energy. Studies are ongoing to delineate the cosmetic and medical indications for multiplex laser treatment.

IPL devices with cutoff filters that deliver increments of light ranging from 515–590 nm have been shown to be effective in the treatment of cosmetic vascular conditions. IPL devices produce a variety of fluences (up to 80 J/cm^2) over 2–10 ns in single-, double-, or triple-pulse modes. The light is delivered by a fiber through an 8×15 mm or 8×35 mm glass window that is pressed directly against the skin. A coupling gel is applied to the skin before light application to protect the epidermis from overheating and improve light penetration. Compared with PDLs, IPL devices require a longer treatment session and potentially a greater number of treatments to achieve similar results.

TABLE 252-4
Treatment of Vascular Lesions: Equipment

- Pulsed potassium-titanyl-phosphate lasers
- Pulsed dye, long-pulsed dye, variable-pulsed dye lasers
- Long-pulsed infrared lasers: alexandrite, diode, neodymium:yttrium-aluminum-garnet (Nd:YAG)
- Multiplex lasers: sequential pulsed dye + Nd:YAG
- Intense pulsed light devices

ANESTHESIA

Vascular lasers and light sources used for cosmetic indications produce a brief stinging or burning sensation. Treatments are generally tolerated without anesthesia. Because discomfort can build with cumulative laser pulses, treatment of lesions with large surface areas may require topical anesthesia with a eutectic mixture of prilocaine and lidocaine or topical lidocaine. Topical anesthetics are removed a few minutes before treatment to reduce vasoconstriction and interference with laser light delivery. Rarely, local anesthesia with lidocaine or nerve blocks are required for full-face treatment.

TECHNIQUE

The technique for treatment of vascular lesions will depend on the type and size of vessel to be treated and the patient's skin type. PDL treatments are delivered through a handheld fiber-optic device with a spot size ranging from 2–12 mm. The pulses are placed adjacent to each other with approximately 18% overlap to avoid missing areas between pulses. In general, lower fluences are used to treat macular lesions, whereas higher fluences are used to treat more hypertrophic lesions. At short pulse durations, a light gray discoloration of the treated area is the therapeutic endpoint, whereas at long pulse durations transient purpura lasting 1–2 seconds is the desired endpoint. Pulsed KTP laser treatment is delivered using a handpiece held perpendicular to the skin surface, and the vessels are traced individually at a speed that heats them without causing epidermal damage. Effective treatment will cause vessels to disappear with a subtle blanching effect.

IPL is delivered with a shorter-wavelength filter (515 nm) in single-pulse mode to treat fine superficial vessels in patients with skin phototype I. Longer cutoff filters (570–590 nm) and double- or triple-pulse modes are needed to treat large and deeper vessels. A layer of cool water gel 1–2 mm thick is applied to the skin, and then test spots are treated at increasing fluences until a faint erythema without epidermal damage is achieved. The individual pulses are applied adjacent to each other with minimal overlap. A second pass may be made perpendicular to the first pass to prevent reticulation.

OUTCOMES ASSESSMENT

The efficacy of laser and light treatment of vascular lesions depends on the caliber and depth of treated vessels. Small superficial vessels are more responsive than larger, deeper vessels. Lesions with a high blood flow, such as some spider angiomas, are also more difficult to treat. Patient response is assessed at 4–6 weeks after treatment, and treatments are repeated if necessary.

COMPLICATIONS

Immediately after treatment, patients may experience erythema and edema, which may last for the next 1–2 days. Patients who are treated with a PDL at short pulse durations will develop purpura, which gradually resolves in 1–2 weeks. Crusting, blistering, and scarring may result from overtreatment with any vascular laser. With all long-pulsed infrared lasers, adequate epidermal cooling is critical to minimizing the risk of epidermal damage and scarring. Given the overlapping absorption spectrum of epidermal melanin, vascular laser treatment can cause hyperpigmentation or hypopigmentation, but this is rarely observed. Suntanned patients and patients with darker skin phototypes should not be treated with KTP, PDL, or IPL devices.

PATIENT INSTRUCTIONS

Application of cold dressings or ice can help minimize the erythema and edema that develop in the first 24 hours after vascular laser treatment. Crusted or blistered areas should be treated twice a day with petrolatum until they have resolved. Patients requiring multiple treatments should wear sunscreen daily to prevent the risk of laser energy absorption by epidermal melanin in subsequent treatments.

TREATMENT OF COSMETIC PIGMENTED LESIONS

PATIENT SELECTION

The treatment of pigmented lesions depends on the type of pigmented lesion being targeted, its anatomic location in the tissue, and whether the pigment is intracellular or extracellular within this tissue. The background skin color must also be considered so that treatment can be directed toward the abnormal pigment while leaving the normal pigmentation intact.

The success of cosmetic treatment of pigmented lesions also depends on certain patient factors. A complete medical history should be taken with specific emphasis on poor wound healing, postinflammatory hyperpigmentation, bleeding disorders, gold therapy, and isotretinoin use in the previous year. Should any of these factors be present, the surgeon should proceed with extreme caution. In addition, all pigmented lesions should be properly evaluated, and biopsy should be performed on any questionable lesions. Laser treatment does not yield tissue for histopathologic analysis. Before treatment, patients should be counseled that the lesion may require multiple treatments and the lesion may not clear completely.

RISKS AND PRECAUTIONS

Pigmentary and textural changes are the most common complications observed when treating pigmented lesions (Table 252-5). Pigmentary changes occur more commonly in patients who are tanned or have darker skin phototypes. Transient hypopigmentation and, rarely, long-term depigmentation may develop. Hyperpigmentation has been reported in up to 16% of cases and is more commonly seen in patients with darker skin phototypes.[7] To avoid pigmentary alterations, patients with tanned skin should be treated very cautiously, because this increases their risk of adverse effects. The risk of scarring is small, but the use of Q-switched Nd:YAG lasers at 1,064 nm may cause textural change, although this occurs in fewer than 5% of cases.

Patients and practitioners must also be aware that laser treatments can alter tattoo pigments, causing a local or systemic reaction. Local allergic reactions to cadmium sulfide and chromium have been reported, and patients with known allergies to these substances should generally not undergo laser treatment for tattoo removal. Q-switched lasers may also alter cosmetic tattoos containing ferric or titanium oxide pigment, creating an immediate paradoxical darkening. It is advised that these eyeliner and lip tattoos first be treated in test spots with single pulses and then observed 2 weeks later to assess clinical outcomes. Often ablative lasers are more effective at removing these lesions without the risk of paradoxical darkening.[8]

TABLE 252-5
Treatment of Cosmetic Pigmented Lesions: Associated Risks

- Postinflammatory hyperpigmentation
- Postinflammatory hypopigmentation
- Allergic reaction to tattoo pigment
- Localized chrysiasis

TABLE 252-6
Treatment of Cosmetic Pigmented Lesions: Equipment

- Pigment-targeted pulsed dye laser
- Q-switched neodymium:yttrium-aluminum-garnet laser (532/1,064 nm)
- Q-switched ruby laser
- Q-switched alexandrite laser
- Diode laser
- Pulsed light source
- Fractionated 1,440-nm, 1,540-nm, 1,550-nm, 1,927-nm lasers

Patients should also be questioned regarding medications because Q-switched lasers have been reported to cause localized chrysiasis in patients who have received parental gold therapy.[9] It is believed that the laser causes a physiochemical transformation of the gold pigments, similar to its darkening effect on cosmetic tattoos.

PATIENT POSITIONING

Most laser treatments of cosmetic pigmented lesions are performed in the office, with the patient and all clinical personnel wearing appropriate eye protection. The treatment site is thoroughly cleansed to remove all makeup, sunscreen, and topical anesthetic, which can hinder delivery of the laser energy. If alcohol has been used to clean the area, it must be thoroughly removed before laser treatment, because it could be a source of flash fire development. Because treatment with Q-switched 1,064-nm Nd:YAG lasers can cause some tissue and blood splatter, universal precautions should be followed at all times.

EQUIPMENT

Lasers used for the treatment of pigmented lesions (Table 252-6) can be categorized as highly selective Q-switched lasers, less pigment-selective lasers, and non–pigment-selective lasers. The Q-switched lasers, including the Q-switched ruby laser (694 nm), the Q-switched alexandrite laser (755 nm), and the Q-switched Nd:YAG laser (1,064 nm), are capable of targeting superficial epidermal and deeper dermal pigment. Epidermal pigment–based lesions can also be treated with the Q-switched frequency-doubled Nd:YAG laser (532 nm) and the flashlamp-pumped PDL (510 nm). Long-pulsed pigment-specific lasers, such as the long-pulsed ruby laser, long-pulsed alexandrite laser, long-pulsed diode laser, and long-pulsed Nd:YAG laser, have pulse durations in the millisecond range. These lasers have been shown to treat certain nevi by targeting nests of cells rather than individual melanosomes.[10]

Nonspecific ablative lasers such as the CO_2 laser (10,600 nm) and erbium:YAG laser (2,940 nm) can remove pigmented superficial lesions secondary to their ablative actions. IPL devices can be used to treat mild pigmentary changes due to photodamage. Fractionated 1,440 nm, 1,540 nm, 1,550 nm, and, more recently, 1,927 nm lasers have demonstrated efficacy for a variety of dermal and epidermal pigmentary disorders. The 1,927 nm wavelength creates superficial thermal injury ideally suited for resurfacing of epidermal pigmentary disorders.

ANESTHESIA

Treatment of the majority of pigmented lesions does not require topical or infiltrative anesthesia. However, treatment of larger tattoos and lesions with large amounts of dermal pigment may require local anesthesia or nerve blocks.

TECHNIQUE

Superficial epidermal pigmented lesions such as ephelides, solar and labial lentigines, café-au-lait macules, and flat pigmented seborrheic keratoses can be effectively treated with Q-switched ruby (694-nm) lasers, Q-switched alexandrite (755-nm) lasers, 532-nm lasers, short-pulsed dye (510-nm) lasers, and IPL devices (Fig. 252-5; see also Chapter 239). Most lesions respond to 1 or 2 treatments spaced 4–6 weeks apart. The response of café-au-lait macules is variable, with up to a 50% recurrence rate. In general, the

Figure 252-5 Solar lentigines treated with a Q-switched ruby laser. **A.** Before treatment. **B.** After treatment.

Figure 252-6 Tattoo treated with Q-switched ruby laser. **A.** Before treatment. **B.** After treatment.

laser handpiece is held perpendicular to the skin, and parameters are selected based on the melanin content of the lesion and background skin type. Lower fluences are used for targets containing an abundance of melanin. The desired endpoint is a uniform but faint whitening of the skin without epidermal disruption.

Dermal pigmented lesions such as nevus of Ota and pigmentation due to medication can also be improved with the Q-switched pigment-targeted lasers described previously in Equipment. Dermal tattoos are generally treated with lasers that are selective for the various colors of inks (see also Chapter 239). Q-switched ruby and alexandrite lasers are best for treating blue, black, and green ink, whereas short-wavelength lasers such as the short-pulsed dye (510-nm) and Q-switched 532-nm ND:YAG lasers are best for treating red pigments. Yellow-pigmented tattoos are usually relatively resistant to Q-switched laser treatment. Dermal lesions and tattoos are treated similarly to epidermal lesions, with the desired endpoint being a whitening of the skin with intact epidermis. Treatments are spaced 6–8 weeks apart, because clearing of dermal pigment depends on the slow mechanism of phagocytosis (Fig. 252-6).

OUTCOMES ASSESSMENT

Patients should be evaluated 4–6 weeks after small test spots within the larger lesion are treated. They should be informed that often multiple treatments are needed to achieve the desired clinical outcome.

COMPLICATIONS

Immediately after laser surgery, the treated area develops a whitening response that typically fades in 20–30 minutes. Some patients may develop an urticarial reaction, which can subside within an hour and responds to antihistamines. A crust will form in the treated area; it resolves in 7–10 days on the face but may take longer to resolve on nonfacial areas. In rare cases, blisters, vesicles, scarring, and pigmentary changes may occur.

PATIENT INSTRUCTIONS

After laser treatment of pigmented lesions, patients may use ice packs, cool compresses, and hydro-occlusive dressings to reduce any postoperative pain. Daily cleansing of the treated areas with soap and water followed by application of occlusive ointments is recommended until the crusts have resolved. All patients are advised to avoid excessive sun exposure and apply broad-spectrum sunscreen daily.

Chapter 253 :: Liposuction

:: William G. Stebbins, Aimee L. Leonard, & C. William Hanke

LIPOSUCTION AT A GLANCE

- Liposuction is one of the most commonly performed cosmetic procedures and is widely practiced by dermatologic surgeons.
- The tumescent technique of local anesthesia is one of the most important innovations in liposuction surgery.[1]
- Liposuction performed with tumescent local anesthesia allows for the removal of large volumes of fat safely and effectively.
- Liposuction is characterized by unparalleled safety, rapid patient recovery, and low postoperative morbidity.
- Importantly, liposuction has been demonstrated to be very safe to perform in the office setting, the preferred venue for the procedure when carried out by dermatologic surgeons.

PATIENT SELECTION

Liposuction should be regarded not as a method of weight reduction or an alternative to diet and exercise, but as a body-contouring procedure. The ideal candidate is a healthy patient near his or her ideal body weight who has disproportionate, localized adipose deposits resistant to diet and exercise. Liposuction should be avoided in patients with unrealistic treatment goals and those with emotional or psychological instability (i.e., presence of an eating disorder or body dysmorphic disorder). A comprehensive preoperative consultation including a screening questionnaire is used to identify patients who are appropriate candidates. During the consultation, the risks, goals, anticipated results, and expected postoperative course are discussed.

PREOPERATIVE EVALUATION

Taking a thorough medical history will screen for patients who may be poor surgical candidates for liposuction (see Section "Risks and Precautions"). Patients at risk for complications should receive medical clearance before surgery.[2,3] A careful review of all medications is essential. All anticoagulant medications, including vitamins and herbal supplements, should be discontinued 2 weeks before surgery. Use of medically necessary anticoagulant therapy is a contraindication for tumescent liposuction. Medications that are metabolized by the hepatic cytochrome P450 3A4 enzyme system should be identified. These medications may interfere with the hepatic metabolism of lidocaine, which leads to the potential for toxicity. They should be discontinued or tapered off 2 weeks before surgery if permitted by the prescribing physician. For patients who are unable to interrupt therapy, a lower maximum dose of lidocaine may be used (i.e., less than 35 mg/kg).

Preoperative laboratory testing includes complete blood count with differential and platelet count, prothrombin time, partial thromboplastin time, and chemistry panel (including liver function tests); serologic testing for human immunodeficiency virus and hepatitis B and C viruses; and serum pregnancy test (for females).[2] An electrocardiogram may be considered when the patient is over the age of 60 or when indicated based on the patient's history or a review of systems.

RISKS AND PRECAUTIONS

Risks and precautions concerning liposuction are presented in Box 253-1.

BOX 253-1 RISKS AND PRECAUTIONS FOR LIPOSUCTION

CONTRAINDICATIONS TO LIPOSUCTION

- Severe cardiovascular disease
- Severe coagulation disorders, including hemophilia
- Pregnancy

CONDITIONS THAT PUT PATIENTS AT RISK FOR COMPLICATIONS

- History of bleeding diathesis, thrombophlebitis, or emboli (fat or thrombotic)
- History of infectious disease (including hepatitis and human immunodeficiency virus infection)
- Poor wound healing
- Diabetes mellitus
- Immunosuppression
- Prior extensive abdominal surgery
- Hepatic disease
- Renal disease
- Morbid obesity
- Underlying systemic disease with functional limitations
- Use of anticoagulant medications, vitamins, or herbal supplements
- Use of medications metabolized by cytochrome P450 3A4 enzyme system

PATIENT POSITIONING

Proper patient positioning is essential for safe and effective removal of adipose tissue. Specific positioning maneuvers differ by anatomic target site and are used to avoid important anatomic structures and optimize cannula access to fatty deposits.

EQUIPMENT

Liposuction requires the following equipment (Figs. 253-1 and 253-2):

- Tumescent local anesthetic solution
- Infiltration needles and/or cannulas
- Intravenous or peristaltic pump tubing
- Infiltration pump
- Liposuction cannulas (manual and/or powered)
- Aspiration tubing
- Aspiration pump with aspirate receptacles
- Monitoring device and emergency equipment

ANESTHESIA

Lidocaine is the preferred anesthetic for tumescent liposuction.[2] The maximum dose reported to be safe is 55 mg/kg.[4] Normal saline (0.9% sodium chloride) is typically used as a vehicle. Sodium bicarbonate is used to buffer the solution, and epinephrine is added to augment hemostasis and slow the absorption of lidocaine. The compositions of tumescent lidocaine solutions ranging from 0.05%–0.1% are shown in Table 253-1. Higher concentrations of lidocaine provide better analgesia and are useful in treating small or sensitive areas. Lower concentrations provide adequate anesthesia and are used when treating large or multiple areas. Accurate recordkeeping of tumescent anesthetic solution preparation and administration is critical to avoid lidocaine toxicity.

Figure 253-2 Liposuction equipment including (from top to bottom) tumescent anesthetic solution, infiltration pump and tubing, aspirate receptacles, and aspiration pump. (Used with permission from C. William Hanke, MD.)

TECHNIQUE

With the patient standing, the target areas for treatment as well as entry sites for cannula insertion are outlined with a permanent marker. The patient is brought to the procedure table and undergoes sterile preparation. Entry sites are anesthetized locally using 1% lidocaine with 1:100,000 epinephrine. These sites are then incised with a No. 11 blade. A blunt-tipped infiltration cannula or 21-gauge needle is inserted, and tumescent anesthesia fluid is delivered to the subcutaneous space. Rates of infiltration and amounts of fluid delivered vary depending on target area and patient tolerance.

Liposuction aspiration cannulas vary in diameter, tip style, and tip configuration. One innovation is powered liposuction using a motorized cannula. In general, larger cannulas with tapered tips and multiple distal apertures allow easier fat removal but also increase tissue injury. The choice of cannula depends on anatomic site as well as surgeon preference and experience. The cannula is inserted into entry sites with the tip apertures facing downward, away from the dermis. Tunneling with the cannula is performed in linear, even strokes with the surgeon's dominant hand, with the nondominant hand, or "smart hand," controlling cannula tip position at all times. The majority of suctioning should be aimed parallel to the axis of lymphatic drainage to minimize tissue trauma. Uneven or overly aggressive suctioning can lead to contour irregularities and should be avoided. Endpoints can be measured as the time spent in a given area, the amount of fat suctioned, patient discomfort, and assessment of the target area by palpation. The transition from yellow adipocyte-rich aspirate into fat-sparse serosanguineous

TABLE 253-1

	0.1%	0.075%	0.05%
Sodium chloride 0.9%	1,000 mL	1,000 mL	1,000 mL
Lidocaine 1%	100 mL	75 mL	50 mL
Epinephrine 1:1,000	1 mL	1 mL	1 mL
Sodium bicarbonate 8.4%	10 mL	10 mL	10 mL

tumescent fluid is an additional endpoint. Comparative suctioned aspirate volumes and vital signs are also recorded throughout the procedure.

OUTCOMES ASSESSMENT

Several studies support the excellent safety profile and high rates of patient satisfaction observed with tumescent liposuction. A 1995 survey of dermatologic surgeons who performed tumescent liposuction on 15,336 patients found no fatalities or serious complications. There were no adverse events that necessitated hospitalization.[5] In 2002, Housman et al reported a serious adverse event rate of 0.68 per 1,000 cases in a survey of 267 dermatologic surgeons who performed 66,570 liposuction procedures. No deaths were reported.[6] In a prospective study involving 688 liposuction patients, Hanke et al found a major complication rate of only 0.14% and a minor complication rate of 0.57 percent. Eighty-four percent of patients reported high levels of satisfaction with the procedure[7] (Figs. 253-3 and 253-4).

COMPLICATIONS

The majority of medical and surgical complications from tumescent liposuction, such as bleeding, hematoma, infection, and lidocaine toxicity, can be avoided by comprehensive perioperative patient evaluation and adherence to published guidelines of care. Aesthetic complications such as surface irregularities, persistent edema, and suboptimal target area fat reduction can be minimized by proper patient selection, patient education, and good technique. Dermatologic surgeons performing liposuction should be knowledgeable about the prevention and management of all potential intraoperative and postoperative complications.

PATIENT INSTRUCTIONS

Anticipated sequelae of tumescent liposuction include copious drainage from cannula entry sites, ecchymoses, edema, soreness, postural dizziness, and temporary dysesthesia. Proper education and instructions regarding diet, activity, and use of compression garments prepare patients for the postoperative period. The patient must be discharged to the care of a family member or friend. Patients are encouraged to ambulate and avoid immobilization. Heavy exercise and hot baths and showers should be avoided.

MONITORING AND FOLLOW-UP

A series of follow-up visits is scheduled to assist the patient through the immediate postoperative period and to assess the long-term surgical outcome. Postoperative healing from liposuction is characterized by a protracted period of edema resolution followed by subsequent skin contracture, which leads to a delayed

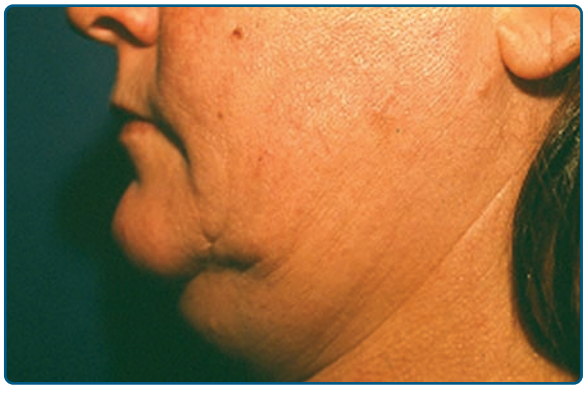

Figure 253-3 Liposuction of the neck, preoperative. (Used with permission from C. William Hanke, MD.)

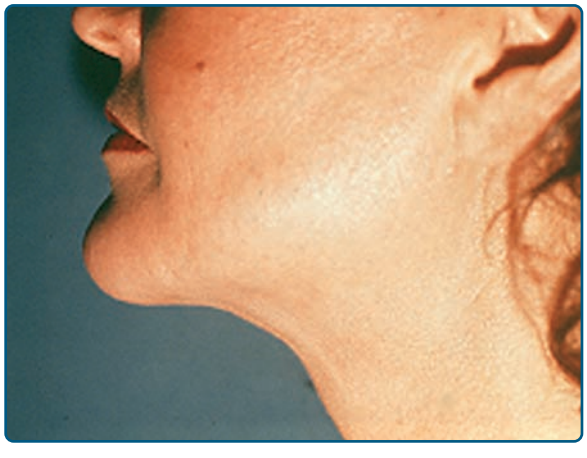

Figure 253-4 Liposuction of the neck, postoperative. (Used with permission from C. William Hanke, MD.)

final treatment result. Taking preoperative and postoperative photographs and weight measurements is essential to address patients' concerns and assess treatment response. Patients are encouraged to wait at least 6 months before judging the final cosmetic result. The performance of touch-up procedures in a treated area should be deferred for at least 1 year.

Chapter 254 :: Soft Tissue Augmentation

:: Lisa M. Donofrio

SOFT TISSUE AUGMENTATION AT A GLANCE

- Soft-tissue augmentation is an excellent way to restore the contours of youthful fullness to an aging face.
- Most common cosmetic procedures performed in dermatology practices.
- Soft-tissue fillers vary in their longevity, allergenic potential, safety, and applications. There is no perfect filler at this time, but the ideal soft-tissue filler should be nonallergenic, noncarcinogenic, nonteratogenic, biocompatible, nonmigratory, and affordable, and should provide effects that are reproducible and long lasting yet reversible.
- Hundreds of soft-tissue fillers are available worldwide.
- Fillers for treatment of lipodystrophy, including antiretroviral therapy–related lipodystrophy are discussed in Chapter 71.

METHOD AND TECHNIQUE

Soft-tissue fillers (Table 254-1) are either injected through a sharp needle or through a blunt cannula. The level of injection into the skin and the chosen length of the needle depend on the type of filler injected, the properties of the filler, the area injected, and the desired result. Threading is a technique in which the needle is inserted into the skin and the filler is deposited in a linear fashion along the track of the needle as it is being withdrawn. Fanning is a type of threading in which, instead of inserting the needle into a new area each time, the needle is just withdrawn so that a new track can be made radially adjacent to the last. In the "push-ahead" technique, an injection is made in an antegrade direction, so that the injectable material flows from the tip of the needle and hydrodissects the tissues as it flows. This technique is often used in areas in which bruising is more likely to occur along the needle track, such as the upper lid and brow. In the depot method of injection, small "pearls" of material are deposited serially, usually along a fold or deep by bone. Cross-hatching is an approach used to diffusely cover an area with the injected material. In this method, linear threads are lined up in succession and a second series of rows is then layered at right angles on top of the first. Figure 254-1 illustrates the different injection techniques. In addition to the methods just described, highly viscous fillers emerging on the US market will most likely be injected in a deep subcutaneous bolus through a blunt cannula or large bore needle. Whatever the technique chosen, care should be taken in highly vascular areas to avoid intravascular injection of filling material. The plunger of the syringe should be pulled back to check for blood flow, and if it is found, the needle should be withdrawn and repositioned.

COLLAGENS

Once considered the "gold standard" of dermal fillers, collagens (bovine, human, and porcine) are no longer available on the US market.

HYALURONIC ACIDS

PATIENT SELECTION

Hyaluronic acid–derived fillers are a good choice for patients who desire a long period of correction or more volume enhancement. They are approved for

TABLE 254-1
Clinical Features of Soft Tissue Fillers

Filler	Uses	Type	Placement	Complications	Longevity
Hyaluronic Acid	Treatment of medium-to-deep folds, lips, acne scars, periorbital hollows, facial contouring	Non–animal-derived stabilized hyaluronic acid	Mid-to-deep dermis or superficial subutis	Allergic reaction or inflammation, blue discoloration, misplacement, lumps	6–12 months
Calcium hydroxylapatite	Treatment of deep folds, nipple reconstruction, nasal reconstruction, jawline, malar augmentation	Calcium hydroxylapatite	Deep dermis to superficial subcutis	Nodules (especially in lips and periorbitally), misplacement with demarcation of product	6–18 months
Poly-l-lactic Acid	Treatment of HIV lipoatrophy, nasolabal fold, cheek, and temple hollows	Poly-L-lactic acid	Superficial subcutis	Visible and palpable papules	2 years or longer
Autologous fat	Pan-facial filling, especially periorbital area	Autologous fat	Subcutaneous tissue	Bumps, vascular occlusive events with injudicious placement	5 years or longer
Silicone	Treatment of scars, HIV lipoatrophy, lips, deep folds	Silicone oil	Deep dermis	Delayed granuloma formation, migration	

augmentation of the nasolabial fold, but other common areas of treatment include the labiomental crease, lips, cheeks, and periorbital areas. Patients often feel that the hyaluronic acid fillers are softer and more natural in appearance than the collagens were, but they need to be warned about the risk of increased erythema, edema, and bruising associated with these products.

FORMULATIONS

Hyaluronic acid (HA) is a polysaccharide that is homologous throughout the animal kingdom. Injectable FDA-approved forms include non–animal-derived stabilized hyaluronic acid products (NASHA) made through a bacterial fermentation process and an avian-derived version isolated from cocks' combs. Brands of injectable hyaluronic acids differ not only in their derivation but also in their concentration of hyaluronic acid per milliliter of product, type of cross-linking or stabilizing agents, viscosity, and particle size. Some hyaluronic acid products exist as biphasic gels containing both crosslinked and uncrosslinked particles and some as monophasic gels containing only crosslinked particles. The biphasic NASHA products are made en bloc initially and then passed through a sieve to create particles ranging in size from 10,000 per mL to 100,000 per mL with a hyaluronic acid concentration of 20 mg/mL. The smaller particle size permits injection through smaller-gauge needles into finer wrinkles and the larger particle size is best for volumetric filling. The small amount of non-cross-linked HA allows for smooth flow with low injection pressures. Monophasic hyaluronic acid gels are produced by varying the amount of high- and low-molecular weight hyaluronic acid producing a hydrogenous gel. The monophasic product is available in two formulations, one containing 24 mg/mL of hyaluronic acid and one containing 30 mg/mL of hyaluronic acid. The crosslinking agent used in both the mono- and biphasic products is BDDE (1,4 butanediol diglycidyl ether). The avian derived hyaluronic acid, contains 6 mg/mL of hyaluronic acid highly cross-linked with divinyl sulfide. All hyaluronic acid products are prepackaged in filled syringes that require no refrigeration.

ANESTHESIA

Due to their high viscosity hyaluronic acid products can cause significant discomfort on injection so most hyaluronic acids are available combined with lidocaine. Topical anesthetic can also be applied before injection. This usually results in adequate anesthesia for periorbital, nasolabial fold, and labiomental crease injections; however, if lips or perioral rhytides are being treated, an ancillary local infiltration of 1% lidocaine or segmental nerve block may be indicated.

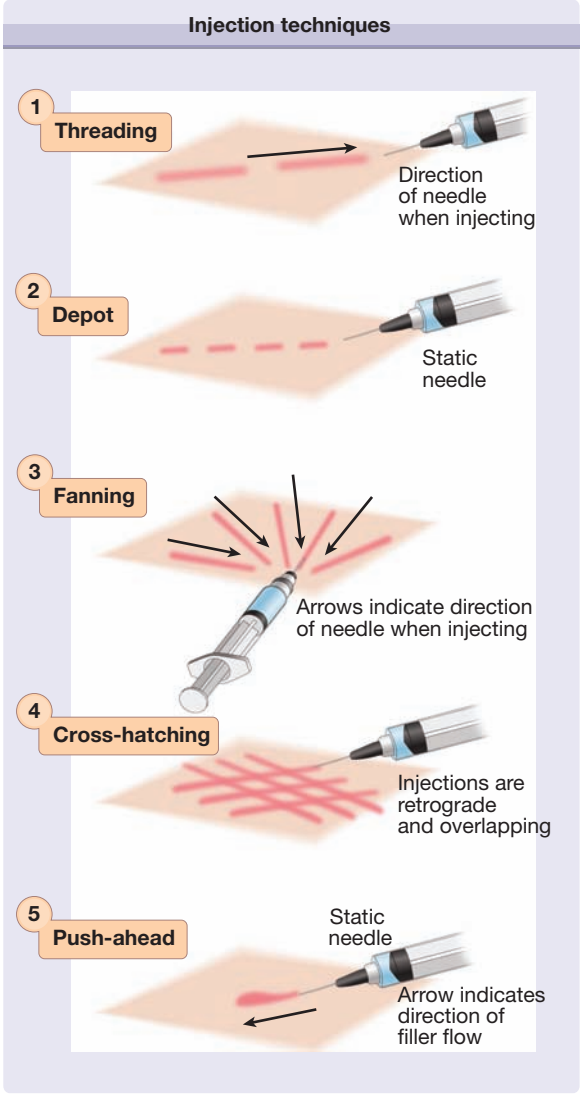

Figure 254-1 Injection techniques.

TECHNIQUE

Hyaluronic acids should be injected with the patient in a position that elicits the defect or creases to be treated and offers ease of injection to the operator. This is best accomplished by reclining the patient to a 45° angle. All the hyaluronic acid products come with a needle in the gauge of choice for ease of injection and preservation of the physical properties of the gel. Due to their viscoelastic properties, however, hyaluronic acids can often be injected through needles tailored to the area or level of injection. For instance, a 32-gauge needle allows for more precise injection of vertical lip rhytides and a 1½ inch needle may facilitate injection into distal sites. Hyaluronic acids are injected in most areas via threading, depot, or fanning. They are particularly amenable to cross-hatching in areas in which a greater density of augmentation is desired. In particular, when hyaluronic acid is injected into the nasolabial fold it is important to span the width of the fold with a serial threading technique and then crosshatch at right angles. This gives structural integrity to the fold and prevents the undesirable result of merely moving the fold medially. In addition, it is often necessary to "suspend" the fold by augmenting the cheek. This is usually done with a deep bolus injection of a high density HA. The labiomental crease can be injected similarly to the nasolabial fold, again blending the product so as not to move the fold medially. Lip injections are made using a depot or threading technique, either along the vermillion border, in the body of the lip, or in a combination of both. Perhaps one of the most exciting off-label applications of hyaluronic acids is the correction of tear trough deformity or suborbital hollows. Injections are made either under the orbicularis oculi muscle near the orbital bone or subdermally above the muscle. Intramuscular injections are to be avoided since the movement in this area increases the risk of lumping of the product. A depot method of injection is preferred in which very small amounts of hyaluronic acid are deposited on each pass, but threading can also be helpful to ensure even blending into neighboring areas. The push-ahead technique is preferred for the sub-brow area. After injection the periorbital area should be vigorously massaged to disperse the product and minimize aggregation of gel particles. Although periorbital injection of hyaluronic acid results in high levels of patient satisfaction, it is an advanced injection method best left to those with the greatest injecting experience.

POSTPROCEDURE INSTRUCTIONS

The application of ice immediately after the procedure and periodically throughout the day is recommended after the injection of hyaluronic acid. Patients are instructed to avoid manipulation of the treated area and extremes of temperature for the first 48 hours after injection. If the lips were treated in a patient with a history of cold sores, then an antiviral medication should be administered prophylactically on the day of the procedure. Patients are instructed to return to the office if they experience any problems such as redness, purulence, or nodule formation.

UNIQUE COMPLICATIONS

Most complications result from improper application of the product. Placement of this clear gel too superficially results in a blue discoloration. Placement of too large an aliquot can result in a noninflammatory bump. Most ill-placed hyaluronic acid can be released by incising with a 20-gauge needle and expressing the material. Hyaluronic acid products also contain small amounts of impurities that can cause hypersensitivity reactions. Patients can react to sterile bacterial proteins or avian proteins by forming sterile abscesses or granulomatous inflammatory nodules. It has been shown that these nodules, which appear clinically to be granulomas, may in fact be small foci of infection. Treatment with an antistaphylococcal antibiotic is the initial treatment of choice. If no resolution occurs, dilute intralesional

corticosteroids can be administered, or hyaluronidase can be injected to cause rapid dissolution of the product.[1]

LONGEVITY

In general, the longevity of augmentation is greater for the more highly cross-linked or stabilized forms and increases with increasing viscosity and particle size. Hyaluronic acid–based products are broken down via isovolemic degradation; they maintain a constant volume throughout their degradation because of their ability to bind water. This property makes possible a very long-lasting product.

In a double-blind multicenter study, the biphasic hyaluronic acid gel was found superior to bovine collagen at al postinjection time points. At 6 months, 67.2% of collagen-treated folds had returned to their baseline severity, as opposed to only 29.9% of hyaluronic acid–treated folds.[2] In a study comparing large particle biphasic NASHA to avian derived hyaluronic acid, at 6 months after treatment, the proportion of patients showing improvement in the Wrinkle Severity Rating Scale score of the nasolabial folds was higher in the group treated with the NASHA product (75%) than in the group treated with the avian product (38%).[3] In a head-to-head study comparing the tolerability and efficacy of small particle biphasic NASHA versus avian hyaluronic acid in the treatment of nasolabial folds, the NASHA product demonstrated higher efficacy and patient satisfaction ratings than the avian product at 12 weeks.[4] The bi- and monophasic NASHA products last up to 12 months quite consistently. To this date, no head-to-head studies between these products has been published. Figure 254-2 shows a 35-year-old woman before and after treatment of the nasolabial folds with a NASHA gel.

POLY-L-LACTIC ACID

PATIENT SELECTION

Poly-L-lactic acid is FDA approved both for the treatment of lipoatrophy associated with human immunodeficiency virus (HIV) infection and for the cosmetic correction of shallow-to-deep contour deficiencies. Currently in the United States, PLLA is gaining popularity as a no-downtime, long-lasting filler with a wide range of applications. PLLA's uniqueness lies in the fact that it is not a direct filling agent but rather a biostimulatory agent, eliciting tissue thickening over the course of many months and many treatment sessions. It is therefore the ideal filler for someone desiring a gradual, subtle change. Because PLLA works by initiating a foreign-body tissue response, it is not suited for patients taking immunosuppressive or anti-inflammatory drugs, and it appears to work most efficiently in younger patients. PLLA can be used for volume enhancement in the nasolabial fold, labiomental crease, chin, jawline, buccal hollows, and temples. Some practitioners have found it to provide good filling for the dorsum of the aging hands but in this area there is a moderate risk of nodule formation. It is not recommended for use in the lips and should be used with care in the periorbital area.

FORMULATION

PLLA is the same substance used in the formulation of absorbable suture material and is biocompatible and biodegradable. It is supplied in a glass bottle as a lyophilized powder containing carboxymethylcellulose as an emulsifier and mannitol as an osmotic agent. Injection of PLLA on repeated occasions presumably initiates an immune response that eventually leads to fibroblast activation and collagen deposition. High-level ultrasonographic images taken before and after a series of treatments in study patients confirms the presence of a zone of dermal thickening, but the exact mechanism is unknown.

ANESTHESIA

PLLA must be reconstituted at least 2 hours in advance of use; however, current standard of care is reconstitution at least 8 hours before treatment to fully suspend and hydrate the particles of PLLA. The package insert recommends reconstitution with 3–5 mL of sterile

Figure 254-2 Thirty-five-year-old woman before **(A)** and after **(B)** infiltration of Restylane into the nasolabial folds.

water, but the consensus of physicians currently using the product is to reconstitute with 5 mL of diluent at a minimum. It is therefore possible to reconstitute the product in advance with 4 mL or more of sterile water and immediately before injection to add 1 mL of 1% lidocaine to the bottle. This tempers the pain on injection. In addition, patients may want to apply a topical anesthetic containing either 4% lidocaine or 20% tetracaine in advance of treatment.

TECHNIQUE

Because of the diffuse panfacial nature of PLLA injections, it is helpful to inject the patient in a supine position. PLLA is injected through a 25- to 26-gauge needle. Because of the risk of particle clumping, the bottle must be agitated frequently throughout the course of treatment. The operator must maintain maximum control over injection amounts, so drawing the material up into 1-mL syringes is highly recommended. The injection technique used when infiltrating PLLA is diffuse crosshatching and threading. Depot deposition of product is no longer recommended. The principle is to inject PLLA into areas that will eventually display a direct impact from local volume change or affect neighboring areas by filling and suspending tissues upstream. Lower-face injections are performed diffusely over a wide surface area and involve the placement of 0.1-mL linear threads of solution 2 mm apart. The recommended technique is to inject across folds to distend them, rather than filling them directly. No attempt at volumetric correction is made during treatment; rather, the intent is to place the PLLA solution diffusely. The level of injection in the lower face (cheek, nasolabial fold, jawline, labiomental crease, chin) is subdermal. In the upper face (temples and periorbital area) treatment is via diffuse threading of 0.05 mL of PLLA solution under or close to periosteum. No more that 0.5 mL total should be distributed in this fashion. If clogging of the needle occurs, it should be withdrawn and either changed or cleared before proceeding. Many practitioners have found that the use of long needles (1½ inch) better facilitates even dispersion of the product.

POSTPROCEDURE INSTRUCTIONS

Immediately after injection, treated areas must be vigorously massaged to distribute the suspension evenly into the tissues. No blebs of material should be palpable. When the practitioner is satisfied that this is the case, the massage may then be continued in a gentler manner by an assistant for the next 5 minutes. Ice is then applied to the face for 20 minutes. The patient may then apply makeup and resume normal activities. The patient must massage the areas of injection for 5 minutes, 5 times a day for 5 days. Because minimal augmentation is achieved in each session, patients are instructed to return at 6-week intervals for additional treatments. The motto "Treat, wait, assess" is an important one to follow when using PLLA. Resultant augmentation can take 4 months or longer to occur, so patience is necessary to avoid overcorrection. For the average patient with cosmetic concerns, between three and six treatments will be required for ample augmentation to occur (Fig. 254-3). For patients with severe lipoatrophy, a minimum of six sessions will be required, often with injection of two vials per session.

UNIQUE COMPLICATIONS

Superficial injection of PLLA most often results in visible papule formation. Reconstitution with inadequate amounts of fluid may also increase this risk. Delayed formation of subcutaneous papules has been reported in the literature. These palpable papules are most often nonvisible, asymptomatic, and noninflammatory, and

Figure 254-3 Thirty-nine-year-old woman before **(A)** and 4 months after **(B)** the last of two Sculptra treatments to the lower face.

require no treatment. If they are of concern to the patient, an attempt can be made to break apart the papules by injecting sterile water into them or by teasing them apart with a 27-gauge needle. Results of an 8-year injectable filler safety study found evidence to support a decreased risk of nodules with increasing dilutions.[5] Rarely large visible nodules can be seen as a late-onset side effect. Intralesional cortisone may be of help since they are often inflammatory or granulomatous in nature. Surgical removal is also an option for large unresponsive or deforming nodules.

LONGEVITY

The results from PLLA infiltration are thought to last 2 years or longer, with gradual resorption and breakdown of the product to lactic acid over the course of 2–3 years.

CALCIUM HYDROXYLAPATITE

PATIENT SELECTION

Patients requiring augmentation of the nasolabial folds, labiomental crease, mandibular ramus, cheeks, or prejowl sulcus are candidates for treatment with calcium hydroxylapatite (CaHA). CaHA has also been used with success in the correction of atrophic acne scars, in the recontouring of nasal defects, and in nipple reconstruction after failed nipple areolar reconstruction. Due to the risk of lump formation, CaHA is not recommended for lip augmentation and should be used judiciously in the periorbital area.

FORMULATION

Originally approved for use by the FDA as a radiographic marker and for the correction of oral and maxillofacial defects and the treatment of vocal cord insufficiency, CaHA has recently gained approval as a nasolabial fold filler. All other areas mentioned above are common off-label uses. The microspheres of CaHA, once injected into the deep dermis, form a scaffold to support the growth of autologous collagen so there is overlap with this product as not only a temporary filler, but also as a biostimulatory agent. CaHA microspheres are suspended in a polysaccharide carrier, which holds the microspheres in place until it is resorbed and neocollagenesis takes place. CaHA contains no animal or human tissues, so allergy testing is not indicated.

ANESTHESIA AND TECHNIQUE

Injection of CaHA is quite uncomfortable, so it is almost always necessary to anesthetize the area first with 1% lidocaine. A current popular practice is to mix 0.2 cc of 1% lidocaine with the CaHA via a female-female adapter. This not only provides adequate anesthesia but also thins the product to allow for smoother injection. Due to its viscosity CaHA must be injected through a 27- to 28-gauge needle. Placing the patient in a supine or at 45 degrees, a threading technique is used, with infiltration staying at the dermal–subcutaneous junction in the area of the nasolabial fold and at the deep fat or supraperiosteal region in the areas of the cheek and mandible. CaHA appears to work best if patients undergo retreatment or touchup at 3 months.

POSTPROCEDURE INSTRUCTIONS

There can be marked swelling and bruising after the injection of CaHA, so post-treatment icing is recommended. Many physicians advocate immediate postinjection massage but feel that continued massage is unwarranted.

UNIQUE COMPLICATIONS

The majority of complications with CaHA (nodules) are seen in the lips, but it is possible for nodules lasting 1–2 years to occur anywhere the substance is injected. There is a paucity of studies of the use of CaHA for soft-tissue augmentation. One small study noted a 3% nodule rate in 29 patients treated with CaHA for soft-tissue augmentation. Nodules are supposedly noninflammatory, and often the material can be extruded from a puncture incision. Persistent nodules may have to be surgically removed. If CaHA is injected too superficially or at appropriate levels in thin skin, its opacity can be seen. Demarcation of product is especially evident in the periorbital area, as is prolonged erythema.

LONGEVITY

In a 12 month, multicenter prospective randomized split face trial comparing CaHA to NASHA in the nasolabial folds, CaHA was found to provide significantly greater correction at all time points. In practice, though, longevity appears variable, with effects lasting from 6–18 months.[6]

AUTOLOGOUS FAT

PATIENT SELECTION

Autologous fat transfer (AFT) is a practical option for those patients desiring a more dramatic global change in facial appearance. Recent anatomic research suggests that facial fat is delineated in discreet fat compartments that change morphologically over time.[7] Therefore, using fat as a filler is done with the intent of restoring the youthful architecture to these fat compartments. This provides broader rejuvenation to the aging face affected by volume loss. Fat is a versatile filler, effective in the periorbital area as well as the lips. Because it is autologous, it is the filler of choice for patients with collagen vascular disease or proven allergic reactions to collagens or hyaluronic acids. AFT is

a more involved surgical procedure than the injection of the other fillers previously discussed. Exclusion criteria for treatment include concomitant anticoagulant treatment and poor health.

TECHNIQUE

PREPARATION AND ANESTHESIA. For 2 weeks before the initial AFT procedure, the patient must stop taking all nonsteroidal anti-inflammatory drugs, vitamin E, ω-3 fatty acid supplements, and ginkgo, ginger, or ginseng supplements. The patient is instructed to begin therapy with an appropriate antistaphylococcal antibiotic starting the day before procedure. On the day of the procedure, the donor fat site and the face are both washed with an antibacterial soap. The physician then delineates the area to be suctioned with a marking pen. Every attempt should be made to choose a donor site that benefits a patient aesthetically. The outer thighs and hips in women and the flanks in men are usually good sites for fat harvesting.

In preparation for fat transfer, a pattern is drawn on the face delineating the areas in which fat is to be placed and highlighting any scars or baseline asymmetry. The patient is then placed on a sterile, draped operating table and the areas requiring fat suctioning are infiltrated with dilute local anesthesia until turgid (tumescent technique; Table 254-2; see Chapter 253).

It takes at least 20 minutes for the epinephrine in the tumescent fluid to achieve hemostasis. The face is then anesthetized diffusely with dilute 0.5% lidocaine with epinephrine 1:200,000, and segmental nerve blocks are established where appropriate. For safety, the total lidocaine dose in the tumescent fluid should not exceed 35 mg/kg of body weight.

FAT HARVESTING. Suctioning of the fat used for transplantation should be done by hand with an open-tipped harvesting cannula attached to a 10-mL syringe. After a hole is made with a 1.5-mm punch or No. 11 blade, the cannula is inserted into the deep fat and moved back and forth while the plunger on the syringe is retracted. Fat collection usually occurs quite rapidly and, due to the vasoconstrictive properties of the tumescent fluid, is nearly bloodless. After fat extraction, the syringes may be placed into a centrifuge and spun at 3,400 rpm for 20 seconds or left to stand for 20 minutes to allow separation of the hydrophilic tumescent fluid from the lipophilic fat. The infranate of tumescent fluid should then be decanted before the fatty layer is transferred to 1-mL syringes in preparation for injection into the face. Any supranate of ruptured fat cells (triglycerides and free fatty acids) should be discarded.

FAT TRANSFER. All AFT to the face is performed with the patient fully supine using an 18-gauge or smaller blunt cannula for infiltration. Incision sites can be made with an 18-gauge needle, a NoKor needle (Becton, Dickinson and Co., USA), or the tip of a No. 11 blade scalpel. Fat is infiltrated in a retrograde manner; that is, fat is injected only as the cannula is withdrawn. Injection is in small aliquots of 0.1 mL or less using a threading or depot method. Placement of fat always starts closest to bone when possible and then proceeds up through muscle and into subcutaneous fat. Fat is deposited in a crosshatched three-dimensional lattice and thus imparts structure as well as augmentation to the tissues. All areas of the face should be addressed to achieve filling laterally as well as anteriorly. The goal is to advance tissues forward and thereby elevate them away from the bone, fill in areas of shadow, and restore youthful contours.

TABLE 254-2
Tumescent Anesthesia Solution

- 1 L normal saline
- 50 mg lidocaine
- 0.5–1 mg epinephrine
- 12.5 mEq sodium bicarbonate

POSTPROCEDURE INSTRUCTIONS

Immediately after the procedure and on and off for the next 2 days, ice should be applied to the face. The area suctioned is dressed with absorbent pads, and a snug garment is applied. Incision sites on the body and face are left unsutured. The patient is instructed not to submerge the body in water until all incisions are healed (approximately 1 week). Antibiotics must be continued for 6 days after the initial procedure. Intramuscular triamcinolone may be given to reduce postoperative edema.

UNIQUE COMPLICATIONS

Postoperative edema and ecchymoses are common and last for approximately 2 weeks. Undercorrection with a gradual decrease in augmentation is common and usually represents a decline in edema rather than absorption of the fat. For this reason, fat transfer should never be recommended as a one-time procedure but rather as a series of treatments with cumulative augmentation and long-term results. Small, persistent lumps can occur that represent either fat cysts or accumulation of fat. They can be treated, usually to resolution, with intralesional injection of triamcinolone (2–4 mg/mL). If a larger fat lump is present, the best option is to feather it into the surrounding tissues with an infiltration cannula. Irregularities can also occur at the harvest site, but operator experience and judicious removal of fat makes this a highly unlikely event. Rarely, infections such as atypical mycobacteria can be seen and should be in the differential diagnosis for any nodules occurring up to 1 year following AFT.

LONGEVITY

Many authors using a standardized, multilevel microinjection technique have published photodocumentation of

Figure 254-4 Fifty-five-year-old woman before **(A)** and 20 months after **(B)** full-face fat transfer treatment series.

long-term follow-up demonstrating persistence of autologous fat (Fig. 254-4).[8] However, the controlled, double-blinded, multicenter studies available for evaluation of other fillers have not been done.

INJECTABLE SILICONE

PATIENT SELECTION

Injectable silicone is categorically a permanent filler with a wide range of applications. It appears to provide permanent, cosmetically superior augmentation for treatment of HIV lipoatrophy, plantar defects, and scars. Historically, silicone injection has been associated with disfiguring tissue distortions and migration of product. These side effects can almost always be traced to the use of large-volume injections or non–medical grade silicone. Because of the controversial nature of silicone augmentation, patient selection for cosmetic indications is currently complex, and use of the procedure should be reserved for those physicians who have extensive experience in the injection of silicone as a filler and understand the concepts outlined in the Technique section.

Patients with a known history or autoimmune disease or with a history of a chronic or active infection should be excluded from treatment.

FORMULATION

Perhaps no other filler has both inspired such a loyal following and provoked such vehement opposition as injectable silicone. The most widely used available form of silicone oil is FDA approved for the treatment of retinal tamponade. It is not approved for the indication of soft-tissue augmentation. It is a sterile, impurity-free, medical-grade silicone oil at a 1,000-centistoke viscosity. It is noncarcinogenic and does not appear to be associated with arthritic disease in mice. After injection, silicone is encapsulated in collagenous fibrous tissue, so that final augmentation is a result of both volume of injected silicone and host tissue response.

ANESTHESIA

Currently available forms of silicone do not contain an anesthetic solution, because such small volumes are injected on each visit that ancillary anesthesia is not often required. If desired, a topical anesthetic agent containing 20% tetracaine or 4% lidocaine may be applied before the procedure.

TECHNIQUE

Improper technique in the injection of silicone oil will almost guarantee permanent adverse sequelae. It is therefore absolutely necessary that a physician considering the use of silicone apprentice with an experienced practitioner. Silicone (1,000 centistoke) is highly viscous and must be injected through either a 26-gauge needle on a 1-mL syringe or a 30-gauge needle on a 0.3-mL syringe. Use of a microinjection technique is paramount to success with silicone, so large-bore needles are never to be used. The microdroplet injection technique involves injecting 0.01 mL of silicone oil, with the needle bevel down, into the deep dermis in a depot fashion at 1- to 3-mm intervals. Note that 100 droplets are therefore required to empty a 1-mL syringe. Except

in the treatment of HIV cheek atrophy, it is rare to use more that 0.3 mL total per injection session. Treated areas are always undercorrected, and patients are instructed to return for multiple injection sessions at monthly intervals until full augmentation occurs.

POSTPROCEDURE INSTRUCTIONS

There is very little postoperative discomfort, edema, or ecchymosis after microinjection with liquid silicone. Ice may be applied if needed to lessen the risk of postinjection ecchymosis. Patients may apply makeup and pursue their daily activities as usual after injection.

UNIQUE COMPLICATIONS

Most authorities on silicone use agree that the incidence of serious complications after the proper use of medical-grade silicone is very low. In an FDA-authorized study involving 1,400 patients over a 20-year period, 2 patients experienced serious side effects: one case involved migration of silicone after treatment with large volumes, and the second involved inflammation and necrosis in a patient with concomitant Weber-Christian disease and rheumatoid arthritis. Local granulomatous nodularities can occur many years after the cessation of treatment and are usually preceded by a systemic infection. Treatment regimens for granulomas include intralesional or systemic steroids, minocycline, and topical imiquimod.[9]

LONGEVITY

The augmentation derived from liquid silicone injection is permanent. Many authors have published reports of long-term studies, some with 30-year follow-up, showing persistence of improvement. Patients receiving liquid silicone injections will continue to age, and, for this reason, additional augmentation may be required should neighboring areas of age-related atrophy develop.

COMPLICATIONS ASSOCIATED WITH THE USE OF ALL FILLERS

Vascular occlusion is perhaps the most devastating complication associated with the use of all fillers. This can manifest as local necrosis, central nervous system infarction, or blindness. Blindness and middle cerebral artery infarction have been described most often after fat transfer, but vascular occlusion with ensuing sequelae has occurred after the use of collagen and hyaluronic acid fillers as well. In theory, the central occlusive events have occurred from high-pressure injections with retrograde flow into arterioles that connect with the internal carotid system. It is therefore of utmost importance to keep the needle or cannula moving during withdrawal while depositing filler and to exert as little pressure as possible on the syringe. For similar reasons, when fat transfer is performed, only blunt cannulas should be used for infiltration.

Other complications common to the use of all fillers include ecchymosis, edema, extrusion or drifting of the filling substance, foreign-body reactions, changes in pigmentation, injection site scarring, overcorrection, undercorrection, misplacement, and infection.

Chapter 255 :: Botulinum Toxin

:: Richard G. Glogau

On April 15, 2002, the US Food and Drug Administration (FDA) approved Allergan, Inc.'s Botox Cosmetic* (botulinum toxin type A) for "temporary improvement in the appearance of moderate-to-severe glabellar lines in adult men and women 65 or younger." This was the first elective cosmetic indication for which any commercially available botulinum toxin on the US market had been approved.

The toxin had previously been approved and was marketed as Botox® for the treatment of strabismus, blepharospasm, and cervical dystonia but existing off-label cosmetic use of the toxin had already propelled annual sales to $250 million per year in 2002. With FDA recognition of the cosmetic indication, sales of both Botox® and Botox Cosmetic® surpassed $1 billion per year by the end of 2009.

The commercial introduction of Allergan's product into the US market has given unprecedented brand name equity to the drug, surpassed only by Pfizer's product Viagra® (sildenafil citrate). Botox has passed into vernacular usage as a trademark used to loosely refer to a class of biologic neurotoxins in the manner of other well-known trademarks such as Coke® and Kleenex®. The clinical utility of the neurotoxin is so widely known today that the word *Botox* has become a generic term in the public mind for all agents used in cosmetic neurotoxin therapy, although the term is properly reserved for Allergan's trademarked commercial version of the type A neurotoxin complex.

In April 2009, the FDA approved a third commercial neurotoxin, a serotype A product, Dysport® (Ipsen [UK]/Medicis [US]) to join Allergan's Botox® /Botox® Cosmetic and a previously approved serotype B product, Myobloc® (Solstice Neurosciences [US]). In July 2011, the FDA approved a fourth commercial neurotoxin for the US market, a serotype A product, Xeomin® (Merz Pharma GmbH [Germany]). To emphasize the noninterchangeability of these biological toxins, the FDA in August 2009 required the manufacturers to adopt new drug names: onabotulinum toxin A (Botox®/Botox® Cosmetic), abobotulinum toxin A (Dysport®), rimabotulinum toxin B (Myobloc®), and incobotulinum toxin A (Xeomin®).

One other commercial serotype A toxins is presently awaiting FDA approval: PurTox® (Mentor [US]). There are at least two other commercial serotype A toxins in use outside of the United States: Meditoxin®/Neuronox® (Medy-Tox [Korea]) and Hengli®/Prosigne® (Lanzhou [China]). Presumably the FDA will supply new drug names for these products when and if they complete the approval process.

*It is the editors' policy not to use trade names in this book. However, in certain instances, the editors had to depart from this policy to avoid confusion.

PHARMACOLOGY

TOXIN STRUCTURE

Botulinum neurotoxins are currently categorized into seven distinct serotypes: A, B, C1, D, E, F, and G.[13] The molecules vary in their biosynthesis, size, cellular sites of action, binding kinetics, duration of effect, and stability. The serotypes currently commercially available, serotypes A and B, are derived from different strains of *Clostridium botulinum*. They both have 150-kDa dichain polypeptides with a heavy chain and light chain linked by disulfide bonds. During biosynthesis, the molecules of A and B can be surrounded by proteins to form a neurotoxin complex, ranging from 500 kDa to 900 kDa (Fig. 255-1). Xeomin® (incobotulinum toxin A) consists of the 150 kDa dichain without accessory proteins.

MECHANISM OF ACTION

The toxin enters the nerves by binding to surface protein receptors and undergoing endocytosis into internalized vesicles. The light chain is released into the nerve cytosol, and the SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor) protein complex is cleaved to inhibit exocytosis of the neurotransmitters such as acetylcholine (Fig. 255-2).

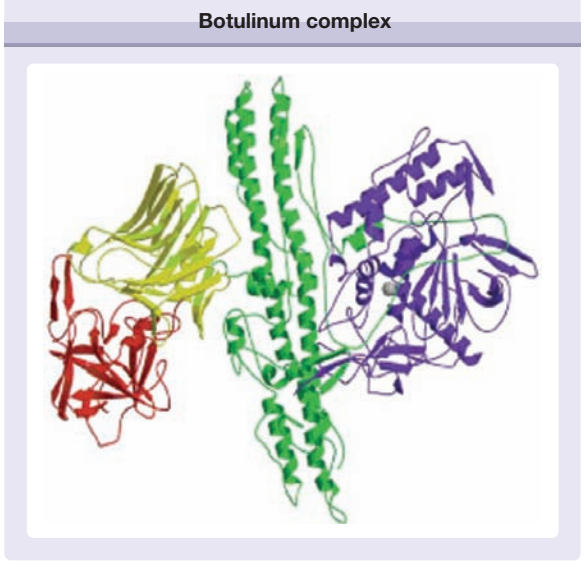

Figure 255-1 Schematic of the botulinum complex showing the binding domain with the *N*-terminus (*yellow*) and the *C*-terminus (*red*), together with the translocation domain (*green*) and the light chain (*blue*). (Used with permission from Turton K, Chaddock JA, Acharya KR: Botulinum and tetanus neurotoxins: structure, function and therapeutic utility. *Trends Biochem Sci* **27**:554, 2002.)

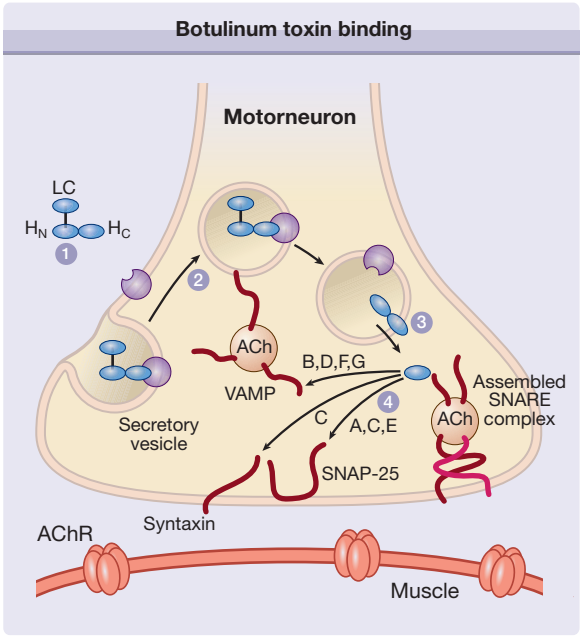

Figure 255-2 The heavy chain domain of the botulinum neurotoxin complex binds to the plasma membrane receptor (1) and the complex is internalized (2). The light chain fragment is then released into the cytoplasm (3), where it cleaves the SNARE (soluble N-ethylmaleimide-sensitive factor attachment protein receptor) protein complex at a site determined by the neurotoxin serotype (4). This disruption of the SNARE complex prevents exocytosis of acetylcholine (ACh) into the synaptic space of the neuromuscular junction. A through G = neurotoxin serotypes; AChR = acetylcholine receptor; LC = light chain; H_C = heavy chain *C*-terminus; H_N = heavy chain *N*-terminus; SNAP-25 = synaptosome-associated protein of 25 kDa; VAMP = vesicle-associated membrane protein. (Used with permission from Turton K, Chaddock JA, Acharya KR: Botulinum and tetanus neurotoxins: Structure, function and therapeutic utility. *Trends Biochem Sci* **27**:555, 2002.)

Type A toxin cleaves SNAP-25 (synaptosome-associated protein of 25 kDa), whereas type B cleaves VAMP (vesicle-associated membrane protein), also called *synaptobrevin* (Fig. 255-3). These proteins are necessary for the release of acetylcholine from vesicles within the cytoplasm of the motor nerve endings. The binding characteristics of each serotype dictate the locus of action on the intracellular SNARE protein complex (Table 255-1).

The end result is a chemodenervation of the cholinergic neurons, either motor nerves or autonomic nerves, leading to localized absence of skeletal muscle activity or autonomic control of target organs such as the eccrine sweat glands. The way in which the nerves escape the effect of the neurotoxin is partially understood.[14] The chemodenervated nerve endings develop collateral sprouting near the primary terminus of the nerve. These sprouts eventually make proximate contact with the targets, either muscle or gland, and begin to overcome the loss of neurotransmitter at the end organ synaptic junctions.

Once these sprouts have reestablished chemical contact with their targets, muscles resume activity and glands begin to secrete. Simultaneously, the original chemodenervated terminal nerve ending begins to degrade the blocked SNARE proteins and develop new proteins to resume the chemical exocytosis of acetylcholine. While these repairs are underway, and while the original terminal nerve ending reacquires communication with the target organ, the collateral sprouts begin to slowly resorb until anatomically nothing is left but the original terminal ending with restored junctional activity.

Four commercially available preparations of botulinum neurotoxin were on the market in the United States and Europe in late 2011, and one was pending approval. All but one are serotype botulinum toxin A, and one is a serotype botulinum toxin B. The products differ in their methods of manufacture, commercial form, and biologic profiles. (Table 255-2).

The units by which these products are described are not interchangeable because of the nature of the assays used to determine their potency. The mouse assays used differ in the diluents used and are not comparable. There is no such thing as a standard neurotoxin unit, hence there is no "International Unit" for neurotoxin. Thus, there is no way of standardizing neurotoxin units to compare a serotype A products to each other, let alone to other serotype B products.

Although the molecule complexes are unique, similar uses are based on clinical observations. For example, in the glabellar frown line pivotal trials, 20 units of Botox® or Xeomin® and 50 units of Dysport® were used.[16,17] Botox® is generally diluted with either 1.0 or 2.5 mL of saline per 100 units, producing concentrations of either 10 units per 0.1 mL or 4 units per 0.1 mL respectively. Xeomin® is diluted with 2.5 ml per 100 unit vial. Allergan's pivotal trial used the 4 unit per 0.1 mL dilution. Dysport® is usually diluted with 1.5 mL of saline per 300 unit vial producing a concentration of 10 units in 0.05 mL as used in the pivotal trial. Notice that the Dysport® pivotal trial used injection volumes that were half those used in the Allergan trial: 0.05 mL (10 U) per injection point (Dysport®) versus 0.1 mL (4 U) per injection site

TABLE 255-1
Binding Sites in the SNARE Protein Complex of the Seven Known Botulinum Toxin Serotypes

Serotype	Intracellular Protein
A	SNAP-25
B	VAMP/synaptobrevin
C1	SNAP-25 and syntaxin
D	VAMP/synaptobrevin
E	SNAP-25
F	VAMP/synaptobrevin
G	VAMP/synaptobrevin

SNAP-25 = synaptosome-associated protein of 25 kDa; SNARE = soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor; VAMP = vesicle-associated membrane protein.

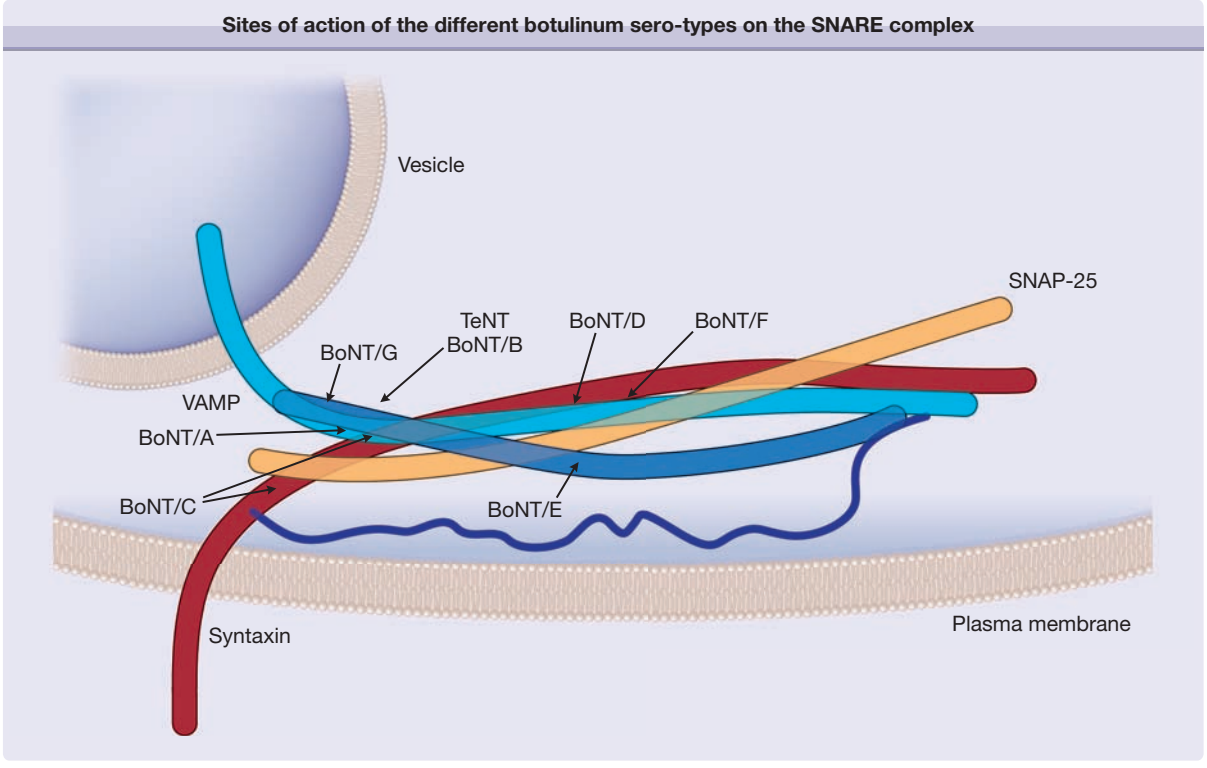

Figure 255-3 Schematic representation showing the sites of action of the different botulinum serotypes on the intracellular protein complex known as the SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor) proteins responsible for exocytosis of acetylcholine from the nerve. Botulinum A serotype cleaves SNAP-25 (synaptosome-associated protein of 25 kDa). Other serotypes impact VAMP (vesicle-associated membrane protein), synaptobrevin, or syntaxin. BoNT/A through BoNT/G = botulinum neurotoxin serotypes A through G; TeNT = tetanus neurotoxin.

(Botox®). It is unclear whether such differences in volume may contribute to behavioral differences between the two products in terms of diffusion and persistence.

The use of sterile saline with preservative (benzyl alcohol) as a diluent appears to lessen the sting of injection with Botox® and Dysport®. Myobloc®, the B serotype, causes more discomfort on injection because of its low pH, but it is stable in liquid form at room temperature for many months.

In addition to the drug name changes, which the FDA required of the manufacturers in 2009, the agency instituted a Risk Evaluation and Mitigation Strategy (REMS), and a boxed warning for these products that warned of the possibility of spread distant from the injection site with potentially life-threatening consequences. Emphasizing the non-interchangeability of these commercial products, the FDA wished to minimize the possibility of medication errors as well as draw attention to the need for tailoring specific doses of each toxin product to specific situations.

IMMUNOLOGY

The possibility of antibody-mediated resistance appears to be largely theoretical. Original Botox® batch No. 79–11, widely used in ophthalmology and neurology for years, produced rare cases of nonresponse in the treatment of torticollis and blepharospasm. Newer batches introduced in 1997, No. 91223US and No. BCB2024, have significantly less protein load. Although cases of primary nonresponse may be rarely encountered, immunologic resistance to Botox® and Botox Cosmetic® does not appear to be clinically relevant in dermatology, even at the dosages used to treat hyperhidrosis, which can average 400 units per treatment session. In addition, the treatment interval does not appear to be a significant factor in clinical resistance for the newer batches and at the smaller dosages used in cosmetic facial treatment, although exposure to the toxin at increasingly shorter intervals may be associated with development of neutralizing antibodies.

INDICATIONS

Botulinum toxin is used in cosmetic dermatology primarily for the treatment of dynamic expression lines in the upper third of the face (the glabellar brow furrow, horizontal frontalis forehead lines, periocular rhytides, or crow's feet) and for the treatment of axillary hyperhidrosis. Less common and therapeutically more challenging indications are platysmal banding in the neck, perioral rhytides, marionette lines at the corners of the mouth from the action of the depressor anguli oris, shaping the lower face with masseter volume reduction, postsurgical synkinesis in the lower face, and palmar/plantar and forehead/scalp hyperhidrosis.

TREATMENT

GLABELLAR BROW FURROWS

A firm understanding of the underlying facial anatomy is the *sine qua non* of successful aesthetic therapy with botulinum toxin. Depending on the muscle mass present and the degree of atrophy from prior treatment, 20–35 units of Botox® or Xeomin® or 50–75 units of Dysport® may be placed in five separate injection points to treat the corrugators and procerus muscle in the average brow (Fig. 255-4). A 30-gauge, 31-gauge, or even 32-gauge needle and a tuberculin or diabetic syringe are used to minimize the trauma of the intramuscular injections. The corrugator injections are placed (1) just at or above the medial brow and (2) in or just medial to the midpupillary line, at least 1 cm above the bony orbital rim (see Fig. 255-4). The fifth injection is placed in the procerus at the midline at a point just above the horizontal creases created in the glabella at the bridge of the nose. Figure 255-5 shows the results of the procedure.

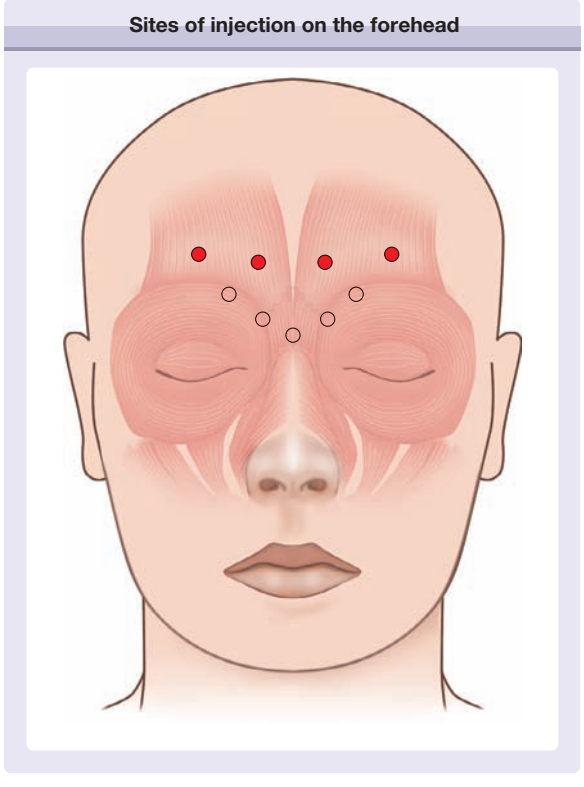

Figure 255-4 Sites of injections on the forehead. The corrugator and procerus muscles are weakened by carefully positioning five injections of botulinum toxin of 5 units each (Botox®) (*open circles*). If Dysport® is used, 10 units would be placed in the 3 central injection points but the lateral corrugator injection points (represented by the red circles) are a little medial and slightly higher than the lateral injection points used for Botox,® in most cases, according to Ascher.[15] Forceful knitting of the brow is prevented. To weaken the frontalis muscle, injections are placed in four or five divided doses along the forehead equator (*closed circles*).

Figure 255-5 Before botulinum toxin treatment of the corrugator and procerus muscles (*upper panel*) and 1 week after treatment (*lower panel*).

Based on earlier experience with ophthalmologic periocular injections for treatment of muscle spasms, patients have been instructed to remain upright for 2–3 hours to limit the incidence of eyelid ptosis, which occurs with diffusion of the toxin down into the levator muscles of the lid (Fig. 255-6). With operator experience, the incidence of ptosis after injection of the brow should be less than 2%.

Temporary stimulation of Müller muscle in the lid can be achieved with 0.5% apraclonidine or 2.5% phenylephrine eyedrops (see Fig. 255-6). These will produce 2–3 mm of elevation of the lash margin, and administration may be repeated at intervals until the distant diffusion effect of the botulinum toxin on the levator muscle disappears, usually in 2–3 weeks.

HORIZONTAL FOREHEAD LINES

The frontalis is treated at the horizontal equator of the forehead or above to avoid inactivation of the lower third of the frontalis muscle, which is responsible for suspension and movement of the eyebrows (see Figs. 255-4 and 255-7). Twelve to twenty units of Botox® or 20–50 units of Dysport® are placed in four or five divided doses equidistantly along the forehead equator. If too large a dose is applied or injection sites are placed too low, brow

Figure 255-6 Patient who developed ptosis of the right upper eyelid due to diffusion of the botulinum toxin from the area above the midbrow down into the levator muscle of the upper eyelid. The lower photograph shows the patient approximately 1 minute after instillation of two drops of apraclonidine 0.5% ophthalmic solution into the right eye. Direct adrenergic stimulation of Müller muscle occurs, which lifts the lid temporarily. The drops may be administered every 4 hours as needed. The botulinum-induced ptosis resolves spontaneously, usually in 3 weeks or less.

Figure 255-7 The upper half of the frontalis muscle is weakened by injecting four or five sites equidistantly along the equator of the forehead with a total of 16–20 units of Botox® or 30–50 units of Dysport®. Patient is shown before treatment (*upper panel*) and 1 week after treatment (*lower panel*).

ptosis and loss of brow arch are produced, which leads to an unpleasant, heavy sensation in the brow as well as an aesthetically unattractive appearance.

Unlike in the treatment of eyelid ptosis, there is no comparable adrenergic agent available to reverse brow ptosis induced by botulinum, and the patient must wait several weeks for the effect to wear off. In a patient, who has never received botulinum toxin before, it is wise to separate the glabellar area from the forehead area and to wait a couple of weeks between treating the two to avoid the possibility of overtreatment and brow ptosis. Many patients find even the smallest drop in brow position very bothersome, and great care should be taken to avoid this complication of aesthetic treatment.

CROW'S FEET

The rhytides at the corners of the eye respond favorably to injections of toxin; however, patients frequently confuse true crow's-feet rhytides with the dynamic expression lines that appear across the malar eminence laterally in conjunction with smiling and contraction of the zygomaticus muscles. Toxin may successfully ameliorate true crow's-feet, which radiate directly from the lateral canthus and are associated with contraction of the orbicularis oculi muscles by themselves. But the "smile lines" that appear over the malar eminence often lie in wait for the unwary injector. Placing toxin at or below the malar eminence in an attempt to weaken these lines may lead to paralysis of the zygomaticus muscles and a drooping corner of the mouth that cannot spontaneously be raised, so that the patient may acquire a poststroke appearance.

To safely approach crow's feet, the toxin is usually placed at one-to-three injection points approximately 1 cm lateral to the lateral canthus. Some practitioners place all of the drug at one point, and others distribute the dose evenly among three points. Typical doses range from 10–18 units of Botox® or 25–30 units of Dysport® depending on the estimate of muscle mass and activity.

Great care must be taken to make the injections into the skin only, raising wheals or blebs that can be gently massaged down. Intramuscular injection in this area will reliably produce unwanted bruising because of the rich venous plexus underlying the skin in this region. The toxin will readily diffuse from the blebs into the underlying orbicularis muscle, relaxing the grip on the overlying skin and smoothing out the wrinkles. As previously mentioned, care must be taken to avoid injecting too low down onto the malar eminence, where diffusion may affect the zygomaticus major muscle and disrupt the symmetrical movement of the corner of the mouth in smiling.

The patient being treated for crow's feet should have good lower eyelid tarsal tone to avoid the appearance of senile ectropion from too much laxity of the lower eyelid. Pretreatment of the crow's-feet area is very useful as an adjunctive technique before laser resurfacing. It prevents the problem of rhytides being readily reformed by repeated squinting during the postoperative healing period; in which case, the resurfacing may give rise to more noticeable lines than existed before the resurfacing.

COMBINATION THERAPY

As clinical experience accumulated with these commercial botulinum toxin products, experts in soft-tissue augmentation soon recognized that a synergy exists between soft-tissue fillers and neurotoxins.[16] Concomitant with the rise in the use of botulinum neurotoxin for cosmetic applications, the marketplace for soft-tissue augmentation expanded with the introduction of injectable hyaluronic acid gels (see Chapter 254). These agents provided the first new directions in cosmetic therapy since the introduction of solubilized bovine collagen in the mid-1970s. The ability to control both muscles of expression and their secondary lines and folds, and to repair age-related volume changes in subcutaneous tissue has revolutionized minimally invasive cosmetic techniques.

Many patients have eagerly embraced simultaneous treatment with both fillers and botulinum toxin to achieve a natural look and forego more traditional incisional surgery. As an example, patients frequently combine treatment of the upper third of the face (glabellar frown lines, horizontal forehead lines, and crow's feet) with volume restoration of the lower and middle face (lip enhancement, filling of nasolabial fold and marionette lines, chin and cheek augmentation) (see Chapter 254).

HYPERHIDROSIS

Focal axillary hyperhidrosis is successfully treated with botulinum toxin by using Minor starch-iodine test to map out the extent of surface area in the axillary vault that is affected. Anesthesia may be achieved with a eutectic mixture of local anesthetics but is usually not needed due to the relative insensitivity of the axillary skin. Doses of 2.5–4.0 units of Botox® are placed every 1–2 cm as intradermal injections in axillary skin. Reliable anhidrosis is produced within 72 hours and will last for 8–12 months with doses of 50–100 units of Botox® per axilla (Fig. 255-8). The duration of effect appears to be dose related, and doses of up to 200 units (Dysport®) per axilla have been reported to produce dryness for up to 29 months.[17] Aside from insignificant bruising from the needle trauma, there are no apparent side effects.

Palmar hyperhidrosis (Fig. 255-9) is more challenging to treat because of (1) the more limited diffusion of the toxin in palmar skin, (2) the pain on injection, and (3) the generally predictable incidence of temporary weakness in the hand.[9] Anesthesia is achieved with regional wrist blocks of the median, ulnar, and radial nerves using lidocaine 1%–2% without epinephrine. Approximately, 100–150 units of Botox® are needed to treat a single palm, divided into 50–60 intradermal injections of 2–3 units each. Onset of anhidrosis peaks in 5–7 days and is accompanied by minor weakness of the intrinsic muscles of the hand, which makes tasks requiring strength and stability (e.g., pushing a button through a buttonhole) difficult to perform. The weakness usually subsides within 3 weeks, whereas the anhidrosis persists for several months. There is wider variation in response to palmar treatment than to axillary treatment, with anhidrosis lasting from 4–12 months, which probably reflects the technical difficulties in achieving even dispersion of the toxin through the palmar skin.

Figure 255-8 Minor starch-iodine test is used to demonstrate the area of axillary sweating (*top panel*). The pattern of intradermal botulinum toxin injections is shown with the starch-iodine material in place to highlight the injection points (*middle panel*). One week later the treated axilla shows a negative result on the starch-iodine test (*bottom panel*).

SIDE EFFECTS AND COMPLICATIONS

Minor needle trauma and bruising on injection with a 30-gauge needle are insignificant short-term

Figure 255-9 Hands showing response to Minor starch-iodine test. The left hand was not treated. The right hand received 100 units of intradermal Botox® 1 week before the photograph was taken.

complications of botulinum toxin injection, and use of a smaller-gauge needle (31 gauge or 32 gauge) will minimize needle trauma. Minor discomfort can be made more tolerable in some patients by pretreating the injection site areas with topical anesthetic and using sterile saline with preservative as a diluent, which greatly reduces the sensation of injection.

The more problematic complications to consider are eyelid ptosis, which can occur after injections in the glabellar brow (see Fig. 255-6); brow ptosis from overzealous treatment of the frontalis muscle; transient lid edema from periocular injections; headaches after injections anywhere in the upper third of the face; and palmar weakness after injections for hyperhidrosis.

Antibody-mediated resistance appears to be an exceedingly rare event and of little clinical consequence in cosmetic dermatologic uses of botulinum toxin. Although millions of doses have been given to date, there is no well-documented evidence of the development of immunologic resistance in patients treated with cosmetic doses. Resistance continues to be observed in patients treated for cervical dystonia, albeit at much lower rates than in the early years, probably due to the lower protein content of current formulations.

Eyelid ptosis is thought to be best avoided by carefully placing the midbrow injections at a minimal distance of 1 cm from the superior orbital rim, keeping the injection rate slow and gentle, and having the patient avoid prone positions and sleeping for 2 hours after injection.

Restricting injections to the upper two-thirds of the frontalis and reducing doses to the minimum necessary to produce the desired clinical effect may minimize brow ptosis. Headaches as a rebound phenomenon after facial injections of botulinum toxin may be triggered by unopposed muscle groups, but their etiology is unclear. Usually nonsteroidal anti-inflammatory agents are sufficient to treat them, unless the patient experiences migraines; in which case, the patient's usual migraine medication will be required.

In hyperhidrosis, palmar weakness is a predictable consequence of injecting the palms. It is transient and dealt with by clear preinjection counseling. There is no similar effect of any clinical significance in either the axillae or the feet.

SUMMARY

The development of botulinum toxin treatment has brought great creativity and capability to cosmetic dermatologic therapy. Further evolution will occur as new serotypes come to market and greater therapeutic synergies evolve as developers of soft-tissue augmentation systems strive to achieve similar effect and elegance. The high degree of efficacy and safety in the use of botulinum toxins in cosmetic dermatology has produced a great level of satisfaction in patients and physicians alike.

Chapter 256 :: Hair Transplantation and Alopecia Reduction

:: Walter P. Unger, Robin H. Unger, & Mark A. Unger

HAIR TRANSPLANTATION AND ALOPECIA REDUCTION AT A GLANCE

- Most patients undergoing surgical procedures for hair loss have either male pattern baldness (MPB) or female pattern hair loss (FPHL).
- Surgical techniques used to treat hair loss include hair transplantation, alopecia reduction (AR) and transposition flaps.
- Follicular units (FU) are the building blocks of modern hair transplantation [follicular unit transplanting (FUT)] (Fig. 256-1).
- The major advantage of FUT over older punch-grafting techniques is that the results appear natural after a single surgery.
- Minoxidil or finasteride may arrest or partially reverse MPB and FPHL so a trial of treatment is appropriate prior to surgery, or concurrent with surgery.[1,2]

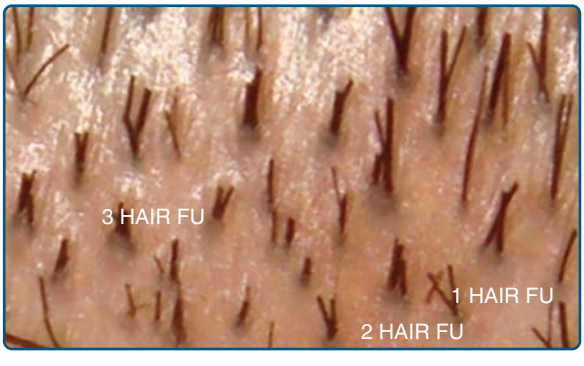

Figure 256-1 A relatively small number of single hairs emerge from the scalp. Most often, hairs grow in small groupings of two to five hairs, as shown in the above photo. These groupings are referred to as *follicular units*.

BACKGROUND

Hamilton and Norwood described the degrees of severity of MPB from a mild Type I to a severe Type VII[3,4] (Fig. 256-2). Fortunately, a large majority of male patients do **not** progress past Types VI: Norwood found that at age 79 only 11% of men have Type VII MPB (Table 256-1), and Unger found that among men older than 65 only 13.7% have Type VII MPB[5] (Table 256-2). Thus, if one treats all or most patients as if they will develop Type VI MPB, one is being reasonably cautious. An exception is for cases with a family history of Type VII MPB, in which case it is wiser to assume an evolution to Type VII MPB.

Ludwig described three degrees of FPHL[6] (Fig. 256-3), while Olsen developed a distinct classification system based on her observation of a "Christmas-tree" pattern of hair loss[7] (Fig. 256-4). According to Hamilton's study, 79% of postpubertal females develop at least a mild Hamilton/Norwood pattern of hair loss.[3] Most female patients do not have a sufficiently high density donor rim to surgically treat all of the affected alopecic areas. For this reason, some practitioners believe that women are rarely candidates for hair restoration surgery (HRS)—a view shared by the general public. In the authors' experience, however, the opposite is true.[8] A poor donor/recipient ratio does not preclude surgery, but does require a treatment plan that focuses on cosmetically strategic areas. In women, this corresponds to the frontal area and the part-line, which is usually a 5-mm-wide anteroposterior corridor (Fig. 256-5). The thickened hair in these areas can then be styled in a way that camouflages untreated areas. When this is done, the cosmetic improvement is significant, and patient satisfaction is high.

In men, the transplantation of areas of MPB should be conceptualized as consisting of four areas: (1) a frontal area extending from the proposed hairline to a coronal line drawn perpendicularly between the tragus of each ear; (2) a midscalp area extending from the posterior border of the frontal area to a point where the caudal scalp changes its orientation from parallel to the ground to more or less vertical; (3) a vertex area that consists of the remainder of

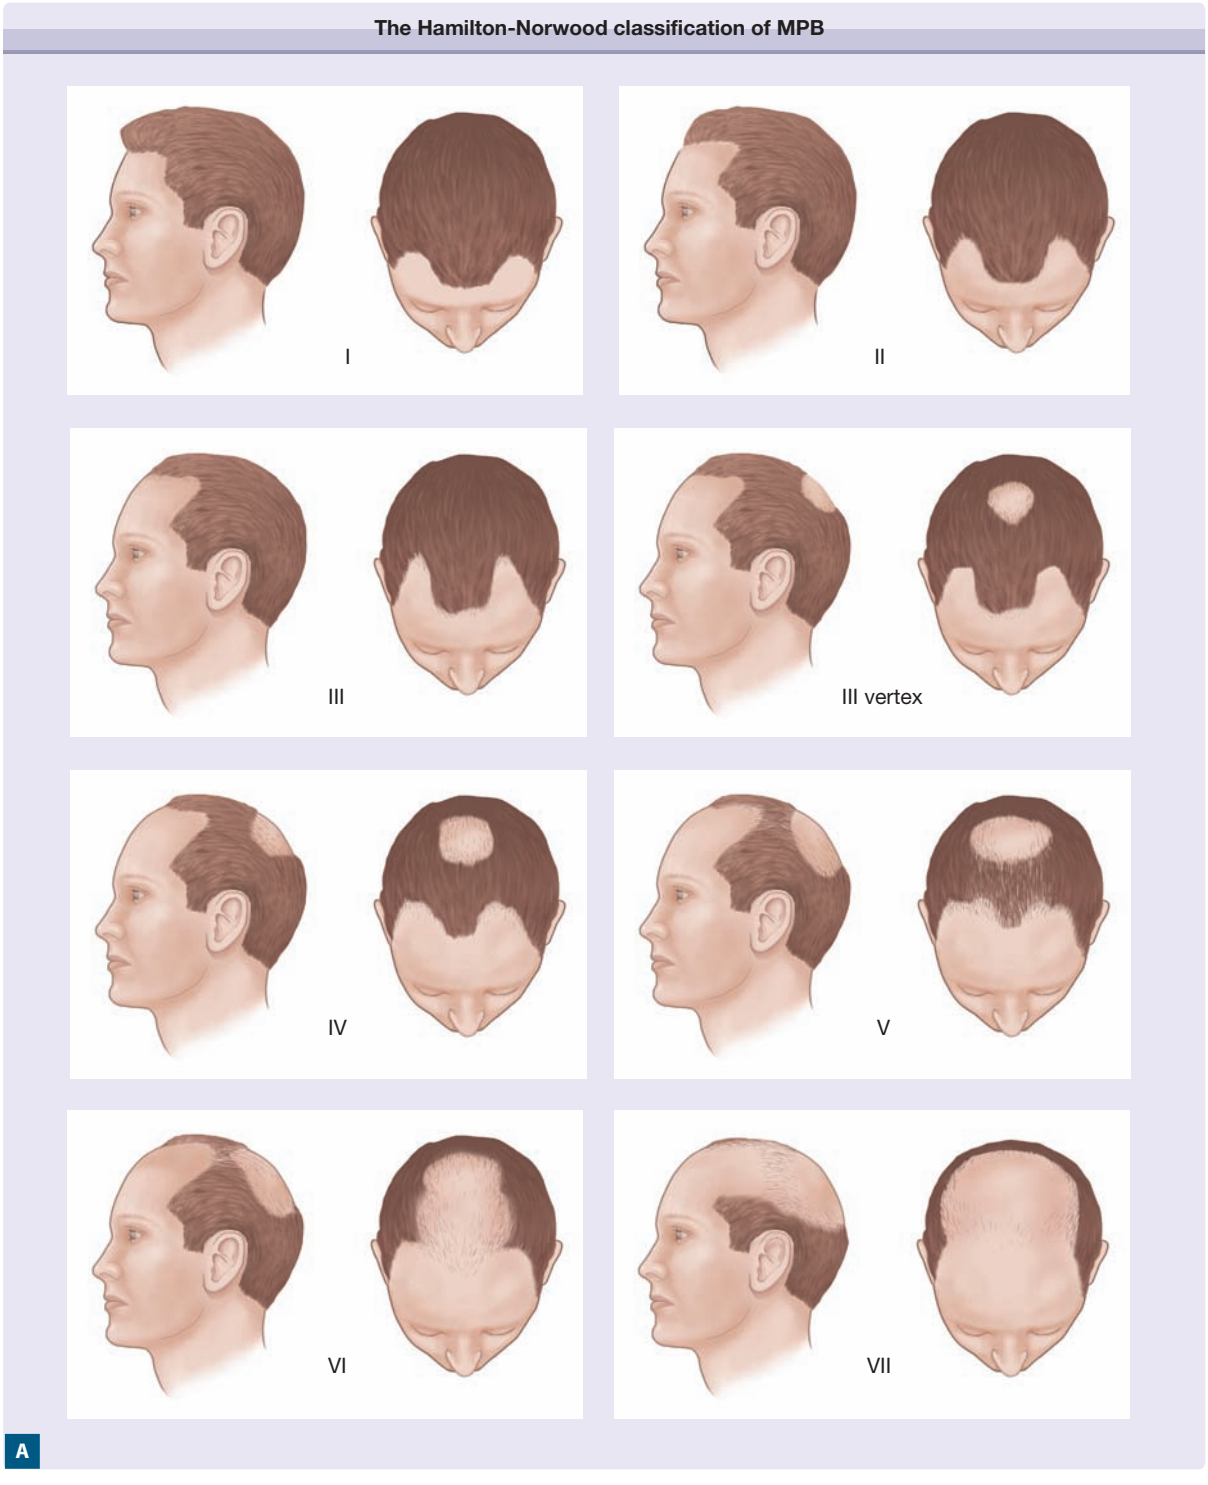

Figure 256-2 **A.** The Hamilton-Norwood classification of MPB. (*continued*)

the alopecic regions; and finally (4) evolving areas of alopecia adjacent to the aforementioned three major areas, which on close inspection contain relatively sparse hair (Figs. 256-6–256-8). Commonly, each transplant session treats one of the three major areas, plus adjacent evolving areas. Occasionally, the treatment of evolving areas of hair loss is deferred to later sessions in order to transplant a larger proportion of obvious areas of hair loss. In such cases, sufficient numbers of grafts must be left in reserve to permit the future treatment of these areas, unless an isolated frontal forelock is the ultimate goal.

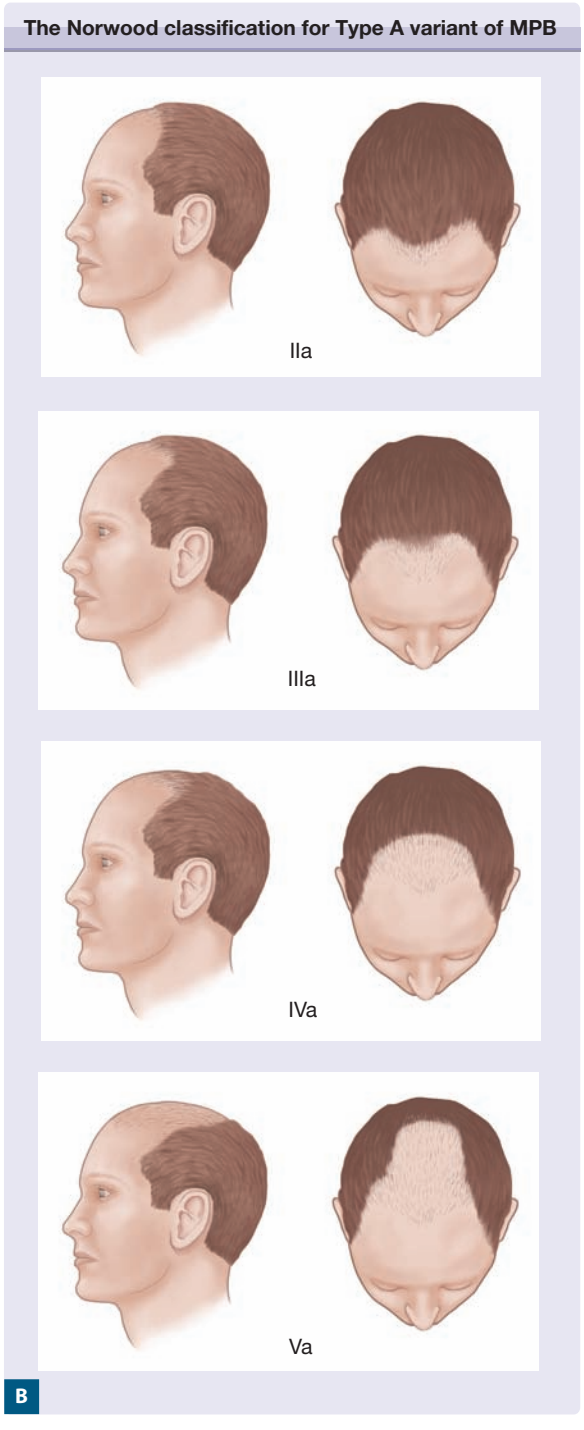

Figure 256-2 (*Continued*) **B.** The Norwood classification for Type A variant MPB.

In Unger's study of 328 males over the age of 65 years, he delineated an area within the zone of rim hair that contained 8 or more hairs per 4-mm circle[5] (Fig. 256-9). He referred to this as the safe donor area (SDA). For most patients, the equivalent of 3–5 strips, each of which is 10 mm, can be excised from the SDA during their lifetime. Each of those strips produces 1,500–2,750 FU, depending on the density of the donor hair.

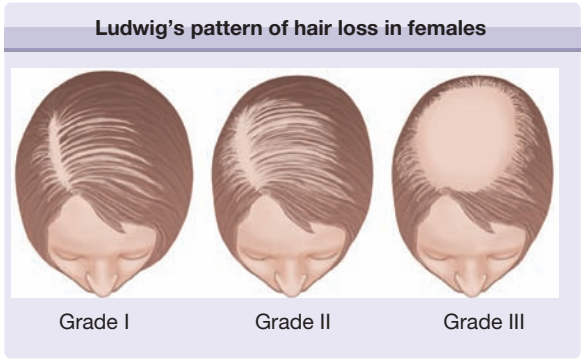

Figure 256-3 Ludwig pattern of hair loss in females.

PATIENT SELECTION

During the initial consultation, surgeons must clarify whether the hair loss is temporary or responsive to medical treatment. A comprehensive discussion of this subject is available elsewhere in this textbook. Provided this is not the case, the first step in the surgical evaluation of a patient is to assess the current and expected size of the donor and recipient areas. An accurate assessment of the donor/recipient ratio depends on professional experience, the family history of patterned hair loss and most importantly the patient's age. The second step is to evaluate hair characteristics. Box 256-1 lists the hair characteristics of the best hair transplant candidates. Not all of these characteristics are necessary for a satisfactory result, but each one improves the final cosmetic appearance (Fig. 256-10).

The authors do not follow any strict rules on patient selection with respect to the stage of hair loss, age, or gender. In regards to the stage of hair loss, it is important to note that the recipient area does not need to be completely alopecic in order to successfully operate. In fact, there are important advantages to transplanting at an earlier stage of MPB, although treating such areas demands a high degree of skill. Similarly, there are no definite age requirements, although younger patients, especially those under the age of 25, should have more conservative treatment plans. As part of this planning, such patients are encouraged to use medical treatment to delay or partially reverse the progression of MPB. In addition, surgeons should leave enough hair in the safe donor area to permit at least one future surgery in the event of unexpected areas of hair loss.

BOX 256-1 IDEAL HAIR CHARACTERISTICS

High density hair in the safe donor area
A mixture of fine and coarse hair
Minimal contrast between the skin and the hair color
Wave or curl

Type VI	2 (1%)	4 (3%)	7 (4%)	10 (7%)	19 (13%)	11 (11%)	10 (13%)
Type VII	0	2 (1%)	5 (3%)	4 (3%)	16 (10%)	11 (11%)	14 (17%)
Total	185 (100%)	165 (100%)	165 (100%)	156 (100%)	149 (100%)	102 (100%)	77 (100%)

[a]Numbers in parentheses under Type III represent Type III Vertex individuals.

With respect to gender, it is worth mentioning again that women are more often than generally thought, excellent candidates for hair restoration surgery, despite the strong disagreement of a few surgeons. In an effort to discern the consensus opinion, the authors informally polled a group of leading experts in the field. From among this group, a majority (13 out of 22) felt that more than 50% of women had enough donor hair to permit *at least* one transplant.[9] In the authors' opinion, the percentage is even higher provided that the patient's expectations are commensurate with what is realistically possible given their donor/recipient ratio and hair characteristics. A strategically planned surgery, with a focus on transplanting the frontal zone and part-line, usually produces a cosmetically significant improvement, and leaves female patients very satisfied (Fig. 256-11).

RISKS AND PRECAUTIONS

Before proceeding with surgery, the patient's physician is contacted in order to discuss any areas of major medical concern. For safety, the operating room should be equipped with the medications and equipment needed for basic monitoring and advanced life support. While

TABLE 256-2
Unger Study of Incidence of MPB (Norwood-Hamilton Scale) in Men Older Than 65

	Age (years)			
Type	**65–69**	**70–74**	**75–79**	**80+**
I	2 (3.6%)	5 (6.2%)	4 (5.5%)	2 (1.7%)
II	9 (16.4%)	7 (8.6%)	7 (9.6%)	12 (10.1%)
III	4 (7.3%)	15 (18.5%)	18 (24.7%)	11 (9.2%)

Figure 256-5 **A**. A 54-year-old female patient with significant hair loss in the hairline and temple regions. **B.** The same patient 2.5 years after a session of 1,248 FU and 264 DFU. The frontal view shows the effect that can be achieved for the overall appearance.

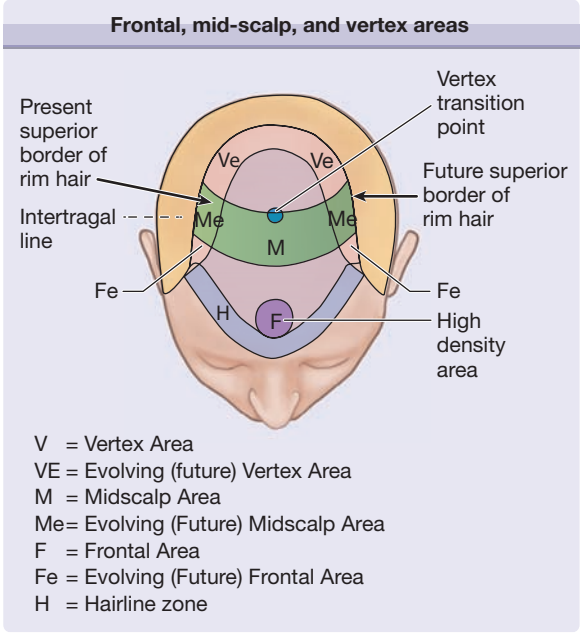

Figure 256-6 A schematic showing frontal, midscalp, and vertex areas, as well as evolving areas of MPB in a patient with Type VI MPB. Ideally, each of the three major areas is treated at the same time as the evolving areas of MPB lateral to them. Typically, only one major area and evolving area are treated during each session, though "touch-up" thickening of previously transplanted sites may also be carried out concomitantly.

rarely necessary, the authors prefer operating with anesthetist when patients have significant underlying health risks, including serious cardiovascular conditions, certain respiratory problems and seizure disorders. Box 256-2 presents a list of significant potential intraoperative complications.

BOX 256-2 MAJOR INTRAOPERATIVE RISKS

Lidocaine toxicity
Respiratory depression secondary to sedatives or narcotics
Excessive intraoperative bleeding

PATIENT POSITIONING

When removing the donor strip, the authors' patients are placed in a prone position, with their head in a doughnut ("prone") pillow that allows them to breathe comfortably. During the creation of the recipient sites and the insertion of the grafts, patients remain in a semisupine position except when working on the inferior portion of the vertex, in which case a prone position facilitates the work of both the surgeon and technicians.

TECHNIQUE

RECIPIENT AREA DESIGN[11]

On the morning of the surgery, a grease pencil is used to outline the treatment area. The frontal recipient area is designed by first drawing the proposed hairline. The midline, anterior-most point of the hairline should be as superior as acceptable to the patient, but always lies within the area in which the vertical forehead changes into the essentially horizontal caudal scalp.

Figure 256-7 **A.** A patient with early MPB. The grease pencil line outlines the areas to be treated, including the supratemporal humps that are currently hair bearing, but can be reasonably expected to lose hair with the passage of time. Designing and transplanting these regions has the advantage of allowing the lateral points of the new hairline to be placed more superiorly than they otherwise could be. This is because if the supratemporal humps were not transplanted and proceeded to lose their hair, the new hairline would eventually end in alopecic areas. **B.** The same patient six months after being transplanted 2,137 FU. The hairline in this patient intersected the temporal humps relatively inferiorly. His family history and examination suggested that he would ultimately develop Type V or, at worst, Type VI MPB, and he had relatively dense hair in his donor area.

Figure 256-8 **A.** A 67-year-old patient, with Type VII MPB and a relatively sparse donor area before treatment. The black crayon lines outline the areas to be treated. Reconstruction of the supra-temporal humps permits a more superior position for the new hairline. This decreases the anteroposterior length of the frontal area, resulting in the consumption of fewer grafts. This hairline runs parallel to the ground when viewed laterally, despite its more superior positioning. **B.** A side view of the same patient 11 months after his second hair transplant and a total of 3,211 FU (one session was to the frontal area and one was further posterior). The advantages of recreating the supratemporal humps are more obvious for patients with Type VII MPB than for patients who have, or will, develop less severe MPB. **C.** A frontal view of the same patient. **D.** The donor area scar 9 months after the third transplant in this patient.

The lateral borders are determined by outlining the supratemporal humps—semihemispheric areas that are superior to the temporal areas in all males, with the exception of those with Type VII MPB. Some of this area may or may not have persisting original hair but, regardless, should be transplanted. The lateral ends of the hairline are then joined to the supratemporal humps with a slight flare, to produce a rounded corner that creates a natural shape, but leaves patients with a mature looking hairline that includes frontotemporal recessions. In some patients, the anterior border of temporal hair is significantly receded, and it may need to be recreated at the same time as the anterior supratemporal humps are being transplanted. The posterior border of the frontal area is completed with an arc that helps create a natural pattern of hair loss in the event that the patient decides not to transplant any further posterior, or does not have sufficient donor hair to do so. When transplanting the midscalp, the posterior aspects of the supratemporal humps are included, and the posterior border of the transplant is similarly finished in an arc. For the vertex area, either the entire region or its periphery can be transplanted, depending on the available donor supply and patient goals.

DONOR AREA DETERMINATION

Choosing the optimal location and width of the donor strip is one of the most important decisions made during hair transplanting. For the first surgery, the authors typically choose a donor area that lies in the middle of the densest zone of the fringe hair, and extends into the temporal region in males, but ends posterior to the ears in females. This location is the most logical, since hair is progressively lost from the superior and inferior borders of the fringe hair in MPB, and hence this position provides the greatest degree of likelihood that transplanted hair is permanent. Each subsequent harvest includes any scar from prior session(s), as well as donor

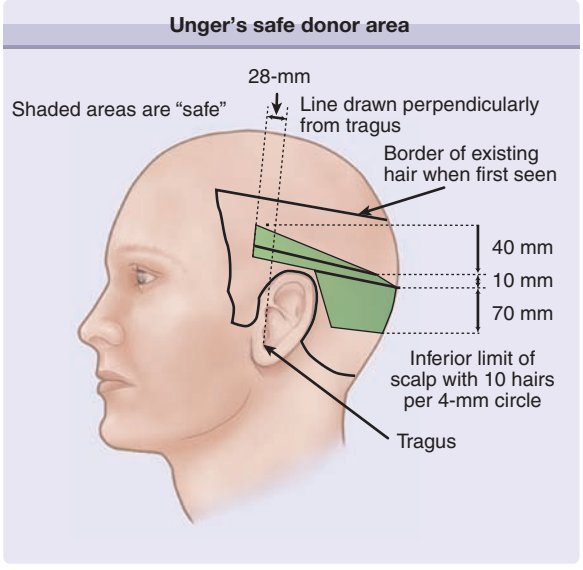

Figure 256-9 Unger's safe donor area for 80% of patients under the age of 80 years, as determined from studies of 328 men aged 65 years or older.[5]

hair immediately superior and inferior to the scar. This results in the presence of only one scar, regardless of the number of sessions carried out (Fig. 256-13). In order to determine the location of the densest zone, it is sometimes helpful to wet the hair to determine the superior and inferior margins of current areas of thinning. Once the donor area is identified, hair in an 10- to 14-mm wide zone is clipped short and cleansed with alcohol- and an iodine-based antiseptic.

DONOR SITE EXCISION[12]

Prior to starting the excision, the effectiveness of the anesthetic block is verified. Scalp laxity is clinically assessed in order to determine the appropriate width of the donor strip, which in the authors' practice is typically 8–12 mm wide. A prudent decision is to take a slightly narrower strip than the examination suggests is possible, thus permitting a margin of error that will minimize the possibility of a high-tension donor closure.

BOX 256-3 INSTRUMENTS NEEDED IN HAIR TRANSPLANTATION

- Double-bladed cutting knife handle
- #10 scalpel blade
- #15 scalpel blade
- Small curved surgical scissors
- Small straight Iris scissors
- Gauze
- Hyfrecator
- Smoke evacuation system
- Needle driver
- Suture material
- Toothed curved forceps
- Straight Adson forceps
- Hypodermic needles (various sizes)
- Clear plastic cutting boards
- Mantis microscope with under-lighting
- Double-sided razor blades
- Razor blade holder
- Divided Petri dishes
- Lepaw coolers
- #5 Planting jeweler's forceps
- #2 Jeweler's forceps
- Telfa pads
- Kerlix Dressing
- Aluminum rat tail comb
- Curved Metzenbaum scissors
- China marker grease pencil
- Syringes (various sizes)
- Stainless steel bowls

Figure 256-10 **A.** A patient before transplanting. **B.** One year after a first FUT session (1947 FU). This unusually dense result was mostly due to the patient's relatively high caliber and wavy hair.

Figure 256-11 **A.** A 52-year-old female patient before hair transplanting in a frontal midline area with embarrassingly low hair density. **B.** 7 years after a hair transplant consisting of 843 FU and 113 DFU (a total of 1,069 FU). The patient was being seen for possible transplanting posterior to the first recipient area. **C.** A photo taken at the same time as B with the hair combed back for critical evaluation. A little hair placed properly and with good hair survival goes a long way cosmetically. The fear that transplanted hair will be lost soon after surgery is misplaced if the donor area has been appropriately chosen.

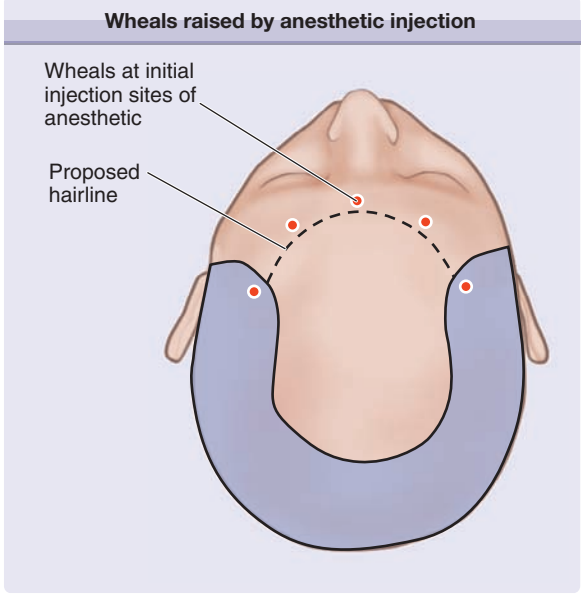

Figure 256-12 A photo showing the wheals raised by anesthetic injection in the midline, middle of the left and right hairline, and lateral ends of the hairline. These wheals are gradually extended left and right, by inserting the needle through them after the onset of anesthesia, to complete the field block almost painlessly.

Figure 256-13 The hair was clipped short in the donor area prior to the fourth session. The narrow scar that can be seen in this photo is the only scar he had after three sessions as we typically excise any scar from prior surgery as part of subsequent donor strips. Scars are usually 0.2–1.5 mm wide regardless of the number of strips that have been excised. We believe that this is mainly because we nearly always try to choose strip widths that create wounds that will close with what we call "minus 1" (-1) to "minus 2" (-2) tension, that is, we believe we could have taken a strip that was 1.0–2.0 mm wider than what we actually took.

Immediately prior to donor tissue excision, the donor area is tumesced with 10–40 mL of normal saline. This increases tissue turgor, thereby minimizing bleeding, but also limiting follicle bending that might otherwise result in FU transection. The authors use a single or double-bladed scalpel to cut donor tissue parallel to the exit angle of the hair: a double-bladed scalpel is used when the angle of hair at the superior and inferior aspects of the donor strip are aligned, and a single-bladed scalpel is used if there is a discrepancy, in order to prevent FU transection at one edge. This usually means that a double-bladed scalpel is used on the initial surgery, and a single-bladed scalpel in subsequent surgeries, since scarring from prior session(s) often distorts hair angle.

The incision begins and ends approximately 2 cm medial to the ends of the clipped donor area. To reduce the likelihood of "dog ears" forming, the two ends are tapered to a 30° angle using a No. 15 scalpel. The depth of the incision can vary significantly. In the first surgery, the blades are placed in high subcutaneous fat, in order to minimize underlying neurovascular damage. In subsequent surgeries, where fibrous scar tissue has formed deep to the original donor site, the depth of the incision is greater in order to permit its removal. This is an important step, since scar tissue is avascular, space occupying, and tethers the edges of the wound, thereby increasing donor closing tension and interfering with wound healing.

The entire strip is removed in three sections, which provides greater control of bleeding. Vessels with exuberant bleeding are cauterized using a unipolar hyfrecator. The wound is closed with a running suture. In practice, the authors use a 2.0 or 3.0 Supramid (a nylon suture) with a CL50 cutting needle.

Rarely, the authors will employ a "trichophytic closure," in order to minimize scar visibility in individuals who have previously healed with a wider than usual scar. In such instances, a wedge-shaped portion of the epidermis of the inferior wound edge is removed prior to donor closure, using either curved scissors or a bent razor blade. This transects the upper portion of hair follicles, and when the two opposing edges of the wound are apposed, most of these transected follicles will lie under the line of closure. If properly done, these hairs then grow *through* the donor scar, thus reducing the noticeability of scar tissue.

An alternative method of donor harvesting referred to as *follicular unit extraction (FUE)*. Using this technique, each individual FU is created directly from the scalp, rather than from a strip of donor tissue.[13,14] FU are excised using a small, sharp cylindrical punch (generally 0.8–1.2 mm in diameter), which incises the skin around each FU. The FU can then be carefully removed with forceps and gentle traction.

On the one hand, this technique offers distinct advantages. Most importantly, it does not leave a linear scar. The resultant punctate scars are minimally noticeable, even with the hair closely cropped (Fig. 256-14). Thus, this is a useful procedure for individuals who have a strong dislike or fear of linear scars, or who are more likely to produce wider than average linear scars. On the other hand, FUE is associated with important disadvantages. Chief amongst them, if a patient is destined to develop greater than Type V MPB, and therefore need more than 6,000 transplanted FU, many of these grafts will need to be harvested from areas outside the boundaries of the SDA (Fig. 256-14). This is because FUE involves the extraction of every third or fourth FU, and therefore the donor area would have to be 3–4 times as large as the donor area required for strip harvesting. The hair within many of these FU is therefore less likely to be permanent. Equally important, the transection rates during graft harvesting are substantially higher for FUE than for strip excision. In FUE, each FU is at risk of transection when it is extracted blindly from the scalp. In contrast, in strip

Figure 256-14 **A.** This is an intraoperative photo of a patient who had a linear scar from prior conventional strip harvesting, and who was undergoing FUE with the intention of placing grafts within the linear scar, and in areas of alopecia. The FUE was carried out by another surgeon. The round holes are the sites of FU extraction. The superimposed rectangle outlines the safe donor area (SDA). Many of the FUE sites were outside of the SDA, and the hair in these harvested grafts will likely be lost with time as MPB progresses. **B.** A photo taken 9 months postoperatively demonstrates the most important, immediately recognizable advantage of FUE: namely the ability for the patient to cut the donor area to any length without visible scarring. The previous linear scar has been effectively concealed with grafting.

harvesting only grafts at the edges of the strip are vulnerable, since other FU are prepared with magnified, direct visualization (see below). For these reasons, in the authors' practices, FUE is used to complement strip harvesting, but not to replace it. In particular, FUE may be used to obtain FU for placement into linear scars produced by strip harvesting. This is desirable when the scar is wider than average or when no further strip harvesting is planned. Such an approach combines the main advantage of strip harvesting—the maximization of the number of permanent hair—with the main advantage of FUE, the lack of a linear scar. Additional points of comparison between FUE and strip harvesting are outlined in Box 256-4.

BOX 256-4 ADVANTAGES AND DISADVANTAGES OF FOLLICULAR UNIT EXTRACTION

ADVANTAGES

- Reduced postoperative pain
- Rapid donor healing
- Absence of linear scar
- Ability to selectively choose FUs according to desired size or texture

DISADVANTAGES

- Difficult to obtain large numbers of grafts without exceeding the limits of the safe donor area
- Higher follicular transection rates
- More difficult post-operative camouflage because hair needs to be clipped short for harvesting
- Longer operative times

GRAFT PREPARATION

The preparation of grafts is accomplished using either stereoscopic microscopes or magnifying loupes or glasses. After removal of a donor strip, the first step is "slivering" the donor strip, in which slices, one FU wide, are carefully produced from the strip, much like cutting a loaf of bread into individual slices (Fig. 256-15A). These slivers, composed of 4–10 FU, are then further divided into individual FU. Occasionally, two very closely spaced FU, that combined are small enough to fit into a typical FU recipient site, are not divided. Such a graft is referred to as a follicular family (FF). Compared with larger multi-FU grafts, FU and FF are far more susceptible to injury during graft preparation, storage, and insertion.[15] Therefore, technicians must have thorough and prolonged training, excellent manual dexterity, an appropriate temperament, and ongoing supervision.

The ideal FU has most of its epidermis removed and is tear shaped, with the tapered end near the epidermis, and the rounded end in the subcutaneous tissue (Fig. 256-15B). The donor tissue is kept moist at all times, and prepared FU are stored in a sectioned Petri dish filled with normal saline, or an alternative physiologic solution.[16] This dish sits on a Lepaw cooler filled with ice. Within the sectioned dish, FU are distributed into labeled compartments depending on the number and caliber of hairs. In this way, the individuals planting grafts can immediately find the type of graft that they need for a particular recipient site. Hairs that are partially transected are not discarded, provided that the distal two-thirds or proximal half is intact. They are, however, placed in less cosmetically important regions, since hair growth from these grafts is unpredictable.

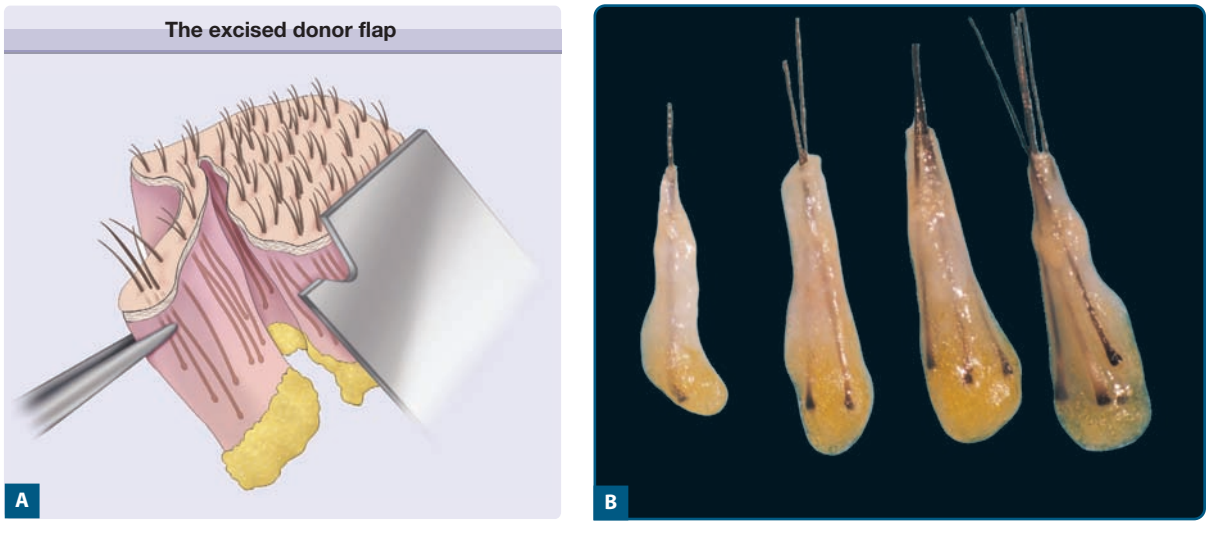

Figure 256-15 **A.** The excised donor strip is initially sectioned into slices that are one FU in width, much as one cuts bread into slices. **B.** Pear-shaped; chubby; one-, two-, three-, and four-haired FU grafts. Note the intact sebaceous glands and the fat pads below the dermal papillae. (Photos used with permission from Dr. David Seager.)

RECIPIENT SITE CREATION[17]

Recipient sites are created using hypodermic needles or small blades cut to match the size of grafts. During this process, a 1/50,000 epinephrine solution or normal saline is injected intermittently and superficially into the recipient area to provide better hemostasis. Such infiltration offers the additional advantage of spreading existing recipient area hairs apart, thus minimizing the risk of injury when making incisions. Furthermore, as the solutions dissipate, the recipient sites move closer together, which ultimately produces higher hair density.

The incisions are made at the same angle and direction as the persisting terminal or vellus hairs. Much of the art of hair transplanting resides in the ability of the surgeon to do this, as both angle and direction vary considerably from patient to patient, and between different areas of the scalp (Fig. 256-16). If one fails to do this, the resultant appearance will be unnatural and preexisting hair in the recipient area can be lethally damaged. Therefore, recipient site creation should be done very slowly in order to ensure accurate angling and direction. Typically, it will take between 1½ and 2½ hours to make 2,000–2,500 sites, depending on the density of preexisting hair in the recipient area and the amount of bleeding.

If hair survival is high, a density of 20–30 FU/cm^2 produces very good cosmetic results while preserving donor hair for future areas; consequently, this is the density that the authors' prefer. Higher density grafting is limited to small cosmetically strategic areas of the recipient area, including an oval in the anterior midline of the frontal area (Fig. 256-6). Greater density in this particular area gives an impression of higher density across the entire frontal area.

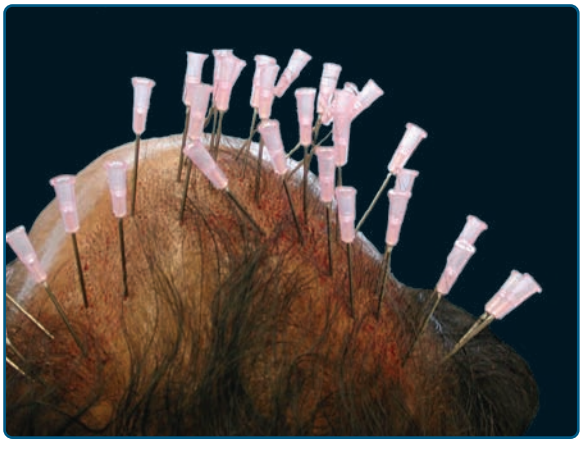

Figure 256-16 Although various directions and angles of hairs in different areas of the scalp have been described, none of these generalities apply to all patients. Hair directions and angles can change dramatically in relatively small areas, as indicated in the above photo showing needles inserted at the angle and direction of hair at these locations. The surgeon should follow what they observe rather than any general rule concerning hair angle and direction.

A second reason for grafting at 20–30 FU/cm^2 is that most studies on hair survival have demonstrated a tendency for unacceptable decreases in hair survival at higher FU densities, especially when the total incision length exceeds 3.0 cm/cm^2.[18,19] In part, this may be because higher densities require smaller recipient sites and, therefore, more graft handling. Although hair survival at high FU densities has improved substantially in the last few years, good cosmetic results can be achieved with 20–30 FU/cm^2, and thus higher densities are reserved for individuals with publicly visible professions. For other individuals, especially younger patients with uncertain long-term donor/recipient ratios, it is an inappropriate use of a limited resource.

With regards to "mega-sessions" of 3,000–5,000 FUs, it should be pointed out that the average recipient site is 1 mm long, and while 1 mm seems quite small, the *total* length of a 3,000, 4,000, or 5,000 graft session is respectively 9.99 ft, 13.33 ft, and 16.67 ft. Obviously, the larger the area treated, the more worrisome any given number of incisions and the resulting vascular damage. It seems reasonable to be cautious about creating 10–16 ft. of incisions on the scalp until high hair survival rates in such sessions have been confirmed.

In order to determine the optimal size of the recipient site, several grafts containing varying numbers of hairs are tested in different sized incisions. The needle or blade size is adjusted accordingly. Typically, 1-hair FU and fine 2-hair FU fit into sites made with 20G needles, coarser 2-hair FU fit into 19G sites, and 3-hair and 4-hair FU fit into sites made with 18G needles. The ideal graft fit is one that is "snug," but not so tight as to require significant handling during insertion. In general, sites for 1 or 2 fine-haired FU are created in the hairline zone, and sites for 2 or 3 coarse-haired FU are created in areas that need greater hair density.

GRAFT INSERTION

After the recipient sites have been created, the surgeon reviews with their assistants the locations where the various sized FUs should be placed. Usually, two or three technicians work on a single patient simultaneously. A group of grafts is removed from the fluid filled wells of the Petri dish, placed in a "ring" filled with saline on the finger, and from there placed in its recipient site. In this way, grafts are kept moist. With an appreciation of the angle and direction of the recipient site, a skilled technician can then insert a graft with one or two swift movements. The recipient area is kept clean by regularly using a mixture of saline (75%) and peroxide (25%), and the grafts are left slightly elevated to help in identifying sites that have not yet been filled. At the end of the procedure, grafts are repositioned to the level of the epidermis, or left slightly elevated, but never depressed as this can cause pitting, or depressions, in the perifollicular skin.

REPAIR SURGERY

The appearance of the recipient area of patients who have visible, unnatural grafting from prior surgeries, in

Figure 256-17 **A.** This 39-year-old patient had a "FUT" procedure carried out by another physician 3 years before this photograph was taken. A number of errors had been made. These included a failure to transplant into evolving areas of hair loss, and the placement of grafts that contained too many hairs, of too coarse a texture, in the hairline zone. The black crayon outlines the area that we proposed to treat. **B.** The patient returned 9 months after his first repair consisting of 1973 FU. A new hairline had been created using finely textured 1- and 2-haired grafts. The rest of the frontal area was repaired by surrounding prior grafts with FU, and by extending the transplant into adjacent areas of evolving hair loss. A third session, this time to the midscalp, was carried out 2 months after this photo was taken.

particular from MFU grafting, can be greatly improved with modern hair transplanting techniques, primarily by placing FU anterior and peripheral to these larger grafts.[20] If FU with too many hairs or too coarse hairs have been inappropriately placed in the hairline zone, these can be dealt with similarly, by surrounding them with properly selected FU (Fig. 256-17). For larger grafts, the excision of all or a portion of any larger grafts may also be useful in minimizing "plugginess," while providing additional hair that can be transplanted elsewhere in the recipient area (Fig. 256-18). For patients in whom poor planning resulted in the unnatural placement of grafts, for example, a hairline that is too far anterior, the grafts can be excised either individually or by employing an "en bloc" excision.

In the donor area, multiple rows of scarring can often be reduced by excising a strip of tissue that contains two rows of scar tissue and an intervening zone of hair-bearing skin (Fig. 256-19). This converts 2 scars into a single scar, while providing additional hair for use in the recipient area. It is important, however, that the removed strip is not so wide as to prevent a tension free closure.Alternatively, donor scarring can be improved by grafting into abnormally wide scars.

SIDE EFFECTS AND COMPLICATIONS

The potential side effects and complications of hair restoration surgery are listed in Box 256-5.[21] Below we elaborate on a few of them:

1. Edema: Severe postoperative edema is unusual, but can be unsightly if it occurs in the frontal region, or interfere with healing if it occurs in the donor area. The risk is minimized by prescribing perioperative corticosteroids, by proper postoperative patient positioning, and by using ice compresses.
2. Infection: Although rare, infection can present as early folliculitis in the recipient area, or more seriously wound dehiscence in the donor area. A number of measures reduce the risk of superficial surgical site infection, and it is worth mentioning that prophylactic antibiotics are one such measure.

BOX 256-5 SIDE EFFECTS AND COMPLICATIONS

SIDE EFFECTS
- Minor bleeding
- Scalp hypoesthesia
- Edema
- Crusting
- Pruritus
- Postoperative effluvium

MEDICAL COMPLICATIONS
- Wound Infection
- Wound dehiscence
- Neuralgia and neuromas
- Arteriovenous fistulas
- Central recipient area necrosis
- Folliculitis

AESTHETIC COMPLICATIONS
- Visible scarring
- Hypertrophic and keloid scarring
- Unnatural appearance
- Poor density

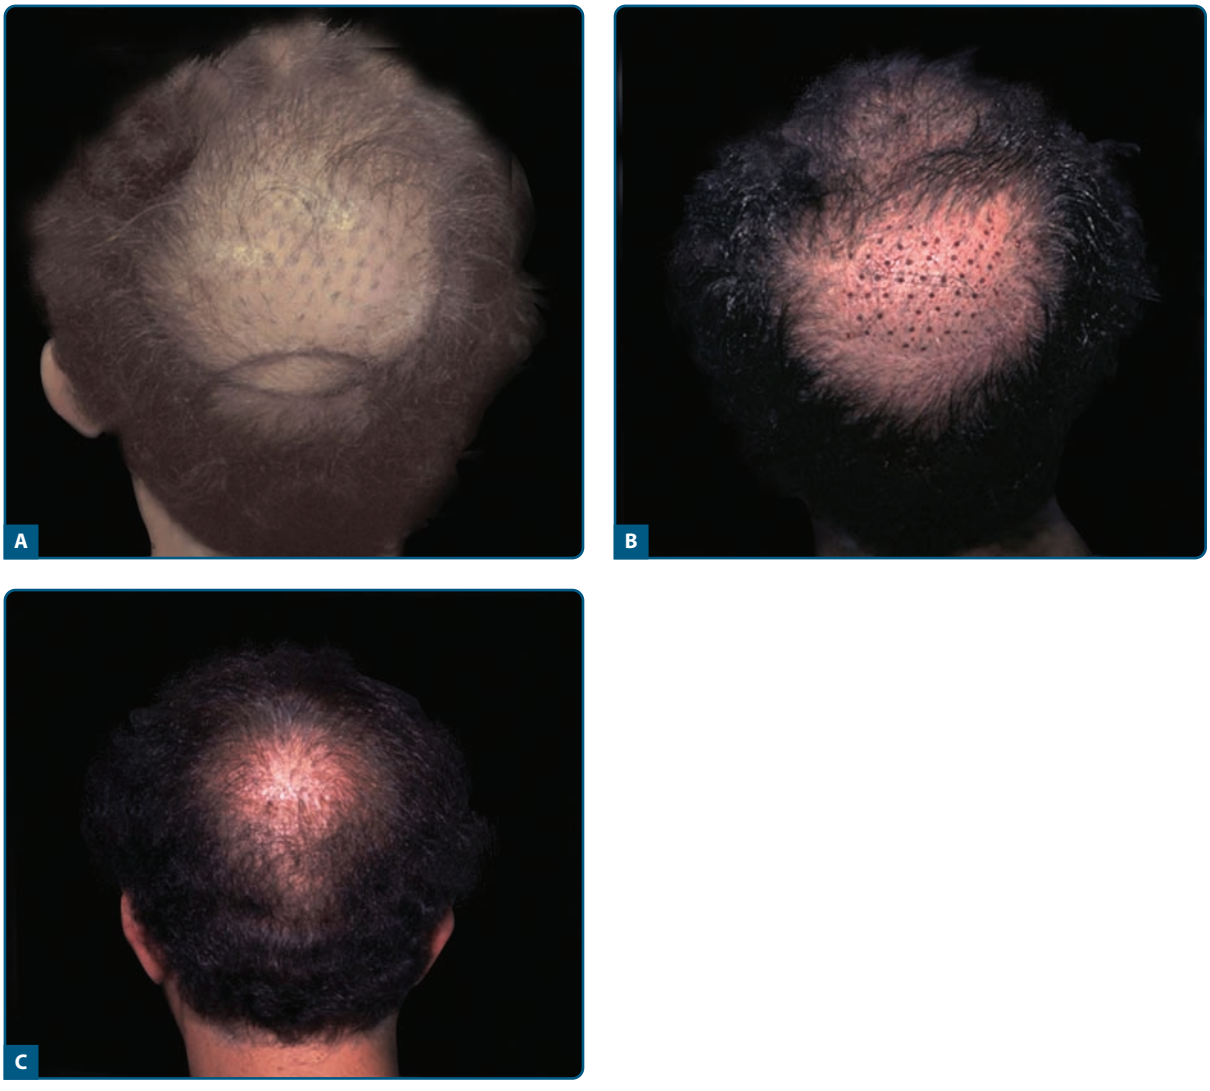

Figure 256-18 **A.** The vertex area of the patient shown above had been transplanted with standard round grafts. His original intention was to correct poor transplanting in the frontal and midscalp areas, but he was so happy with the progress in those areas that that he decided to correct the vertex problem. Because I was concerned about running out of donor tissue, he had an alopecia reduction (AR) performed on the right and posterior aspects of the vertex 3 months prior to the above photo. The hair in the standard grafts had been cut short to facilitate the excision of a portion of each of them. **B.** An intraoperative photo showing the holes where a 2-mm punch had been used to excise a portion of each of the standard grafts. At the same time 129 FUs, 398 DFU, and fifteen 1.5-mm-round grafts were scattered throughout the vertex area, some of which were obtained from the excised portions of the old grafts. A faint scar from the AR can also be seen in the posterior aspect of the vertex. **C.** Nine months later, a light but very natural looking coverage of hair was present in the vertex. The ultimate results of the transplanting in the midscalp and frontal areas can also be appreciated in the above photo. The hair in the vertex has been parted for critical evaluation with regard to both hair density and the minimal noticeability of the multi-FU grafts.

3. Bleeding: Minor donor area bleeding can occur in the first few days postoperatively. Usually this resolves with firmly applied pressure, but rarely extra suturing is required.
4. Donor area scarring: In the authors' office significant attention is given to measures that minimize the likelihood of wide donor scarring: the wound is closed with the absolute minimum of tension; postoperative edema is minimized through the aforementioned measures; and postoperative care is meticulous. Although this prevents wide scars in most patients, intrinsic poor wound-healing characteristics and severe scarring from old surgeries can result in wider than average scars. In such situations, grafts harvested from FUE can be transplanted into the scar, or alternatively trichophytic closures or double-layer suturing can be carried out during subsequent strip excisions.
5. Poor density: This may reflect poor graft growth, suboptimal graft distribution, or poor postoperative care. This problem is probably entirely avoidable.

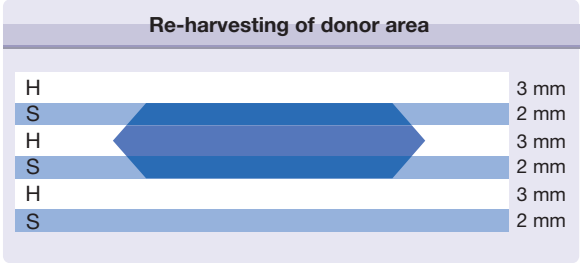

Figure 256-19 The shaded area represents a zone excised from a previously harvested donor area consisting of alternating bands of hair (H) and scar (S). *Note:* (1) As much or more scar tissue is excised as hair-bearing tissue. (2) Two hair-bearing strips are left adjacent to each other after the excision. The result is that the hair will appear to be denser in that general area, despite the removal of additional hair from it.

6. Postoperative effluvium: This problem may occur in hair-bearing areas in the recipient or donor areas. It is presumably due to the interruption of blood supply and is always temporary. Approximately 10%–20% of male patients and 50% of females experience some degree of postoperative effluvium.

PATIENT FOLLOW-UP

In the authors' practice, all patients are seen the day after surgery for bandage removal. The hair and scalp are thoroughly washed and postoperative instructions are reviewed. A clean cap is used to cover the surgical area before sending the patient home. All patients are seen 7–10 days postoperatively to check the surgical area and remove sutures. A follow-up appointment is generally booked for 6–12 months later to assess the surgical results and determine the need for further treatment.

ALOPECIA REDUCTION

Alopecia reduction (AR), or scalp reduction, is defined as the excision of an area of alopecia or future alopecia.[22] In the past, the technique was used in conjunction with hair transplantation as a means of reducing the size of the prospective recipient area, and thus conserving grafts for cosmetically vital areas of the scalp. Unfortunately, the technique is technically demanding, and the high frequency of medical and aesthetic complications, in inexperienced hands, led to the procedure falling out of favor. Currently, the technique is used to repair esthetically unsatisfactory hair transplanting or to excise areas of cicatricial alopecia.

TECHNIQUE

A variety of AR patterns have been described, but the most common patterns employed are the ellipse, the inverted-Y pattern, and the "lazy-S" shape. The inverted-Y pattern should be used if one anticipates insufficient donor tissue to transplant the entire bald area, even after AR. This design avoids a scar in areas that cannot later be covered with transplanted hair.

AR is usually carried out on an outpatient basis under sterile conditions. The procedure begins by drawing the chosen pattern on the scalp, followed by the creation of a field block. If the pattern is an ellipse, a variant of an ellipse or a "lazy S," an incision is made through the galea aponeurotica along one side of its entire length, usually in a staged fashion. Care is taken to angle the blade so as to not injure any adjacent follicles. If previously transplanted grafts are nearby, a 2-mm margin of safety is observed. Initially, Mayo scissors are used to undermine the region between the periosteum and galea aponeurotica. Undermining can usually be completed with blunt finger dissection, for a total of at least 10 cm on either side of the wound.

The amount of redundant scalp tissue is estimated by overlapping the tissues, followed by perpendicular incisions made through the top flap, stopping at the points where the flaps meet. The perpendicular cuts are then joined and the excess tissue is removed. If the AR is done in the shape of an inverted Y, each arm of the Y is treated as a separate ellipse. ARs are closed in two layers and an overnight dressing is applied. If the wound is closed with minimal tension, less than 10% of the original gain is lost through "stretchback."

As a variation of conventional AR, Patrick Frechet has incorporated the use of scalp "extenders".[23] In this procedure, a thin, stretched sheet of silicone elastomer is inserted into the subgaleal space. Rows of titanium hooks are attached to the lateral ends of the "extender," and subsequently hooked into the galea. The wound is then sutured closed in two layers. The extender has a natural tendency to return to its original size, thus stretching of the tissue located lateral to the hooks and contracting the scalp between them. After a period of approximately 30 days, the extender is removed. Substantial scalp laxity is then present, permitting a second consecutive AR session. Another extender can be inserted at the time of the second and even a third AR. Eight to twelve centimeters of alopecic skin can be excised after each extender is removed, yielding substantial results rapidly (Fig. 256-20). Disadvantages include considerable discomfort during a postoperative 2- to 7-day period, an infection rate of approximately 0.5%, and a slot defect that must be repaired if the entire area of alopecia is excised. Because of the steep learning curve, this potentially valuable procedure is currently carried out by fewer than 10 practitioners in the world.

COMPLICATIONS

Complications of AR include postoperative bleeding, infection, nerve damage, persistent hair thinning or loss in the fringe areas, disorientation of hair direction,

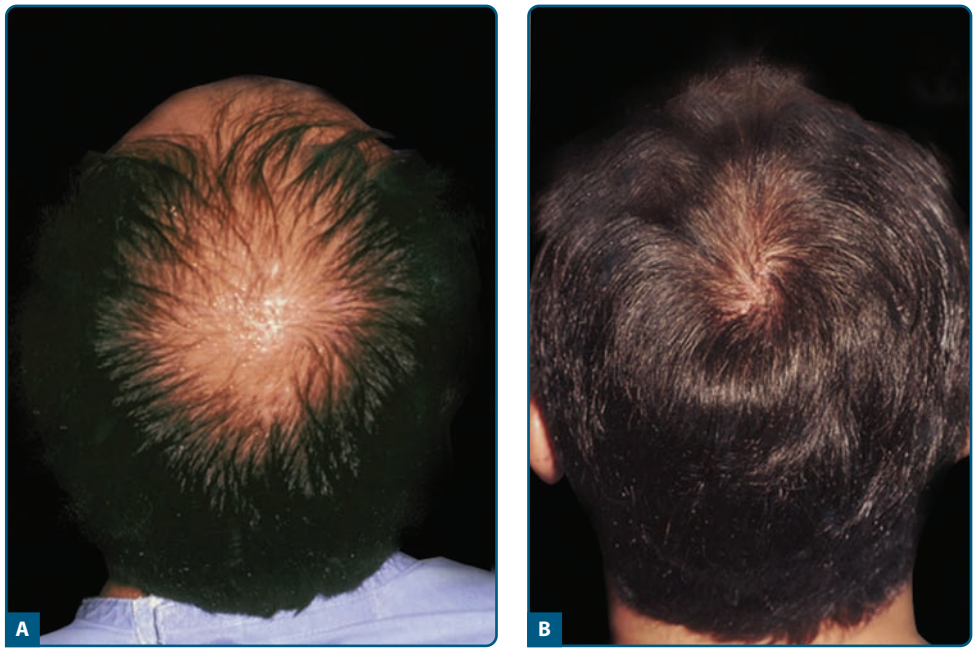

Figure 256-20 **A.** This photo shows a patient with a 10-cm-wide area of alopecia before treatment. **B.** The same patient 30 days later, after one scalp extension plus slot correction. (Photos used with permission from Dr. Patrick Frechet.)

and poor scars. All of these occur infrequently or not at all if the procedure is carried out properly. With the passage of time, excision scars may become noticeable as hair is lost in areas through which the scar passes. This is obviously a problem of poor planning rather than an intrinsic unavoidable complication of the procedure.

CONCLUSION

The evolution of hair transplanting, over the last 10–15 years, has resulted in a remarkable increase in the number of patients who are candidates for the procedure and an even more impressive improvement in the naturalness of the results. Unfortunately, these new techniques also require far more skill and patience from not only the surgeon, but also their surgical team. Additionally, hair restoration surgeons, are not miracle workers, and individuals must be educated as to what they can realistically expect from hair transplanting. When this is done, the reward is nearly always a satisfied and grateful patient.
