Smart homes may be beneficial for individuals living alone who are unable to seek help in emergencies (e.g., falls, strokes, unconsciousness), older adults with cognitive (e.g., memory loss, visuospatial deficit) and/or physical (e.g., hearing, visual, or mobility) impairments, and individuals needing assistance in performing basic and instrumental activities of daily life. Additionally, smart homes may provide integrated telehealth tools that can connect people living in rural or underserved areas with medical providers. With regard to the use of smart homes, important questions such as health outcomes, clinical algorithms for predicting potential health problems, user perception and acceptance and privacy issues are yet to be fully addressed. Ideally a smart space, depicted in Figure 57.6h–1 for health monitoring should be able to integrate implanted, body-worn, and environmental sensors to measure changes with the individual's body, their behavior and changes in the environment. Such a space would also incorporate mHealth approaches (described above) and machine learning and big data analytics (described below) to generate relevant health information with the capability to be predictive of health events.

PERS are another set of important applications of ICTs. These are relatively inexpensive devices designed to facilitate emergency responses

for older adults. They may reduce mortality rates and hospital utilization and may be especially useful in rapid detection and early response to falls, and use of this technology is a subject of great interest and study.

Overall, it remains to be seen how sophisticated home-based solutions and the growing number of advanced ICT applications are tolerated and utilized by older adults in general and specific groups such as those with disabilities or dementia.

FIGURE 57.6h–1. Smart room. This figure indicates the multiple parameters of interaction between persons and their environment that can be quantified by sensors. This figure includes both existing and in-development sensor technology.

Games

Interest in clinical and cognitive applications of video games and game-based interventions continues to grow. Broadly, computerized games can be classified into three types—(a) games developed for, or played on commercially developed gaming systems such as the Sony Playstation, Microsoft Xbox, or Nintendo Wii, (b) commercially available cognitive games such as Lumosity or Posit Science modules, and (c) games developed for research purposes.

In one study conducted by Rosenberg and colleagues in 2010, researchers utilized the Nintendo Wii system, which relies on the persons using the system to perform physical tasks, to administer an intervention of physical exercise, conducted indoors, to assess improvements in subsyndromal depression in older adults. In a small sample of 19 patients, they noted that exercise using this game, performed for 35 minutes three

times a week resulted in statistically and clinically significant improvements in depressive symptoms. The researchers proposed that use of indoor gaming systems may provide incentives for older adults to engage in physical activity. Additionally, the use of the Nintendo Wii to play games that stimulate sports (e.g., tennis, golf) was found to burn approximately 50 percent of the calories that may otherwise be burned by playing the actual sport.

Several cognitive games have been marketed in the past 5 years, aimed at improving cognitive function in older adults who have experienced cognitive decline, and also at younger adults who are cognitively intact but invested in maintaining a high level of cognitive function. However, evidence of the efficacy of such games remains mixed. Despite early promise, large meta analyses of data from studies of such games indicate that at best, they may result in some domain-specific improvement in the cognitive abilities specifically targeted by each game. However, there is no evidence so far to suggest that such gains may be more generalizable to other domains.

There is also existing evidence of efficacy of a game that was custom developed to require multitasking. This game—a 3D racing game called Neuro Racer—was administered to older adults, and the authors noted that by performing the multitasking required by the game, older adults demonstrated benefits in multiple cognitive domains, including those such as sustained attention and working memory, which were not targeted by the game. Moreover, the resultant cognitive enhancement persisted for up to 6 months. This study provides a counterpoint to previous studies on cognitive games, and suggests that rather than targeting specific domains, games that tap multiple skills may be efficacious in improving cognitive outcomes.

Overall, use of a computer gaming interface has been found to be an acceptable and enjoyable method for a wide range of tasks and tests for older adults. Given the ease with which games can now be accessed on ICTs, this application is likely to grow rapidly over the coming years.

Tablets

According to the most recent available data, 18 percent of older adults use tablet devices. Unlike smartphones, which are most popular in younger adults aged 18 to 25, tablets may be more popular among middle aged and older adults. Older adults (65+) are the only demographic that is more likely to own a tablet or e-reader than a smartphone.

Given the larger screen and the consequent versatility of the touchscreen, tablets are increasingly being used for a variety of applications in older adults.

Several existing cognitive screening tools and other performance-based standardized tests are being adapted to iPad versions, including the UCSD

Performance Skills Assessment. Clinical applications, especially for comprehensive neuropsychological testing using tablets as the platform for administration are beginning to gain acceptance. A study by Mielke and colleagues has demonstrated that use of iPad tablets may be especially acceptable to older adults and that testing scores are comparable to those from regular pen-and-paper testing.

In addition to applications developed for delivery using tablets, there is evidence that simply learning to use a tablet device may be beneficial. Older adults are believed to be more receptive to learning these devices over computers, because of larger screens, intuitive interfaces, and touch screens. Learning to use an iPad may result in improvement in cognitive domains including episodic memory and processing speed, though there is no evidence it can improve visuospatial function. Programs created for teaching older adults to use technology, including tablets may also promote well-being by enhancing intergenerational activity and new learning. In a small pilot study, Kamat and colleagues have demonstrated that iPads may be effectively used to control behavior symptoms in older adults with dementia. In this study, the authors noted that because the iPad is a versatile device that can be used as a platform for a broad range of tasks, it may be an especially effective mechanism for administering nonpharmacologic interventions. Its primary advantage would be the ability to administer multiple interventions (e.g., reminiscence through pictures, music therapy, alternative engagement through videos, cognitive stimulation) using a single device.

An 87-year-old male of Russian origin, with a history of dementia and impulsive agitated behavior, typified by explosive outbursts was hospitalized on a geriatric psychiatry inpatient unit for management of behavioral symptoms. The patient was primarily Russian-speaking and struggled to communicate with staff. It was noted that the patient tended to be withdrawn, and kept largely to himself with minimal involvement in the treatment milieu. He was often irritable, though at other times he could be pleasant and friendly. A comprehensive medical assessment and workup was noncontributory. The patient frequently required two to three doses of antipsychotic medication (risperidone 0.5 mg) to control his episodes of agitation.

On one occasion, an iPad was utilized in one of the group activities, that involved showing patients how to access newspapers from their place of origin. Staff observed that the patient demonstrated a clear change in affect, when he was able to access digital content in Russian through this iPad, which was connected to the hospital's secure Wi-Fi network. Based on this observation, the physicians and clinical staff identified multiple apps that could help facilitate opportunities for the patient to get in touch with Russian language material online. This included Russian newspapers, blogs, videos, and other reading material. Staff also used a translation app and taught the patient how to use this to initiate communication. This gave the patient more opportunities to express himself. After this approach was initiated, staff noted a decrease in the patient's apathy and irritability, greater engagement in the milieu, and a reduction in the number of medication doses he required. It was hypothesized that at least part of his symptoms may have been triggered by a combination of boredom, lack of stimulation, and inability to communicate. The iPad provided a platform to address all three issues, and subsequent clinical impact was clearly observed by the treating staff.

Social Media

Older adults are the fastest growing segment of users of social media such as Facebook; this population is increasingly leveraging this technology to remain connected with family and friends. A 2013 survey by the Pew Research Center found that 45 percent of adults over 65 use Facebook. There is growing interest in creating Facebook interfaces that are simplified to facilitate use by older adults. Improving social connectedness among older adults can have a broad range of implication for enhancing well-being. The behavioral and psychological correlates of social media use in older adults warrant close empirical attention.

Caregiver Applications

ICT applications have the potential to be useful not only to older adults, but also their caregivers. These tools include peer networking, professional support, and resource identification. One innovative intervention for caregivers utilized a computer-mediated, automated, interactive system to reduce caregiver stress and provide assistance with managing disruptive behaviors exhibited by patients with Alzheimer disease. While these applications are promising given the rising number of people serving in caregiver roles, the outcomes associated with these technologies are yet to be fully characterized.

FUTURE DIRECTIONS

Robotics and Nanotechnology

With the rapid growth of technology, there has been a greater emphasis on developing robotic devices that can take over many physically demanding tasks of daily life. Promising ICT applications such as robotic-assistive devices for activities of daily living and other voice-activated technologies have been receiving greater attention for their potential use to reduce the physical demands of daily activities such as cooking, but further research is required to examine how they are suited for the needs of older adults. Robotic devices may even be implantable or flexible and wearable, and may play an assistive role in limb or organ function. Similarly, nanotechnology, which is growing rapidly, is considered a modality for intervention at the cellular level for aging-related disorders, especially those related to telomere dysfunction, reversal of oxidative cellular damage, and fabrication of stem cells and stem-cell–based therapies.

Big Data

Big data is a broad term used to loosely denote large volumes of data, whether collected in a structured or unstructured manner that can be mined and analyzed for information. The rise of big data has paralleled the development of sensor technology and rapid real time- analytics. As sensors allow one to collect extremely large volumes of behavioral and

other data in real time, big data analytics will be essential to allow for rapid, effective analysis of this data to generate information, and decision making. Big data analytics are also likely to play a key role in developing applications aimed at prediction of health events and preventative medicine.

BARRIERS AND LIMITATIONS

Although there have been significant technologic advances, older adults continue to experience barriers to using technology effectively. These include inadequate training to use the devices, lack of knowledge about the technologies available, inadequate design and equipment suitability, and cost/payment issues. Some of these are reviewed below.

Integration with Healthcare System

Despite rapid growth and interest in technology and aging, significant issues persist. For technologies that involve gathering personal health data, there remains incomplete integration with electronic health records. As a result, physicians often view such data (e.g., accelerometer data, sleep data) as burdensome as it involves the additional step of accessing, processing, and interpreting data. However, several companies that develop electronic medical records (e.g., Epic) are in the process of developing health apps that integrate with patients' electronic medical records. Manufacturers of commercial healthcare monitoring devices are also in the process of establishing ways for smoother integration of device data health with records.

Ultimately, it is likely that personal health data will be automatically integrated with electronic medical records as a routine procedure, allowing physicians to review both sets of data simultaneously.

Billing

The ICT applications for older adults hold great promise for the improvement in their quality of life and physical wellness. However, these technologies are often prohibitively expensive. In the United States, a large number of assistive technologies are not reimbursed by public or private insurance systems. The prospect of restricted payment hinders the development and widespread use of technology by those who can benefit from it the most. Congress and the Federal Government may promote the use of health technologies by incentivizing their use by providers and changing the policies regarding reimbursement through the Medicare program.

Literacy and Usability

Although ICTs have considerable potential for benefit in aging contexts,

literacy and physical limitations may pose a barrier to their utility in this population. Unsurprisingly, older adults' perceptions regarding the usability of ICTs appear to be related to their acceptance of technology. Factors such as perceived usefulness, perceived ease of use, and subjective norm have a strong impact on older adults' acceptance and use of ICTs.

Privacy and Ethics

Privacy concerns regarding the data generated by wearable and environmental monitoring systems have significant bearing on the motivation of older adults and their caregivers in adopting these technologies. The security of these data is often trusted to a third party and this may be associated with real or perceived disadvantages, which at present are not well characterized.

Information Overload

Although the large volume of data generated from wearable sensors and smart home devices is central to the appeal of these technologies, there are important issues that warrant consideration. The devices available tap different modalities (e.g., gait, skin conductance, diet, sleep) and provide heterogeneous longitudinal data. There is no consensus regarding the best methods to appropriately aggregate, analyze, and interpret the data collected. Episode Discovery, an unsupervised algorithm, has shown early promise in monitoring the health of elderly persons and identifying unusual or dangerous changes in behavior. Algorithms such as this are yet to be fully characterized with clinical populations.

Age-Related Impairments

Declines in working memory, attention, and processing speed commonly accompany normal aging. These age-related declines in cognition have important implications for technology access and use in older adults. For example, training older adults to use new platforms or technologic skills may be impacted by declines in working memory and attention, while their ability to discriminate and select targets from complex displays may be impacted by declines in information processing skills. These are important aspects that warrant close consideration during the development of technology for older adults.

Lack of Regulation and Evidence

Sensors and other healthcare devices remain both understudied and unregulated. Although the FDA is stepping up its effort at monitoring health sensor technology, significant work will be required to establish the safety, validity, and reliability of these devices, before they are widely deployed. A further issue is that despite a recent wave of technology

targeting older adults, the majority of these technologies are developed by technology firms and marketed without sufficient evidence to establish safety, efficacy, reliability, and validity of these devices to perform the tasks they are designed for. There is a great need for data on how these technologies are used, and how effective they may be. Geriatric psychiatrists have a great opportunity to be leaders in the area of establishing parameters for technology use and development in medicine.

57.6i Positive Psychiatry of Aging

DILIP V. JESTE, M.D., AND BARTON W. PALMER, PH.D.

There is a growing recognition that medicine should encompass not only treatment of symptoms, but also promotion of well-being. For geriatric

psychiatry this means greater attention to promotion of "successful aging" as well as to other aspects of well-being among elderly people. The notion that mental health is more than the absence of symptoms or disorder is not new. In 1946, the World Health Organization (WHO) published a definition of *health,* which was not merely the absence of disease or disability, but rather "a state of complete physical, mental, and social well-being." While seemingly self-obvious, this definition is potentially revolutionary in its implications for the practice of geriatric as well as general psychiatry. Yet, approximately 70 years later, the implications of that revolution are only now beginning to materialize in psychiatry. Contemporary geriatric and general clinical psychiatric practice and training remain primarily restricted to diagnosis and treatment of mental illnesses, while psychiatric research mainly focuses on elucidating the underlying pathology and ameliorative interventions to treat and prevent relapses of mental illnesses. Yet, largely outside the field of psychiatry, and particular within the field of Positive Psychology founded in the late 1990s by Martin Seligman and colleagues, a growing body of research strongly suggests that positive psychosocial factors (PPSFs) such as resilience, optimism, and social engagement are associated with higher levels of subjective well-being as well as lower morbidity and greater longevity. Although many key questions still need to be addressed through empirical research, the last few years have finally brought together the beginnings of Positive Psychiatry as a potentially key aspect of 21st century psychiatry.

DEFINING POSITIVE PSYCHIATRY

Positive Psychiatry is the science and practice of psychiatry that seeks to understand and promote well-being through assessment and interventions aimed at enhancing behavioral and mental wellness. As a part of psychiatry, itself rooted in the field of medicine, Positive Psychiatry is grounded in biology, and ultimately seeks to determine the neurobiologic underpinnings of the PPSFs associated with positive outcomes, and to use that information to develop more effective biologic and psychosocial preventive, therapeutic, and rehabilitative interventions. As a branch of medicine, an important facet of Positive Psychiatry that at least partially distinguishes it from the complementary field of Positive Psychiatry, is that it is primarily focused on promotion of PPSFs and positive outcomes among those with or at high risk for psychiatric or physical illnesses.

HISTORY

In 1906, William James, a psychologist and physician by training, spoke of the need for a new approach to psychology that would study and apply principles underlying the success of the "mind cure." The concept of *mind cure* referred to the purported healing powers of positive emotions and beliefs. Although in retrospect the mind cure movement itself appears an

anachronism of questionable validity, James' emphasis on positive emotions and beliefs illustrates an early effort to include PPSFs during the emergence of psychology as an independent field. Yet these inclinations were largely neglected until the mid-20th century which brought the Humanistic Psychology movement of Abraham Maslow and colleagues. Their focus was on study and promotion of health and creativity among individuals. But that movement too failed to fully shape psychiatry, as well as mainstream clinical psychology. Instead, Positive Psychiatry traces its most immediate lineage and debt to the Positive Psychology movement initiated by Martin Seligman and colleagues in the mid to late 1990s. In his 1998 Presidential Address, Seligman spoke of the need for "a reoriented science that emphasizes the understanding and building of the most positive qualities of an individual: optimism, courage, work ethic, future-mindedness, interpersonal skills, capacity for pleasure and insight, and social responsibility." In the ensuring decades, Positive Psychology has grown and flourished into an international movement, but much of the research has focused on promoting well-being among the psychiatrically and physically healthy, and it has had less impact on the day-to-day practice of clinical psychiatry. This situation has begun to change. In his May 2013 address as President of the American Psychiatric Association Dilip Jeste commented that "I expect that the future role of psychiatry will be much broader than treating psychiatric symptoms. It will seek to enhance well-being of people with mental or physical illnesses. That is positive psychiatry." Positive Psychiatry is allied with and partially overlaps with Positive Psychology in concepts and goals, but also complements in that psychiatrists are first trained as physicians, an applied biologically rooted profession focused on treating diseases and disabilities.

POSITIVE MENTAL HEALTH OUTCOMES

There has been a growing recognition that medicine should encompass not only treatment of symptoms, but also promotion of well-being. Similarly, the goal of psychiatric interventions should not be just a reduction in psychopathology but also promotion of positive mental states. Some of the better known outcomes are summarized below.

Successful Psychosocial Aging

There is no single consensus definition of successful aging. A 2006 review of the empirical literature revealed 29 definitions in 28 published empirical reports. But there were some common themes. Traditional notions of successful aging have emphasized how much one has not aged, that is, the relative absence of physical, cognitive, and social disability. However, more recent studies focused on the perspectives of older adults themselves showing that self-perceived successful aging is not dependent on physical

health. Large proportions of older adults with chronic physical illnesses, who would not meet objective disability-based criteria of successful aging, perceive themselves as aging successfully. Qualitative studies indicate that older adults consider the ability to adapt to circumstances and positive attitude toward the future as more important than an absence of physical disease and disability. This distinction between physical disability and self-perceived successful aging may help explain a now well-documented paradox of aging. Specifically, although physical health and functioning, as well as some aspects of cognitive performance, tend to decline with increasing age, subjective well-being begins a steady improvement from youth or at least mid-life that continues into old age.

Other Positive Outcomes

Well-Being. Echoing the WHO definition of health, Positive Psychiatry construes *well-being* as representing the presence of pleasant positive experiences and states such as life-satisfaction and happiness (hedonic well-being), as well as eudemonic well-being, including a sense of purpose or meaning in life and self-acceptance. The concept of well-being has risen to prominence in recent years in economics, with self-reported well-being considered as a measure of national development, alongside traditional constructs such as the Gross Domestic Product. Well-being is associated with better health outcomes, and is correlated with reduced mortality/greater longevity.

Low Perceived Stress. The concept of stress has a complex history; the term may be used to refer to objective pressure or tension or the body's objective response to demands or change. In the context of Positive Psychiatry, however, the emphasis is on the individual's perception of stress which appears to be a better predictor of deleterious changes in some biomarkers such as telomere length than is objective stress. Perceived stress specifically represents the degree to which individuals perceive demands, problems, or challenges as exceeding their ability to cope with them. Recurrent unhealthy stress responses lead to cumulative wear and tear.

Posttraumatic Growth. The link between severe stress and posttraumatic stress disorder (PTSD) is self-evident, but not inevitable. Some people who experience significant traumatic events experience a form of personality growth that is referred to as *Posttraumatic growth*. It is characterized by an increased appreciation of life, altered priorities, closer interpersonal relationships, greater sense of personal strength, and/or recognition of new possibilities for one's life. Posttraumatic growth is fostered by the individual's resilience in the face of severe stress—it is not the opposite of PTSD, as they may be copresent within the same individual

in response to the same stress or trauma.

Recovery in Serious Mental Illnesses. Contemporary empirical data paint a brighter picture of the course of psychopathology and disability among older people with serious mental illnesses than traditional conceptualizations. For example, relative to their younger counterparts, older adults with schizophrenia tend to have better psychosocial functioning, including better adherence to medications and self-rated mental health, and lower prevalence of substance abuse and psychotic relapse. There is no consensus definition of recovery (e.g., there are differences of opinion regarding the need for full symptom remission), but there is general consensus that recovery involves decreased functional dependence and reduction of the impact of the illness on one's life. Elyn Saks has described this capacity as finding "wellness within illness."

Prevention. Prevention is one of the key positive outcomes in Positive Psychiatry. The focus on prevention has long roots in community psychiatry where there have been efforts directed at primary, secondary, and tertiary prevention. In recent decades, medicine and psychiatry are experiencing a paradigm shift from an almost exclusive focus on treating pathology to promoting health, as well as from caring for individual patients to enhancing health of communities through preventive measures. Prevention is no less meaningful in the context of geriatric psychiatry. A wealth of empirical data indicate that prevention in later life can be practical and cost-effective. Some examples including findings that treatment or prevention of depression following stroke, myocardial infarction, and/or bypass surgery results in significant reductions of morbidity and mortality. Likewise, interventions aimed at altering partially malleable risk factors such as social isolation, physical disability, and sleep problems can prevent or at least delay the onset of depression. Similarly, the risk of developing PTSD can be decreased with counseling older victims of natural disasters, wars, or tragic events.

POSITIVE PSYCHOSOCIAL FACTORS

A key tenet of Positive Psychiatry is that positive outcomes such as those described above are at least partially mediated by and can be fostered by enhancement of intrapersonal positive psychosocial traits as well as positive environmental/social factors, together subsumed under the rubric of PPSFs. Most of these factors are valued highly by the society, yet until recently they have been generally neglected in the biomedical sciences as imprecise, amorphous concepts that lack relevance to traditional medicine or to neuroscience research. There have been numerous studies in recent years suggesting that the PPSFs are tightly linked to human biology and are associated with positive health outcomes.

POSITIVE PSYCHOSOCIAL CHARACTERISTICS

PPSFs may have as strong (if not stronger) an impact on patient well-being as common health risk factors such as obesity, hypertension, sedentary lifestyle, and smoking, and even overall objective health status. Provision of effective interventions to strengthen PPSFs in older psychiatric patients could substantially increase the prevalence of recovery in seriously mentally ill older adults. Some of the key intrapersonal constructs (Positive Psychosocial Traits) and then Positive Environmental Factors are considered below.

Positive Psychosocial Traits

Resilience. *Resilience* refers to ready recovery from or positive adaptation to illness, depression, or other adversities. Resilience is associated with greater well-being and reduced mortality risk among older adults. People in their 90s who endorse higher levels of resilience have a 43 percent higher likelihood of living up to 100 years compared to their peers with lower resilience. Among people with medical illnesses, resilience is also associated with better treatment adherence, better self-care behaviors, and improved quality of life. Among physically ill patients, resilience is associated with improved physical health, health-related quality of life, self-care, and treatment and exercise adherence. Resilience is also associated with better emotional health and well-being.

Optimism. The term *optimism* refers to a characteristic of people who tend to expect good outcomes. Optimism is associated with lower risk of depression and higher overall subjective well-being, lower mortality, as well as less pain, better cardiovascular, oncologic, and other physical health outcomes, and better immune function. The precise mechanisms through which optimism has these effects is not fully clear but it may partially operate through its effects on health behaviors. Older adults with higher optimism are more likely than less optimistic age-comparable peers to consistently engage in healthy behaviors.

Personal Mastery and Coping Self-Efficacy. *Personal mastery* refers to an individual's expectations of his/her ability to achieve self-desired outcomes. A closely related concept is that of *coping self-efficacy,* that is, the individual's self-perceived ability to perform the requisite coping behaviors needed to overcome life challenges. Individuals high in personal mastery or coping self-efficacy have a belief in control over their life circumstances and future—that is, they have a general sense of control over things that happen to them and have greater confidence they can solve problems in their lives. In contrast, *optimism* more broadly denotes a tendency to expect positive outcomes regardless of whether or not one is

the agent of those outcomes. In the context of chronic life stress, personal mastery, and coping self-efficacy may promote specific, adaptive, goal-oriented behaviors, as well as maintenance of those behaviors, despite ongoing stresses. High levels of personal mastery tend to protect people from the potentially negative effects of stress on general health.

Wisdom. *Wisdom* is a construct with heuristic value in that it appears across most cultures and contrasts with factual knowledge or even intelligence. Wisdom may be defined as a complex trait with several domains including pro-social attitudes and behaviors (compassion, empathy, and altruism), social decision making or problem solving, capacity for self-reflection and understanding/insight, decisiveness, acknowledgment and acceptance of uncertainty, emotional regulation, tolerance of divergent value systems, openness to new experience, spirituality, and a sense of humor. What unites these components is their utility for the self (e.g., greater well-being) and for others (better relationship with others, and serving common good). Cumulative experience of life with age may promote some of the dimensions associated with wisdom. Some, although not all, studies suggest an increase in several domains of wisdom with aging that may be important for an older adult's ability to survive and even thrive in spite of worsening physical health. The so-called Grandma Hypothesis suggests that wisdom transmitted to younger generations may provide fitness advantage and help neutralize the evolutionary pressure associated with loss of fertility in old age.

Spirituality and Religiosity. Religious and spiritual practices are reportedly associated with greater well-being as well as better health outcomes throughout the lifespan. It may be argued that *religiosity* is better conceptualized under the umbrella of positive environmental factors (see next section) as the term *religiosity* is usually reserved in reference to involvement in organized religion, and thus has an inherent social connotation whereas spirituality can be personalized. However, religiosity too ultimately rests on the beliefs and behaviors/choices of an individual. The term *spirituality* refers to an internal experience, that is, the degree to which one's personal beliefs, thoughts, and behaviors focus on transcendent topics such as the meaning of life, belief in a higher being, power or level of consciousness, awareness, or existence. Religious and spiritual practices are associated with positive outcomes such as greater well-being as well as better health outcomes. These positive effects of religious practices may partially rest on the emotional support derived from the religious community. Religious and spiritual beliefs also tend to confer a sense of optimism. Spirituality has been reported to increase with age.

Positive Environmental Factors

In addition to intrapersonal Positive Psychological Traits, the interaction of the person with the environment and the nature of that environment also impact likelihood of positive outcomes. These environmental factors are described below.

Social Engagement and Support. *Social Engagement* refers to integration into a social network or social participation—that is, how well integrated one is into a social network. Within this construct is the number and quality of close relationships, frequency of socialization, and the degree to which one finds meaning or pleasure from social integration/interactions. A related construct of *social support* refers to the degree to which other people are available for emotional and physical support. Empirical research has shown that the quantity and quality of one's social relationships are associated with better mental and physical health outcomes, including lower mortality, as well as more specific health outcomes such as lower prevalence of hypertension, cardiovascular disease, dementia, depression, anxiety, and substance use disorders in young and old adults.

Family Dynamics. A particularly influential form of social engagement and support is the family. There is a large empirical literature showing that family dynamics and degree of a supportive family environment affect mental and physical health including symptom severity, treatment response, and recovery.

Other Environmental Factors. Access to quality physical and mental health care as well as environmental factors such as availability of safe parks and walking paths, community centers, access to grocery stores for healthy eating alternatives, can promote or discourage physical activity and exercise, nutrition, and stress reduction, especially in older adults.

BIOLOGY OF POSITIVE PSYCHIATRY

As noted above, psychiatry, as a branch of medicine, is rooted in biology, and so is Positive Psychiatry. Biology of relevant constructs involves neuroscience as well as genetics and epigenetics involving interactions among genes, environment, and structure and function of the brain. This type of research has implications for developing biologic interventions to enhance positive traits and impact mental and physical health. To date the amount of such research in relation to positive outcomes and PPSFs has been limited to specific aspects only, and there is an obvious need for additional investigations in this arena.

Potential Biomarkers of Positive Mental Health

Allostatic load and telomere length are among putative biomarkers of stress

and aging, but can also be conceptualized as potential biomarkers of well-being in reverse.

Allostatic Load. Allostatic load reflects the body's cumulative physiological response to frequent and sustained exposure to environmental stressors; it represents dysregulation of one or more biologic systems, multiple pathways to disease, and cumulative cost of antecedent challenges which together can serve as an indicator of morbidity, as well as affecting cognitive functioning and psychological factors. There is no single measure of allostatic load, but a commonly used composite includes systolic and diastolic blood pressure, body-mass index, serum cholesterol (with an emphasis on HDL), and plasma norepinephrine and epinephrine.

Telomere Length. Telomere length is an indicator of biologic age, and may represent a cumulative index of the number of cell divisions and a cumulative record of exposures to genotoxic and cytotoxic processes such as oxidation. Telomere length is maintained by the enzyme telomerase, and there is some preliminary evidence that healthy lifestyle changes as well as psychosocial stress reduction interventions can increase telomerase activity.

Oxidative Stress. Oxidative stress, caused by an overproduction of free radicals or an underproduction of antioxidant molecules, damages DNA, protein, lipids, and other macromolecules in many tissues, with the brain being particularly sensitive. Oxidative damage to cellular components by free radicals may be an important component of the aging process. Thus, prolonged or repeated exposure to oxidative stress may accelerate aspects of biologic aging, leading to greater comorbidity and mortality.

Inflammation and Immune Function. Neuroinflammation and immune function also relate to several PPSFs. For instance, low level of optimism has been reportedly associated with increased inflammation markers. Reduced personal mastery resulting from chronic stress may provoke excessive activation of the autonomic nervous system, which may in turn affect immune functioning. Several studies report direct associations of engagement in pleasant events with better health, including reduced plasma concentrations of inflammatory biomarkers and lower catecholamine response to stress.

Genetics and Epigenetics. Genes clearly play a role in determining the lifespan and health status in older age. Many PPSFs are also influenced by genetic factors. For example, resilience and optimism are both partially heritable. Beginning in development, an individual's genes and their

interactions with environmental factors may shape the neural circuitry and neurochemical function expressed in PPSFs. Various genetic polymorphisms affect a person's limbic reactivity and prefrontal-limbic connectivity. Adaptive functioning of fear, reward, emotional regulation, or social-behavior circuits underlies a resilient person's capacity to face stress. Stochastic epigenetic changes occurring during brain development, that drive resilience and hardiness, may affect response to periods of high stress.

About 20 percent to 30 percent of variability in human lifespan appears to be attributable primarily to genetic factors. Overall, longevity seems to be promoted by an absence of genes that predispose people to diseases, rather than by presence of "life-extending" genes. Risk for cognitive impairment in older age is clearly raised by presence of the ApoE4 allele, but this may be attenuated by higher educational attainment or greater "cognitive reserve." In short, genetic vulnerabilities may be amenable to modification through intentional or incidental environmental changes.

Neuroplasticity across the Lifespan

Empirical findings in recent decades have challenged previously held concepts about brain development in later life. There are now convincing empirical demonstrations that neuroplasticity, with associated brain growth and development, can continue into old age. Mechanisms underlying neuroplasticity include compensation for aging-associated degenerative changes (e.g., involvement of larger numbers of neuronal networks in the performance of an activity) as well as synaptogenesis, increase in the number of dendritic spines, and even neurogenesis in selected areas of the brain such as the hippocampal dentate gyrus and periventricular region. Such neuroplasticity is related less to the genes inherited than to the behavior, attitude, and environment which affect expression of those genes. It is this neuroplasticity that may enable PPSFs to affect an individual's well-being throughout the lifespan, although the brain is admittedly less plastic in later life than it is in childhood and early adulthood.

INTERVENTIONS

Research on interventions aimed at promoting PPSFs is in early stages, but seems highly promising. Treatment trials have shown beneficial effects of behavioral strategies buttressing resilience, changing attitudes toward aging, or incorporating meditation, on outcome measures such as well-being, as well as alcohol consumption, biologic response to stress, and mortality rates in older adults. There is considerable diversity in the types of psychosocial or behavioral interventions reported, which include writing gratitude letters, practicing optimistic thinking, acts of kindness, replaying

positive experiences, socializing, life review, mindfulness, cognitive behavior therapy, life coaching, goal training, and forgiveness therapy. Cognitive behavior therapy has been shown to be effective in enhancing optimism and facilitating reappraisal of traumatic events in a more positive light. Increasing optimism has been found to increase adherence to pharmacotherapy in formerly pessimistic individuals. Interventions aiming to improve social engagement, while not specifically targeting depression, appear to have antidepressant effects in older people. Studies of longer-term effects of meditation have reported reduced mortality rates in older adults at risk for negative cardiovascular outcomes.

Interventions to Enhance Healthy Aging

A key component of Positive Psychiatry in the context of working with older adults is the concept of successful or healthy aging. The quest for "antiaging" therapies and interventions has gone on for thousands of years, with as yet little in the way of "cure" for aging being found. But there are interventions that can delay the onset of disability and disease, and prolong "healthspan." In contrast to earlier assumptions, many of these interventions such as physical exercise appear to produce benefits even among older adults.

Lifestyle Interventions. Lifestyle behaviors are a logical place to start when thinking about enhancing positive outcomes in older people. Physical exercise, proper nutrition, activity participation, and regular health screenings and vaccinations are among the most powerful and modifiable predictors of the healthspan. In addition to the positive effect of healthy behaviors on the cardiovascular system, recent research has provided compelling data that improvements in brain structure and functioning can be attained from improving lifestyle habits.

Physical Activity. The axiom "what's good for the heart is good for the brain" has gained research support in recent years. There is strong evidence from randomized controlled clinical trials conducted among sedentary older people that increasing aerobic physical exercise can enhance performance on cognitive tests. Together, the empirical literature suggests that initiating exercise participation in later life may have significant effects that extend beyond physical outcomes, and include cognitive and emotional improvements.

Using animal models and examining the biologic effects of exercise, it is likely that physical activity has multiple pathways leading to improvement in cognitive and emotional health. By reducing hypertension, the risk for cerebrovascular diseases decreases. By reducing obesity, stress on the skeletal system is diminished. Physical activity may also have a secondary benefit of increasing social engagement. Fall risk may be decreased by

increasing muscle mass. Research from animal models suggests that at the cellular level, exercise may provide a mild stressor that may act as a kind of "inoculation" against other kinds of stress, and may promote neuronal growth.

The Centers for Disease Control and Prevention suggests that adults engage in 3 to 5 days per week of moderate intensity of exercise (equivalent to brisk walking) for 30 minutes or more; stretching every day, and strength-building activities 2 to 3 days per week. Only about one-third of Americans meet the minimum exercise recommendations, and the prevalence of meeting these criteria decreases with age. At particular risk for not engaging in recommended levels of physical exercise are older people from ethnic minority groups, who have lower educational attainment, or who have sub- or supernormal body mass indices.

A central challenge to increasing exercise participation is identifying the barriers to exercise in routine life. The "walkability" of the built environment is an important consideration for enhancing engagement in physical activity, especially for older adults because they appear to prefer walking over other exercises.

Diet and Nutrition. Diet and nutrition are clearly related to health and other positive outcomes, and no other strategy for healthy aging has received as much research support as caloric restriction. Caloric restriction has been examined in worms (*Caenorhabditis elegans*), rodents, primates, and humans. Reducing caloric intake has been associated with increasing the lifespan of certain strains of mice and primates. In addition to extending the lifespan, deceleration in other aging phenotypes accompanies caloric restriction. The exact mechanism of caloric restriction is unclear, but it may involve reducing the rate of metabolism, perhaps limiting cellular wear and tear. Whether and how calorically restricted diets can be safe and palatable in humans remains to be seen; however, there are ongoing studies examining the impact of caloric restriction in older overweight or obese adults.

The content of dietary intake is also of interest to promoting health, results from an epidemiologic study suggest a recommended "low-risk" diet that includes a higher ratio of polyunsaturated to saturated fats, high in cereal fiber and marine fatty acids, and multivitamins, low in glycemic load, minimal trans fats. Additionally, moderate alcohol drinking (one to two drinks per day), especially of red wine, appeared to be better in the Nurses Health Study. As with exercise participation, only a minority of older adults conform to such a diet, and a growing proportion of people, including older people, are obese. Indeed, the rising incidence of obesity in the United States may significantly slow the rate at which life expectancy increases over the next 30 years—that is, obesity may decelerate the dramatic gains that have been made in life expectancy. Practitioners

working with older adults need to provide dietary education, explaining the risks associated with unhealthy diets and encouraging healthier alternatives.

Biologic Treatments. The potential for biologic treatments in Positive Psychiatry is largely awaiting further research, but there does seem to be potential for advances in this arena. Recent research suggests that it might be possible to use neurobiologic approaches to enhance resilience in the context of anxiety and mood disorders. With increased understanding of the neural circuitry underlying resilience, new interventions may also be developed using findings indicating that individuals can be trained to modulate their own brain activity with the help of real-time fMRI-based neurofeedback. Biologic interventions may be developed on the basis of improved understanding of neuroplasticity as well as gene variations related to positive traits. In addition, findings from animal and human studies might eventually yield new pharmacologic agents that can maximize the adaptive function of the HPA axis as well as monoamine, neuropeptide, and other neurochemical stress response systems.

58 Public Psychiatry

▲ 58.1 Public and Community Psychiatry

LEIGHTON Y. HUEY, M.D., ROBERT F. COLE, PH.D., AND JULIAN D. FORD, PH.D.

INTRODUCTION

The subject area of public and community psychiatry embodies a fundamental core of experience and tradition of this medical specialty. In the context of the upheaval and re-examination of American health care before and since the passage of the 2010 Patient Protection and Affordable Care Act (referred herein as the ACA), the experience of public and community psychiatry is poised to serve as a foundation for a transformation of behavioral health care.

Each term in the phrase public and community psychiatry is burdened by a complex past and needs interpretation to clarify its current meaning. The term public can refer to psychiatric programs, treatment, or institutions paid for by public funds or as objects of public policy, whether paid for or not. In recent decades, the scope has been narrowed to encompass chiefly populations of low-income adults disabled by persistent mental illnesses or substance use disorders, and for children, those with serious emotional disorders. These categories of public funding, represented in Table 58.1–1, identify target or priority populations that usually are defined by the presence of at least one qualifying major mental illness or substance use disorder, an assessment in which the illness or disorder is considered severe and persistent and affects the individual's ability to function in multiple areas. An evaluation of the individual's resources and ability to obtain private mental health services is also part of the assessment.

Public psychiatry stands in stark contrast to personal or private psychiatry, the latter being the entrepreneurial practice of delivering services to individuals having some means of purchasing them.

The care and treatment offered under public psychiatry are delivered in a variegated mosaic of inpatient and community-based services that are

more or less integrated into a coherent network sponsored by public agencies. Funding for public and community psychiatric services tends to be provided by federally legislated appropriations that are passed through state, county, and municipal government agencies (such as departments of mental health; substance use treatment services; children, youth, and family services; and public health, social services, education, adult corrections, and juvenile justice agencies). Ultimately, most public psychiatry and community services are provided by not-for-profit community mental health, substance use treatment, child guidance, social services, or health care organizations that either are funded by or subcontracted to government agencies. Thus, the very existence of public and community psychiatric services and the policies and resources determining how they are delivered are extremely dependent on legislative mandates and fiscal appropriations from all levels of public government. Psychiatry practitioners and administrators working in the public sector thus must be knowledgeable and savvy concerning the laws, regulations, and funding mechanisms relevant to their services. Increasingly there is recognition of the prevalence of substance use disorders, both as primary disorders (often in combination with mental disorders, i.e., "co-occurring" substance use and psychiatric disorders) and as secondary disorders (when mental disorder[s] are the condition of the first onset of primary concern, i.e., "comorbid" psychiatric and substance use disorders). While there has been some tortured historical debate on whether the more accurate phrases that should be used are "mental disorders" versus "behavioral disorders" or even "mental and behavioral disorders" as an inclusive term, this chapter will use "mental" and "behavioral" interchangeably. Finally, mention should be made of the significant prevalence of co-morbid physical disorders with mental and behavioral disorders which is true regardless of whether one is discussing "public" or "private" or "community" psychiatry. Therefore, this section specifically includes in "public psychiatry" not only the concept of "mental illnesses," but also that of co-occurring or comorbid serious substance use disorders.

The term community, as historically applied to psychiatry, connotes the mental health status of a specific, geographically defined population. It is synonymous in all respects with "not the state hospital" and is contrasted to institutional care, especially in the move to community mental health in the second half of the 20th century. Community psychiatry in this context refers to psychiatric practice in the community as part of the community effort to care for individuals with major mental illnesses and substance use disorders in a specific geographical catchment area. Community psychiatry initially was an attempt to break with traditional public psychiatry, which was seen as inextricably linked to hospital-based services. At the end of the 20th century, it obtained still broader connotation in terms of the health of the community: community psychiatry activities involve the effect of

psychiatric disorders in individuals on the health of the community and formulate treatment strategies to improve community health. Now, in the 21st century, with the decline of long-term institutional psychiatric care and the ascendance of in-home approaches to delivering integrated psychiatric and psychosocial services, community psychiatry is the dominant force in a de facto merger with public psychiatry.

The term psychiatry originally described the medical specialty focused on the care of persons with mental illness in the state hospital setting. Its domain was strengthened by the dominant role of the medical superintendents of the state hospitals (who would eventually be called "psychiatrists") and their medical colleagues in the latter half of the 19th century and first half of the 20th century. However, in the era of community mental health in the latter half of the 20th century, the term exploded to cover a host of disciplines and new personnel were recruited to staff the community-based supportive treatment systems that were supposed to take the place of the institutions. Nursing, social work, clinical psychology, various therapeutic specialties, and non-degreed direct care providers all became labeled as part of psychiatry. One of the most dramatic changes emerging since the late 1990s is the role of consumers of psychiatric services as providers in their own right through networks of peer-support services and advocacy initiatives. Family members of people with these disorders are also increasingly taking a more assertive role in treatment and support. In fact, a recent national report argued that the concept of "workforce" correctly includes both patients and families as members of the workforce, whether paid or volunteer.

Table 58.1–1.
Eligibility for Mental Health Service Grants

The following definitions are currently used to determine eligibility for services provided by the federal Center for Mental Health Services and by state public Mental Health agencies.

Adults with serious mental illness are persons

- 18 years of age and older
- Who currently or at any time during the past year
- Have had a diagnosable mental, behavioral, or emotional disorder of sufficient duration to meet diagnostic criteria specified within DSM-5
- Which has resulted in functional impairment that subsequently interferes with or limits one or more major life activities and
- Lasts less than 6 months of the past year

Adults with serious and persistent mental illness are persons who are

- Recently severely impaired, and
- The duration of the impairment totals 6 months or longer of the past year.

Children with a serious emotional disturbance are persons

- From birth to as old as 18 years of age
- Who currently or at any time during the past year
- Have had a diagnosable mental, behavioral, or emotional disorder of sufficient duration to meet

diagnostic criteria specified within DSM-5

- That resulted in functional impairment that substantially interfered with or limited the child's role or functioning in family, school, or community activities.

From the Federal Register.

This has broadened the traditional concept of public and community psychiatry, which previously had a narrow focus on the psychiatrist in his or her role as the medical specialist, trained in the discipline of medical science and exercising medical and legal authority to take defined actions on behalf of individual patients. In this paradigm, the public psychiatrist practices psychiatry in publicly funded services and carries out programs that are mandated by public policy. As a public and community psychiatrist, he or she is engaged with a specific geographically defined population using community programs for the care of its individuals with mental illness in order to improve the health of the community as broadly defined.

The experience of public and community psychiatry as it has evolved over the last two centuries in the United States, then, is a particularly valuable asset for the challenges facing US psychiatry as part of a health care system that has been characterized as chaotic and out of control. Three contemporary trends illustrate the importance of this basic (and rather narrow) conceptualization of public and community psychiatry to the daunting challenges facing US health care. The first is the realization that the effect and pervasiveness of psychiatric disorders imposes a global burden on society. The second trend has been the shift in funding for public psychiatric services from state expenditures, tied to the historic funding for state hospitals, to Medicaid, a health insurance model driven by the "medical necessity" for intervention. Finally, the power of reform efforts in general medical care and psychiatry have led to increasing demand for the use of evidence-based interventions defining quality, for safety standards, and for efficiency in the delivery of health care.

The first trend—the recognition of the burden of these disorders—can be most directly linked to a landmark study called the Global Burden of Disease. This study, funded by the World Health Organization (WHO), the World Bank, and several foundations, considered the leading causes of disability and premature death worldwide as a result of various health and situational problems. Of the ten leading causes of disability worldwide, five are neuropsychiatric, with the leading cause of disability being depression. When considering the leading causes of healthy years of life lost using the concept of disability-adjusted life years (DALYs), which reflects premature death and disability, depression was found to be second in the United States and was expected to rank second in the world by the year 2020. Mental health disorders were the fourth most costly health problem in the United States in 2000, 2004, and the most recent year for which data are

available 2008, according to the federal Agency for Healthcare Research and Quality. When the cost to society of trauma-related disorders (which include post-traumatic stress disorder [PTSD]) are added in—and exposure to traumatic stressors has been found to play a role in both causing and moreover severely worsening most psychiatric disorders—the cost to the United States as a society in 2008 was estimated at $138 billion, 50% more than the annual cost of heart disease and almost double the annual cost of cancer. This was true despite the fact that the cost per person was three to four times higher for heart disease and cancer than for mental health or trauma-related disorders, due to expensive high-technology and pharmacological treatments, and high rates of death or total disability. Many more persons, an estimated 50 million or more in the United States in 2008, suffer from mental health or trauma-related disorders than from either heart disease or cancer.

The broadly conceived "healthy city" and the Global Burden of Disease both have particular relevance to public and community psychiatry. The implications and the importance of properly addressing primary and comorbid psychiatric disorders across a spectrum as part of enlightened health policy are compelling. The prevalence of psychiatric disorders warrants a systems-based approach, which is the conceptual strength of public and community psychiatry. A systems-based model of psychiatry involves understanding and drawing on the wide range of biopsychosocial factors that underlie mental illness to develop psychiatric treatment and rehabilitation interventions to reduce the disease burden associated with severe and persistent mental illness. Recent estimates are that mental and behavioral health disorders are more common than previously thought, with about a quarter of adults experiencing one or more of these disorders, with a third receiving treatment, and only 12% of these, having treatment that would be considered adequate. Of the total number of Americans with mental and behavioral disorders, about 6% struggle with the most seriously disabling mental illnesses. Care for a significant number of these individuals is poorly coordinated and there is a recurring whorl of decompensation, emergency room visits, hospitalizations, various outpatient and sometimes residential programs, variable compliance and funding struggles with treatment, diagnostic confusion (e.g., schizophrenia vs. bipolar disorder, borderline personality vs. post-traumatic stress disorder vs. depression, etc.), polypharmacy with lack of attention to guidelines or to metabolic consequences leading to the iatrogenic production of physical health problems for these individuals who then enter the cycle multiple times. The early death of such individuals, primarily because of physical health problems, has been well documented. Many of these individuals end up in the justice system. The historical separation of psychiatry from the rest of medicine, partly self-imposed and partly extruded by mainstream medicine will hopefully be corrected as

delivery systems change and as greater knowledge comes to influence a more focused and effective interdisciplinary effort for the most afflicted in particular.

The second trend relates to financing. The role of Medicaid in shaping public services for people with mental illnesses is difficult to overstate. For state governments, the appeal was almost immediate. When the states assumed the onus of care for people with mental illnesses, largely through the mechanism of state institutions, 100 percent of those expenditures came from state budgets—competing with all of the other priorities facing state legislatures. Medicaid, which is a state–federal partnership, allows states to shift between 50 to 80 percent of their cost for covered services to the federal budget. Because of a provision in the original design of Medicaid, referred to as the "IMD exclusion," states were prohibited from using Medicaid to pay for services delivered in "Institutes for Mental Disease," namely state hospitals. So a policy movement toward community-based care was reinforced by a federal financing shift. For a large portion of the newly financed services, however, the role of the physician was highlighted because services had to meet the "medical necessity" threshold as certified by a medical doctor—typically primary care physicians, not psychiatrists, with the effect of limiting the scope of services for persons with more severe disabilities. More recent federal laws and regulations mandating parity in eligibility and reimbursement for mental health (compared to medical/physical health) have attempted to direct more services to more individuals with mental illnesses. As will be seen, recent analysis of Medicaid state expenditures has documented this trend, which has contributed to a dramatic increase of funding for mental health services in the last 50 years.

The third trend is a period of critical evaluation of US medical practice sparked by the Institute of Medicine (IOM) in its 2001 report entitled Crossing the Quality Chasm: A New Health System for the 21st Century. This is a call to American medicine to reform inadequate service delivery systems and to apply effective practices systematically. It documents the need for a fundamental overhaul of the entire US health care system, addresses the problems caused by insufficient quality in the health care system, and offers a road map for creating a new health system. A key principle in enhancing the quality of health care services is that treatments and practices must have a clinical and scientific evidence base in order to justify their utilization and costs. The Quality Chasm report was a primary influence among a series of reports from the IOM and other authoritative agencies in the two decades that laid the foundations for the health reform that has been codified in the Affordable Care Act (2010). Table 58.1–2 lists a selection from the hundreds of IOM reports and workshops, seminars, etc., that represent the ferment of these years that provided the content of the legislation and is setting the course of its implementation.

While these landmark reports were focused on inadequacies throughout the American health care system, public and community psychiatry qualifies as a primary target for the reform measures.

The connotation associated with public and community psychiatry has been synonymous with care for the poor and underprivileged, care for special populations normally not attended to by the private sector, overwhelmed systems, low reimbursement and inadequate resources, inferior and unresponsive care, and a final common pathway for individuals no longer able to afford private care. This is not for want of their providers' dedication: it is the paucity of the providers' numbers and the general public neglect of this sector. The patients of public and community psychiatry as a group lack the most basic resources to sustain themselves (food, clothing, housing, financial support, social support, etc.), and they are arguably the group least likely to be able to advocate for themselves and to have the capacity to recover from this default position. The needs of the patients, the inadequacies of the delivery systems, the lack of an adequate workforce, and the lack of coverage make the sector of public and community psychiatry a poster child for the attentions of the ACA reforms.

Improving the Quality of Health Care for Mental and Substance-Use Conditions: Quality Chasm Series. Washington, DC: The National Academies Press; 2006.
Graduate Medical Education That Meets the Nation's Health Needs. Washington, DC: The National Academies Press; 2014.

The reform is opening up a new community paradigm for American health care. It is a shift away from solo or corporately based practice models; emphasis on specialty care to the neglect of primary care; awkward payment methodologies that encourage volume over value and mechanical reliance on defined procedures; little accountability for population health; and a strange separation between main stream private health care and the care of the poor and disabled. It is a shift toward the public health emphasis on education, prevention, early identification and the health of populations; emphasis on primary care and the patient-centered medical home; physicians working with multidisciplinary teams; effective and evidence-based care; organization of accountable clinical entities meeting the individualized needs of each patient. Public and community psychiatry will benefit particularly from the reform. There will be a shift from the psychiatrist as solo therapist to be integrated into the multidisciplinary primary care team where it will be possible to register the earliest identification of developing mental health issues and to provide selective care for emerging psychiatric symptoms, while avoiding the stigma that has been assigned to mental health care. Primary care will also provide an organizational base for chronic illness care for patients burdened with disability and special treatment systems that can sustain a constant and continuing clinical process that will bring these patients to a degree of recovery.

Reform will lead to profound changes for public and community psychiatry. To take full advantage of this period of reform, it will be important to understand its past and the factors that shaped it development and its culture. American public and community psychiatry began in colonial times over two hundred years ago and was one of the first public health programs. It began in the village poorhouses, moved to asylums and stayed there until the middle of the 20th century when the state hospitals were replaced with uneven efforts at community care. Mainstream American medicine, as it was fortified by its use of the natural sciences, leaped ahead of psychiatry in the 20th century, but, in recent decades, psychiatry rapidly catching up as a science of the brain has become more accessible. The concerns of public and community psychiatry, as well as private sector psychiatry, have been prominent as the groundwork of the reform took shape. Before turning to the particulars of the reform agenda, a quick review of its history is appropriate.

HISTORICAL PERSPECTIVE OVERVIEW

Mental health policy and treatment has been a public issue in the United States from the beginning. A broad brush overview of this complex history can distinguish four stages. Colonial times and the early years of the Republic were the era of the poorhouse, during which the great majority of persons with mental illness found refuge or were confined for their own

and others' protection as part of local community management. Care and custody were the operative functions, and treatment was nonexistent. In the 18th century, the ideals of the Enlightenment formed the basis for a paradigm shift toward fostering a better life for persons with mental illness rather than condemning and isolating them, ushering in an era of "moral treatment" (aimed at restoring the capacity for ethical conduct) through a return to the pastoral rural environment of the pre-industrial age ("the Retreat"). In the mid-19th century, the protection and moral rehabilitation of the mentally ill was scaled up and institutionalized through the pioneering work of Dorothea Dix, resulting in an age of the asylum, during which public inpatient facilities, generically called state hospitals in the United States, were constructed in every state. A century later, advances in medicine, psychodynamic psychiatry, biological psychiatry, and cognitive behavioral psychology along with a remarkable policy consensus moved federal legislation to shift from institutionally based care to an era of community mental health. Finally, as health care costs began to soar at the end of the 20th century, and as employer purchasers and government moved to create market-driven health care, mental health policy moved conceptually to tightly organized systems of care that focused on prevention, early intervention, and intensive community care for children with severe emotional disturbances and their families and community support and recovery for adults with serious, acute, and persistent mental illnesses. The policy and concept, although ideal, remain partially operational with the smooth provision of care constantly jostled by bureaucratic, regulatory, and economic potholes.

The movement of history is best understood at its transition points. To get a sense of this history, the following quick review of public and community psychiatry in the United States focuses on three vignettes at the transition points that separate these stages.

From the Poorhouse to the Asylum

> Now for near five years I have been indulged by the gracious Heaven in my long holiday in this goodly house of mine entertaining and entertained by so many worthy and gifted friends and all this time poor Nancy Barron the madwoman has been screaming herself hoarse at the poorhouse across the brook and I still hear her whenever I open my window. — Ralph Waldo Emerson, Journals, 1840.

In the American colonies and in the early days of the Republic, the care of the mentally ill was modeled on the practices of 18th-century England, where the Enclosure Laws disrupted the rural social order and set thousands on the road to seek shelter and employment in the cities. People with mental disabilities were at a particular disadvantage. They were saved from vagrancy by confinement in poorhouses, prisons, and jails, along with criminals, debtors, and other people with disabilities. In the American colonies, most towns would establish a poorhouse, and persons with

mental illness, especially those who were found to be disruptive, would be committed by the actions of local government to extended stays in them. It is not that there were no hospitals. The construction of a public hospital was first proposed in Virginia in 1766. The money was appropriated in 1770, and the Public Hospital at Williamsburg opened in 1773, which was the first public mental hospital in the colonies. In Massachusetts, McLean Asylum opened in Charlestown in 1818. The first large state hospital opened in Worcester, Massachusetts, in 1833.

The physician superintendents of these early hospitals were the reformers of the era, following the ideas of moral management put forth by the French reformer Philippe Pinel. Pinel believed that if people were removed from their urban environments, relocated to an asylum in a beautiful pastoral setting, engaged in agriculture and the trades, lived in close proximity with staff, and were treated with kindness, then soon they would fully recover from the behavioral changes that they manifested as a result of having lived in a stressful, demanding environment. Benjamin Rush, a signer of the Declaration of Independence and considered the founder of American psychiatry, applied many of these theories and methods of his own in the treatment of the insane in the years after 1783 in the Philadelphia Hospital.

The great majority of those who experienced mental illness, however, were kept in poorhouses or jails under deplorable conditions and became a cause for reform. The Unitarian reformer, Dorothea Dix, had begun a 2-year survey of the conditions in which these people lived. In 1843, she compiled her findings in a Memorial to the Legislature of Massachusetts: "I tell what I have seen, to present the state of the insane persons confined within the Commonwealth in cages, closets, cellars, stalls, pens! Chained, naked, beaten with rods, and lashed into obedience!"

After the Massachusetts Legislature appropriated funds for a substantial expansion of the Worcester Hospital between 1844 and 1854, Dix traveled more than 30,000 miles, visiting hundreds of prisons, almshouses, jails, and hospitals, collecting data and arousing public opinion to her cause. In 1848, with the example of federal support given to education, she sought federal support for national hospitals. President Franklin Pierce, who stated, "I cannot find any authority in the Constitution that makes the Federal Government the great almoner of public charity throughout the United States," and vetoed the bill for federal support. Public mental health was, for the next century, exclusively in the hands of the states and the state hospitals that continued to be built only to be quickly filled and become hopelessly overcrowded.

Community Mental Health

I am proposing a new approach to mental illness and to mental retardation. This approach is designed, in large measure, to use Federal resources to stimulate state, local, and private action.

When carried out, reliance on the cold mercy of custodial isolation will be supplanted by the open warmth of community concern and capability. Emphasis on prevention, treatment, and rehabilitation will be substituted for desultory interest in confining patients in an institution to wither away. — John F. Kennedy, Message from the President of the United States Relative to Mental Illness and Mental Retardation, February 5, 1963.

In a little more than a century after President Pierce blocked the federal government from involvement in the problem of mental illness, another president reversed this direction and committed the federal government to the cause of persons with mental disabilities and their families. President John F. Kennedy signed the Mental Retardation Facilities and Community Mental Health Centers Construction Act (PL 88–164) in October 1963. He did so perched on a wave of reform that defined a new era of community mental health. The reform was founded on a century of steady progress in which asylums were built and their weaknesses discovered. The advances of medicine offered new hope to psychiatry, and that optimism gathered the momentum of public opinion. Consumers and advocates for the mentally ill found their voice in the mental hygiene movement. A series of research-oriented institutions was established. Significant therapeutic improvements were discovered. Finally, a coalition of skillful bureaucrats, advocates, and politicians set the scene for the public policy shift that President Kennedy declared would supplant the "cold mercy of custodial isolation" with the "open warmth of community concern and capability."

It has been said that US medicine reached a critical juncture toward the beginning of the 20th century. Science and medicine had established a strong alliance in the major university medical schools, and the profession had established a powerful public credibility as breakthrough after breakthrough transformed medicine. Psychiatrists were not in the forefront of this transformation, but they were profoundly affected by it. One of the most prominent psychiatrists of the period, from 1890, until his retirement at the eve of World War II, was Adolf Meyer, and his life and career may be thought of as representative of what was happening to psychiatry. Meyer was born in Switzerland in 1866, and was trained as a neurologist. He came to the United States in 1892, and worked for 8 years in state hospitals in Illinois and Massachusetts. In this sense, he came from the ranks of the asylum psychiatrists who were the bulwark of the state hospital system that had, by that point, spread throughout the country.

The first public psychiatrists were state hospital superintendents, responsible for all institutional clinical and administrative functions. Within a few short years, the populations of state hospitals grew so that their treatment function was eclipsed by care and custody concerns. The superintendent became more of a manager and administrator than a treatment provider. The ability to organize and to bring order to the institution became a necessary skill.

The New York State Hospital system had established, in 1895, the

Pathological Institute, which had two mandates: the study of mental diseases from the standpoint of cellular biology and the offer of instruction in brain pathology to state hospital physicians. The Institute sought to become the cutting edge of reform—not without opposition from the asylum psychiatrists, who were more oriented toward managerial and administrative concerns and clear demarcation of the diseased state of institutional inmates from the normality of functioning people in the community. Meyer became its director in 1901. When Henry Phipps endowed a psychiatric clinic at Johns Hopkins, Meyer was chosen as its first head. From Johns Hopkins, he played a leading role in American psychiatry for more than three decades.

In the beginning of the 20th century, the concept of dynamic psychiatry opened the possibility of psychiatry practiced in the community. Dynamic psychiatry blurred the distinction between health and disease and saw mental illness on a continuum. This allowed the center of attention for psychiatric practice to move beyond the institutions and to include troubled individuals in the early stages of illness. This approach elevated the significance of the life history and prior experience of each person. It was a short leap of faith to suggest that early community treatment might prevent the onset of severe mental illnesses that, up to then, had required institutionalization. The once strong bond between the asylum and psychiatry was unraveling. Dynamic psychiatry expanded the jurisdictional boundaries to include psychologically troubled individuals, as well as allegedly dysfunctional social structures and relationships. From 1880 to 1940, psychiatrists identified new careers outside of institutions. Psychiatrists articulated novel and sometimes bizarre theories and therapies; expanded jurisdictional boundaries to include not only mental disorders, but also the problems of everyday life; proposed solutions for society's ills; and defined a preventive role. In retrospect, it was an over-reach which subsequently led to questions about the credibility of the field and its foundations. What had been hypotheses initially were interpreted by some as factual, and often damaging (e.g., the so-called "schizophrenogenic mother," asthma as "a cry for help," etc.). It was also during this "pre-chlorpromazine era" that psychiatry alienated itself from the rest of medicine. Despite its good intentions, it was, in retrospect, gross overstatement based more on conjecture and opinion than a scientific basis.

Meyer was a leading figure in advocating "a fresh and courageous pragmatism" and held "a biological conception" of human beings: "We must ... accept the statement that all mental activity must have its physiological side and its anatomical substratum." He developed a genetic-dynamic or developmental approach to mental illness, which he named psychobiology. He stressed the interaction of the organism with its environment and defined mental disorders in behavioral terms, tracing

their origins to defective habits. He recognized the importance of consumer advocacy and supported Clifford Beers, a former mental patient, who wrote a celebrated work, A Mind That Found Itself, and who founded the Mental Hygiene movement.

Meyer was an empiricist, urging his colleagues to assemble and to catalogue facts. He was not a theoretician or a systematizer. Perhaps he realized that biology did not yet have the scientific tools to construct adequate theories about human mental processes. In this regard, he did not favor Sigmund Freud and what he viewed as the tendencies to dogmatic pronouncement. The eminent social historian of American mental health policy, Gerald Grob, observed that "psychoanalytic concepts ... had far greater influence on culture and thought than on medicine in general or psychiatry in particular." This seems to overstate the case, given the great enthusiasm for psychoanalysis that came after World War II and that dominated popular perceptions of psychiatry.

On the eve of World War II, as Meyer retired, public psychiatry had advanced on three fronts. On the first, research institutes and psychopathic hospitals were developed alongside the state asylums in which research and training would benefit the care of persons with mental illness. These hospitals and institutes had limited success, in that their research efforts to establish the efficacy of psychodynamic treatment progressed slowly, and they suffered a degree of mission drift away from the seriously and persistently mentally ill in the asylums and toward less severe mental health problems in the community. Second, an active consumer advocacy movement began in the founding of the National Committee for Mental Hygiene in 1909, which developed into a national movement focusing first on the plight of individuals in the asylums and then on mental health issues in the community. Finally, the ideas of dynamic psychiatry made it possible to think of the various stages of mental illness and the possibility of the prevention, amelioration, and potentially even cure of mental disease.

Before World War II, there were fewer than 3,000 psychiatrists in the United States, with more than one half of them working in the public sector. At war's end, the American Psychiatric Association (APA) still represented hospital psychiatry. However, a bitter and divisive power struggle ensued. By 1950, the APA had been transformed into a visible and active organization that represented psychodynamic and psychoanalytic viewpoints. Adherents to these perspectives controlled virtually all university departments, ensuring that psychiatrists trained in the 1950s and 1960s shared these concepts. By 1957, only 1,700 of the 10,000 APA members worked in state hospitals. Within less than 20 years, the overwhelming majority of psychiatrists in the United States went from working in state hospitals to working in other settings that had little or no interface with the populations having serious mental illness or serious and persistent mental illness or with children with serious emotional disorders.

As World War II ended, two factors entered the US public psychiatry arena that would have a catalytic effect. The first was the corps of 2,400 physicians assigned to psychiatry along with prominent leaders in US psychiatry who had screened recruits and successfully treated neuropsychiatric symptoms in noninstitutional settings. Many psychiatrists left military life convinced of the need for change in the ways in which the needs of persons with severe mental illness and individuals with mental health problems were addressed. They entered the nonmilitary world confirmed in the ideas that dynamic psychiatry had articulated. The second factor was the appearance of the so-called "French drug" chlorpromazine (Thorazine). Chlorpromazine was tested in a Parisian mental hospital after encouraging findings of its effect on trauma patients in the war. The positive findings of these trials led to its marketing under the name Thorazine in the United States in the early 1950s. The new drug was cautiously and ambivalently received by psychiatrists committed to psychodynamic concepts as there were comments that the drug would alter the transference of the therapeutic relationship, but it opened a new world of possibilities for the academics and researchers who came to represent biological psychiatry.

The 1950s were a time of great therapeutic optimism. Biological psychiatrists pointed to the efficacy of drug therapy; their psychodynamic colleagues could point to psychological, psychosocial, and environmental therapies that would reach the most severely disabled institutionalized patients. Milieu therapy (the therapeutic community) arose in this period and had much in common with moral therapy. It appeared that medications were going to allow patients to engage in the therapeutic community, and then other innovations, such as unlocked wards and partial or day hospitals, were going to help some chronic patients transfer to the community.

As all of this momentum for change was building, a remarkable partnership for political action was developing among Robert Felix, the head of the newly formed National Institute for Mental Health, Senator Lister Hill, and Representative J. Percy Priest. Hearings were held aimed at focusing public attention on mental health problems and thus strengthening the case for an enhanced federal role. The Mental Health Study Act was passed in 1955, creating the Joint Commission on Mental Illness and Mental Health (JCMIMH). That Commission's final report, Action for Mental Health, did not make a clear-cut distinction between individuals with serious and persistent mental illness and psychologically troubled individuals. Although the JCMIMH report was a compromise among the 26 participating constituency organizations, nonetheless there was strong support for fundamental change. Faith in the effectiveness of treatment in community programs was based on belief in the efficacy of early intervention, psychodynamic theories, epidemiological efforts to

elucidate the prevalence of mental illness in the community, and the putative identification of environmental variables.

At the end of the decade, with a new administration with an aggressive domestic agenda, the National Institute of Mental Health (NIMH) convened the Interagency Task Force on Mental Health, which developed the Blueprint for Action and, more importantly, activated the political coalition that made President Kennedy's initiative possible. The final policy sidestepped the provisions recommended by the JCMIMH for the refurbishment of the state hospitals and the provision of acute institutional care for the most severely disabled and devoted its attention to community mental health clinics, which it recommended to be enhanced to comprehensive community mental health treatment centers—the community mental health centers (CMHCs).

The national program for comprehensive CMHCs was in place. For the next 15 years, grants flowed to the localities and then through the states to the localities to the new centers, and states proceeded to build two community systems while beginning the process of phasing out the old state hospitals. The immediate discovery was that the CMHCs were able to expand mental health services for the communities but were not at all prepared to care for persons with serious and persistent mental illness who had spent most of their lives in state institutions. The discharge of 90 percent of the state hospital population (the deinstitutionalization process) without adequate community resources available was chaotic and often precipitous. It led to a class of homeless and generally untreated or transinstitutionalized individuals (put into nursing homes, prisons, squalid rooming houses and hotels, etc.) who deteriorated outside the state hospitals. There also arose a peripatetic subpopulation with serious and persistent mental illness who often had comorbid substance abuse and generally avoided any beneficial involvement in treatment for a significant portion of the early phase of their illness. However, the states, to varying degrees, were set on a course of dismantling state hospitals that were becoming increasingly expensive. As federal staffing grants to the CMHCs were phased out and state contract dollars replaced them, the states gradually narrowed the focus of the community programs to its priority clients—the former residents of the state hospitals. Special programming models were developed to provide supportive programming for them that focused on community support and rehabilitative approaches rather than clinical ones.

As community mental health programs developed, it became clear that psychiatrists were, for the most part, playing limited roles: reimbursement could not support them full time, and they gravitated to private practice models that were appropriate for individuals with less severe mental health issues. The psychiatrists who were involved in the early CMHCs were quickly outnumbered by practitioners from the other disciplines and often

sidelined themselves in private practice models in which they could treat educated and functional people with relatively mild disorders. One tongue-in-cheek publication during this era described the "YAVIS" individual as the "ideal" psychotherapy candidate … Young, Attractive, Verbal, Insightful, Successful. Many psychiatrists and others in behavioral health gravitated toward this profile for their ideal caseloads. These practice models limited their ability to treat persons with severe mental health disabilities without appropriate outreach and supportive care.

It was a chaotic period in US mental health services. The different states advanced unevenly in the development of community programs while, uniformly, political pressure built to reduce the census in the expensive state hospitals. In some cases, appropriate community-based programming was ready to receive the newly discharged individuals, but in many cases it was not. There are those who have come to look back in dismay at the massive changes that the federal community mental health programs put in motion. The durable and revered concept of the asylum was to be abandoned in this process. With the picture of many deinstitutionalized former state hospital residents, homeless or living marginally, especially in the nation's cities, the optimism and faith in the effectiveness of the new treatment modalities that drove these policy decisions might be judged (in hindsight) to be unwarranted. The process had been driven by rhetoric, single-mindedness, and unbridled enthusiasm, and, strangely, the NIMH had ignored the more balanced recommendations that supported improvement measures for the hospital facilities and the community programs.

Many mistakes were made, but many valuable lessons were learned. In 1977, President Jimmy Carter signed an executive order creating the President's Commission on Mental Health to review the progress and needs of the national programs and to make recommendations. The reports and monographs prepared by the Commission documented and catalogued what had been gleaned from the development of community programs and the process of deinstitutionalization that had ensued. Overall, they represented a more balanced and informed conceptualization of the agenda and the problems that needed to be addressed. The Commission's findings led to the passage of the Mental Health Systems Act (PL 96–398), which President Carter signed in October 1980. It enabled a National Plan for the Chronically Mentally Ill, which was released a month after Carter's defeat for re-election. Under his successor, President Ronald Regan, the Omnibus Budget Reconciliation Act of 1981, repealed most of the Mental Health Systems Act in favor of block grants to states. The role of federal leadership and national policy was substantially diminished, and the states were largely on their own.

Organized Systems of Care

The psychiatric hospital is a special target of health care corporations. Its profit margins are large, investment costs are low, inpatient psychiatric care is now widely insured, and the complexity (and perhaps ambiguity) of psychiatric diagnosis and treatment makes cost control efforts by insurers and the government difficult. In 1968, for-profit hospital chains were nonexistent in psychiatric care. In 1980, investor chains owned 25 percent of private psychiatric hospitals and, just two years later, these corporations owned a full 43 percent market share. Between 1982 and 1983, the number of investor-owned psychiatric hospitals rose 42.5 percent, from 106 to 151. The increase was partly attributable to investor groups' acquisition of existing facilities, but new construction of psychiatric hospitals, which grew 53.3 percent, accounted for most of the growth. "Ad-Psych" (Adolescent Psychiatry) units are so lucrative that corporations have closed units providing other types of services in order to establish the more profitable adolescent units. Admission data reflect the current domination of the private sector in the provision of adolescent inpatient psychiatric services. In 1980, for example, private facilities admitted 61 percent of all adolescents who underwent psychiatric hospitalization; since that time, juvenile admissions to these facilities have increased substantially. — Lois A. Weithorn, Stanford Law Review, 1988.

US health care costs began to increase dramatically in the 1970s. By the end of the 1980s, they were spiraling. The article just cited by Lois Weithorn in the Stanford Law Review addressed the possible violation of children's rights posed by their involuntary hospitalization in commercially operated psychiatric hospitals. It documented a trend of which US employers—and the insurance companies that they hired to administer their health benefits—were all too aware. While employee health care costs overall were climbing, behavioral health expenditures were increasing by 50 percent each year. Venture capital had discovered a chink in the armor of health care finance. Even though there were lifetime limits for mental health benefits, a substantial amount of money lay in those coffers. Psychiatric hospitals were relatively cheap to build and could be designed to be converted to elderly housing facilities once the gap was closed. The criteria for mental illness were sufficiently permeable and standards of care were sufficiently undefined that decisions for hospitalizations were made on behalf of many patients when more considered judgments would have found other alternatives. In fact, many hospitals launched deliberate marketing campaigns to fill their beds, and many practitioners participated. The trend was an abuse. Its most cynical aspect was that benefit dollars that could have been devoted to the care of persons with severe mental illness were quickly extracted—a $50,000 lifetime limit could be spent in 60 days of private hospital care—so that sick patients were discharged to the care of public sector agencies.

Although several examples of health maintenance organizations (HMOs) had demonstrated their effectiveness in improving the health status of enrolled populations for several decades, US employers were reluctant to require their employees to sign up for a plan instead of the traditional indemnity (or fee-for-service) health insurance. However, the growth of behavioral health expenditures was so dramatic that they overcame their reluctance for this sector. Within a few years, an industry of managed behavioral health organizations was created by the contracting

activities of human resources executives of the major US corporations. The new companies were staffed by a corps of seasoned mental health professionals, most of whom had been prepared in the ranks of the community mental health movement. They introduced, in a business-like fashion, utilization review techniques reinforced by elaborate information and communication technology. They selected panels of providers who could be trusted to care for enrolled members without inappropriate or extended use of hospital or other expensive care. Their impact was dramatic: Within a few years, behavioral health expenditures stabilized, at least temporarily.

The success of the carve out of behavioral health care inspired employers to apply their contracting techniques to the rest of health care. Even though in 1987, only 27 percent were in managed care, by 1995, 73 percent of insured employees were enrolled in some form of managed care. Simultaneously, in the early 1990s, President Bill Clinton undertook a health care reform that attempted to provide universal health care as a highly regulated public entitlement. The Clinton health plan was labeled "managed competition" as a nod to the rapid move to competitive health care markets. However, the originators of that term—an assembly of business and health care experts known as the Jackson Hole Group—were much clearer about an approach in which government and government regulation would play a minimal role.

Nonetheless, a health care marketplace was created in the course of the failed Clinton health care reform. A wide variety of health care entrepreneurs would organize providers to bring their products to the markets, and consumers were encouraged to make choices that would ensure the value of the care that they would receive. The employers, through their contracting practices, sought to apply the principles of industrial organization to health care delivery to advance the ideal of organized systems of health care that were accountable and attractive to value-driven consumers. Although, certainly, some excellent health care delivery systems have developed, most have fallen far short of these ideals in a full array of organizational structures. All of these structures and models fell under the term "managed care."

In a systematic review of the dramatic changes in US health care in the last 15 years, Ginsberg described a "backlash" in the rapid growth of managed care. In the early 1990s, managed care's utilization review techniques and benefits had restrained providers; HMOs and other plan types restructured health care delivery; the insurance industry transformed itself, acquiring HMOs and creating a new array of "products" for employers to purchase; risk was cascaded to hospitals, in many cases making them insurers and encouraging them to consolidate their positions in physician hospital organizations (PHOs); and physicians reorganized their practices into independent practice associations (IPAs) and multi-

and single-specialty groups. By the mid-1990s, the rise of health care costs leveled off (temporarily), but there was widespread dissatisfaction among consumers and the rest of the system. By 2000 many of these measures were relaxed. Instead of benefits that restrained professionals, copays for consumers restrained their utilization. Employers encouraged broader networks, preferred provider organizations, and eliminated gatekeeper access to specialists. The insurance industry consolidated itself through cross-market mergers and large national contracts.

Quality and accountability began to dominate the health care market by the end of the 1990s, and consumers were encouraged to look to quality ratings by major accreditation organizations in making their choices. Managed care has had an indelible impact on the US health care system, introducing issues of quality and accountability, reinforced by the Institute of Medicine's report Crossing the Quality Chasm.

At the End of the Century

The last decade of the 20th century was a period of change, reflection, and revision. While the rise of health care costs were slowed temporarily by managed care, 50 million people were projected to be uninsured by 2020, and health care costs would hit 20% of the Gross Domestic Product (GDP). Health economists considered this unsustainable, seriously eroding the ability of the country to attend to infrastructure, education, and other critical societal factors (see Chapter 58.2 on Reforming Health Care). What has happened to public and community psychiatry was documented in three important retrospectives. Historian Gerald Grob and psychiatrist Howard Goldman have chronicled the complex policy formulation processes that lead to federal mental health policy initiatives and maneuvers in the 1990s and early 21st century. Two health economists, Richard Frank and Sherry Glied, have provided a sweeping and data-rich review of the mental health policies in this period and the performance of the resulting programs. Finally, President George W. Bush's New Freedom Commission on Mental Health in 2004 revisited the task of the last presidential commission under the Carter Administration to provide a thorough review of current mental health policy and formulate a comprehensive policy to address specific problems and plans for the future. All three efforts are reflections on the very eventful changes in the last years of the 20th century as public psychiatry moved from institutions into the community. They are also among the public documents that laid the groundwork for the Affordable Care Act in 2010.

Grob and Goldman tell the story as an alternation between policy idealists seeking radical reform and policy realists intent on incremental reforms. In 1980, the Mental Health Systems Act (MHSA) had authorized a radical reform of 15 years of community mental health programming. As noted earlier, this was repealed in the first months of the Reagan

Administration. The National Plan for the Chronically Mentally Ill, which had been developed by an interagency task force in the course of the congressional review of the MHSA, became a blueprint for incremental reform and established a degree of success in implementing its objectives over the decade of the 1980s. This provided the context for NIMH's Community Support Program (CSP) for adults, the Child and Adolescent Service System Program (CASSP) for children with serious emotional disorders and their families, and the administration of the mental health Block Grant program to the states.

With a meticulous assembly of state/federal Medicaid data, Frank and Glied documented a general improvement in every aspect of mental health care. Remarkably, public financing for mental health care from all sources increased 70-fold from 1956 to 1997. The increase is 100-fold if reported expenditures of $100 billion in 2003 are considered. The picture they present, however, is complex. As the process of deinstitutionalization proceeded and patients were moved from state hospitals to care in community programs, the financing also moved from institutional budgets to the categorical budgets of the state mental health agencies to fund the community programs. As employers moved dramatically to managed care in the 1990s, however, state Medicaid agencies followed suit and contracted with the Behavioral Health Managed Care Organizations (BHMCOs) to manage their mental health benefit. States quickly realized that by moving mental health categorical dollars into their Medicaid program they could leverage Federal Financial Participation (FFP) into their state's general fund. Almost all of the states shifted large portions of their mental health budgets for direct services into the Medicaid program—hence the substantial increases in mental health funding. However, these services ended up in the stewardship of Managed Behavioral Health Organizations (MBHOs), whose products tended to be modeled on private sector mental health care for general populations.

The shift of mental health service dollars to Medicaid and then to the control of the MBHOs was considered a critical mistake both by Grob and Goldman and by Frank and Glied. For Grob and Goldman it derailed the possibility of genuine reform that would fulfill the vision of coherent specialized delivery systems fully integrated in the community. For Frank and Glied it meant a loss of focus when patients were mainstreamed into communities, where they discovered the fundamental fragmentation of US social welfare programs. Frank and Glied argued for "exceptionalism" as opposed to "mainstreaming" for mental health services, with mental health exceptionalism evolving historically into mental health mainstreaming, the latter being what is typically found in state systems today. They proposed, as the next step, a federal regulatory agency (Fig. 58.1–1).

The more formal and official retrospective is that of the 2003 President's New Freedom Commission on Mental Health. Its landmark

finding was the recognition that a measure of recovery is possible for persons with even the most severe and persistent mental illness. The Commission had in hand the recently prepared Mental Health: A Report of the Surgeon General by Satcher, which reviewed scientific advances in the understanding of mental illness. These were, of course, dramatic. Despite this very hopeful news, the Commission's report was confronted with "unmet needs … many barriers to care for people with mental illnesses" and a severely "fragmented mental health delivery system." The states, on a fast track to wind down the state hospitals and, in most cases, to build community support programs, had uneven success. In many large cities, persons discharged from the hospitals with serious mental illness joined the ranks of the homeless or lived in substandard conditions in welfare hotels or board-and-care facilities. The Commission's report proceeded to lay out the goals and priorities through which the mental health system could be rebuilt at the family and community level so as effectively to transform it to enhance the resilience and recovery of individuals who suffer from mental illness.

Ascendance of Biological Psychiatry

In the year 2000, the Nobel Prize in Medicine was awarded to Arvid Carlsson, Paul Greengard, and Eric Kandel "for their discoveries concerning signal transduction in the nervous system"—work that explained at the level of molecular biology the effect of chlorpromazine and the psychotropic medications that followed it. In June of that same year, the Human Genome Project of the U.S. Department of Energy announced the completion of a working draft of the entire human genome sequence. Using sophisticated microarray techniques, it might one day be possible from a simple blood sample to determine what "type" of depression or psychosis an individual has and, in turn, target specific treatment to that specific mental disorder.

FIGURE 58.1–1. Possible futures for the evolution of mental health exceptionalism versus mental health mainstreaming. (Adapted from Frank FG, Glied SA. *Better But Not Well, Mental Health Policy in the United States since 1950*. Baltimore, MD: Johns Hopkins University Press; 2006.)

Reprise

It may appear that, in two centuries, US mental health has come full circle, that individuals severely disabled by mental illness are back living marginal or tragic lives in US communities and wander through cities without receiving appropriate care. There is certainly much truth in this. However, on the very spot where Nancy Barron was restrained in the poor house and screamed through the day in Emerson's Concord, there now stands a community residential program for adolescent girls with serious emotional disturbances that is part of a community system of care. They are treated by clinicians who understand the brain chemistry underlying their illnesses and who have pharmaceuticals and psychotherapy interventions that can alleviate them. With the increased knowledge-base and treatment evidence base that now informs public and community psychiatry, children and adults with serious and persistent emotional disturbance and mental illness can receive exceptionally high quality evaluations and treatments—if the health system and its psychiatric resources are accessible to them and able to follow through with the care that they need without letting them fall between the cracks. But this is the business of health care reform.

CONTEMPORARY PUBLIC AND COMMUNITY PSYCHIATRY'THE AFFORDABLE CARE ACT'S CALL FOR TRANSFORMATION

The emerging road map of contemporary psychiatry in the 21st century is largely conditioned by the impetus of the ACA for the whole of American Medicine. This has been characterized by the implementers of the new law as the "Triple Aim"—Better Care, Better Health, Lower Costs. Better Care refers to the emphasis on quality and safety which generated the "Quality Chasm" reports of the Institute of Medicine (IOM) including that focused on Behavioral Health and Substance Use Conditions as well as the development of the Patient-Centered Outcomes Research Institute (PCORI) and the work of the Agency for Healthcare Research & Quality (AHRQ). Better Health refers to the emphasis upon population health that has long been the focus of Public Health, its methods of surveillance, epidemiology, health promotion and prevention. And Lower Costs refers to improvements in quality and safety, the application of treatments that are demonstrated as effective, the organization of health service delivery and the integration of health care delivery systems leading to improved efficiency and a better process of care for the individual. The authors will use these three aims as a framework in which to discuss the challenges ahead for Public and Community Psychiatry. With a majority anti-ACA

government from the 2016 election, the outcome remains unclear whether the ACA will be totally replaced or improved upon, and what the results will be in either scenario.

Better Care: Evidence-Based Psychiatry, Integrated with Primary Care, in the Context of Coherent Health Care Delivery Systems

The developments in the last decade leading up to the ACA, as well as the statute itself, have laid the groundwork for the agenda of improving health care for public and community psychiatry. The Surgeon General's Report (2000) celebrated the impressive scientific advances in neuropsychiatry in anticipation of the New Freedom Commission's review of mental health policy and programs (2003). As several prominent medical societies came together to formulate a common definition of a "Patient-Centered Medical Home," SAMHSA and HRSA, crafted a joint commitment to integrate psychiatry into Primary Care in their Center for Integrated Health Solutions. The National Committee for Quality and Accountability (NCQA) provided detailed standards by which a Patient-Centered Medical Home could be certified. HRSA invited CMHCs to apply for status as Community Health Centers or Federally Qualifies Health Centers (FQHCs), as well as strengthening the behavioral health services in the existing FQHCs. In states and localities new programmatic models developed based upon evidence-based findings. Many of these models were "manualized" (i.e., formally documented in written protocols and decision rules that guide clinicians step-by-step in the application of specific therapeutic procedures) to support their fidelity to research-validated practices in implementing treatment and replication as the therapeutic model is disseminated throughout the field. The Agency for Health Research and Quality (AHRQ) supported an ambitious program of research designed to strengthen the evidence base of clinical interventions across the board. These efforts gained more focus by the ACA's creation of the Patient-Centered Outcomes Research Institute (PCORI). Finally, in order to meet the glaring need for an increased Primary Care workforce, the ACA included the concept of a "Primary Care Residency" program to be based in community-based practices as Teaching Health Centers including the FQHCs and CMHCs. Psychiatry was included as one of the nine medical subspecialties that would be active in this new program.

In order to be specific about the dimensions of Public and Community Psychiatry in improving patient care, it will be important to identify the obstacles that Public and Community Psychiatry will confront. The first is the relative absence of psychiatrists working in Public and Community Psychiatry. Surely there are wonderfully dedicated psychiatrists caring for adults and children with behavioral health disabilities in public programs—but their numbers are very small. The second obstacle is the fact that the bulk of psychiatrist time that the heavily stressed and under-resourced

public mental health systems does employ is largely limited to writing medication scripts and supporting medication management to some degree. Finally, there is a strange and persistent historical separation between mainstream American physical medicine and psychiatry, apparently due to the lagging scientific advance of psychiatric practice in the last century and the lack of acknowledgement or knowledge of the dramatic progress in the science of the brain in recent years. But this is changing as it becomes clear that a significant percentage of individuals presenting with physical health disorders have co-morbid psychiatric disorders that must be addressed as well.

Adults with Severe and Persistent Mental Illness. Although psychiatrists that do work in public and community settings encounter patients with mild impairment or acute disorders, the preponderance of their work involves people with severe psychiatric disorders and chronic psychosocial impairment. Adults who have been faced with socioeconomic deprivation for most or all of their lives (often over several generations) are at risk for chronic psychiatric disorders that often are complicated by medical illness, violence, social stigma, and cultural or political marginalization. These adversities, as well as the cognitive, emotional, biological, and interpersonal impairments often experienced by adults with severe and persistent mental illness, may obscure their personal strengths and resilience and the resources potentially available to support them in their families and communities. A major challenge to psychiatrists serving adults who have the dual burden of mental illness and socioeconomic disadvantage is the identification and enhancement of the psychological and sociocultural resources that can promote illness management and reintegration in a support system.

The traditional foci for private sector psychiatric practice—evaluation and diagnosis of psychopathology, psychotherapy and pharmacotherapy—should be essential components in a fully operational program of assisting adults with severe and persistent mental illness to make the best possible adjustment in the least restrictive public and community settings. This would be consistent with the Affordable Care Act's integration of effort across public agencies, professional collaboration, and health systems as learning communities. There is, in fact, a full array of treatment models that include multidisciplinary psychiatric rehabilitation teams that are demonstrated as effective recovery-oriented interventions.

Evidence-Based Manualized Interventions for Adult Psychiatric Rehabilitation. Public and community approaches to psychiatric rehabilitation involve an array of complementary services that must be coordinated to assist people with severe mental illness or behavioral disorders and their families and support systems to manage symptoms, to

access and use resources effectively, and to gain the greatest degree of autonomy in the least restrictive setting possible. Compendia have been developed on a national level in the United States to catalogue evidence-based mental health treatment (e.g., the SAMHSA National Registry of Evidence-based Programs and Practices [NREPP] and National Child Traumatic Stress Network [NCTSN] Empirically Supported Treatments and Promising Practices; the Office of Juvenile Justice and Delinquency Model Program Guide) and prevention (e.g., Blueprints for Violence Prevention) interventions. Several states in the United States also have developed registries listing evidence-based mental health treatments (e.g., California, North Carolina, Oregon, Vermont, Virginia, Washington).

The development of this array of evidence-based program models marks the transition in public community based supportive programs to interventions that are proven to be therapeutic. They have demonstrated that a substantial degree of recovery is possible. They all assume and incorporate a coherent clinical process that is carried on by a multidisciplinary team guided by rehabilitation and mental health specialists—including the diagnostic and clinical expertise and medical/legal authority of the psychiatrist. Not all of these programs explicitly specify psychiatric participation, largely because few psychiatrists have been available to serve these populations. Nonetheless, the engagement of psychiatrists with the treatment of patients with persistent disability will strengthen these proven intervention models. An illustrative but not exhaustive sample of these interventions is detailed in Table 58.1–3.

The need for psychiatry's engagement in the care of adult patients whose mental illness has led to persistent disability cannot be overstated. In the past, little could be offered to these patients. They were cared for and confined in institutions or supported in community programs. Now they can be treated holistically in primary care settings (avoiding the stigma of mental illness) and work with their multidisciplinary team specialized in chronic illness care with a strong psychiatric component.

Children with Severe Emotional Disturbance. Children from all strata of society experience severe psychiatric illnesses (such as developmental, affective, and anxiety disorders) and behavioral problems (such as attention-deficit, oppositional defiant, or conduct disorders). Access to Primary Care can be a barrier for many families, especially those in poverty. Public and community psychiatry treatment is provided by five categorical agencies, which are all responsible for their care and often hopelessly fragmented in their response. In this context of social and governmental disorganization, children with severe emotional disturbance and their families require the cross-agency organization of a clinical process that will direct a coordinated combination psychiatric and

psychosocial services that wrap around the child and family.

It has generally become accepted that children with severe emotional disturbance and adolescents with severe behavioral disorders do better in families that are appropriately supported than having them removed from their families and placed for extended periods in alternative programs. These placements are often more restrictive or protective—such as psychiatric inpatient wards, residential group homes, and juvenile detention centers. Placements are often extended and usually break the continuity of whatever clinical process has begun in their homes. Placement separates children from their natural family, school, peer group, and community environments. While short-term placement in a skilled program working closely with the family and the clinical team can provide a healing respite, if extended and detached from community and family, it disrupts and fragments the clinical process. Home and community-based care for troubled children has been made possible by the development of evidence-based program models for children with severe disorders and their families. These have been developed, tested, and disseminated in replicable manuals and training programs, and prominent models are presented in Table 58.1–4.

Table 58.1–3.
Evidence-Based Manualized Interventions for Adult Psychiatric Rehabilitation

Modality	Goals and Targeted Areas	Results of Evaluation Research
Social and independent living skills	Teaches skills for managing symptoms and preventing relapse (mental illness and addictions), improving social communication with providers, peers, and family, and choosing and engaging in activities that match the person's abilities, limitations, and interests	Social and independent living skills evaluated in randomized, clinical trials show positive outcome, with increased successful community living and reduced rehospitalization
Assertive Community Treatment (ACT)	Provides ongoing care coordination and case management to increase ability to live independently in the community and prevent/manage psychiatric crises	Randomized effectiveness trials with adults and adolescents with serious and persistent mental illness and co-occurring addictive disorders demonstrate increased psychiatric, residential, and vocational stability
Cognitive-Behavior Therapy (CBT)	Teaches skills for recognizing and modifying thoughts and beliefs that increase or prolong distress, and strengthening thoughts and beliefs that are self-affirming	Meta-analyses support CBT's efficacy in reducing the severity of anxiety disorders, somatoform disorders, bulimia, anger control problems, and generalized stress reactions, and offer modest support for CBT as an adjunctive treatment with addictive disorders and serious mental

	and interpersonally assertive.	illness.
Dialectical behavior therapy	Teaches skills for regulating intense emotions, tolerating extreme emotional distress, achieving interpersonal effectiveness, and developing mindfulness	Evaluated in randomized clinical trials with parasuicidal adult patients with borderline personality disorder, resulting in reduced behavioral and psychiatric crises greater than that achieved by expert psychiatrists' treatment
	Originally developed for adults with borderline personality disorder, but has been adapted for use with a wide range of Axis I disorders in which extreme dysregulation and poor impulse control are problematic	Randomized clinical trials and observational studies show positive psychosocial outcomes with adults with severe and persistent mental illness and chronic addictions and with adolescents who are suicidal or self-harming, including those who have substance abuse or posttraumatic stress disorders
Acceptance and commitment therapy	Teaches skills for identifying and managing (rather than avoiding and feeling controlled by) the symptoms of psychosis, affective, anxiety, eating, traumatic stress, and addictive disorders. Acceptance of symptoms facilitated by explanation that psychotic symptoms are extreme versions of normal perception and cognitive phenomena (private experiences)	Randomized clinical trials show evidence of increased awareness but reduced distress and impairment due to psychiatric symptoms across a variety of psychiatric disorders in outpatient and inpatient treatment settings
Relapse prevention therapy	Teaches skills for identifying the warning signs of potential or actual resumption of substance use or psychiatric symptoms	Randomized clinical trials show efficacy in delaying, reducing the severity of, and preventing substance use relapse with adults with chronic addictions and co-occurring or comorbid psychiatric disorders
	Uses cognitive–behavioral skills for proactively modifying patterns of thought and behavior that are likely to escalate into a full relapse	
Interpersonal psychotherapy	Teaches skills for interacting and communicating effectively in close relationships, with a particular focus on overcoming four core interpersonal problems: unresolved grief, role conflict (e.g., dissatisfaction with parenting), role transition (e.g., marital separation), and interpersonal deficits (e.g., isolation and anger	Randomized clinical trials show evidence of reduced severity and risk of relapse of moderate to severe depression; PTSD, anxiety disorders, and eating disorders

	management)	
Behavioral Therapy	Provides systematic reinforcement contingencies to increase adaptive behavior and to extinguish maladaptive behavior	Randomized effectiveness trials show evidence of reduced alcohol, drug, and other addictive behaviors
Motivational Enhancement Therapy	Teaches skills for recognizing and aligning choices and behavior with personal motivations	Randomized effectiveness trials show evidence of reduced alcohol, drug, and other addictive behaviors
Trauma-focused cognitive–behavior therapy for posttraumatic stress disorder (PTSD)	Teaches skills for safely recalling rather than avoiding troubling memories of traumatic events and for recognizing and managing PTSD symptoms, such as intrusive memories or flashbacks, emotional numbing, dissociation, and distress (e.g., guilt, grief), and problems with sleep or anger, or concentration problems due to hyper arousal or hypervigilance	Randomized clinical trials of seven approaches with adults (prolonged exposure therapy, cognitive processing therapy, eye movement desensitization and reprocessing, narrative exposure therapy, seeking safety, skills training for affect/interpersonal regulation with modified prolonged exposure, and emotion-focused trauma therapy) show evidence of safety and efficacy for adults with severe PTSD, co-occurring addictive disorders, problems with anger, dissociation, grief, and guilt, including one study with adults with chronic mental illness
Self-regulation focused cognitive behavior therapy for PTSD	Teaches emotion regulation skills for recognizing and modulating traumatic stress symptoms without requiring re-working of traumatic memories	Randomized effectiveness trials of three approaches with adults (Trauma Affect Regulation: guide for education and therapy; patient-centered therapy; skills training in affect/interpersonal regulation) show evidence of safety and efficacy for adults with severe PTSD, co-occurring addictive disorders, problems with anger, dissociation, grief, and guilt, including in individuals with comorbid serious mental illness, and incarcerated women.

Violence in the Lives of Children. A major impetus for reform of public and community psychiatry, and the mental health services systems more generally, has come from calls for reform from the public and policymakers in response to a more unavoidable crisis than the largely invisible suffering of most individuals with serious mental illness or severe emotional disturbance. This is the epidemic of violence against children in all walks of society. Most evident in the tragic and highly publicized incidents are the rash of mass shootings in schools and colleges, as epitomized by the Columbine high school and Virginia Tech university shootings. The larger issue of endemic violence against children that occurs on a daily basis was the catalyst for a commission in 2012, by the U.S. Attorney General of a Task Force on Defending Childhood Against Violence, which issued a comprehensive report detailing the epidemic scope of the problem and the need for comprehensive initiatives by law enforcement, the courts, child

protective services, family services, and mental health to protect children from violence and hasten recovery from the debilitating psychosocial effects of being victimized by violence. A preponderance of the recommendations directly or indirectly involve enhancing the funding, staffing, delivery systems, and use of evidence-based practices by public and community mental health systems and providers.

The Task Force report was released on December 12, 2012. Two days later, on December 14, 2012, a mass murder was perpetrated in which 26 children and teachers were killed in the Sandy Hook elementary school in Newtown, Connecticut.

The Sandy Hook Tragedy. The shooter was a young man who had a lengthy documented history of autism spectrum and related (e.g., obsessive compulsive disorder) psychiatric illness. A report by the Connecticut Child Advocate's Office was released on November 21, 2014 (http://www.ct.gov/oca/lib/oca/sandyhook11212014.pdf) describing in detail the decidedly mixed role played by psychiatry and mental health providers in identifying and attempting to respond to the shooter's serious emotional disturbance.

The Child Advocate's report describes how early childhood intervention services were determined to be necessary for problems with sensory hypersensitivity and expressive communication, and were provided to him as a preschooler and extended to address subsequent learning problems through Individualized Education Plans developed while he was in elementary, middle, and high school. However, neither a psychiatric admission to a hospital emergency department at age 12, nor a remarkably thorough and prescient biopsychosocial evaluation at age 13 by an academic child psychiatrist, with recommended psychiatric and psychosocial services, prompted the required level of monitoring. Instead, the boy was seen for only a handful of sessions over the next three years by an adult psychiatrist. No medications were prescribed. The boy was kept entirely out of school, despite the academic child psychiatrist's warning that what was needed was an increase in supported socialization (along with appropriate psychotropic medication and social-emotional rehabilitation services). After a year's hiatus on homebound status, the boy returned to middle school. A teacher noted that the child seemed preoccupied with violent fantasies to the point of not being able to complete writing assignments without what the teacher considered to be a disturbing intrusion of violent material. This observation apparently had never been noted when he resumed attendance at public high school the following Fall, with IEP accommodations that allowed him to attend a few classes at the school, take classes at a public university, and ultimately to graduate ahead of schedule. From the point of high school graduation there is no record of further contact by the schools or with any mental health providers, as he became increasingly isolated and embroiled in Internet communities that promoted mass violence and pedophilia.

The implication of this tragic case study for psychiatry is definitely not that psychiatrists can, or ever should be asked to, detect future mass murderers. In fact, there are studies suggesting that the ability to predict future violence, whether self-directed or toward others, is not strong. While there were numerous red flags that might seem, with hindsight, to presage the development of a violent killer, in fact there are thousands of youth who are similarly troubled, impaired, and isolated who never commit acts of violence. Instead, what the case study illustrates is the tragic deterioration that occurs when severely disturbed youth either never come to the attention of mental health providers or, perhaps even more disturbingly, are definitely identified by competent psychiatric and mental health

providers but then are lost to follow-up and never receive adequate evidence-based services.

The Child Advocate's report illuminated gaps and limitations in several interconnected public systems, including those in which public and community psychiatry should be involved. The report made a number of recommendations for enhancing public and community systems serving children and families. These include requiring that universal mental health screening be conducted and followed by timely provision of coordinated prevention, and support services by pediatric providers, schools, child welfare, and social/family services as well as mental health providers. Finally, the report concludes with three recommendations to increase the "Expertise and Services to Support Children with Developmental and Mental Health Challenges": namely, (1) to address the major issue for families—the paucity of services and supports for children and youth, particularly older youth and adults, who have Autism Spectrum Disorders with or without co-occurring mental health challenges; (2) to address the dramatic workforce development needs, increased technical support, and expertise to help mental health, pediatric, and educational providers meaningfully meet the needs of children with complex developmental or mental health disorders, and their families; and (3) to enable schools to provide, or even to import, comprehensive behavioral health or developmental supports to children, and will need significant support to ensure adequate expertise and related services for children with highly specialized needs. This latter recommendation will need to accommodate the schools' federal Special Education mandate to allow collaboration (and cost sharing) with other public agencies.

The challenges presented by the gathering currents of transformation of the health care system are especially acute for child and family mental health needs because of the complexity of responsibility among the child serving agencies. (1) The first need for public and community psychiatry is to work for an integration of effort among all the responsible parties for each individual child and family, starting with the Patient-Centered Medical Home in the primary care organization. Primary Care should be the center of collaboration since it will avoid much of the stigma of mental illness and inappropriate use of labeling; it will enable early intervention for the child and preparation of the family to meet the special needs of the child; and it will encourage the other categorical agencies to commit themselves to a "common plan of care" and draw the needed resources from across the federal funding silos supporting each agency. (2) The second need for public and community psychiatry is to work for funding mechanisms that allow compensation for seasoned clinicians to provide collateral support and consultation for front-line direct care providers who provide day-to-day care for children and their families. This will also make it possible for seasoned clinicians to participate in treatment team meetings

and to guide diagnostic discussions so that the team has a deeper understanding of clinical goals that are to be set and expectations of patient outcomes sought. Under the ACA there is an array of financing mechanisms involving bundled rates, risk-adjusted capitations, and pooled funding streams from the categorical silos that can be used to fund this kind of collateral support and consultation. (3) Finally, there is a critical need for child and adolescent psychiatrists nationally and, again, very few of them work in public and community psychiatry. Somehow the children who are most distressed, whose families are devastated by the severity of poverty, who have suffered profound trauma, and who present the most complex psychiatric symptoms are assigned to the most minimally prepared caregivers—young and untested child welfare workers, overworked probation officers, unqualified special education teachers—often without adequate supervision and with no access to the most highly trained specialists. It is the kind of neglect that leads to agony in the lives of children and their families and squanders community resources.

Table 58.1–4.
Evidence-Based Manualized Intervention for Child Psychiatric Rehabilitation

Modality	Goals and Targeted Areas	Results of Evaluation
Problem-solving skills training (PST)	Teaches children skills and supports parents in helping children with self-monitoring, prosocial goal setting, developing peer positive environments, setting limits with friends, and developing problem-solving and communication skills	Randomized, clinical trials show evidence of improved problem solving and interpersonal skills and modest reductions in oppositional and inattentive behavior
Cognitive behavior therapy	Teaches skills for recognizing and modifying thoughts and beliefs that increase or prolong distress, and strengthening thoughts and beliefs that are self-affirming and interpersonally prosocial and assertive.	Meta-analyses demonstrate efficacy in reducing children's anxiety and depressive symptoms
Parent behavior/Teacher classroom management training	Parent management training changes how parents use tangible incentives and consequences and model effective communication and to help their child change disruptive or defiant behavior and to model behavior and interact with their children	Randomized effectiveness studies with two approaches (Incredible Years; Oregon PMT) demonstrate reduced antisocial, oppositional, impulsive behavior, extending to adolescence for children with severe early antisocial problems
Brief strategic family therapy (BSFT)	A problem-focused family therapy that focuses on improving family relationships by addressing family leadership, alliances, behavioral control, and parental responsibilities; it was developed and used extensively with inner-city children and families of color	In a randomized, clinical trial with inner-city families whose children had a variety of behavior problems and varying degrees of juvenile justice involvement, BSFT was superior to usual community care services

Functional family therapy (FFT)	FFT teaches skills for problem solving and behavior management and delivers to parents and children together	Randomized and quasi-experimental studies show reduced juvenile recidivism for youths receiving FFT
Multidimensional family therapy (MDFT)	MDFT identifies family interaction patterns and restructures them to increase trust, cooperation, and emotional support among all members of the family; MDFT has evolved from a primarily clinic-based intervention to delivering services in the home and community settings to enhance youth engagement and the immediacy of services; MDFT is developing a variant for traumatized youth incorporating trauma affect regulation: Guide for education and therapy (TARGET).	Randomized clinical trials of MDFT across a variety of ethnocultural and socioeconomic subpopulations have shown that it is associated with reduced youth substance abuse and legal problems and enhanced family functioning and school involvement
Multisystemic therapy (MST)	MST involves up to 6 months of individualized, community-based contact by an M.A. or Ph.D. level therapist, supported by a 24-hour back-up team; MST addresses all relevant environments by empowering parents with the skills and resources needed to independently prevent and manage crises and maintain family rules; variants of MST are under development for sexual offending youth, youth in psychiatric crisis, and youth who have experienced childhood maltreatment	In randomized, clinical trials, MST has been shown to reduce juvenile delinquent recidivism and crime severity, psychiatric symptoms, out-of-home placements, and drug use while improving family functioning and school attendance; large-scale dissemination studies in the United States, Canada, and Scandinavia show that MST is superior to usual services on some, but not all, psychosocial outcomes
Intensive in-home child and adolescent psychiatric services (IICAPS)	IICAPS provides low-income families with children with serious emotional disorders a team led by a child psychiatrist and including psychological, social work, and educational consultation and crisis intervention in the family's home	One randomized effectiveness trial and observational studies with a system of community agencies treating psychiatrically impaired, socioeconomically disadvantaged children demonstrate reduced psychiatric morbidity
Trauma-informed affect regulation therapies for posttraumatic stress disorder (PTSD)	Dyadic therapies for young children and their primary caregivers, and group and individual therapies for adolescents, teach children and caregivers skills for affect regulation to reduce PTSD-related emotional and behavioral problems	Randomized controlled trials with young traumatized children (child–parent psychotherapy, parent–child interaction therapy) and youth (trauma affect regulation: guide for education and therapy; trauma and grief components therapy for adolescents) demonstrate improvements in parent-child relationships and child/youth emotional, behavioral, and interpersonal functioning
Multidimensional treatment foster care (MTFC)	MTFC provides training and ongoing support, parent education, family therapy, and youth mentoring to enable	Three randomized controlled trials showed that MTFC reduced adolescents' psychiatric

	foster parents to maintain a structured therapeutic environment for teaching children skills, setting limits, and modeling communication and problem-solving strategies	rehospitalization, arrests and incarceration, running away, and drug use while improving vocational and educational outcome
Cognitive–behavioral intervention for trauma in the schools (CBITS)	CBITS provides 10-session groups in school mental health or counseling settings for preadolescents or adolescents with PTSD due to family or community violence; CBITS includes education about traumatic stress, skills for anxiety management, and desensitization of trauma memories	Two randomized, controlled trials with inner-city children (one with Spanish-speaking youth) showed CBITS to be associated with reductions in PTSD and depression but not in teacher-reported behavioral or emotional problems
Trauma-focused cognitive–behavioral therapy (TF-CBT)	TF-CBT guides traumatized children and their parents in recognizing and managing PTSD symptoms and in desensitizing trauma memories	Randomized, controlled trials with sexually and physically abused children and children who experienced traumatic losses, disasters, or violence showed reductions in PTSD and depression and improvements in social functioning, but no improvement in disruptive or oppositional behavior

Roles of Psychiatrists in Public and Community Psychiatry Multidisciplinary Teams

Psychiatrists in the public sector should work within a team that includes professionals from several disciplines (e.g., psychology, social work, nursing, occupational therapy, rehabilitation or addiction counseling, social services, housing, and employment specialists) and non-degreed direct care workers (e.g., bachelor's degree–level counselors or case managers, high school graduate indigenous outreach workers, peer-support specialists, and family advocates), each of whom brings unique skills and experience to address the varied needs of people with severe and persistent mental illnesses. The team, rather than any single provider, assumes responsibility for the ongoing care of each patient across the many levels of services and often for many years. Its success is based on effective communication and coordination. Communication and coordination should be explicitly focused on the individual's (i.e., patient's and/or family's) stated goals, as well as on the community resources available and the team's technical and logistical capacities. Maximizing the individual's motivation to participate actively and productively in the comprehensive treatment plan that is patient-centered and collaborative is essential.

Psychiatrists can play four primary roles in multidisciplinary psychiatric rehabilitation teams: (1) conducting psychiatric diagnostic and treatment evaluations with significant involvement from members of the team; (2) providing thoughtful pharmacotherapy; (3) coordinating care with physical medicine in order to promote both physical and mental health; and (4)

serving as the team's medical director, mentor, sometimes clinical supervisor, peer, and colleague.

Psychiatric Evaluation and Diagnosis. The goal of evaluation and diagnosis is to develop the most clinically effective individualized approach to treatment and rehabilitation for each patient by culturally-literate clinicians. Psychiatric evaluations in public and community settings must provide for the full participation of the patient (and family where appropriate). The discussion should carefully review the individual's psychosocial strengths and resources rather than weaknesses or failures. A positive approach should be offered to help overcome systemic factors (e.g., eligibility regulations for governmentally funded services or benefits), as well as an emphasis on helping the person to overcome disability and the limits to the individual's or family's access to services or benefits (e.g., welfare-to-work regulations that place time or other eligibility restrictions on types of temporary aid, such as food stamps or vouchers for household supplies or housing). Following a comprehensive assessment, a full multiaxial psychiatric evaluation is in order.

Pharmacotherapy. The psychiatrist's most visible role usually is providing pharmacotherapy. This role will be enhanced as Personalized Medicine in psychiatry becomes operational. The most difficult challenge in public sector mental health settings often is not the technical formulation of an effective medication regimen, but, instead, the arranging of a plan of care so that the patient reliably follows the prescribed regimen (i.e., adherence or compliance). A recent review of interventions designed to enhance adherence to psychotropic medication regimens by patients with schizophrenia found that education alone often was the only strategy used, despite it being less effective than approaches that focus on "concrete problem solving," "motivational techniques," and "reminders, self-monitoring tools, cues, and reinforcements" or that provide "an array of supportive and rehabilitative community-based services." Thus, although the psychiatrist must address technical medical issues accurately to formulate diagnoses and to establish an effective psychotropic regimen, effective pharmacotherapy depends heavily on providing—directly, in encounters with patients, or indirectly, by working closely with nonpsychiatric mental health professionals and non-degreed care workers —practical assistance to patients to enable them to anticipate and to manage the psychosocial stressors or problems that can render even the most technically sound medication regimen completely ineffective as a result of nonadherence by the patient.

Pharmacotherapy must be essentially "therapy" that the prescriber and his/her clinical team administer in a coordinated way. The new funding mechanisms being developed under the ACA will make this possible and

more recognized as the reform continues.

Team Participant-Leader and Mentor. The psychiatrist is being called upon to play a special role as the project or program medical director—with the attendant responsibilities of monitoring the medical safety and well-being of all patients and establishing or supporting management and clinical procedures that support quality of care and a cohesive treatment team. As the team's clinical Mentor, or simply as a team member, the psychiatrist serves as a role model for compassionate and professional behavior in relation not only to patients, but also to all other team members. Formal or informal leadership is especially important when psychiatry residents and medical students work on a team as a training experience. The team psychiatrist serves not only as a mentor and a role model for the core aspects of psychiatric practice, but also should demonstrate the values and skills necessary to integrate psychiatry within the framework of psychosocial interventions that are multimodal, community-based, and longitudinal.

For example, psychiatric rehabilitation adapts and extends the traditional psychiatric services and roles by embedding them within the context of a set of psychosocial interventions designed not only to alleviate psychiatric symptoms, but also to promote optimal readjustment in the community: A recent review of the "requirements for multidisciplinary teamwork in psychiatric rehabilitation" summarized the challenge facing public and community psychiatrists. Psychiatrists who work with persons with severe mental illness and who wish to contribute as key members or leaders of their teams must go beyond their prescription pads to acquire knowledge, attitudes, and skills congruent with contemporary practice guidelines for psychiatric rehabilitation; give respect and support to the family and to multidisciplinary team members; gain their respect and support in return; cope with large caseloads; collaborate with agencies and programs to ensure continuity, consistency, and coordination of care; and value the roles and expertise of staff who provide case management, supported employment, skills training, and family and housing supports. If psychiatrists can incorporate these attitudes and skills, they can expect reciprocity and cohesion from other team members, and clients will benefit.

The shift from a narrow focus on treatment of a solo therapist to a broader psychiatric rehabilitation model, and now to models that stress the recovery of the individual, requires solid training (and continuing education) and hard work, as well as a combination of personal qualities, competencies, and expertise that have been summarized as "persistence, realistic optimism, a collaborative style, teaching ability, and networking and system coordination skills." Surveys of psychiatrists in the public sector indicate that those who embrace the rehabilitation perspective by

expanding their roles to be consultants and teachers for patients, families, trainees, and colleagues from other mental health disciplines are more satisfied professionally than those who focus on diagnosis and treatment alone.

New Paradigms. The paradigm shift active in the current reform calls for virtually all health care to be integrated and coordinated to deliver effective, rational, and cost-efficient care. If the focus is on the role of the individual physician and public and community psychiatrist, the new paradigm calls for practice in an organized system of care accountable for the health status of a designated population, operating through a clinical team, providing comprehensive primary care coupled with chronic illness care management, rehabilitation, or recovery models in an integrated system (Fig. 58.1–2).

This continuum requires four other components: (1) the application of new research to improve care and the application of bench-to-bedside models to translational research; (2) meaningful involvement of patients and families in a shared decision-making and patient-centered paradigm; (3) integration with primary and specialty care systems; and (4) the development of the clinical system as a system of advocacy. Training pre-professionals in such a model is one approach to introduce meaningful and sustained change to health care and its delivery. In short, it is developing the workforce of the future for psychiatry and behavioral health, especially as accountable care models populate the health care landscape.

Better Health: The Tools of Public Health Leading the Complex of Public Agencies to Coherent Health Care Delivery Supporting Population Health

Public health is not simply publicly funded health care but is rather a specific discipline and tradition. It is a complicated field that historically has been defined negatively by the dominance of personal health, that is, the health care delivery centered on individual doctor-entrepreneurs focused on the care of individual patients. Until the advent of managed care in the 1990s, US health care was an industry organized largely in terms of these individual doctors who dominated the corporate entities and associations in hospitals and insurance organizations. Each jurisdiction uniquely defined and organized its public health programs, and the particular pattern of personal health practices had substantial influence—hence the wide variation in public health programs throughout the country.

The passage of the ACA in 2010 has changed the significance of American Public Health. Despite the stunning successes of American Medicine, the series of critical reports by the Institute of Medicine and the process of crafting and passing the Act itself, which aims at universal coverage, opened up all the issues of the Public Health movement. As a discipline and tradition, public health's mission is to assure the conditions

in which people can be healthy. Public health consists of organized community efforts aimed at the prevention of disease and the promotion of health. It involves many disciplines, but rests on the scientific core of epidemiology. It provides as well an essential template for contemporary public and community psychiatry.

FIGURE 58.1–2. A model clinical and training system. An academic community health system for quality practice integrating public health, acute care, and rehabilitation and recovery models with science and advocacy.

Mental illness and substance use problems certainly are public health concerns. Mental illness affects the lives of as many as one in four individuals across all walks of life, with as many as 6 percent of all adults (i.e., more than 10 million adults in the United States alone) experiencing mental illness that is so severe and persistent as to constitute a major impairment to their ability to live and to work safely, independently, happily, and productively. Mental illness and substance abuse constitute an enormous financial burden on communities and states, as well as on the federal government. As community mental health efforts developed in the last 50 years, mental health professionals increasingly assumed the responsibilities called for by the Institute of Medicine's Committee for the Study of the Future of Public Health. This included fostering the development of competency in people, promoting effective leadership, ensuring a scientifically sound knowledge base, providing tools to monitor health problems and measure progress, operating within a productive organizational structure, having adequate financial resources, and having a solid legal foundation that supports effective action, all motivated by a vision of the public's health that is understood and supported by that public.

The 2000 Surgeon General's report on mental health underscored the necessity of a public health approach to care and rehabilitation for people

experiencing mental illness that is "broader in focus than medical models that concentrate on diagnosis and treatment." Although diagnosis and treatment are core areas of expertise for all psychiatrists, the Surgeon General recommended that—even when psychiatric diagnosis or treatment is the primary focus for practitioners, researchers, or educators—they should ground their professional activities in a vision and knowledge base that is "population-based ... encompass[ing] a focus on epidemiologic surveillance, health promotion, disease prevention, and access to services." These fundamental public health functions define the public health perspective in public and community psychiatry. In the discussion that follows, these four public health components are framed in current terms of health care reform to define a coherent "public health" strategy for public and community psychiatry.

Epidemiology. Based on epidemiological studies of nationally or regionally representative samples of adults and children in countries around the world, more than one half of the population experiences a mental illness involving at least one distinct psychiatric disorder in their lifetime, often as many as three or four comorbid disorders. It is important for psychiatrists to be prepared to identify not just the most obvious psychiatric disorder, but also other potential comorbid disorders, and to recognize the potential effects of culture, community structure and environment, and socioeconomic status on the ways in which people describe and understand mental illness and their expectations for care.

An immediate implication of population-based epidemiological studies is the need for timely identification of people with or at high risk for psychiatric disorders. When systematic diagnostic research studies are done in the most accessible arena for risk factor surveillance—primary and specialty medical care settings, schools, and child and family services programs—the findings consistently demonstrate that most psychiatric disorders are underdiagnosed (by 25 to 75 percent). Subthreshold psychiatric disorders (i.e., significant symptoms and impairment but not sufficient to meet full diagnostic criteria) are even less well identified, although they are potentially more responsive to treatment and often associated with substantial psychosocial impairment. Despite the existence of strong evidence from prospective risk factor studies, as noted earlier, surveillance of the principal risk factors for psychiatric disorders (e.g., family history, life stressors, and prodromal signs and symptoms) is not systematically done by most psychiatrists or by the public mental health treatment system in most states and local communities.

A potentially related problem that has been revealed by psychiatric epidemiology is that at most half of all people with psychiatric or substance use disorders receive treatment for these problems. Results of studies of representative community populations from the United States, Canada,

and the Netherlands consistently reveal that about 7 percent (or 1 in 14 persons) believe that they need mental health treatment but have not received such treatment. For low-income families served by public and community psychiatrists, inability to pay for the costs of treatment was a more significant barrier to getting help in the United States than in countries like Canada and the Netherlands where public mental health services are more universally available (see Reforming Health Care, Chapter 58.2).

Further analyses of data from an epidemiological sample from the United States (surveyed in the early 1990s) and a replication sample surveyed 10 years later in the early 21st century determined that persons with demographic and economic advantages that arguably increased their ability to access health care (e.g., older age, mainstream ethnicity, employment, insurance) and who had a perceived need for help were most likely to get treatment for psychiatric problems. However, the providers of services in the more recent survey were more likely to be nonpsychiatric medical practitioners and less likely to be psychiatrists or other mental health or human services professionals than 10 years earlier. Those persons fortunate enough to receive services for serious mental health problems tend to receive a lesser amount of poorer quality of services than research suggests is necessary to achieve meaningful improvement in the generally severe impairment and disability they are experiencing. Thus, the economically disadvantaged and often socially stigmatized segment of the population that is served by public and community psychiatry consistently is the least likely subpopulation to get this help. These sub-populations increasingly have had to turn to nonpsychiatric providers for the limited mental health treatment that is available, and only a fraction of these sub-populations get any treatment at all. These epidemiology research findings highlight a crucial dilemma facing psychiatric practitioners and systems of care: getting adequate help to people with severe psychiatric problems, particularly to the most disadvantaged families and communities where such help is especially scarce and inaccessible. In some communities, some established psychiatrists will not see individuals having low-paying insurance or will only see people who can afford to pay cash, refusing those with insurance coverage altogether. The implications and ramifications on society and the credibility of the profession of such practices are hopefully apparent in this time of health reform.

A strategic implication for a public health approach to psychiatry is that primary care medicine and, schools and child and family services agencies are the frontline for epidemiological surveillance not only of the incidence and prevalence of psychiatric morbidity per se, but also of the mental health professionals' ability to identify and get psychiatric services to the persons and communities most in need.

Health Promotion

Generally, psychiatry in the last half of the 20th century has been quietly on the sidelines, absorbed in private practice, caring for a segment of society that could appreciate its highly refined approaches to dealing with life's problems. Academic psychiatry, in the meantime, made strides laying the foundations of a science of the brain; and a small cohort of psychiatrists led and mentored the structural changes of the public mental health systems, closing the state hospitals and building community care systems. American health care is now in the midst of a reform driven largely by the visions of public health. The public promotion of community health is an integral part of this; and it is intriguing that the role of public and community psychiatry is to promote mental health care by participating in a series of models of treatment and community engagement.

Psychiatric professionals can contribute substantially to the promotion of public health by working with primary health care professionals and educators to identify and provide front-line treatment and referrals for adults and children who have undetected psychiatric symptoms, subthreshold syndromes, and psychiatric disorders. Collaborative care models bring psychiatric professionals into primary care and school settings as consultants for medical, nursing, and education professionals who work in those settings, as well as for social service, educators and direct treatment providers.

Furthermore, the organization of various forms of intensive outpatient care can benefit people with chronic health conditions, and behavioral health disorders. Achieving recovery and regaining physical or mental health often depends on a person's or family's access to social and psychological resources and integration into supportive social networks. Illness Management (also known as disease management or chronic illness care management) is a framework that has been adapted from medicine to guide mental health professionals in delivering services that go beyond traditional diagnostic treatment to promote the health and recovery of people with mental illness or addiction. A number of approaches to illness management have been scientifically and clinically evaluated and have been found to enhance standard psychiatric treatment.

Patients and families understandably want to feel that treatment is consistent with their personal and cultural beliefs and practices, and that it will improve their lives in ways that matter to them. In a word, the key to actualizing the potential benefits of psychoeducation and psychosocial skills is motivation. If the patient and family view the treatment as enabling them to achieve their specific personal goals, they are most likely to actively participate in, utilize, and adhere to the treatment. There are several evidence-based approaches to communicating with patients and families that enable psychiatrists and other mental and behavioral health providers

to maximize the patient's and family's motivation and adherence in treatment. These include motivational enhancement therapy (also known as motivational interviewing), acceptance and commitment therapy (also known as mindfulness-based cognitive therapy), client-centered therapy (also known as Rogerian therapy), working alliance interventions (also known as the therapeutic relationship), solution-focused therapy, and relapse prevention.

Providing patients and families with education about mental illness and the process of treatment and recovery has been shown to increase their knowledge and potentially to enhance adherence to treatment. An effective approach to promoting adherence to medication treatment is called behavioral tailoring—the careful design of practical reminders, routines, and positive incentives that adapt medication regimens to the preferences, lifestyle, and limitations of each individual patient.

Teaching patients skills for recognizing and coping with stressors, symptoms, or potential relapses of remitted symptoms in a timely and effective manner has been shown to reduce the severity of psychotic, anxiety, mood, or addictive symptoms and to prevent re-hospitalization or the resumption of potentially harmful (e.g., suicide or substance use) behaviors.

For lower-functioning patients, encouraging active, pleasurable social activities or, directly setting up structured opportunities (e.g., social activities) or milieus (e.g., social clubs or partial hospital programs) that foster safe and rewarding social interaction and membership in an ongoing social support system has been found to reduce symptoms of affective, anxiety, addictive, and psychotic disorders, as well as to enhance participants' overall social adjustment, self-esteem, and quality of life.

Illness management thus offers an added set of tools to the psychiatrist's toolkit that promote the health and well-being of patients and do not replace, but rather complement, the more traditional approaches to psychiatric diagnosis and treatment.

The illness management model of health promotion provides psychiatry with a critical role in the integrated delivery system. An illness management strategy promotes mental health while it engages patients as active collaborators in their care and enables them to enhance their health and well-being, as well as to recover from mental illness.

Another approach to health promotion for persons with mental illness or addictive disorders is supported by the Substance Abuse and Mental Health Services Administration's (SAMHSA) Center for Mental Health Services uses services led by persons in recovery (and in the case of children, by their families). Peer- or parent-led and -designed psychiatric services involve consumers ("persons with lived experience") and family members in collaborative efforts with psychiatric professionals to design, deliver, and evaluate educational, support, care coordination, and

counseling services.

Prevention. Prevention is a natural impulse for the Public Health model. A disease or debilitating condition that can be avoided through early intervention and timely treatment can save a neighborhood or community and secure the overall health of the population. The reform that is moving physicians forward reinforces the power of prevention. Health plans who will participate are asked to assume risk for carefully designed benefit packages for their enrollees and they manage this by contracting with networks of providers and health care systems to whom they contractually cascade that risk. The major public payers, Medicare and Medicaid, are creating funding mechanisms that create the same kind of accountability for the most medically vulnerable patients. Smart public and community psychiatry will position itself in accountable clinical entities that are actively engaged in early intervention and intensive, individualized care management.

Application of the traditional public health concepts of primary, secondary, and tertiary prevention has been confusing in psychiatry. Primary prevention involves addressing the root causes of illness with healthy individuals, with a goal of preventing illness before it occurs. Secondary prevention involves the early identification and early treatment of individuals with acute or subclinical disorders or high-risk persons to reduce morbidity. Tertiary prevention attempts to reduce the effects of a disorder on an individual through rehabilitation and chronic illness care management.

The Institute of Medicine, in an effort to clarify different aspects of prevention, developed a classification system with three different categories. Universal interventions are those intended for the general public, such as immunizations or media campaigns providing information about illnesses, early warning signs, and resources for health promotion and timely treatment. Selective interventions focus on individuals at higher-than-average risk (e.g., persons with prodromal symptoms or a family history of psychiatric disorders) to reduce morbidity by enhancing resilience and preventing the onset of illness. Indicated interventions target individuals who are experiencing impairment as a result of illness as early as possible in the course of the illness, to reduce the burden of the illness on the individual, family, community, and treatment system.

Psychiatric disorders most often follow a course over time that begin with an often lengthy period in which prodromal or sub-threshold symptoms or functional problems precede the full onset of an impairing disorder. Psychiatry integrated into primary care is in a position to identify these early symptoms and intervene effectively. In primary care, surveillance for very early universal intervention is possible, and selective interventions can be easily made as symptoms are recognized. Intensive

psychiatric services can be organized in the form of indicated interventions when disabling symptoms appear to establish a path to recovery.

A public health–oriented strategy for disease and disability prevention will involve early identification and intervention in cooperation with consumers, families, health care professionals, and educators. Psychiatric professionals can play a key role by bringing their expertise to the development of appropriate screening, assessment, education, and treatment strategies that, if implemented on a wide scale, may reduce the burden of mental health disability and facilitate recovery. Psychiatrists also can become involved in the social marketing of prevention services and programs to add expertise and credibility to support legislation, regulations, and commercial investment that will provide the economic base necessary for broad-based prevention programs.

Prevention interventions have been found to be effective with adults with a variety of risk factors or preclinical problems. For example, women who have been raped are less likely to develop PTSD if they receive a five-session cognitive–behavioral treatment than if their recovery is left to chance. Men and women identified with sub-threshold symptoms of depression in primary care settings are more likely to remain free from the full syndrome of depression or, if they do become clinically depressed, they will be able to recover rapidly with treatment if their standard medical treatment is enhanced by education about depression and learning skills for coping actively with depressive symptoms or stressors. This includes women who are at risk for postpartum depression, who have been shown to benefit from in-home cognitive behavior therapy in the first year after giving birth. Children who show early signs of severe behavioral problems (e.g., aggression, impulsivity, stealing) have been found to be less likely to become severely and chronically behaviorally impaired and antisocial when they and their caregiver(s) participate in therapeutic programs designed to enable the child and caregiver to deploy executive functions (i.e., anticipating consequences, inhibiting reactive behaviors, problem solving) while simultaneously strengthening their attachment bond with each other.

The Medicaid program includes a mandated program for Early Periodic Screening Diagnosis and Treatment (EPSDT) that broadly covers very early intervention and extends services through the twenty-first year. States have been slow to meaningfully implement the periodic screenings and full use of the program because of the potential financial liability of the program to the states. Consent decrees have in some cases been used to expand these services for children with severe emotional disturbances. EPSDT could provide a complete framework for the early identification of young children with psychiatric risk factors, and would support the effective targeting of comprehensive mental health and parenting services in the primary care setting of the family's "medical home."

Access to Effective Mental Health Care. As noted in the Preface to the Surgeon General's 2000 report, "even more than other areas of health and medicine, the mental health field is plagued by disparities in the availability of and access to its services." First, it is important to acknowledge that access to behavioral health services confronts a full array of what might be called demographic barriers—race (i.e., people of color), age (i.e., children and older adults), gender (i.e., female), sexual preference (i.e., homosexual), language (i.e., monolingual, non-English speaking or English as a second language), national background (i.e., self or family from nations in Central or South America, Africa, or Asia), education (i.e., less than college), and financial status (i.e., low income). These barriers apply not only to mental health care, but also to health care and health insurance of any kind, even to health insurance that specifically covers psychiatric disorders. People whose primary access to mental health or addiction recovery services come through publicly funded programs or agencies tend to have some, if not many, of these characteristics. Public sector mental health providers tend to provide services to people of varied backgrounds but primarily to people who have been marginalized due to these characteristics.

There apparently is not a consensus on how to measure disparities and, there are different definitions employed. The Institute of Medicine (IOM) defines a disparity as a difference in health care quality not due to differences in health care needs or preferences of the patient. It is known that ethnic and racial minorities, when compared to whites, have less access to mental health services, are less likely to receive the care needed, and more often receive care that is of poorer quality. But the patterns of disparities are complex. Even though ethnic minorities in the United States have higher rates of poverty and poor health than Caucasians, all of the minority subgroups (with the exception of Puerto Rican Americans) have lower rates of lifetime behavioral health disorders than white Americans. While overall rates of treatment for psychiatric disorders increased between 1990 and 2003, African Americans were only 50 percent as likely as whites to receive treatment. Nonetheless, there is evidence that African Americans are over-diagnosed with schizophrenia and underdiagnosed with mood disorders which strongly calls into question the field's diagnostic acumen and practice as noted earlier in this chapter. It is hard to ignore the likelihood that Caucasians have easier access to mental health services.

There are also barriers to access that are more structural, such as a shortage of trained mental health professionals. For most people with severe mental illness or addictions access is a serious problem. In The United States, the National Comorbidity Study (NCS) and the National Comorbidity Study-Replication (NCS-R) found that fewer than 40 percent of people with severe psychiatric disorders had received any mental health

treatment in the last year, and fewer than one in six (15 percent) had received minimally adequate mental health services. Young adults, African Americans, people residing in certain geographical areas, people with psychotic disorders, and patients treated by medical but not mental health providers were at highest risk for inadequate psychiatric treatment. Although income was not a predictor of inadequate treatment, it is likely that many of the people who did not receive adequate mental health services were uninsured or had insufficient insurance coverage for mental health conditions. They had no viable source of mental health care other than through a medical provider or clinic or in the public mental health system. A recent study with the NCS and NCS-R epidemiological databases found that persons of minority ethnic-racial backgrounds and those who were not employed or did not have health insurance were least likely to gain access to mental health services from medical, psychological, social work, and counseling professionals. However, race and socioeconomic resources were unrelated to the amount of mental health treatment received by persons who were able to gain access to these services.

Numerous studies have determined that a large number of individuals having mental and behavioral health problems are in jails or prisons. The Treatment Advocacy Center estimates that approximately 350,000 of the combined 2.1 million individuals in prisons and both county or city jails in the 2011–2012 time period were seriously mentally ill. With state hospital beds dropping from a high of about 560,000 in 1955 to 35,000 today, this means that there are ten times as many individuals with serious mental health problems incarcerated in the criminal justice system than in state mental hospitals.

Even when mental illness is identified, people with socioeconomic adversities often do not, or cannot, get adequate mental health services in their communities. For example, although it is estimated that more than a quarter of a million incarcerated adults in the United States have psychiatric disorders, few were detected or received treatment until they reached jail or prison. Federal and state correctional systems have instituted mental health screening and treatment programs to address psychiatric disorders as a health problem for incarcerated adults and to manage the problematic behavior that can occur in controlled settings as a result of mental illness. On returning to the community, the vast majority of prisoners with psychiatric disorders cease to receive more than minimal mental health services: A recent study found that fewer than one in six (16 percent—strikingly similar to the National Comorbidity Study finding) received steady mental health services, and only 1 in 20 with addictions received steady substance abuse recovery services. Thus, access to mental health and addiction treatment services is far better in prison than in the community! This has caused great concern because of the possibility that correctional facilities may be a de facto system of care for low-income

people (often of minority backgrounds) with serious mental illness.

Evidence of serious and pervasive barriers to accessing mental health care can be found in several kinds of crisis situation. Children and adults in poverty increasingly are deferring physical and mental health care until illnesses become chronic and severe and then find it difficult to gain entry into any setting for services except public hospital emergency departments. Children with severe psychiatric or behavioral disorders are often held in emergency department facilities for days and even weeks because the staff cannot locate any treatment facilities with an appropriate level of care that have an opening, or are willing to take the child as a patient (or to accept the child or family's insurance coverage or lack thereof). People who must rely on the public sector services thus face daunting obstacles when seeking appropriate mental health care because of the serious underfunding of practitioners and programs. The economic forces and public policy dilemmas that drive the ever-increasing cost of health care bear directly on public sector psychiatry, as well as on the lives of tens or hundreds of thousands of people who do not receive adequate care.

Access to appropriate behavioral health services is a bramble bush of factors from the demographic barriers that defined diversity to the structural barriers that keep physicians from responding fully to patient needs. The challenge for public and community psychiatry is to take advantage of the opportunities offered by the ACA to level the barriers to access for everyone in need of care. The primary obstacles to access are social disparity, socioeconomic adversity, and the fragmentation of the health and social service systems. Social disparity and socioeconomic adversity will diminish as the reform approaches close-to-universal health care coverage. It is estimated that by 2016 some 24 million Americans will have been enrolled in health plans that provide an appropriate benefit package. The fragmentation of the health and social services systems will be addressed by developments in three areas. First, the consensus model of the Patient-Centered Medical Home will ensure an appropriate expansion of primary care capacity organized so as to integrate ready access to specialty care, including psychiatry under the Medical Home's umbrella. Until recently Primary Care has not been functionally available to patients with severe and persistent mental illness; the increasing integration of psychiatry into primary care will allow for early intervention without stigma and appropriate treatment interventions to avoid more severe problems. Second, the development of new payment mechanisms led by the CMS's Center for Innovation will provide "accountable clinical entities" the flexibility to provide individualized care through risk adjusted rates appropriate for the needs of defined populations. This will support the development of chronic illness care programing including primary care-based programs for persons with serious and persistent mental illness. Third, value-based standards of care based on the efforts of AHRQ and

PCORI to support evidence-based research and to catalogue the most effective clinical practices and programs, will lead to "learning health care systems" for continuous improvement of care as well as lay the foundations for pay-for-performance mechanisms.

These measures, which are being actively pursued in the reform effort, will lead to a transformation of the health and social service systems to create a continuum of care capacity to meet the needs of every stage of mental illness, as well as realize the possibilities of public and community psychiatry.

Psychiatry and Public Agencies

Psychiatry's relationship to public sector agencies has, with some specific exceptions, been one of detachment because of the dominance of the private practice models before the advent of managed care and also largely because of the nature and structure of US social welfare programs. This is a divide that often began during residencies, in that historically many psychiatry training programs eschewed meaningful rotations in public sector settings. In contrast to most industrialized nations in which comprehensive social welfare reforms were integrated, US social welfare programs grew incrementally and categorically, that is, one category of service at a time. Large-scale initiatives, such as President Johnson's War on Poverty, have been implemented in piecemeal fashion by fragmented federal, state, and local government bureaucracies. Various social service agencies have been created through a process and set of alliances that has been called the iron triangle. Advocates form an organization to champion a particular cause, such as blindness, developmental disabilities, primary care, or mental health, among others. They find key legislative sponsors who advance the cause through legislation and appropriation. This creates a bureaucracy and then bureaucrats who join the alliance. Through successive legislative sessions, the alliance of advocates, lawmakers, and bureaucrats builds a stronger categorical agency; for example, adults and families with dependent children or people with biologically based, severe mental illness. From the 1930s, through the end of the 20th century, US social welfare agencies were created on this pattern: The system has resulted in generous funding and hopeless fragmentation of effort at local service delivery levels in which each agency depends on separate funding silos that also deliver conflicting rules and regulations.

It has been said that "mental health is not a place." Psychiatrists have a role at the receiving end of every categorical silo because the clients of each categorical agency experience mental illness or various addictions. Services for children with severe emotional, mental, or behavioral disturbances are a dramatic case of the importance of psychiatrists taking a leadership role in promoting comprehensive rather than fragmented services. Five categorical agencies—child welfare, education, primary health, substance

abuse, and juvenile justice—all have a responsibility to care for these children. Especially for the children with the most severe disabilities, protective services, special education, the juvenile probation officer, and the child's pediatrician all need the consultation and support of a skilled psychiatrist. The situation is similar for adults with severe mental illness, for whom case managers, vocational rehabilitation counselors, basic needs benefits specialists, social workers, psychotherapists, substance abuse counselors, parole or probation officers, legal conservators, visiting nurses, peer specialists, and physicians all may be mandated to deliver services. The need for psychiatric leadership is equally important for those who care for persons with mental retardation or developmental disabilities, for the elderly, for persons in vocational rehabilitation programs, and for persons in correctional programs. Virtually all public resources come through this complex of categorical agencies.

FIGURE 58.1–3. Conceptual map for initiatives and concepts for public and community psychiatry.

Figure 58.1–3 provides a conceptual map of this very complex governmental and social structure in which categorical government programs cascade through the levels of US federal, state and community systems. Health policy is formulated between government and employer purchasers and expressed unevenly through public health functions in communities, consumers, and advocates. Academic psychiatry bears responsibility for research, training, education and workforce development for a behavioral health system that is only loosely integrated into the health care system. The ACA has laid the groundwork for clarifying the accountability of all parties and establishing the validity and efficacy of

health care activities.

It will be impossible to achieve the ideals of the public health perspective on public and community psychiatry unless ways are deliberately devised to engage committed and proficient psychiatrists in meaningful roles in the operations of these agencies. Again, the factors at play in health care reform provide an opportunity to integrate the efforts of the complex and fragmented array of health and social service agencies by emphasis on the primacy of the clinical process (maintained within the PCMH), the revision of funding mechanisms to encourage clinical sponsorship by accountable clinical entities, and emphasis upon the implementation of evidence-based practice standards.

Workforce Challenges. The Health Care reform that is underway will make significant demands on the public and community psychiatry workforce. It has been noted that the National Comorbidity Survey reports that less than 40% of those with severe psychiatric disorders have had an encounter with a psychiatrist in the last year; that one in six (15%) have received minimally adequate care; that one in 20 persons with substance use disorders have received care. Meanwhile, the Bureau of Labor Statistics reports (2013) that, of the 36,000 psychiatrists, about 28% are self-employed in solo practices; 53% are working in private sector hospitals, group practices, or outpatient clinics; about 6% are in academic settings; and around 10% work in public and community psychiatry. The geographical distribution of psychiatrists is about 50% along the Atlantic seaboard, with concentrations in Texas and California as well as Illinois and Missouri. Access for persons with severe and persistent mental illness is already at crisis proportions and, as universal coverage is approached, it will become more critical. There is a recognized imbalance of the specialty care workforce over primary care and new medical schools are opening to meet the primary care need. If ACA-driven coverage for 24 million new patients are enrolled by 2016 as projected, many of them will come from the ranks of the most neglected and most severely disabled mentally ill. This imbalance will be even more critical.

The reform impulse that has been codified in the ACA contains many implications for the preparation of new generations of public and community psychiatrists and the adaption and retraining of the current workforce. The regime of quality, effectiveness, safety, and integration of effort represented by models like the Patient-Centered Medical Home will align psychiatry closely with primary care and its multidisciplinary teams. Constant reference to the evidence base of clinical interventions will enhance the value of accurate diagnostic assessment and the application of clinical treatment and the use of effective programmatic models. And the needs of newly covered patients with serious and persistent mental illness will demand the attention and skills of psychiatrists who can guide them to

recovery.

There are promising developments that will support the changes ahead. The Decade of the Brain sponsored by the NIMH in the 1990s, contributed to this change. Medical students are increasingly stimulated to enter the field by recognizing the importance of psychiatry to health care in general. They realize that this is still a field in which the practitioner (and by extension the interdisciplinary team) is an instrument of change through integration of contemporary knowledge, skillful learned interactions with patients, and a willingness to commit to providing value in quality care.

The Annapolis Coalition on the Behavioral Health Workforce has devoted years to the study of the workforce and to advocacy for needed change. Responding to the New Freedom Commission's call for a national blueprint for workforce development, SAMHSA commissioned the Annapolis Coalition to produce a national action plan for change. That report, published in 2007, identifies seven strategies for change, grouped in three broad domains. Achieving these seven goals would substantively affect the future quality of care: (1) Broadening the concept of the workforce by engaging individuals in recovery and their families when appropriate and (2) by expanding the capacities of communities to identify their needs and to promote behavioral health and wellness; (3) Strengthening the workforce by implementing systematic recruitment and retention strategies, (4) by making training and education relevant, effective, and accessible, and (5) by actively fostering leadership; (6) Implementing structures to support the workforce by enhancing its capacity and workforce development efforts and (7) by implementing a national research and evaluation agenda for behavioral workforce development.

Finally, the Institute of Medicine has issued a report calling for the Reform of Financing and Governance of Graduate Medical Education (2014) which has been for decades funded by Medicare in the residency programs of Academic Medical Centers and in Teaching Hospitals. The Report calls for a ten-year transition period in which the residency programs will be phased out while transformative and innovative residency formats are created in primary care settings as well as interdisciplinary organizations providing intensive care programs for persons with severe disabilities and multiple chronic illness conditions.

Lower Costs: Accountability for Quality, Safety, Efficiency, Effectiveness, and Evidence-Based Care

The goal of achieving lower costs for American health care is recognized as the critical priority of the nation's economic and civil wellbeing. It also presents very difficult challenges for this thriving sector of the American economy. The introduction of market forces by the ACA's health exchanges has yet to be fully demonstrated. But the ACA legislation itself introduces

strong tools to encourage cost control by exercising accountability on the part of individual providers and their health care organizations, for meeting standards for the quality of care (its safety, efficiency, effectiveness), and its recognition of care as being evidence-based. The enhancement of primary care is of critical importance and NCQA has crafted standards for a Patient-Centered Medical Home supported by all the related major medical disciplines. Effective treatment models are being recognized and catalogued by the Administration for Healthcare Research and Quality (AHRQ) and the Patient-Centered Outcomes Research Institute (PCORI). A host of innovative payment mechanisms (e.g., bundled rates) have been launched by the Center for Medicare & Medicaid Innovation (CMMI). Integrated Service Delivery Systems in the form of Integrated Care Organizations (ICOs) are being demonstrated in several states providing risk-adjusted global rates for dual eligible (Medicare/Medicaid) patients with profound disabilities—forty percent of whom are persons with serious and persistent mental illness. Specialized delivery systems models such as Accountable Care Organizations (ACOs) are being demonstrated for targeted populations through the CMS Innovation Center. All of these movements for the exercise of accountability will have an impact and will reshape public and community psychiatry.

The Health Care Marketplace. The most explicit cost control feature of the ACA is clearly the introduction of market forces through the development of the Health Care Exchanges on the part of states or on the part of the federal government on behalf of the states. While the health plans have brought competitive rates to the Exchanges in many instances, it cannot yet be determined the degree to which this will be effective in lowering costs. Many have observed that traditional health insurance organizations may evolve in the coming years into new business models. Health Care insurance, as it is currently known, may not survive. But the creation of a health care marketplace is not the only means for cost control that is presented in the ACA and the health policy ferment that accompanied its passage. First, there is a clear emphasis on the development of accountable clinical entities able to direct the care of patients; second, there is a renewed emphasis on limiting coverage to effective evidence-based care; and third, there is recognition that redesigned financing methods will enhance the quality of care and lower its cost.

Accountable Clinical Entities. As the implementation of the ACA is unfolding, it is clear that there is a growing appreciation of the role of "accountable clinical entities" in transitioning American health care delivery systems from their chronic fragmentation of functions and resources to coordination and integration of effort. By accountable clinical

entities, the authors mean health care systems that support interdisciplinary teams that sustain an individualized, ongoing clinical process for each patient (and family) and control the allocation of resources for the benefit of the patient's health. The statute itself identifies the need to improve and expand the provision of coherent Primary Care services as well as the need to provide more intensive chronic illness care delivery systems; employer purchasers have supported the concept of organized systems of care for over two decades; and the Institute of Medicine's reports on health care quality have repeatedly called for reform of the organizational structures of the health care delivery system.

In 2007, four prominent medical organizations endorsed Joint Principles of the Patient-Centered Medical Home (PCMH): the American Academy of Family Physicians, the American College of Physicians, the American Academy of Pediatrics, and the American Osteopathic Association. The PCMH elaborated the basic concept of a "Medical Home" for children with complex illness or disability proposed by the American Academy of Pediatrics in 1967, to apply to the basic need for expansion of Primary Care. The National Committee for Quality Assurance (NCQA), with the support of employer purchasers, as well as these medical organizations, developed standards for certification of clinical entities as Patient-Centered Medical Homes. Public and private payers have provided monetary incentives for organizations that gained certification. Between 2008 and 2014, over 8,300 practices were certified as PCMHs.

The Center for Medicare/Medicaid Services (CMS) has moved deliberately to support the enhancement of accountable clinical entities. Its Innovation Center, influenced by demonstration projects under the Medicare Modernization Act (2003), has developed a series of "Accountable Care Organization" (ACO) grants that encourage health care delivery systems to assume responsibility for specific high need populations, providing some form of bundled rates risk-adjusted to meet their patients' specific needs. These projects are budget neutral, but any savings are shared between the providing organization and the federal program. From 2010 to 2014, over 400 ACOs have been developed. CMS's Medicare/Medicaid Coordination Office has developed Integrated Care Organizations (ICOs) in a dozen states aimed at populations that are dual eligible, that is, eligible for both Medicare and Medicaid. These programs combine the Medicare and Medicaid dollars (and expenditures from other service silos) to provide a global capitation that is risk adjusted to the needs of the different populations. The dual eligible populations account for the highest health care expenditures. They are either elderly or disabled and they are poor. They suffer the most from the fragmentation of the health care delivery system. As noted, about 40% of them are persons with serious and persistent mental illness.

Health care delivery organizations that function as accountable clinical

entities and assume responsibility for managing, over the long term, the comprehensive care of specific populations will save money and lower costs. Fragmentation of health care services is expensive and these organizations will coordinate care whether it manages a properly enhanced Primary Care operation or an intensive program serving persons with multiple chronic conditions in home and community settings. Accountable clinical entities will be intent on early preventive intervention; they will control and advance effective care; they will be focused on the quality of care and its safety. They will maximize the value of each health care intervention and control costs.

Evidence-Based Care. It is fairly obvious that there can be lower costs if the health care system does "things that work" and avoids practices that have uncertain effect. The dramatic progress of medicine in the last century has been based on a methodical clinical process that constantly measures the effect of every intervention and constantly examines the accuracy of the diagnosis of the health problem. But one of the great stimuluses' to the movement for health care reform was the analysis of utilization in the national Medicare billing data by John Wennberg and his associates. They found surprising variation in practice in communities throughout the country and were able to distinguish interventions that were "preference-sensitive" (for patients and their practitioners) and "supply-sensitive" in that given equipment or training were readily available—and that these far outweighed interventions that were demonstrated as "effective."

Two agencies have emerged in the quest for evidence-based care. Within the U.S. Department of Health and Human Services, the Agency for Healthcare Research and Quality's (AHRQ) has a mission "to produce evidence to make health care safer, higher quality, more accessible, equitable, and affordable," as well as "to work and with other partners to make sure that the evidence is understood and used."

The second agency, the Patient-Centered Outcomes Research Institute (PCORI), a nonprofit nongovernmental organization, was established by the ACA to lead a national effort to develop patient-centered outcomes research (PCOR). With more than $100 million in annual federal funding, PCORI conducts peer review and funds more than 150 clinical research investigations developing and testing innovative approaches to patient-centered health care and its outcomes. As described on the PCORI website (www.PCORI.org), this involves funding clinical effectiveness research with the particular mission to help "people make informed healthcare decisions, and improves healthcare delivery and outcomes, by producing and promoting high-integrity, evidence-based information that comes from research guided by patients, caregivers, and the broader healthcare community."

Psychiatry is prominently represented in the portfolio of more than 350

investigations funded (with a total cost of more than $600 million) by PCORI since its inception in 2010. Studies of patient-centered and community-guided approaches to public sector treatment of depression with low-income women, rural Native American community members, and inner city Latino and African-American adults are three of the 20 research in action projects highlighted by PCORI. Other PCORI-funded mental health treatment studies address serious mental illnesses in adults and children (e.g., autism spectrum disorders), behavioral disorders (e.g., ADHD), substance use disorders, and PTSD.

The work of both of these agencies will create an ongoing framework to determine "what works" in health care. The best evidence for effective care will be systematically catalogued; standards of care will be refined; and ways will be found to improve care while lowering its cost.

Financing Methods. The primary method of payment that has dominated American health care has been the Fee for Service (FFS) system. Activities and procedures that are performed based on a patient's diagnosis are billed and reimbursed by the insurance-payer based on the terms of the insurance contract. This system encourages volume over quality; it is easily gamed; payment rates are constantly in dispute; there is no way to assure expected performance; it reduces medical care into a kind of piece-work.

As noted, CMS has addressed the question of financing or payment methods in the context of the demonstrations launched through its Innovation Center. The models of ACOs include different payment models including bundled capitation rates, risk adjusted to meet the needs of proposed populations. These have demonstrated savings that are shared between the government and the provider organization. CMS's program for the dual eligible populations developed as ICOs by its Medicare/Medicaid Coordination Office provides a kind of capitation determined as a "financial alignment" of the two programs. It is not clear that the service expenditures contracted by other categorical agencies such as a state Mental Health Department, and included in the state's Title XIX claim, are part of this financial alignment.

Other similar initiatives for payment reform include the Medicare shared savings models developed under the Prescription Drug, Improvement, and Modernization Act (MMA) of 2003; the Innovation Center's Multipayer advanced Primary Care Program; the Primary Care Initiative and many other experiments. Each of these program experiments are designed to limit unnecessary costs, to encourage integration of effort across various sectors of health care delivery, to enhance efficiency, effectiveness, and quality of care, and to maximize value and reward performance.

Public and Community Psychiatry in the Mainstream of American

Medicine. Finally, it is important to survey where and how Public and Community Psychiatry will participate in the changes that are afoot for American health care. The state hospitals were the first publicly funded health care, but they were separated in a strange way from the rest of health care as American medicine found its scientific legs in the reforms sparked by the Flexner Report in 1910. The strides that were made by medicine and science in the early 20th century were not possible for psychiatry because the tools were not yet available for a science of the brain. Psychiatry remained in the state hospitals with patients supported with public funds and the separation between psychiatry and the rest of medicine widened. By the end of the century this had changed dramatically and psychiatry is building on a flourishing base of science. The change was advanced in the middle of the century when biological psychiatry and the new medications began to be used and understood. But the hospitals were still operating and the strange separation of psychiatry from the rest of medicine persisted. The former Commissioner of Mental Health in Massachusetts and Director of the NIMH's Joint Commission on Mental Health and Illness (1961), Jack Ewalt, MD who had played a key role in the development of community mental health wrote a small book that methodically detailed the operational decline of the state hospitals at the same time that the Hill-Burton legislation was funding sparkling new general hospitals in communities throughout the country. The meaning of the word "hospital" was changing dramatically and that strange separation remained.

The term Public and Community Psychiatry may change just as dramatically in the process of achieving better care, better health, and lower cost. Community care, organized to be accountable for effectiveness, quality and safety will certainly survive. But, as a policy of universal access to health care is approached, a "public psychiatry" may make little sense. Patients who are impoverished by their disability will be indistinguishable. Public psychiatry itself may disappear as well as that strange separation between psychiatry and the rest of medicine.

▲ 58.2 Reforming Health Care

LEIGHTON Y. HUEY, M.D., JULIAN D. FORD, PH.D., AND ROBERT F. COLE, PH.D.

INTRODUCTION

Numerous studies and reports have documented for years the problems in the US health care system and the overall unfavorable comparisons to other industrialized countries when considering quality, access, efficiency, equity, public health, and costs (Table 58.2–1). A 2014 report by the Commonwealth Fund shows the US health care system ranked last among eleven industrialized countries overall in access, efficiency, equity, and achieving healthy lives.

However, with the passage of the Patient Protection and Affordable

Care Act (ACA) in 2010, a watershed event, health care reform in the United States has moved into the forefront of the national discourse despite rear-guard objections to the ACA's enactment. The ACA is the law.

The following chapter traces the movement toward health care reform, first in the 20th century, and then in the 21st century culminating in the passage of the ACA. The context of the larger health care system is discussed, the problems driving the need for reform, along with the role of and implications for behavioral health and psychiatry.

Based upon his considerable influence, virtually all of US health care has rallied around Don Berwick's 2008 "Triple Aim" concept that, simply put, involves:

- Improving the individual patient's experience of care
- Improving the health of populations
- Reducing per capita costs of care

Meeting these three inter-related concepts is required to achieve high-value care as reform shifts from a *volume-based* to a *value-based* system. The concept of the Triple Aim will guide the discussion in this chapter. The larger health care systems in which psychiatrists and other behavioral health specialists work have a profound impact on the delivery and outcomes of both psychiatric and physical health care services. Internationally, and over the last decade in the United States, the dominant theme in reform of health care systems shifted from an emphasis on managed care to a tripartite focus on patient-centered care (as a complement to provider-driven disease management), improvement of the health of entire populations with interventions tested in comparative effectiveness research (as opposed to individual level observational or clinical trial research), and the development of incentives to maximize health care cost-effectiveness (as opposed to containing costs by restricting access to or reimbursement for health care). The Triple Aim serves as a foundation for health care reform (see Fig. 58.2–1).

As shown in Figure 58.2–1, the guiding principle of the Triple Aim is that health care quality should be defined based upon the vantage of the recipient, the patient, and not externally by technical or clinical considerations. Beginning with a patient-centered (as opposed to disease-based) perspective, health care must be teamed up with public health (i.e., prevention and health promotion) and social services in order to fully meet the needs of individuals and families and create a healthy overall population. This biopsychosocial approach integrates otherwise fragmented or missing services, and makes primary (rather than specialty) health care the driver for the delivery of services—containing and reducing costs as well as promoting health. These are not new or radical concepts, but have been recurrent themes in efforts to reform health care for more than a century in the United States as well as playing a central role in the

more successful health care systems in other affluent and industrialized countries internationally.

The benefits of designing health care delivery practices and systems based on the Triple Aim are described by the Institute for Healthcare Improvement as:

Organizations and communities that attain the Triple Aim will have healthier populations, in part because of new designs that better identify problems and solutions further upstream and outside of acute health care. Patients can expect less complex and much more coordinated care and the burden of illness will decrease. Importantly, stabilizing or reducing the per capita cost of care for populations will give businesses the opportunity to be more competitive, lessen the pressure on publicly funded health care budgets, and provide communities with more flexibility

to invest in activities, such as schools and the lived environment, that increase the vitality and economic wellbeing of their inhabitants.

The Triple Aim's relevance for psychiatry, and a key role that psychiatry and behavioral health can play in health care reform, was articulated by Wayne Katon, an academic psychiatrist who has been a pioneer and leading proponent and researcher in the area of collaborative mental and physical health care. He stated in a 2013 interview:

FIGURE 58.2–1. Design of a Triple Aim Enterprise. (Reprinted with permission by the Institute for Healthcare Improvement Triple Aim; 2012.)

Health reform initiatives will bring primary care, hospitals, and other centers into accountable care models in order to improve continuity and quality of care and reduce costs. We don't want psychiatrists to be left behind in the changes that are rapidly going on. Many psychiatrists are involved in efforts to integrate mental health services into primary care and medical specialty care as well as collaborative care and dissemination trials. Health reform has provided a tremendous stimulus for positive change in terms of integrating mental health care into primary care . . . There is also an overrepresentation of people with mental illness among the currently uninsured individuals who may gain access to insurance through health reform. That's another incentive to adopt collaborative care models to help provide mental health care more efficiently. Otherwise, this influx of patients will really stress the system.

Integration of psychiatry into a comprehensive "patient care medical home" that provides a full range of coordinated cost-effective physical and mental health services. The integration continuously monitors the patient's response in order to enable timely adjustments to the services involving a transformation that will affect all psychiatric and behavioral health providers and sub-specialties. This chapter will describe the challenges and opportunities facing psychiatry and behavioral health as a field and psychiatrists and others as practitioners as the Triple Aim guides health care reform in the 21st century.

HISTORICAL OVERVIEW

Health Care Reform in the 20th Century

The reform of the US health care system has been periodically and repeatedly proposed since and before the social reforms of President Franklin Roosevelt. Presidents Harry Truman, Jimmy Carter, Gerald Ford, George H. W. Bush, and Bill Clinton all considered and proposed plans for reform. Earlier proposals for national health insurance set the framework for these proposals. Table 58.2–2 provides a summary of the major periods of legislative activity since the early 20th century and the complex elements that were involved in the proposals. Earlier proposals coupled health with other social welfare programs; later proposals narrowed in on health care as health care costs increased dramatically in the later part of the 20th century. Proposals were designed on either the model of social insurance or that of public assistance or welfare. As the importance of universal coverage became clear, these models merged. The locus of administration or control of the proposed health insurance programs—by employers, the federal government, or the states—became important. In particular, the most critical issue was the financing of the system: Through government funds, the requirement that employers pay for their employees ("employer mandate"), or the requirement that individuals buy their own insurance ("individual mandate").

In the last decade of the 20th century, as health care costs continued to spiral upward, the proposed Clinton Health Security Act generated a tremendous amount of energy but eventually failed to be enacted. Large employers changed their methods of purchasing care, hiring companies to introduce a variety of cost control techniques, generally described as "managed care." Meanwhile "incremental" measures were taken in the 1996 Health Insurance Portability and Accountability Act; the 1997 Balanced Budget Act, which limited payments to hospitals; and the 2003 Medicare Prescription Drug Improvement and Modernization Act, which, in addition to providing partial coverage to Medicare enrollees for medications, also provided the Medicare program with the flexibility to introduce more aggressive health care purchasing techniques to control cost. These measures also supported individual incentives to control cost through new insurance models such as medical savings accounts, which were designed to combine tax-exempt personal savings for health care with catastrophic insurance coverage. The movement toward "managed care" purchasing did slow the rising costs for a few years, but its requirements had to be relaxed due to the strong reaction against control by both patients and providers.

Table 58.2–2.
Five Periods of American Legislative Activity for National Health

Insurance

Dates: Proposed Reform	Benefit	Administration/Financing	Model/Outcome
1912–1919 American Association for Labor Legislation (AALL): Opposed by American Medical Association (AMA), American Federation of Labor, businesses	Medical care, sick pay, funeral expenses for lower-paid workers (<$1,200/year) and dependents	Administered by states; financed by payroll tax collected in regional funds	Model: Social insurance Failed to pass
1946–1949 Wagner-Murray-Dingle Bill: Supported by President Truman; opposed by AMA	Retirement, disability, unemployment, and health insurance: Physician and hospital care	Expansion of Social Security; employer/employee contributions to "social insurance trust fund"	Model: Social insurance Failed to pass
1963–1965 Medicare and Medicaid	Medicare: Hospital care (Part A) physician care (Part B); medications (Part D) Medicaid: Comprehensive health care, long-term care	Medicare administered federally, Medicaid by the states; Medicare financed through Social Security, federal income taxes, and individual premiums; Medicaid financed by general state and federal tax revenues	Medicare: Social insurance model Medicaid: Public assistance (welfare) mode Both programs were enacted
1970–1974 Kennedy-Griffiths Health Security Act: President Nixon countered with an employer mandate plan; Physicians for National Health (PHN) proposed "single payer"	National health insurance for the entire population	Administered federally, eliminating all public and private insurance; Nixon plan featured employer mandate, privately administered, plus Medicaid and Medicare; PNH plan financed by federal tax with single fund in each state	Model: Combined social insurance and public assistance; failed to pass Nixon plan: Maintained public assistance; added social insurance; failed to pass PNH plan: Merged social insurance and welfare; failed to pass
1991–1994 Clinton Health Security Act: Opposed by insurance and pharmaceutical industries and small	Comprehensive health care	Administered federally; financed through governmental funds, employer mandate and individual mandate (with subsidies); voluntary: Tax	Model: Integrated social insurance and public

employers, single-payer advocates; proposed voluntary approaches	incentives for employers; medical savings accounts (MSAs) for individuals	assistance Failed to pass

Managed Care: A Phenomenon on the Path to Health Care Reform

The freewheeling spirit resulting from having generous public and private financial support for health care during roughly the period from 1950 to 1980 led to a heady time for US medicine. Society supported the clinical advances built on research that promised breakthroughs just over the horizon. Practitioners were, by association, part of this new era, and, as authorities in their professions, their determination of what patients needed was funded almost without question by public and private sources. As resources became limited owing to many factors, such as inflationary pressures and legislation, payers began to question what it was that health care was delivering for the dollar; that is, the issue of *value* was raised for the first time in the health economic equation by those paying for health care. A corollary of the issue of value was the question of the *accountability* of practitioners. Subsequent landmark studies demonstrated geographically differing practice-patterns and consequently different costs but similar outcomes for the same disorder or disease. This raised the general question of why this should be the case? Other fundamental issues that have emerged include the following: How can access to care be broadened? How can clinical outcomes as a result of health care be improved? What about the uninsured? How can costs be controlled?

Utilization Review

Employers and purchasers embraced the concepts of *utilization review* and *utilization management* as strategies to try to ensure that the most appropriate and most cost-effective clinical decisions with the best outcomes were being made on behalf of any given patient. For the purposes of this discussion, *utilization management* is considered the global concept that subsumes various aspects of the review process. These days, virtually all care, with the exception of the increasingly rare full fee for service, is under some form of review and management process, whether public or commercial payer.

The review process is considered by some practitioners as an intrusion into the clinician–patient relationship. The fact that the process can be cumbersome and that there is often disagreement about the decisions reached during a review contributes to the resentment engendered. With some justification, practitioners are irked by the fact that third parties with no clinical relationship to the patient have the authority to influence the process of care, challenging the practitioners' clinical autonomy. At one point, the clinical criteria used in the review process were considered "proprietary" and not available to clinicians so they might see how the

process of their care was being reviewed. At the same time, if practices were reasonably standardized and if practitioners had training (or retraining) that was uniform with a focus on (1) diagnostic accuracy, (2) evidence-based, cost-effective practice, and (3) attention to clinical outcomes, perhaps a great deal of the variance seen in practice might diminish, thereby reducing the need for third-party reviews.

Selective Closed Panels and Networks

Another strategy to improve care while reducing costs was to create selective or preferred provider networks in which clinicians applied to become members of the clinical panel of a managed care organization. By applying to be a network provider, clinicians agreed to practice within the guidelines established by the managed care organization, so, in theory, the network had some degree of compliance and fidelity to the standards of practice of that particular managed care company. However, this was more of an idealized system of care for a number of reasons. In many parts of the country, the clinical marketplace is highly competitive because of a glut of practitioners vying for limited clinical dollars. Functionally, what this means is that there may be many individual practitioners who apply to be on a particular managed care panel because of simple economics (i.e., they need the income) rather than an interest or willingness to practice within a managed care framework. So, there may be little that is selective about a particular panel of providers because the process is more open-ended until the managed care organization has determined that there are sufficient numbers of providers for a given geographical area. Whether justified or not, some managed care organizations have reputations for being difficult to work with, reimbursing at what are viewed as "low rates." Such organizations may have difficulty attracting sufficient numbers of providers and may be less selective than is preferable. In more affluent areas, some practitioners, especially well-established ones, do not accept insurance of any kind so utilization review is not part of overview of their patients' clinical care.

Care Management and Intensive Case Management

A large portion of psychiatric care is to be done with persons with chronic mental health conditions. Driven largely by demographic realities of an aging population, health reform considerations are focusing on chronic illness care and the concept of *care management and intensive case management, virtually identical concepts*. By analyzing the process of care for various disease entities, care management attempts to introduce discrete improvement steps to improve the efficiency and coordination of care, enhance patient compliance, achieve better outcomes, and reduce costs. Care management has been used with chronic illnesses, such as

diabetes or hypertension. In psychiatry, care management has been applied to mood and anxiety disorders with success. The high degree of practice variability not only by provider, but also by geographic section of the country reflects the historic inability and failure of the health care system to incorporate readily and to standardize quality improvement and evidence-based ideas into the system in which clinician, patient, and health system engage.

Managed Behavioral Health Care

In the late 20th century, costs for psychiatric and substance-abuse services were rising at a considerably faster rate than the costs for physical health care. The effort to instill accountability among practitioners, expect value for payment, improve access, provide cost-effective services, and use to the extent possible evidence-based approaches to treatment to improve outcomes created a backlash by mental health practitioners against managed care. Scandals in the 1980s and 1990s of for-profit managed behavioral health care companies engaging in unethical practices overshadowed the equally scandalous accounts of practitioner excesses of use and inappropriate, often misguided, treatment. Managed behavioral health care became synonymous with denial of care and, in for-profit systems, the image of fat-cat corporate leaders with large salaries and generous stock options derived from the misfortune of patients and beleaguered practitioners, the latter mired in an endlessly confusing system of external review, was readily accepted by many as the only reality. What was missing in the tumult was the perspective that managed behavioral health care was a way station on the path to behavioral health care reform.

Public Sector Managed Behavioral Health Care

Governmental agencies, at federal, state, and local levels, purchase 60 percent of all behavioral health care. As resources followed patients out of the state hospitals, much of the state expenditures remained in the control of agencies responsible for specific populations such as mental health, criminal justice, child welfare, and social services. Medicaid, the entitlement program for those unable to afford health care, began in 1965, and is the primary funding source for local governments to pay for public behavioral health care services. Medicaid's overall costs rose dramatically, by 2000, accounting for more than 15 percent of all US health care costs, with behavioral health care accounting for about 10 percent of Medicaid spending.

At the level of state or county government, Medicaid's behavioral health costs became a serious liability because of yearly cost overruns. Government agencies turned to managed care contracting of Medicaid services as a way of shifting risk to non-profit behavioral health care

provider organizations, and thus limit the state's liability.

State governments also soon learned that they could redirect the bulk of their behavioral health expenditures for severely disabled persons in the categorical agencies into the Medicaid program, thus increasing their match base for the Medicaid Federal Financial Participation (FFP) and leveraging federal revenues into their state general fund. Medicaid expenditures continued to increase, and this was a major contributing factor to the 100 percent increase in public mental health dollars from 1956 to 2003. The downside from the point of view of the seriously and persistently mentally ill was that the control of these services went from the public agencies responsible for behavioral health care to commercial managed care companies whose networks and capacities were more in tune with the needs of employed populations.

Safety-net hospitals, community mental health centers, and academic medical centers were under extreme financial distress and endured substantial service limitations. Thus, while public sector experiments with large-scale managed behavioral health care produced some successes, costs and quality of care continued to be problematic.

Private Sector Managed Behavioral Health Care

Government deregulation of the hospital industry enabled the astronomical growth of for-profit mental health and substance abuse facilities, many organized as large hospital chains. Use of mental health and substance abuse treatment increased dramatically, exemplified by the fourfold increase in adolescent inpatient admissions that occurred between 1982 and 1987. The proliferation, financial success, and perceived abuses of proprietary psychiatric hospitals caused great consternation among employers, insurers, legislators, and the public at large. Many hospitals, including presumably less exploitative, not-for-profit hospitals, seemed to provide treatment based on reimbursement potential rather than actual medical necessity. One of the physician pioneers of the managed behavioral health care industry commented that it was a myth that the treatment of substance abuse required a fixed length (usually 28 days) of inpatient treatment. Rarely has such a fixed false belief had so little factual support, or been so fervently adhered to. As early as 1983, a report from the Office of Technology Assessment that the literature failed to demonstrate a general superiority of inpatient over alternative treatment settings, as measured by outcome. Subsequent studies have confirmed that hospital or residential treatment is neither a necessary nor sufficient for most people with substance use disorders.

Long inpatient stays for adolescents with behavioral or substance abuse problems nevertheless became common. Inappropriate hospitalizations for excessive periods of time became exposed as proprietary systems flourished. Health care payers (employers, insurance companies, Medicare

and Medicaid) all became quite rightly concerned by the rising costs and the suspect practices. They questioned the true medical necessity of costly services such as long psychiatric inpatient stays. The psychiatric profession also successfully argued that inpatient stays for psychiatric patients could not be actuarially determined with any precision, thus making federal Medicare mental health inpatient criteria exempt from federally determined diagnostic-related groups (DRGs) for reimbursement purposes. In this climate, it became more and more difficult to maintain adequate oversight or regulation of mental health and substance abuse treatments. Private employers became the first to respond proactively to these concerns by contracting with the pioneer entrepreneurs of the first generation of managed behavioral health organizations (MBHOs) led by mental health professionals who had the credibility and specialized knowledge and skill to provide oversight of mental health and substance abuse practitioners.

This initial phase of managed behavioral health care (approximately 1983 to 1987) began with traditional indemnity insurers changing benefit designs in the hope of discouraging excess use. Tactics included limiting mental health coverage for specific disorders or treatments and instituting deductibles, copayments, and benefit maximums. These efforts were ultimately all unsuccessful. Entrepreneurial companies, led by psychiatrists and psychologists, began their entry into the health care marketplace through contracts with HMOs struggling to administer behavioral health care benefits. The dramatic success of these initial efforts was driven through limitation of access to mental health and substance abuse services. Access was limited through tight medical management (instituting strict medical necessity criteria for level-of-care determinations, limiting authorizations for inpatient admissions and continuation of stay, proliferation of denials of payment for care, etc.), as well as by restricting the network of caregivers and institutions credentialed to provide care for the population covered.

The **first phase** of limitation of access, aimed at restricting access for patients, was successful but led to dramatic customer complaints. As large employers (not HMOs) became the target for MBHO marketing, patient choice was increased by expanding provider networks, but overall costs were now saved through dramatic reduction in rates paid to providers. Typical discounts were 20 to 25 percent of professional fees and 25 to 35 percent of hospital charges. These discounts seemed draconian at the time and were widely seen as threats to the solvency of behavioral health care providers; but even larger fee reductions were to come. This network expansion and reduction of provider rates characterized the **second phase** of the managed behavioral health care revolution (approximately 1993 to 1998).

The **third phase** (1998 to the present) has been termed the phase of

industry consolidation. The proliferation and financial success of MBHOs in the 1980s and early 1990s led to the development of administrative models, information system infrastructure, large provider network management techniques, and sophisticated medical management strategies that resulted in significant economies of scale. Provider rates continued to fall, along with profit margins. Utilization patterns also changed dramatically. The average commercial inpatient days per 1,000 members declined from approximately 150 in 1983, to 75 in 1990, to 10 to 15 in 2000 in tightly managed markets, such as Minneapolis and Los Angeles. Cost to employers of behavioral health care under traditional indemnity plans was approximately $9 per member per month. By 2000, these costs fell dramatically to less than $3 per member per month. To sustain these reductions, the MBHO industry experienced dramatic consolidation. Within a few years, through mergers, acquisitions, and growth of the market, the industry became concentrated into a small number of very powerful behavioral health care corporations.

Health Care Reform in the 21st Century

Whether admired or not, many of managed care's innovations are irreversible. Managed care's financial success was dramatic (i.e., decreased behavioral health care costs). Utilization management by managed care companies led to significant decreases in average length of inpatient stays for psychiatric patients and fewer total inpatient days for populations of patients as a whole. Despite widespread complaints of diminished physician, hospital, and patient autonomy, constraints of decreased physician and hospital reimbursement, and anecdotal horror stories of sacrificed patient health care quality, there is no convincing evidence that managed care destroyed the quality of the US health care system. One could reasonably argue that the health care system was already imploding which was the impetus for yet another effort at reforming the system. Recent evidence collected by the National Committee on Quality Assurance points to significant improvements in health care quality resulting from efforts at self-improvement by the managed care industry. Managed care contributed to health care quality through its emphasis on population-, evidence-, and guideline-based health care, chronic illness care management, and information technology to evaluate and change the process and outcomes of care.

However, by the beginning of the 21st century, health care costs continued to spiral upward in the United States, and health care quality remained substantially below standards set in other comparable affluent societies (see Table 58.2–1). With overall health care costs rising at more than twice the rate of inflation, employer groups could not sustain the resultant increase in premiums.

Waste in Health Care

In recent years, considerable attention has been paid to eliminating waste in US health care, not just redesigning a dysfunctional health care system with improved access, better quality, improved efficiency, expanded coverage to enhance equity, and lowered costs. It has been estimated that a third of the annual health care expenditure ($2.8 trillion in 2014) could be eliminated without any adverse health consequence to individual patients. Unnecessary administrative expenses, care that provides little or no value, costs associated with medical errors and fraud are examples of some of the waste. There have been six areas identified that are responsible for the waste: (1) poor care delivery, (2) poor care coordination, (3) excessive care, (4) excessive administration, (5) pricing failures $, (6) fraud and abuse (Table 58.2–3).

These six areas are projected to push US health care expenditures to 20 percent of the gross domestic product by 2020 which is unsustainable. Not surprisingly, therefore, in the first two decades of the 21st century, the urgency of health care reform has intensified as the growth of US health care spending is projected to double in 8-year intervals representing almost 18 percent of the gross domestic product in 2011. The competitive position of the United States in the global economy is threatened and many argue that the economy cannot be fixed until health care is fixed. Influential reports show that the United States spends considerably more on health care than any other country, with the growth in spending consistently outstripping collective income. Yet the United States ranks poorly among industrialized countries in common measures such as life expectancy and infant mortality, and it is unable to provide health insurance to at least 15 percent of its population. Health care is at the forefront of the domestic agenda.

Table 58.2–3.
Waste and Costs

Waste and Costs in Health Care in 2011	Billions ($)
► Poor Coordination of Care	35
► Poor Delivery of Care	126
► Excessive Care	192
► Excessive Administration	248
► Excessive Costs to What Should Be	131
► Fraud	177

Adapted from Berwick D, Hackbarth A. Eliminating waste in US health care. *JAMA*. 2012;307(14):1513.

It is also clear that reform of an industry approaching $3 trillion in annual costs will involve a gradual transformation over many years. The

passage of the ACA in 2010, now law, has laid the foundation for the transformation. Key policy reports in the first decade of the 21st century set the stage for the ACA.

The 2001 Institute of Medicine *Quality Chasm* Report

The Institute of Medicine (IOM), in its influential 2001 report, *Crossing the Quality Chasm: A New Health System for the 21st Century*, noted "Between the health care we have and the care we could have lies not just a gap, but a chasm." The report went on to highlight the disparity between best practice and current practice and the effect of this on widespread variability and escalating health care costs. It established Six Aims for the twenty-first–century health care system.

Expanding the concept of best practice to include public health and prevention efforts and coupling this with chronic illness care management are among the key points of the IOM monograph, as are the pivotal roles of pre-professional training and the retraining of the existing workforce. With finite resources for health care amid competing priorities, the reformed health care system and, specifically, the reformed behavioral health care system must find ways to integrate effectively multiple factors, such as (1) practitioner, system, and patient accountability; (2) economic support for public health efforts, such as prevention and early identification; (3) the linkage of acute care with chronic illness care/collaborative care/coordinated care management; (4) improved access; (5) effective integration with primary and specialty care; (6) development of models of the most clinically effective and cost-effective care (e.g., integrated with public and physical health, interdisciplinary in practice, with continuity of care across venues); and (7) meaningful involvement of patients and, where feasible, their families, in the process of care, and so on. Managed care can be viewed as a sign and a symptom within the broader construct of health care reform. Health care reform and reform of managed care are possible.

Soon after this report was issued, The National Committee for Quality Assurance (NCQA) reported that despite important strides made in the general medical and surgery sectors, there continued to be disturbing exceptions to overall health care quality improvement in mental health, that the situation remained poor and concerning. The IOM's recommendations centered first on linking mental health and substance use treatment more closely with general medical care; second, the details of the original *Quality Chasm* report, its aims, rules, and redesign approaches, should be operationalized in the treatment of mental health and substance use disorders. Inadequate leadership and resources have been cited along with these areas having fewer objective, standardized diagnostic methods compared to physical health disorders; weakness of the evidence base for supporting quality measures; lack of coherent strategies for adopting quality measures that gets back to the problems in leadership

in assuming this responsibility to move the field along. Fewer than 5 percent of the National Quality Forum's list of 650 quality indicators relate to the care for individuals having mental health and substance use problems.

The 2006 Institute of Medicine Report: Improving the Quality of Health Care for Mental and Substance Use Conditions

The 2001 IOM Quality Chasm Report articulated a strategy for health care improvement but because health care for mental and substance use disorders has numerous distinctive characteristics, a separate report focused on this specific area was undertaken. These distinctive characteristics include the greater stigma associated with mental and substance-use conditions, more frequent coercion of these patients into treatment, a less developed system for measuring quality and improvement, a more educationally heterogeneous workforce, the fragmentation of the behavioral health care system with inadequate communication and coordination of care among its components, and a perverse funding structure. This report and its related series called for a profound paradigm shift for US health care and proposed a set of ten new rules for how care should be delivered. The changes were intended to foster the Six Aims and support redesigned health care systems. The differences between the old and new rules are outlined in Table 58.2–4.

The report's findings and recommendations are summarized in Table 58.2–5.

At the time of the publication of this report, more than 33 million Americans were using health care for their mental conditions or conditions resulting from their use of alcohol, inappropriate use of prescription medications, or illegal drugs.

The report also noted the considerable societal and workplace burden that mental and substance use conditions bring with substantial employer costs from absenteeism, "presenteeism" (i.e., being at work but essentially not functioning fully), sub-par educational achievement by children having such conditions leading to a variety of emotional and behavioral problems. Children with poor educational achievement enter a cycle of emotional and behavioral problems leading to risk for delinquent and antisocial behaviors, dropping out of school, eventually affecting the child welfare and juvenile justice systems. This in turn becomes a feeder phenomenon into the adult justice system that has seen an increasing number of inmates in prisons and jails with mental and substance-use conditions. The U.S. Bureau of Justice Statistics estimated that 16 percent of all persons in jails and prisons have a mental and/or substance-use disorder. Systematic assessment studies document prevalence estimates that are twice as high, with as many as one in every three incarcerated adults and youths having a behavioral health disorder.

Table 58.2–4.
The Institute of Medicine's Rules for Health Care

Old Rules for Health Care Delivery	New Rules for Health Care Delivery
1. Care is based on visits.	1. Care is based on continuous healing relationships.
2. Professional autonomy drives variability.	2. Care is customized to patient needs and values.
3. Professionals control care.	3. The patient is the source of control.
4. Information is placed in a record.	4. Knowledge is shared, and information flows freely.
5. Decisions are based on training and experience.	5. Decision making is evidence based.
6. "Do no harm" is an individual clinician responsibility.	6. Safety is a system responsibility.
7. Secrecy is necessary.	7. Transparency is necessary.
8. The system reacts to needs.	8. Needs are anticipated.
9. Cost reduction is sought.	9. Waste is continuously decreased.
10. Preference for professional roles over the system.	10. Cooperation among clinicians is a priority.

The Institute of Medicine committee responsible for the 2006 report, *Improving the Quality of Health Care for Mental and Substance Use Conditions,* found that the framework of the Quality Chasm Report could be applied to health care for mental and substance use conditions and the following strategy was described:

- Individual patient preferences, needs, and values prevail in the face of residual stigma, discrimination, and coercion into treatment;
- The necessary infrastructure exists to produce scientific evidence more quickly and promote its application in patient care
- Multiple providers' care of the same patient is coordinated
- Emerging information technology related to health care benefits people with mental or substance-use problems and illnesses
- The health care workforce has the education, training, and capacity to deliver high-quality care for mental and substance-use conditions
- Government programs, employers, and other group purchasers of health care for mental and substance-use conditions use their dollars in ways that support the delivery of high-quality care
- Research funds are used to support studies that have direct clinical and policy relevance and that are focused on discovering and testing therapeutic advances

An over-riding theme throughout the report was that *treatment can be effective* and that *recovery is possible*. The report noted that quality problems hinder effective treatment and recovery, noting that numerous studies have shown the discrepancy between what is considered *effective care* and what is actually provided, echoing the Quality Chasm report. Low rates of adherence to clinical practice guidelines and evidence-based practice standards were noted across major diagnostic categories. For example, adequate rates of adherence to established practice guidelines occurred in only 27 percent of studies reported that covered alcohol withdrawal, bipolar disorder, depression, panic disorder, psychosis, schizophrenia, and substance use.

The 2003 New Freedom Commission and the 2008 Commonwealth Fund Report

The New Freedom Commission on Mental Health's 2003 report, *Achieving the Promise: Transforming Mental Health Care in America* opined, similar to the conclusions of the IOM's *Crossing the Quality Chasm* report, that the behavioral health care system "is in shambles." Five years later, the Commonwealth Fund described the US health care system as fragmented, delivering poor-quality, high-cost care. The report noted that achieving a high-performance health care system was not possible without reorganization at the national, state, community, and practice levels. It further identified key factors contributing to the fragmentation, including the absence of a single national entity or set of policies guiding the system, the states dividing responsibilities among multiple state agencies, and care often not coordinated among practitioners seeing the same patient. The report noted that:

- *Patients and families navigate unassisted across different providers and care settings, fostering frustration and dangerous patient experiences*
- *Poor communication and lack of clear accountability for a patient among multiple providers lead to multiple errors, waste, and duplication*
- *The absence of peer accountability, quality improvement infrastructure, and clinical information systems foster poor overall quality of care*
- *High-cost, intensive medical intervention is rewarded over higher-value primary care, including preventive medicine and the management of chronic illness.*

Table 58.2–5.
Summary of the Institute of Medicine's Recommendations of Care for Individuals with Mental and Substance Use Conditions

1. Emphasize patient-centered care and the importance of supporting patient decision making and preferences	The current health systems place a number of barriers to patient-centered care. Insurance discrimination is manifested by less benefit coverage for mental and substance use (M/SU) conditions. There are higher copays for these services. ► Clinicians, organizations, accrediting bodies, health plans, and payers need to support a patient-centered care (PCC) approach that respects decision-making capacity b patients. ► Stereotypes of patients being unable to arrive at decisions have resulted in coercion of care and discrimination historically.
2. Improve the infrastructure for quality improvement and evidence-based care	Significant problems with the current infrastructure for quality improvement. Assessment and treatment practices not well codified and captured in administrative data sets. Outcome measurements not widely applied; performance measurement for M/SU health care receives insufficient attention in the private sector; public sector efforts have not yet achieved consensus. Quality improvement methods are not permeating day-to-day service. This leads to systems of care that are not based on the principles of quality measurement,

and they fail to demonstrate continuous improvement.

3. Coordinate care across systems of care

- Poor linkages across systems of care; there is general fragmentation between M/SU and general health care and between mental and substance use care for both children and adults. Unclear accountability for coordination of care among providers.

4. Ensure that the National Health Information Infrastructure Initiative (NHIII) benefits people with mental and substance use conditions

M/SU conditions are not well incorporated into the strategic design of the NHIII. The proposed solutions are as follows:

- Charge the Office of the National Coordinator of Health Information Technology and the Substance Abuse and Mental Health Services Administration (SAMHSA) to jointly develop a plan that addresses M/SU health care.
- Leaders in M/SU health care should become proactive in the national process to set health care data and information technology standards.
- Public and private purchasers of health care should decrease the burden of variable reporting and billing requirements.

  Public and private purchasers of health care should encourage widespread adoption of electronic health records, computer-based clinical decision support systems, computerized order entry, and other forms of useful information technology.

5. Increase the workforce capacity

A crisis in the M/SU workforce exists. There is greater variation in the quality of the M/SU workforce than in that for general health care. There are across-the-board deficiencies in education, and there is no "core knowledge" base across disciplines. The resulting variation in licensure, credentialing, and continuing education across disciplines does not assure agreed-on core competencies or adherence to the same standards of practice.

The remedies include the following:

- Creation of an ongoing, federally funded public–private Council on the Mental and Substance-Use Health Care Workforce.
- Collaboration of the Council with institutions of higher education, licensing and accrediting bodies, purchasers, and other private sector initiatives developed by the Association for Medical Education and Research in Substance Abuse (AMERSA) and the Annapolis Coalition (http://www.annapoliscoalition.org).

6. Restructure the marketplace to promote incentives for quality and improvement

The Institute of Medicine (IOM) report finds problems in the way in which M/SU care is purchased. Government (state and local) purchasers dominate, and frequently insurance is purchased for M/SU health care separately from general health care. This results in "carve-out" arrangements. Private insurance tends to avoid coverage or offers more-limited coverage to individuals with M/SU illnesses. Government purchasers often use direct purchasing by contract rather than insurance arrangements.

- Government should pass laws designed to enact coverage parity by purchasers so that individuals with M/SU conditions are not discriminated against when enrolling in health plans.
- Examples of tools that could be used to bring about parity are risk adjustment, payer carve-outs, risk-sharing or mixed-payment contracts, and benefit standardization across health plans.
- State-level procurement for M/SU care should give the greatest weight to quality and use M/SU health care quality measures in procurement and accountability.
- State and local governments should reduce emphasis on grant-based systems of financing and increase the use of funding mechanisms that link some funds to measures of quality.

Adapted from the Institute of Medicine. *Crossing the Quality Chasm: Adaptation to Mental Health and Addictive Disorders*. Washington, DC: National Academies Press; 2006.

This report was a harbinger of the ACA. Its recommendations focused on *Payment Reform* to stimulate greater organization as well as higher performance; *payment* would move beyond fee-for-service toward *bundled payment systems* that would reward coordinated, high-value care, expanding *pay-for-performance* to reward high-value, patient-centered care (see Fig. 58.2–2).

FIGURE 58.2–2. Feasibility of payment reform according to nature of the organization. (From Shih A, Davis K, Schoenbaum S, Gauthier A, Nuzum R, McCarthy D. Organizing the US Health Care Delivery System for High Performance. *The Commonwealth Fund*; 2008.)

Other recommendations included *patient incentives* (patients being able to choose to receive care from high-quality, high-value delivery systems), *regulatory changes* (to facilitate clinical integration among providers), *accreditation* (information and care is coordinated across all settings with providers having accountability to one another), *provider training* (train providers to practice in organized delivery systems), *government infrastructure support* (assist regions in establishing care coordination networks), *health information technology* (providers implementing an electronic health record that is functional, interoperable, and secure).

It is important to view these recommendations in the context of the behavioral health care system and its relationship to patients and families

and to the rest of health care. The importance of the integration of behavioral health into physical health care systems cannot be overstated. Numerous studies have shown the high prevalence of behavioral health conditions in physical health. Comorbid illnesses, that is, mental, substance use, and physical health disorders, represent the most costly group of patients in health systems. Many of these individuals are seen in public sector systems, often ending up incarcerated or homeless with inadequate physical **and** behavioral health care.

A dramatic example of the need to find ways to integrate primary care and behavioral health care in coherent delivery systems are the "dual eligibles," i.e., the Medicare and Medicaid eligible population. This is among the most costly of any population of patients, not only because a large portion of the poor and very elderly patients are in long term care (nursing homes and hospice), but also because those in the community find it difficult to negotiate consistent access to health care due to their disabilities. It is typical that a given state might find that 40 percent of their dual eligible population are persons with serious and persistent mental illness.

The 2008 Mental Health Parity and Addiction Equity Act

The Mental Health Parity and Addiction Equity Act enacted in 2008—the Wellstone-Domenici Parity Act—tightened the requirements for parity laid out in the Mental Health Parity Act of 1996. Parity was designed to bring individuals with behavioral health disorders into the mainstream US health care system to correct the historical inattention and inequality of care in this population, and to reduce the stigmatization such individuals experienced compared to people having physical health problems alone. The intent was to have behavioral health care benefits equivalent to benefits provided in medical and surgical care. In addition, about two-thirds of primary care physicians had reported difficulty in accessing outpatient behavioral health services for their patients, a rate twice as high as that for other services. Lack of coverage or inadequate coverage, health plan barriers, and a shortage of behavioral health providers were cited by primary care physicians as problems contributing to accessing good behavioral health care. The Mental Health Parity and Addiction and Addiction Equity Act required group health plans with behavioral health benefits to provide the same level of coverage as physical health plan coverage. Access to behavioral health services has been particularly problematic for low-income uninsured and Medicaid patients. Ironically, primary care physicians practicing in areas with a high number of psychiatrists had a greater probability of not being able to secure behavioral health services for their patients because of a variety of plan barriers and the inadequacy of coverage these patients had. Recent studies showing that psychiatrists, compared to all other areas of Medicine, have

the lowest acceptance rate of Medicare (i.e., less than 50 percent of psychiatrists accept Medicare, with figures lower still for Medicaid). The speculation about such an observation, its effect on how other specialties, professionals, trainees, and policy-makers, along with the general population, view adherents to such a practice is important to consider. Some have advocated tying partial or total medical school debt-forgiveness, or even state medical licensure, to having a reasonable percentage of one's practice tied to practitioners seeing individuals covered by Medicare and Medicaid.

The major impact of the ACA will strengthen the quest for parity as it attempts to reduce the number of uninsured in the United States. Otherwise parity by itself, regardless of the law, is likely to not have an effect on the severe access problems the uninsured and the low-insured population experiences in gaining behavioral health care.

THE PATIENT PROTECTION AND AFFORDABLE CARE ACT

Before the ACA, the American health care system was literally killing the country. Government estimates that the population of uninsured Americans would rise from 45 million in 2009, to 54 million in 2019. For more than 4 decades health care costs were rising much faster than the growth in the economy, sucking off tremendous amounts of money. It built tremendous academic health centers and modern community hospitals, spurred development of many new medical technologies, and filled medicine cabinets with groundbreaking new pills that were more potent with fewer side effects. But it also diverted resources away from many other vitally important social programs, from education to infrastructure to middle-class wage increases. Bridges were aging and crumbling as adjacent hospitals were brand new and stuffed with amazing technology. And even worse, over this 4-decade period cash wages for private-sector workers stagnated . . . and health care was a major contributing factor . . . the inexorable rise in the nation's debt was fueled not by defense spending or Social Security but rather Medicare and Medicaid spending as Ezekiel Emanuel noted.

After decades of fits and starts, the ACA was passed and became the nation's health care reform law in 2010. The ACA, a major centerpiece for the Obama Administration, represents the greatest change to health care since the 1960s. The rationale for reform has been articulated earlier in this chapter so reiterating the problems in access, efficiency, equity, prevention, and spending will not be belabored. The *need* for reform has been clear for decades but with increasing numbers of people not having health care coverage and the expanded complexity of health care in the context of poor coordination and burgeoning costs, reform is now imperative.

While some in Congress might have buyer's remorse and will generate predictable political machinations (enhanced by the ACA's bungled introduction to the nation in 2013), the ACA is nevertheless the law of the land and represents a major effort toward enhancing the common good. With a Republican majority in the Senate and House, and now an ACA-hostile President, controversial components of the ACA might have a chance of being repealed. However, the general sense is that the ACA is now so insinuated into the fabric of American health care, that it would be very difficult, if not impossible, to fully undo and repeal its essence. This section will address the key components of the ACA as it aims to reform both public and private health insurance systems.

The key provisions of the ACA are designed to:

- Provide coverage for more people
- Provide more benefits, better protection, and transparency
- Lower costs for consumers and government
- Provide quality and efficiency
- Provide a stronger workforce and health care infrastructure.
- Provide a greater focus on public health, prevention, and chronic illness care
- Support innovative techniques and technologies

The ACA is projected to provide coverage for more people, extending coverage to 24 million more Americans by 2023, nearly half of the 45 million uninsured in 2012. It is also predicting that the uninsured rate will be cut in half by 2016.

As of this writing, the initial results are showing the ACA is having the predicted impact with the percentage of uninsured dropping in areas where the ACA impact is being studied. Costs of health care are also declining with falling premium rates. Initially, this was partly the result of the recession that began in 2008. More recently, in some areas of the country, premiums and deductibles have risen, further driving the push to repeal the ACA by some; others sound "Reform not Repeal" as a rallying cry, i.e., work to improve the ACA, not dismantle it. However, the Center for Medicare and Medicaid (CMS) has projected that the average annual health care spending will be 5.7 percent from 2012 to 2013, compared to the 7.2 percent annual average between 1990 and 2008. Health care spending was at an historic low in 2013 (3.6 percent) but is projected to increase with an expanding economy and insurance coverage under the ACA.

Other key aspects of the ACA include care not being denied because of pre-existing conditions, maintaining dependents on parents' insurance until they are age 26, and certain preventive services are required of insures at no cost to consumers. Insures cannot charge higher premiums based on gender or health condition, and there are no lifetime or annual limits of coverage.

NEW MODELS IN HEALTH CARE

Patient-Centered Medical Homes and Medical Neighborhoods

In 2007, the American Academy of Family Physicians, the American Academy of Pediatrics, the American College of Physicians, and the American Osteopathic Association issued joint principles for the *Patient-Centered Medical Home (PCMH)*, a model to provide comprehensive primary care to children and adults, where appropriate care is structured, delivered, and coordinated around the specific needs of each patient. The medical home model was originally developed by the American Academy of Pediatrics in 1967 for children with special health needs where it was important to have a centralized location for a child's medical records. The joint principles of PCMHs (personal relationship with licensed provides, team approach, comprehensive/whole person approach, coordination and integration of care, quality and safety, expanded access to care, added value recognized, are all hallmarks) cover many of the characteristics of *Accountable Care Organizations (ACOs)* where PCMHs are seen as the building blocks for ACOs.

Some of the more recent literature suggested that early PCMH interventions led to only modest improvement in quality and patient

experience, with little evidence of effects on costs, and no reductions in utilization of hospital, emergency, or ambulatory care services over a 3-year period. At the same time, these studies suggested refinement of the outcomes associated with PCMHs was needed and that the development of the standards by the National Committee on Quality Assurance (NCQA) for medical home recognition had not been fully developed and applied in the early PCMH development. Nonetheless, the studies concluded that further refinement in PCMH development and function was important.

As the conceptualization of the organization of health care delivery systems developed, it was logical that the PCMH model would expand to include a constellation of entities and activities that would be responsible for the care of populations of patients. Thus, the concept of the *Medical Neighborhood* was spawned encompassing PCMHs with comprehensive primary, secondary, tertiary, services that are community-based, responsive to the needs of individual patients at different times, a truly integrated system of care with good coordination, effective communication, attention to patient education, and cost-effective. Such a concept forms the basis for *accountable care*.

Accountable Care Organizations

With the advent of the ACA, the Department of Health and Human Services (DHHS) began developing new approaches in conjunction with the private sector to improving care and to meet the Triple Aim for Medicare and Medicaid recipients. ACOs are voluntary groups of physicians, hospitals, and other health care providers that assume responsibility for a defined population of patients on the basis of the population's use of primary care services. The ACO is responsible for the entire continuum of care that the defined population of patients might need, including access to specialists, provision of social services, public health, and assessment of other socioeconomic factors such as housing, transportation, education, poverty, and nutrition. Providing preventive care for all patients and case management for individuals with chronic diseases is a component of an ACO as well. If the ACO succeeds in delivering high quality, improved care at a lower cost, there is an incentive built into the model whereby the ACO can share in the savings achieved through meeting the Triple Aim. Under the ACA, an ACO agrees to manage the health care needs of a minimum of 5,000 Medicare beneficiaries for at least 3 years. Under an ACO, providers are held *accountable* for the health of their patients and have strong incentives to cooperate and create savings through avoiding unnecessary care. Functionally, ACOs need to be fully integrated through an electronic medical record so that needed information can be shared among providers. Different ACO models exist to give hospitals and clinicians choice in how they work with one another.

The Teaching Health Center

There has been interest in providing post-graduate medical education in the primary care environment of the Federally Qualified Health Centers for some years. These programs have demonstrated that physicians trained in these settings are three times more likely to work in Federally-Qualified Health Centers (FQHCs) and twice as likely to serve underserved areas of the country. The ACA provided funds to establish Teaching Health Centers training physicians in nine primary care-related disciplines (one of which is Psychiatry) and at this writing 60 programs have been established in 24 states preparing 550 residents. In the same vein, the Institute of Medicine issued a report in 2014, "Graduate Medical Education That Meets the Nation's Health Needs" calling for the reform of financing, governance, and transparency of graduate medical education (GME). The Report calls for a 10-year transition period in which the current funding for more traditional residency programs will be modified. Transformative and innovative residency programs will be created and supported in primary care settings as well as in interdisciplinary organizations providing intensive care programs for persons with severe disabilities and multiple chronic illness conditions.

Comparative Effectiveness Research and Patient-Centered Outcomes Research

Comparative effectiveness research (CER) and patient-centered outcomes research (PCOR) are essential to fulfilling each of the three goals of the Triple Aim, and correspondingly have been allocated substantial funding support by the ACA through the Patient-Centered Outcomes Research Trust Fund (PCOTF). PCORTF receives funds from the general fund of the Treasury and from a small fee assessed on Medicare, private health insurance and self-insured plan revenues. An institute established specifically to facilitate and support PCOR, the PCOR Institute (PCORI) is slated to receive approximately $3.5 billion from the PCORTF over a 10-year period ending September 30, 2019. Each year, PCORTF transfers 20 percent of these revenues to the Department of Health and Human Services to support PCOR and the dissemination of PCOR to build the capacity of the health care system to provide and evaluate patient-centered and outcome-driven services. The remaining 80 percent of PCORTF funds are transferred to the Agency for Healthcare Research and Quality (AHRQ) in order to support and evaluate PCOR in US health care organizations.

PCOR is intended to provide methods and data repositories that can inform health care services by monitoring key health outcomes. Critical research questions for this agenda include how patients, families, and clinicians deal with the complex and often confusing choices involved in achieving and sustaining health, preventing and treating diseases and other health problems, and accessing and navigating health care systems.

Traditional medical research has produced vital advances in the understanding of disease conditions and their treatment, but it has not been intended or designed to enhance the current understanding of how patients subjectively experience, participate in, and are affected by health care and interactions with health care providers. Patient-centered medical research does exist, but its results typically are not systematically disseminated to either clinicians or patients and families. Research linking the patient's involvement in health care and health outcomes also exists, but its findings have not been extended beyond demonstrating that a collaborative provider-patient relationship plays a key role in patient motivation, adherence, and clinical and functional outcomes. PCOR takes on these critical questions that patients and their clinicians face daily in health care encounters and in their personal lives. PCOR is a systematic approach to patient-centered CER, in which patient and clinician preferences, choices, actions, and interactions are studied in order to determine tools, strategies, resources, and courses of action that are associated with cost-effective health care outcomes. For patients, PCOR involves testing and then providing guidance about which approaches to care work best, given their particular health conditions, personal and familial concerns, socioeconomic circumstances, and sociocultural preferences. For clinicians, PCOR is designed to provide evidence-based guidance addressing the questions they face daily in practice. For insurers, PCOR produces evidence that can help them make the best decisions on how to improve health outcomes for their members while also containing costs, especially with high-burden, high-impact disease conditions.

For psychiatry and the broader mental health field, PCOR provides opportunities and an impetus to conduct real-world clinical research on topics such as these recently-funded PCORI projects:

- Integrative Medicine Group Visits: A Patient-Centered Approach to Reducing Chronic Pain and Depression in a Disparate Urban Population
- A Community-Based Executive Function Intervention for Low-Income Children with ADHD and ASD
- Improving Transitional Care Experience for Individuals with Serious Mental Illness
- A Helping Hand to Activate Patient-Centered Depression Care among Low-Income Patients (AHH)
- Integrated Care and Patient Navigators for Latinos with Serious Mental Illness
- Patient-Centered Trauma Treatment for PTSD and Substance Abuse: Is It an Effective Treatment Option?

Pay for Performance, Public Reporting of Performance, and Meaningful Use

The effort to improve quality and therefore outcomes has taken many

guises, from revamping training to produce clinicians and systems that practice in a quality paradigm, to imploring clinicians and systems to do the right thing. At its most basic level, change can also be brought about by behavioral shaping and the use of incentives and disincentives to achieve the desired result—in this case quality improvement and patient-focused, high-quality care. Two such initiatives, Pay for Performance (P4P) and Public Reporting of Performance (PR), are designed to achieve these results. P4P and PR have been common in physical health care for a number of years. CMS has adopted P4P and has launched initiatives to demonstrate different ways to implement it. More than half of commercial health maintenance organizations are using P4P, and the acceptance of performance measurement among physicians and organized medicine has been acknowledged if not fully realized. P4P and PR, in essence, link physician reimbursement and nonmonetary rewards to improve quality of care. In addition, physicians, recognized for providing high-quality care and more efficient care deliver it at a lower cost than physicians who do not participate.

P4P and PR can reward health plans, provider groups, and individual clinicians in varying ways. Payment is made based on meeting pre-specified goals. In behavioral health, P4P has had limited presence, but efforts to expand it into common disorders such as depression and substance use disorders have received considerable attention. For example, a P4P paradigm in behavioral health might involve the percentage of patients diagnosed with a new episode of depression who were treated with an antidepressant at an adequate dosage, who were given the medication for a full 12 weeks; or patients who are given at baseline and subsequently, the Patient Health Questionnaire (PHQ), where the scores are used, along with routine clinical assessment, to track response to treatment over time. If P4P and PR achieve similar penetration in behavioral health care as in physical health care, then the modeling for this approach ideally would begin in training programs.

Within the ACA is embedded the concept of "Meaningful Use." Meaningful Use entails financial incentives for providers (professionals and hospitals) in their "meaningful use" of certified *electronic health records* (EHR) to improve patient care. Examples of Eligible Professional Core Objectives are: use of computerized physician order entry (CPOE) for medication, laboratory, and radiology; generating and transmitting permissible prescriptions electronically (eRx); recording certain demographics (preferred language, sex, race, ethnicity, date of birth); recording smoking status for patients 13-years-old and older; use of clinical decision support to improve performance on high-priority health conditions; a provider who receives a patient from another setting of care or provider of care should perform medication reconciliation; a provider who transitions their patient to another setting of care or provider of care

or refers their patient to another provider of care provides a summary of care record for each transition of care or referral.

In addition, to receive an incentive payment, providers are required to submit Clinical Quality Measure (CQM) data through the EHR that measure and track the quality of health care services. These include areas such as: health outcomes, clinical processes, patient safety, and efficient use of health care resources, care coordination, patient engagements, population and public health, adherence to clinical guidelines. Going back to the IOM Quality Chasm report, measuring and reporting CQMs is seen as ensuring that the US health care system is delivering effective, safe, efficient, patient-centered, equitable, and timely care.

Integration of Behavioral Health Care and Primary Care

Although nearly 50 percent of patients with chronic medical diseases have comorbid behavioral health conditions, more than 80 percent of the behavioral health conditions remain untreated or ineffectively treated in primary and medical specialty care settings. For a third of the patients with behavioral health conditions who receive their treatment in primary care, treatment for only one in nine is evidence-based. The data on public sector patients receiving behavioral health services in stand-alone behavioral health settings have a shorter life expectancy attributed to lack of adequate primary care services. Some ACOs have employed psychiatrists for both direct care and to provide supervision of care for non-physician behavioral health staff.

Rather than physical health care systems contracting with an MBHO to provide behavioral health care services to its enrollees, some systems have developed a variety of different models that attempt to integrate behavioral health care directly into physical health care settings. This is the dominant model of integration, perhaps accounting for 90 percent of the integrative efforts underway with physical health integrating into behavioral health systems accounting for the remainder. In this arrangement, in ambulatory settings, primary care physicians and clinicians work together with behavioral health care physicians and clinicians as part of the same health care organization. Given what is known about the high prevalence of comorbid psychiatric disorders in primary care practices, a variety of approaches are used to try to determine which patients might have a behavioral health problem and, once this is done, to provide proper assessment, treatment, and follow-up. Use of brief screening instruments to identify the more common and anticipated psychiatric disorders (e.g., depression, anxiety, and substance abuse) is one approach. If it is determined that a patient has a psychiatric problem, then there are a range of options that vary according to the particular system. In some systems, depending on the scope and gravity of the clinical psychiatric problem, the PCP directly assesses and treats it but then refers to a behavioral health

clinician if the treatment is not satisfactory or if a complication arises. Given the data showing that the level of recognition, assessment, and care of behavioral health problems within primary care systems is not of sufficient caliber, efforts to train PCPs in the proper recognition and approach to patients having behavioral health disorders has been a high priority. In other systems, once a psychiatric problem has been identified, there may be more immediate behavioral health involvement. Such integrated efforts to establish direct linkages between primary health care and behavioral health care, in essence forming a true, functional, interdisciplinary team approach, have been shown to be cost-effective, to result in improved patient satisfaction, and to have good outcomes. Some primary care systems, using a PCMH model, have chosen to employ psychiatric social workers as members of a PCMH, the implication being that PCPs can provide the necessary biomedical treatment of individuals having behavioral problems. However, there are recent studies suggesting that some patients with comorbid behavioral health disorders seen in primary care settings do not receiving adequate specialty behavioral health services.

In some hospital settings, psychiatrists are embedded directly into medical/surgical teams, a departure from the traditional consultation-liaison model. This model is relatively new and represents recognition of the high comorbidity of behavioral health disorders with physical health disorders.

Behavioral Health Care Services for Children with Serious Emotional Disorders

Children and adolescents with serious emotional disorders (SEDs), such as those with suicidal depression or early-onset psychotic disorders, represent another specialized population. On an annual basis, approximately 2 to 3 percent of children 3 to 5 years of age and 6 to 9 percent of children 6 to 17 years of age use mental health services. Of these, only a small percentage is defined as having serious emotional disorder, approximately 0.5 percent. These children, particularly the adolescents, often require complex case management and intensive (e.g., residential or inpatient) services that are costly to provide and pay for.

The most problematic aspect of the care of children and adolescents with serious emotional disturbances is that five categorical agencies have responsibility to provide it. **Child Welfare** has the largest group of these children and the largest budgets. **Special Education** obligations in local school districts are second in expenditures. **Mental Health** agencies have a clear mandate, but less funding despite usually caring for those in greatest need. **Juvenile Justice** programs serving youth who come before the courts, and **General Health and Primary Care** systems, often are the first to identify children with SEDs but tend to operate separately from mental health specialty services and to rely upon psychotropic medications

even though psychosocial treatments are considered the first-line intervention for most pediatric and adolescent psychiatric disorders.

This division of responsibility for child and adolescent services makes it very difficult to organize a coherent delivery system, and in most jurisdictions confusion and fragmentation are the rule. In the 1990s, following a decade of National Institute of Mental Health (NIMH) planning grants, the Robert Wood Johnson Foundation developed the Mental Health Services Program for Youth (MHSPY) to come up with coherent systems of care for children with SEDs and their families, integrating the efforts of the responsible agencies at the community level. This was followed by a large grant program by the Substance Abuse and Mental Health Services Administration (SAMHSA). A number of the more than 80 communities that received these grants have developed advanced care management program models providing individualized, intensive care services to children (and their families) who might otherwise have been confined in institutional settings. Services under these models are often funded by risk-adjusted case rates derived from the blending of funds from different agencies' budgets and often administered by the Medicaid program. Children with SEDs were identified in a 2014 policy brief by the Center for Health Care Strategies as:

> . . . a compelling high-cost, high-need group that can potentially benefit from the integrated care provided under health homes . . . The Medicaid health home state plan option is designed to provide a comprehensive system of care coordination across medical, behavioral, and long term services and supports for Medicaid beneficiaries with chronic physical or serious mental health conditions . . . states can tailor behavioral health-focused health homes to meet the unique needs of both children and adults." The health home is envisioned as a comprehensive set of services that wrap-around the patient and address the full range of complex health problems. For children with SEDs, this could include pediatric, psychological, educational, behavior modification, case management, social work, family therapy, child welfare, and legal/juvenile justice services as well as psychiatry. When working within the health home rubric with children, psychiatrists play a vital leadership role in collaboratively informing and coordinating with multiple behavioral health and social/educational services providers as well as with the pediatric primary care provider.

Behavioral Health Care for Adults with Serious and Persistent Mental Illness

The data are compelling for establishing an integrated and universal approach to the management of chronic illnesses. By the year 2030, approximately 150 million people in the United States will have a chronic condition of some type, and of this number, 42 million will be limited in their ability to be functional and to live independently. Chronic conditions also account for 70 percent of all deaths, 50 percent of total health care costs, and $234 billion in lost productivity each year. There are a number of strategies to induce the type of sweeping changes needed. CMS is rewarding quality initiatives and is restructuring its reimbursement system to reward chronic illness care management initiatives. Its Innovation Center is one of the leading forces driving new models, new systems, again,

along the line of fulfilling the Triple Aim.

The Robert Wood Johnson Foundation has been actively engaged for years with two important programs focused on introducing innovations in this area. The basic tenets of the first program, Chronic Care Initiatives in Health Maintenance Organizations, are to change provider and patient behaviors in several ways, including (1) moving from a focus on cure to symptom relief; (2) making the patient a critical part of the care process through shared decision-making; (3) creating active roles for the patient's significant others; (4) expanding the boundaries of care among providers and between traditional medical and social services; and (5) tying patient satisfaction to clinical outcomes.

The second national program sponsored by the Robert Wood Johnson Foundation is entitled Building Health Systems for People with Chronic Illnesses. This program attempts to better coordinate medical and supportive services for the chronically ill and, in so doing, challenge the fact that most insurance systems tend to fund acute care rather than supportive care for individuals with chronic conditions. The program attempts to do the following:

- Integrate services that care is provided across diverse settings; systems of care link clinical and nonclinical support services
- Reallocate resources by redirecting existing and acute care—focused delivery and financing to better serve the chronically ill
- Promote early medical and nonmedical interventions
- Help individuals maintain independence as long as possible in their homes and communities
- Give the chronically ill and their caregivers a role in designing and improving their health care and support services
- Support the development of models of care that can be used by people with different chronic health conditions.

These demonstrations set the stage for two operational models for fundamental system changes in the effort to improve quality and outcomes. Many of the proposed and expected system reforms surround efforts to implement the *chronic illness care model* and the *collaborative care model*. The chronic illness care model was first elaborated and tested for chronic general medical illnesses such as diabetes, congestive heart failure, and asthma. Recent efforts have attempted to apply the principles of chronic illness care to depression in primary care settings. The collaborative care model, on the other hand, was first described and tested for depression in primary care and has been broadened for other psychiatric illnesses that can also be treated in general medical settings with the support of care managers and psychiatrists, such as panic disorder and posttraumatic stress disorder (PTSD).

Widespread adoption of these two evidence-based models of care will

profoundly affect the future practice of psychiatry. Both the chronic illness care model and the collaborative care model successfully integrate psychiatric principles and practice into general medical systems. It should be possible to extend variations of the chronic illness care model to the behavioral health care system to improve quality and outcomes for chronic psychiatric illnesses (e.g., substance abuse, schizophrenia), and collaborative care models for psychiatric illnesses treated in general medical settings will continue to expand in depth and breadth. Both models of integrated health care require psychiatrists to learn to function as one component in elaborate systems of care, formally and routinely collaborate with other providers (including care managers and primary care physicians), and monitor the quality of their care and outcomes using quantitative indicators.

The Chronic Illness Care Model for Behavioral Health Services

Medical education and most health care are oriented toward the needs of patients with acute illness. However, the health care system is poorly organized to address prevention or care of patients with chronic illness, but chronic illness dominates health care: perhaps 70 percent of all care focuses on the chronically ill. Evidence of effectiveness from applications of the model in both the public and private sectors is quite robust for several chronic illnesses: congestive heart failure, diabetes, chronic obstructive pulmonary disease, asthma, and depression in primary care. In models testing the chronic illness care model for depression in primary care, psychiatrists generally function as educators and system/patient-care consultants to primary care providers and care managers, those who deliver basic treatment. Psychiatrists in the system can evaluate non-responding patients and either continue to provide care for non-responding patients or refer them back to the primary care provider with a recommendation for continuing care. The Bureau of Primary Healthcare (BPHC) and the Institute for Healthcare Improvement applied this model of care to their underserved populations. Using the PHQ-9 as the basic measure of severity and outcome, the faculty of these collaboratives developed 13 indicators to monitor individual patient progress and aggregate quality for specific populations with depression. These include indicators such as: percentage of patients with major depression who have a documented clinical contact within 1–3 weeks after initiating antidepressant treatment; percentage of patients who have a PHQ-9 reassessment within 4–8 weeks of beginning treatment; percentage of patients who have a 5-point drop in PHQ-9 score; percentage of patients who have a 50 percent drop in PHQ-9 within 4 months of treatment initiation, etc. Psychiatrists, like their general medical counterparts, who practice in settings using a chronic illness care model will need to function in new ways, including coordinating care with care managers, monitoring

patient progress and outcome with quantitative measures, providing routine support of patient self-management, and using real-time decision support.

The Collaborative Primary Behavioral Health Care Model

The collaborative care model originated with pioneering work on the identification and treatment of patients seen in primary health care who are impaired by depression or anxiety. These patients require more complex treatment plans than other primary care patients, and often do not adhere or respond positively to treatment regimens, thus incurring substantial additional costs and creating a burden for primary care providers (PCPs) and society. Katon and Unutzer note:

> After controlling for socioeconomic factors and medical comorbidity, primary care patients with anxiety and depressive disorders have been shown to have up to twofold greater medical costs compared with patients without mental health disorders . . . Patients with anxiety and depressive disorders have also been shown to present to primary care approximately 70% of the time with physical rather than mental health complaints . . . Those presenting with physical complaints are more likely to have delay in mental health diagnosis or misdiagnosis . . . Patients with anxiety and depressive disorders have also been found to have two to threefold more physical symptoms on medical review of systems even after controlling for medical comorbidity, which may explain the large increases in medical costs these patients have.

In order to address these challenges, similar to those that led to the development of the chronic illness care model, the collaborative care model integrates primary medical care and psychiatric care with a third "team member" who serves as a care manager. The care manager (typically a social worker or nursing professional) works in the primary care practice and meets at greater length and more frequently with the patient than either the primary care physician or psychiatrist. The care manager provides the patient with health education, monitors the severity of the patient's mental health symptoms (often with brief validated questionnaires) and impairment, develops a personalized practical plan for the patient to follow in putting prescribed medical and psychiatric treatments into effect on a daily basis, and monitors and assists the patient in achieving and maintaining adherence to the medical and psychiatric treatment regimen.

In the collaborative care model, the psychiatrist primarily serves as a consultant to the PCP, with the care manager serving as communication bridge between the doctors and as a physician extender for both the PCP and psychiatrist. The psychiatrist may have no direct contact through appointments with the patient, unless symptomatic worsening indicates a need to transfer the mental health care to the psychiatrist in order to prevent or resolve crises. The key role for the psychiatrist is managing the psychotropic regimen and patient adherence to it. This model has robust research support from more than 75 studies over the past two decades, and

has been implemented on a large scale in several ongoing projects.

Although very similar to the chronic illness care model (as applied to depression in primary care), the collaborative care model generally emphasizes the role of the care manager and has been extended to other psychiatric illnesses, such as panic disorder and PTSD. Collaborative care generally rests on shared care among the three providers. The role of the psychiatrist is generally more formally integrated than in chronic illness care applications (some chronic illness care implementations have been successful without a psychiatrist). Extension of the collaborative care model will require psychiatrists to learn to function as part of a team caring for psychiatric patients in general medical.

The Care Coordination Model

The concept of Care Coordination is built into the ACA framework and is one of the core concepts associated with an improved health care system. Care Coordination involves the integration and efficient coordination of care that spans all conditions, needs, capabilities, and preferences an individual patient might have, catalyzes meaningful, timely communication across all providers, and ensures that the communication involves patients and their families. The goal is to reduce fragmentation of care and improve the experience of care. Whereas *collaboration* involves the process of working together, *coordination* involves a higher-order functioning of developing and guiding a therapeutic plan and integrating the inputs from multiple sources. Clearly if Care Coordination is to be effective in the way envisioned by the ACA, the multiple steps involved in such coordination, virtually unprecedented in health care, will require time and patience. The question posed to payers is whether adequate compensation has been built into the incentivizing component of meaningful use to drive what is needed in true Care Coordination. Communication between generalists and specialists has been a documented problem for decades. For example, one study found that communication from specialists back to referring generalists occurred from 55 to 80 percent of the time; another study reported that referring generalists reported receiving communication from specialists 50 percent of the time within 3 months after the referral was made. On the other side, a survey of pediatric specialists reported that less than 30 percent receive communication about the majority of patients referred from other physicians and two thirds of specialists receive no information from referring physicians before seeing those patients. Care Coordination goes beyond this aspect of communication and coordination, involving not just health care providers but potentially community and state agencies, schools, workplaces, etc.

Role of Training in Health Care Reform

A hundred years after the Carnegie Foundation published Abraham Flexner's penetrating and important work on *Medical Education in the United States and Canada* in 1910; the Carnegie Foundation released its *Educating Physicians: A Call for Reform of Medical School and Residency* in 2010. The authors noted that in undergraduate and graduate medical education, inadequate attention was being paid to patient populations, health care delivery, effectiveness of care, and that there was insufficient focus on attending to the knowledge and skills required by trainees to meet the health care needs of the United States. One observation was that the inculcation of fundamental professional values was being impeded by the pace and commercial nature of health care. In the process of training and educating, there needed to be standardization of learning objectives with a focus on the individual learner, have formal knowledge and clinical experience better integrated, help trainees develop habits of inquiry and innovation, place greater emphasis on professional identity formation, and train in integrating education, advocacy, investigation, innovation, and systems management.

The Annapolis Coalition on the Behavioral Healthcare Workforce has called for sweeping reform in both pre-professional training and in the retraining of the established workforce across disciplines as part of the movement toward health care reform. Standards for training tend to lag behind societal need and the politics of change. Introducing reform concepts into any discipline is challenging for that particular discipline. Historically disciplines have a self-concept of being separate from others and focus on those elements that make them unique. In addition, standards for training in any discipline may be subject to intra-discipline politics as "schools of thought" vie for inclusion or even pre-eminence (e.g., in psychiatry, the historical rift between biological and psychological emphases). The extent to which standards for training have considered how health care reform fits into pre-professional training is unclear. It would seem that for a discipline to be relevant, it must incorporate a societal reform perspective. The Accreditation Council for Graduate Medical Education (ACGME) set in motion some profound changes in establishing its core competencies that determine proficiency across all of medicine: Practitioners must be competent in patient care, medical knowledge, interpersonal communication, practice-based learning, systems-based practice, and professionalism. The IOM's six aims for health care—that it be safe, effective, patient centered, timely, efficient, and equitable—interdigitate well with the ACGME core competencies. The Accreditation Council for Continuing Medical Education (ACCME) is placing greater emphasis on professional life-long learning, linking education with quality improvement and patient safety rather than simply "meeting" compliance standards for "CME credit." The American Board of Medical Specialties (ABMS) is focusing on meaningful quality improvement for physicians as

part of their Maintenance of Certification (MOC) for their specialty boards.

The retraining of the existing workforce in a reform perspective is complicated. People tend to work in learned patterns, and if there are no incentives or disincentives to change those patterns, the likelihood of change is reduced. Once trained, do clinicians pretty much do the same thing, or do they incorporate meaningful advances into the ways they practice?

The impetus for health care reform is broad, with issues pertaining to economics, access, outcomes, equity, quality, and increasingly, interdisciplinary teamwork being at the forefront. Many appear to have interpreted the raison d'être for health care reform as primarily economic, and the main mechanism used is withholding care to save costs. On this basis, many understandably would find the concepts of reform difficult to accept. What gets blurred in the interpretation and understanding of the need for reform is the conclusion by influential reports that the US health system is fundamentally broken: it frequently causes harm, quality problems abound, and sweeping changes are needed that will have a multitude of effects on the people who work within it, as well as on the people who are served by it. New models of training at the pre-professional level within the framework of an interdisciplinary collaboration will be the sustaining force of reform. For example, having inter-disciplinary training begin at the pre-professional level at the level of graduate professional training where the relevant disciplines have, as part of their core experience, being trained in the context of the Interdisciplinary Team, mirroring what is happening in PCMHs and ACOs. Even earlier, at the collegiate level, developing "pipelines" for trainees where they engage in cross-discipline clusters, simulating the interactions and processes necessary for there to be functional collaboration once these individuals enter the workforce (e.g., students who are pre-medical, pre-nursing, pre-social work, pre-psychology, etc., engaged in learning how to work in effective team structures). However, this will be very difficult to achieve. It is important that those individuals involved in training and those who establish the standards be capable of presenting the full picture of the rationale for reform and how training needs to respond to this rationale. The most effective arguments for changing practice and training are likely to be ones that are broadly embraced, which means that they have to be broadly understood. Improving quality in health care is a goal shared by all, but understanding why improvements are needed is more fundamental to change.

For societal relevance pre-professional training programs should do the following:

- Train in an interdisciplinary model in which trainees from the relevant behavioral health disciplines learn to work together, coordinate care, and

focus on outcomes and the application of evidence-based approaches; training in innovative concepts such as P4P and PR should be incorporated into training programs.

- Train in the integration of behavioral health services into primary care systems.
- Explore the development of a behavioral health facilitator or concierge with whom individuals and their families make first contact and whose role is to direct individuals to the proper care required.

The qualities and capabilities of the psychiatrist of the 21st century who could provide credible care within this type of paradigm are outlined in Table 58.2–6.

Health Care Reform and Psychiatry: Future Challenges and Opportunities

Achieving the systemic changes recommended by the IOM 2006 Report and put into play at least partially by the ACA, and ultimately fulfilling the goals of the Triple Aim, is an exceedingly complex challenge. Key questions for continued health care reform include the following:

- ***Social contract***. What social contract or premise underlies health care? Is health care a "right"—as economists would say, a *public good* worthy of public support?
- ***The social safety net.*** What should its scope be? Individuals with limited financial means and older adults are most at risk.
- ***Financing method***. What approach should be used to finance health care—a nationally administered system financed by taxes ("single payer")? Shoring up the existing employer-based system for workers and their families ("employer mandate")? Or requiring individuals to buy insurance with the support of tax incentives ("individual mandate")? On the provider side, CMS' Bundled Payment for Care Initiative (BPCI) is showing interesting results when applied to high-cost procedures.
- ***Empowering consumer choice***. Should *consumer choice drive market forces* to shape the operational features of a patient-centric health care system? How can consumers be supported to make good decisions for themselves and have their interests represented collectively in the face of the complexities of modern health care?
- ***Market structures***. How should market forces be structured so that they focus plans or organized delivery systems on *quality, safety, and efficacy* as defined by both consumer preferences and standards formally set by the medical/scientific community?
- ***Cost containment.*** What is a fair and effective way to finance basic health care for everyone at reasonable cost?
- ***Quality and Workforce/System Improvement.*** How should the rate of improvement in health care increase?

Table 58.2–6.
Profile of the Psychiatrist of the 21st Century

Knowledge Base	Skills
An excellent physician and diagnostician; has core knowledge of the range of psychopathology	Provides cost-effective, quality mental health care; works to preserve patient benefits; uses benefits stringently and only as required
Knowledgeable at a mechanistic level in sophisticated psychopharmacology; strong knowledge base in drug–drug interactions	Interfaces readily with primary and specialty care physicians and systems; can be a teacher to them and a caregiver to their patients; possesses strong consultation-liaison skills
Knowledgeable about brief therapies, care coordination	Works comfortably within a multidisciplinary team system; can assume team leadership role if indicated
Strong sense of individual and group dynamics and systems	Effectively deals with acute and chronic patients; uses shared decision-making in working with patients and families
Sense of economics and fiscal realities; understands the implications of health care reform, managed care, and utilization management; can work quickly and efficiently	Refers patients to the most appropriate level of care and matches treatment with patient; can use the continuum of care in treating patients
Can comprehend quality research and can understand the potential application of research to clinical work	Has good outcomes
Has a public health perspective and population-based focus; can work in the context of recovery and rehabilitation	Has demand management skills, especially for high-use patients; engages in prevention, health education, health literacy

Adapted from Meyer RE, McLaughlin CJ, eds. *Between Mind, Brain, and Managed Care: The Now and Future World of Academic Psychiatry*. Washington, DC: American Psychiatric Press; 1998 and Huey LY. Problems in Behavioral health Care: Leapfrogging the status quo. *Admin Policy Ment Health*. 2002;29:403.

As of 2014, of 230 quality measure established by the Agency for Health Care Research and Quality, about 160 have been adopted at a median rate of 2.3 percent/year with a median improvement rate in quality of care at only 1.6 percent/year: improvement is a slow process. How can health care workers improve their competency in what they do? Research shows, for example, that physicians are not very good at self-assessment of their competency and what they need to learn. How can systems improve more rapidly? In recent years, the concept of the *Rapid Learning Health Care System* has evolved, another body of reform work emanating from the Institute of Medicine and the Patient-Centered Outcomes Research Initiative, the latter spawned by the ACA, to speed up the process for practical research related to clinical improvement that can be introduced quickly to make a difference in health care function and outcomes.

At the same time, Emanuel predicts six megatrends that have been projected by 2025. These are:

- Health insurance companies will no longer function as they have historically
- Physicians and hospitals will focus on health maintenance for people having chronic illnesses, keeping them out of emergency rooms and avoiding hospitalization; routine screening for mental illnesses will be widespread with rapid intervention the norm
- Approximately 1,000 of the roughly 5,000 acute care hospitals will close; remote technologies for assessment and monitoring will be commonplace
- Employer-sponsored health insurance will become less common, projected to be available to fewer than 20 percent of workers
- Health care inflation will end
- Medical education will be transformed with 3-year medical schools and shorter residencies; half of training will be outside of hospitals; interdisciplinary team training will be the standard; population health and prevention will be significant components of medical education and training

The issues involved in reforming health care, including the ACA, and the transformational processes that they entail, are major public policy questions that require the expertise of a broad range of disciplines, from economics to ethics to basic public philosophy. It will take a decade or more for the reform process to play out to see what happens, but as mentioned earlier, there are encouraging initial signs. It is important to ensure that behavioral health providers and the medical specialty of psychiatry provide a clear vision, are a meaningful part of the dialogue, and are prepared to play a constructive role in the process of transformation brought about by the ACA and the necessity of reform.

▲ 58.3 The Role of the Hospital in the Care of Persons with Mental Illness

JEFFREY L. GELLER, M.D.

INTRODUCTION

Throughout the 19th century and for the first half of the 20th century, public psychiatric hospitals (and some private ones as well) provided all the roles necessary to take care of psychiatric patients. The state hospital was the source for inpatient, outpatient, case management and outreach, and emergency services. If someone needed admission, a family member could simply transport him to the front door. With the shift from inpatient to community-based services that began in earnest in the mid-20th century, admission to, discharge from and services within the psychiatric hospital became both more complex and more convoluted. Layer upon layer of agencies, services, and regulations facilitated and impeded the psychiatric hospital in its mission (see Fig. 58.3–1).

The reasons for the evolution of this relationship between the psychiatric hospital and its prospective and actual patients are multifactorial. As Figure 58.3–1 illustrates, there are entities with overlapping but competing agendas at every turn. Fundamentally, there are two predominant factors that account for the contemporary, tortuous, labyrinthine interface between the psychiatric hospital and the community. First, the psychiatric hospital, in a manner quite distinct from the general hospital, plays two roles: clinical services and public safety, thus, the extensive interface between the psychiatric hospital and the criminal justice system (see Fig. 58.3–1). And second, psychiatry, more than any other field of medicine, has been inundated by gyrations of conflicting actions to decrease the cost of care and treatment, thus the barriers and alternatives to psychiatric hospital admission (see Fig. 58.3–1).

The first one-and-one-half decades of the 21st century have not been kind to psychiatric hospitals. Virtually every state in the United States is experiencing a shortage of psychiatric beds. These shortages include acute care beds, intermediate and long-term care beds, and forensic beds. The effects of these bed shortages are increased waiting lists for state hospital beds, increased waiting lists for other psychiatric beds like general hospitals and Veterans Administration (VA) psychiatric beds, overcrowding in state hospitals, backups and boarding in general hospital emergency departments (EDs), and premature discharges from acute care settings. These shortages have also meant a shift of persons with serious mental illness (SMI) behind locked doors from public hospitals to jails and prisons. These psychiatric bed closures come from all types of hospitals. Sixty-four

percent of states have experienced declines in the number of general hospital specialty unit psychiatric beds, and 19 states have experienced a decline in the number of private psychiatric hospital beds. Nationwide, the number of state and county hospital beds declined by 86 percent (369,999 to 52,612) between 1969 and 2002; the number of VA medical center psychiatric beds declined by 84 percent (51,696 to 8,386) within the same time period. The inaccessibility of psychiatric beds is a regular feature in news stories and editorials, often with a link between that and a local or national tragedy.

Lengths of stay have plummeted. Between 1990 and 2010, the length of stay of hospitalizations for SMI in acute care settings decreased by 50 percent (from 14 days to 7 days). Private insurers represent a shrinkage percentage of payments for hospital services, especially for substance abuse services. About 50 percent of all payments for psychiatric inpatient services were from government programs; state governments' funding increased by 65 percent just between 2000 and 2001.

Hospital-based outpatient services grew by 78 percent (242,301 episodes to 1,104,300) between 1969 and 2002. In 2002, however, hospital-based outpatient services represented only 31 percent of all outpatient episodes of care for psychiatric disorders.

The shift of resources from hospital to nonhospital services is reflected by the changing distribution of expenditures by state mental health authorities (SMHAs). Inpatient services received 63 percent of the SMHA budget in 1981, 50 percent in 1993, 28 percent in 2004, and 23 percent in 2012. Although the overall inpatient percentage decreased, the proportion going to forensic patients increased to 33 percent of all state hospital expenditures.

While there has been a shift in public expenditures from inpatient to outpatient services, there has been an overall decrease in public expenditures for psychiatric treatment. In fiscal years 2010 and 2011, the biggest cuts were directed at state hospitals with 20 and 15 states, respectively, cutting state hospital funding. Less funding meant fewer individuals could be serviced in state hospitals with 31 states decreasing the persons they admitted comparing 2007 to 2009.

At the same time, the demand for state hospital utilization increased in 18 percent of the states, in part because states were also making cuts in all manner of community-based services. Between fiscal years 2009 and 2011, 17 states had cuts in their overall state mental health expenditures by greater than 1 percent, with 5 of those states exceeding 20 percent (one state approached 50 percent).

FIGURE 58.3–1. The psychiatric hospital in the context of the community.

Marshalling scarce resources has led to synergies among various sectors within a state. In just more than 75 percent of the states, community-based programs (often at general hospitals) perform a gate-keeping function to state hospital entry. Some states (38 percent) require general hospital admission prior to a transfer to a state hospital. And in all but five states there are assisted outpatient commitment (AOT) (involuntary outpatient commitment) laws on the books with an expectation these can be used to decrease both inpatient and overall mental health services costs.

The picture does not look optimistic, at least for the immediate future. About half of the states are reorganizing their state hospitals, including downsizing, reconfiguring, closing, and/or consolidating. Despite this, 11 states still have 6 or more state hospitals each. And a surprising number of states are building new state hospital buildings, but these generally replace one or more existing state hospitals and usually do not reflect an increase in beds (see Table 58.3–1). As more patients are admitted under forensic commitments, lengths of stay increase, and so does the unavailability of beds to others. In 2006, about 40 percent of patients found not guilty by reason of insanity had lengths of stay of 1 to 5 years and about 38 percent had lengths of stay of greater than 5 years.

While the place of psychiatric hospitals as a tool in the resources box of treatment for mental illness is shrinking, the need is growing. On any given day in fiscal year 2010, the number of noninstitutionalized individuals with an episode of serious psychological distress in the past was 3 percent of the population. In 2012, 4.1 percent of the adult U.S. population had an

episode of SMI in the past year. The 12-month prevalence for schizophrenia in adults was 1.15 percent, while it was 3.5 percent for post-traumatic stress disorder (PTSD) (one-third of these classified as severe), 9.1 percent for any personality disorder, and 18.1 percent for anxiety disorder (23 percent of these classified as severe). The mismatch between need and services is no better represented than by the fact that in 2008 over 40 percent of adults in the United States with an SMI did not receive any treatment for a mental health problem. Of those that did, 7.5 percent had an inpatient and 40.5 percent had an outpatient episode of care.

The state of hospital psychiatry raises questions about how it came to play the roles it does. What were the historical influences that brought the psychiatric hospital to where it is, and what keeps it there? How does the psychiatric hospital (this term will include general hospital psychiatry units) fulfill its current role? And what should be the roles of psychiatric hospitals in the future?

THE HISTORICAL EVOLUTION OF THE ROLE OF THE HOSPITAL

Prior to the 19th century, the care of insane persons was custodial in nature, took place largely in almshouses, and was predominantly a local endeavor. State care, at the beginning, meant an institution established, built, and managed by the state but whose operation was not funded by the state. Payers were, in descending order of priority, the patient, the family, and the county. The earliest public facilities—in Williamsburg, Virginia, and Columbia, South Carolina—functioned in this manner. The state taking responsibility for all insane persons and performing its responsibility through state-managed and funded hospitals began with Worcester State Hospital in 1833.

VA	Western State Hospital	2013	250

Before there were any more than a few public hospitals, there was already a well-established group of private psychiatric hospitals. Three of these began as parts of general medical hospitals: The Institute of the Pennsylvania Hospital, Bloomingdale Hospital (New York), and McLean Hospital (Massachusetts). Three more were freestanding institutions: Butler Hospital (Rhode Island); Brattleboro Retreat, which began as the Vermont Asylum for the Insane; and the Hartford Retreat, which subsequently was renamed the Institute of Living (Connecticut). Two of the hospitals began under the aegis of religious organizations: The Friends Asylum (Pennsylvania) was initiated by a Quarterly Meeting of the Philadelphia Society of Friends and the Mount Hope Institution (Maryland) was a Catholic hospital that began as the Mount Saint Vincent Hospital.

Of these larger private facilities, all but one preceded the state's first public hospital, sometimes by more than 50 years. The private hospitals helped the state to meet its obligations to the insane poor by admitting "public" patients. Payments were made by the state to the private facility,

and some treatment was given without charge. Thus, the states' purchase of beds from the private sector was not a novel concept of the late 20th century but is actually how U.S. hospital psychiatry began.

Many public and some private hospitals throughout the country were built under a design put forth by Thomas Kirkbride, a founding member of the American Psychiatric Association (APA). In his book, *On the Construction, Organization, and General Arrangements of Hospitals for the Insane*, Kirkbride prescribed every aspect of hospital construction and operation. His prototype hospital, variations of which can still be seen across the United States (but are fast being torn down), is shown in Figures 58.3–2 and 58.3–3. Noteworthy among his recommendations is that a 250-bed hospital would have 16 wards, with about 15 patients per ward.

By the 1880s, most psychiatrists agreed that "insane patients can best be managed away from their own homes." Parsons, an alienist of the era, opined, "well-equipped and well-managed asylums for the insane are among the most important of the outgrowths of modern civilization and benevolence." By the end of the 19th century, it was clear that private facilities were for the wealthier, more genteel class of citizens, who were able to pay fees and were provided remarkably comfortable accommodations. Public hospitals were entities of state, county, or municipal governments that served not only the poor but also the middle class, given that the latter could not afford private hospitals.

A major difference between the public and private facilities is that public institutions sought to lower their censuses as state hospital populations grew and patients had progressively longer lengths of stay, whereas private facilities sought patients to maximize their occupancy rates. A fundamental criticism of private facilities was pointed out by Parsons: "It is not for the interest of the proprietor of a private asylum to cure his patients, and hence they may not make an honest effort to promote their cure." Much of what many consider to be modern developments in hospital psychiatry were well under way before the end of the 19th century: Oversight of private hospitals by state boards, advertising by private hospitals, involuntary admissions to private hospitals, more perks for higher fees, and the "dumping" of patients from the private to the public sector.

FIGURE 58.3–2. Exterior of hospital prototype designed by Thomas Kirkbride. (From Kirkbride TS. On the Construction, Organization, and General Arrangements of Hospital for the Insane. Philadelphia, PA: J.B. Lippincott; 1880.)

Work and recreation were both seen as important to the mental health of patients in the 19th century. Generally, the public hospitals did better with the former, and the private ones with the latter. Recovery, employment, and wellness are not novel ideas of contemporary hospital psychiatry. Each was endorsed more than 150 years ago in both public and private hospitals.

Nor is evidence-based psychiatry a new thought. Andrews articulated in 1887 that "the unparalleled progress in neurology, cerebral anatomy, physiology, pathology and localization of function has enlarged the horizon of our knowledge of disease and of the action of causes." This progress, he said, "furnished a scientific and positive basis for treatment in many cases of insanity which before was unattainable." Inpatient treatments near the end of the 19th century included such modalities as electricity, massage, oophorectomy, enforced rest, hydrotherapy, and physical training.

Changes in hospital psychiatry over the first half of the 20th century were dramatic. Psychoanalysis was introduced to the inpatient setting in the 1920s and somatic treatments such as insulin coma, Metrazol shock, and electroconvulsive therapy in the 1930s. In the 1940s, attention was focused on developing milieu therapy, whereas in the 1950s, the introduction of the first antipsychotic medication, chlorpromazine, fundamentally altered inpatient psychiatry.

FIGURE 58.3–3. Interior of hospital prototype designed by Thomas Kirkbride. (From Kirkbride TS. *On the Construction, Organization, and General Arrangements of Hospital for the Insane*. Philadelphia, PA: J.B. Lippincott; 1880.)

The mid-1950s began the shift from hospital-based to nonhospital-based care and treatment of persons with mental illness, a movement retrospectively labeled "deinstitutionalization" but perhaps better termed "dehospitalization." General hospital psychiatry and day hospitals became major loci of care and treatment, and the role of the psychopathic hospital expanded. Units in general hospitals were not always welcomed by hospital medical staffs, who were concerned that psychiatric patients, whom the physician thought would overwhelmingly be noisy, destructive, violent, or suicidal, would disrupt the general hospital.

The darkest era in U.S. hospital psychiatry was in the 1940s, a time when care of persons with mental illness was described as a national disgrace. Attempts were made to improve inpatient treatment through the promulgation of principles and standards, such as those put forward by the Division of Mental Hygiene of the U.S. Public Health Service, the National Committee for Mental Hygiene, and the APA's Committee on Psychiatric Standards and Policies. These probably had less effect than exposés such as Mary Jane Ward's *The Snake Pit*, a fictionalized first-person account of life in a state hospital.

Whereas the public sector was overburdened and overrun, by 1950 the private sector was also facing financial difficulties. The Medical Director of McLean Hospital stated at the 1950 APA Institute, "The time when you could run a private hospital as a hospital and make money has gone. Operating expenses have so increased that it is almost impossible to collect the cost from our patients."

In the 1960s, as health insurance for hospitalization expanded to include psychiatric treatment, psychiatric hospital treatment outside of state hospitals became more available. Misuse of insurance for hospitalization for mental illness was quickly recognized. To remedy the manipulation of hospital benefits, interventions were introduced: Peer review, reimbursement for partial hospitalization, and reimbursement for other alternatives to inpatient treatment. "Dumping" and "cost shifting"

emerged as part of the everyday life of inpatient psychiatry.

In the 1970s, states were contemplating phasing out state hospitals. General hospital psychiatric units were becoming more of a presence. The expanding role of general hospital psychiatry drew caution from some who warned workers in general hospitals to be watchful of efforts to convert general hospital psychiatric units into mini state hospitals. Declining numbers of individuals willing or able to pay for private hospital treatment and more available third-party coverage led private hospitals to admit patients of different socioeconomic classes and ethnic backgrounds and to keep all patients for shorter lengths of stay.

In the 1980s, there was a remarkable growth in private sector hospital beds. Private corporations were rushing to build psychiatric hospitals as less regulation, lower overhead, and greater latitude in insurance reimbursement meant there were huge profits to be made in the "psychiatric hospital industry." For-profit psychiatry grew, but with it came a new set of problems. For-profit hospitals were the least likely to treat the most functionally disabled; would treat few if any patients who could not pay for treatment; usually had poorer staff-to-patient ratios than nonprofit hospitals; failed to provide education and training; failed to contribute adequately to research; and overall provided a lower quality of care. These hospitals tended to be totally disengaged from the communities in which they were located; they paid higher salaries and thus hired away graduating residents from academic and public sector positions.

The heyday of for-profit hospitals (most private psychiatric hospitals) did not last long. Throughout the 1990s, the total and average number of beds per private hospital decreased, as did the average length of stay. Between 1992 and 1998, private psychiatric hospital beds declined by 23 percent. For-profit companies had built "chains" of hospitals so rapidly that there quickly came to be too many private psychiatric beds, and hospital chains began experiencing major financial losses. Lawsuits against the chains for unscrupulous practices such as recruitment of patients and manipulative billing practices were settled in the hundreds of millions of dollars.

The 1990s also witnessed the privatization of public mental health services. Medicaid, Medicare, and state funds were directed to the private sector to greater degrees during the 1980s and 1990s. States assisted freestanding private hospitals in obtaining waivers of the Institution for Mental Disorders (IMD) rule (see later discussion). A greater reliance on the private system for those formerly treated in the public system created many unintended consequences that varied state by state, including inpatient treatment further from one's community, less continuity of inpatient treatment, new patterns of recidivism, and certain patients being blacklisted at some hospitals.

In 2001, 37 percent of general hospitals had psychiatric inpatient care.

This percentage is higher than those with psychiatric emergency, consultation-liaison (C-L), or even outpatient services. Hospital psychiatry in the United States continued to be a *business*. However, in the business of psychiatry, nonprofit psychiatric care providers compared favorably with for-profit providers.

It is interesting to note how the practice of hospital psychiatry appears to have shifted in response to shorter lengths of stay. A study at McLean Hospital in 2002 that compared inpatient antipsychotic medication use in 1989, 1993, and 1998 showed the chlorpromazine-equivalent final total dose of all antipsychotic medications used at discharge in 1998 was 29.3 percent greater than in 1993 and 46.1 percent greater than in 1989. The average time from admission to first antipsychotic dose decreased dramatically from 6.8 days in 1989 to 1.5 days in 1993 and .9 day in 1998. Two or more antipsychotic medications were used during 20 percent of inpatient days in 1998, compared to 5.7 percent days in 1993 and 1.7 percent in 1989. Pressures to discharge patients reduced not only the length of treatment but also the content of treatment.

In the first decade of the 2000s, the prospects for the private psychiatric hospital and for general hospital psychiatric units did not look good. Although overall health care spending increased by 15.7 percent between 1992 and 1999, mental health and substance abuse spending decreased by 17.4 percent. Behavioral health care spending went from 7.2 percent of total private health insurance spending to 5.1 percent over this same time period. Reimbursement rates fell such that they often did not even meet the total costs of care and treatment. While reimbursement rates fell, costs to deliver treatment increased.

Private hospitals were offering fewer services. Those hospitals offering partial programs decreased from 82.5 to 66.7 percent, and those offering outpatient services dropped from 64.2 to 49.2 percent between 2000 and 2001. At the same time, oversight increased. The Office of the Inspector General (OIG) of the Department of Health and Human Services, the Joint Commission on Accreditation of Healthcare Organizations, and the Center for Medicare and Medicaid Services all stepped up investigations of hospitals. Medicaid's progressive decrease in disproportionate share payments (DSHs) to public mental hospitals is taxing some states' ability to operate their public system at its pre-2000 scale.

The landscape of U.S. inpatient psychiatry became so rough that well-established private hospitals closed or moved. Those in the former category include Taylor Manor and Chestnut Lodge in Maryland. In the latter category, the best known is the Menninger Clinic, formerly of Topeka, Kansas, and now in Houston, Texas. In the public sector, state hospitals, well established since the 19th century, began reinventing themselves, usually by consolidation of multiple public hospital and by new construction such as Worcester State Hospital (Massachusetts), Oregon

State Hospital, and Western State Hospital (Virginia). Furthermore, the need to serve and contain persons with mental illness and histories of sexually problematic behaviors is diverting resources from the treatment of psychiatric disorders. California built a 1,500-bed facility for forensically committed individuals—mostly sexually violent predators—representing the first new California facility in more than 50 years. Even elderly individuals with such histories can often not be discharged for the public psychiatric hospital as federal law prohibits nursing homes form admitting persons who are classified in the highest level of sex offenders.

As components of psychiatric services in the second decade of the 21st century, psychiatry hospitals are shrinking, growing, being torn down, and being newly built all at the same time. As hospitals are unable to meet the needs of the population requiring inpatient level of care, local police have become the triage agents for persons with serious mental in the streets; jails and prisons are unofficial replacement facilities for state hospitals; and mental health courts provide mores case management than anything else. One potential positive note is the growing number of new public psychiatric hospitals built with a hope that the building's design will facilitate patients' recovery (see Table 58.3–1). It is well worth remembering, however, the observation made in the wake of newly constructed community mental health centers (CMHCs) with inpatient units in the 1970s: the latest in "psychoarchitecture" and design elements do not result in behavioral remediation since clinical improvement does not result simply from changing bricks, mortar, and furniture. That being said, newly built hospitals, most of which have had significant problems with translating programmatic and life safety design concepts into actual hospital structures, have brought more pleasant surroundings, in an overall safer environment, with more available space for in- and outdoor programming (see Figs. 58.3–4 and 58.3–5). These figures are presented as an example and not as a model.

Available psychiatric beds in general and private hospitals appear to be made inaccessible to patients by insurance providers because limiting admission to hospitals with which they have negotiated rates is one means to control cost. As reimbursement rates drop below the actual expenditures of the general hospital, these hospitals limit the third-party payers with which they will contract or further reduce or eliminate psychiatric beds, exacerbating the bed shortage.

Public psychiatric beds are highly disproportionately occupied by forensically committed patients. This makes beds for civil admissions less available and patients are stuck in general or private psychiatric hospital beds, which in turn delays the movement of psychiatric patients needing admission out of the ED. Waiting time in an ED can be up to 1 month for a psychiatric bed, or the patient is prematurely discharged from the ED, sometimes with lethal consequences.

Despite ascriptions of causality for the current state of hospital psychiatry to malevolence, malfeasance, and malversation, it would seem more accurate to see the role of the psychiatric hospital in the second decade of the 21st century as still the result of a basic tension between clinical benefit, social control functions, and parsing out of costs. Each governmental level and each government agency wants another one to fund the treatment of mental illnesses.

Despite all of these uncertainties, there is no indication that psychiatric hospitals will cease to play some role in the future. The remainder of this section focuses first on defining the role of the hospital and then on implementing that role.

DEFINING THE ROLE OF THE PSYCHIATRIC HOSPITAL

Clinical Rationale

The clinical rationale for the role of the psychiatric hospital was well established by the mid-18th century. Edward Jarvis, a nonpsychiatrist physician well enmeshed in psychiatric care of his era, stated it as well as anyone. First, Jarvis discussed his thoughts on "diseases of the mind":

> Maladies of the mind, like those of the body, require that the causes that produced them shall cease to act upon them. Unfortunately the diseases of the mind frequently find their origin in the circumstances and associations of home, in the cares and anxieties of business, in the relations of neighborhood, in the affairs of the town, in the movements of religious, political or other associations, in the habits of indulgences which are practiced. Or when the diseases are once established, they may be kept up by some of these. Moreover, the natural perceptions and moral sensibilities being disordered, the scenes, circumstances, and the persons, which are usually agreeable and favorable, in health, become objects of aversion and sources of irritation and keep the disorder alive.

Then Jarvis provided his thinking on why hospitals were needed to treat persons with these diseases:

> As the lunatic cannot be separated from these, while in his own house, he must go from them and generally among strangers. It is needful that the mentally disordered not only go away from home, but be placed where all the circumstances and associations are different from those to which he has been recently accustomed, and where all the influences that may reach him, can be controlled and modified, so that none but such as are favorable may affect him. They will be found in the hospital [where] the officers and the attendants are selected on account of their peculiar fitness for their work. They have the high intelligence, the scientific knowledge, and the moral endowments of gentleness, and firmness, and sympathy that are required, and they know how to occupy the diseased mind and lead it from its morbid fancies, and fix it upon cheerful and satisfactory subjects.

FIGURE 58.3–4. Worcester Recovery Center and Hospital (WRCH). Exterior view.

FIGURE 58.3–5. Worcester Recovery Center and Hospital (WRCH). Interior view.

Jarvis provided a quite optimistic prognosis if his recommendations were followed, but one quite consistent with those of his professional colleagues: "If insane persons are allowed to enjoy the means of healing in the early stages of their disorder, within one year after it appears, about 75

to 90 percent, can be restored to health." Furthermore, he argued for prompt hospitalization with the onset of symptoms:

> But in this class of maladies, time makes rapid havoc, and diminishes the changes of cure. If the means of healing are not tried within the first year, the ratio of cures is reduced perhaps a half in the second and still more in the third year, and when five years of neglect shall have elapsed, the hope of restoration is reduced to a mere accident, which no human skill can promise to accomplish.

By the mid-19th century, it was also clear to those who treated persons with insanity that the hospital had much to offer those in need of acute treatment due to advances in the field. Samuel Woodward, the first president of the APA, noted the following in 1846:

> The abandonment of depletion, external irritants, drastic purges, and starvation, and the substitution of baths, narcotics, tonics, and generous diet, is not less to be appreciated in the improved condition of the insane, than the change from manacles, chains, by-locks and confining chairs, to the present system of kindness, confidence, social intercourse, labor, religious teaching, and freedom from restraint. In this age of improvement, no class of mankind have felt its influence more favorably than the insane.

Hospital treatment continued to improve in the mid-19th century. Charles Nichols, superintendent of the Government Hospital for the Insane (St. Elizabeth's), commented as follows in the 1870s: "Much less mechanical restraint, and much less seclusion are now used in our institutions for the insane than were formerly resorted to in them. . . . I trust that we shall be able to still further reduce the proportion of cases in which restraint will be deemed advisable."

The role the physician could play in the hospital was also clear by the mid-19th century. Luther Bell, superintendent of the McLean Asylum, indicated in 1849:

> Domiciliated with our patients, ready at all hours, by day or night, to watch the effect of our prescriptions, sure of their being fairly and fully carried into effect, without hazard of the interference of timid friends or unfaithful nurses; obliged to make no disguise, no prescription for form or appearance sake, it is in our power to follow out the best convictions of our judgment, uninfluenced by aught extraneous to the object desired.

That the psychiatric hospital played a far greater role than just treating acutely ill insane persons and restoring them to health was quite clear by that time. William Awl, superintendent of the Ohio Lunatic Asylum in Columbus, wrote in 1849:

> More effort and skill is often demanded, to better the condition and make some improvement in the shattered intellects of those who are deemed hopeless, than to effect recoveries. . . . We must never permit ourselves to lose sight of humanity, but always remember the importance of the institution to all classes, and the advantages which may be secured to those whom we are obliged to regard as incurable.

Thomas Kirkbride expanded on this note in 1864, indicating the importance of the safety function played by the hospital:

Owing to various causes, but especially to a neglect of treatment in the early stages of the disease, there are a large number of the insane, in every community, whose chances of restoration are slight, but whose comfort and happiness are promoted, and their protection from ill treatment secured by a residence in these institutions, where they are under circumstances which give them the best chance for permanent improvement. To provide for this numerous class is another important object, attained by the establishment of such hospitals. Next to these come the protection of the community and the relief of private families.

These roles quickly became compromised by the services being overwhelmed by the number of patients needing to be served. By 1890, W. W. Godding, the APA's seventeenth president, was observing:

The overcrowding goes on, cots are brought out at night and laid down on the corridor floors, at first one or two in nooks and alcoves that seem quite designed for this sort of thing, but the business grows, the special adaptation of recesses and alcoves becomes less apparent as the line of beds side by side stretches in lengthening vista down the hall. And still the floors fill up until one, two, three hundred are thus nightly not accommodated but provided for. From ground floor to attic your hospital, spread with its white beds seems a very bivouac of lunatics. . . . Day by day, year after year, I have seen the individualized treatment of special cases swamped by the rising tide of indiscriminate lunacy pouring through the wards, filling every crevice, rising higher and higher until gradually most distinctions and landmarks have been blotted out.

These trends persisted, such that by 1954 Kenneth Appel, the eighty-second president of the APA echoed Godding:

There is overcrowding 20–30% in 70% of the hospitals, and 50% overcrowding in 8% of the hospitals. Hospitals are 40% understaffed in physicians; 15,000 more psychiatrists are needed; 37,000 patients in 29 hospitals have no psychiatrists, and 2,000 patients are in 5 hospitals which do not employ a full-time physician. In 4 hospitals with 6,000 patients, there are no graduate nurses.

Four years later, Harry Solomon, director of the Boston Psychopathic Hospital, proclaimed:

The large mental hospital is antiquated, outmoded, and rapidly becoming obsolete. We can still build them but we cannot staff them; and therefore we cannot make true hospitals of them. After 114 years of effort, in this year 1958, rarely has a state hospital an adequate staff as measured against the minimum standards set by our Association . . . I do not see how any reasonably objective view of our mental hospitals today can fail to conclude that they are bankrupt beyond remedy. I believe therefore that our large mental hospitals should be liquidated as rapidly as can be done in an orderly and progressive fashion.

Clinical concerns fueled the changing role of the hospital and the changing role of various classes of psychiatric hospitals (state, county, private, general hospital), but clinical concerns were never separate from fiscal concerns. It has never been clear which has been the predominant concern, but there is ample evidence accumulated over the last 150 years that economic considerations have been of no less importance than clinical considerations in defining the role of the hospital.

Social Control Rationale

Every state has statues that govern the admission of persons with mental illness, over their objection, to hospitals within their state; the involuntary

continued hospitalization of these individuals should they want to leave; the commitment of persons who have been charged with a crime and there is a question of their competency to stand trial and/or their criminal responsibility; and the transfer of inmates from jail and prisons to hospitals. Every state sets forth criteria under which an individual can be held on an emergency detention and then civilly committed and these criteria are uniformly danger to self, danger to others, and some variant of gravely disabled. The statutes for civil commitment are generally, uniformly applied across hospital type, while forensic commitments are to government run hospitals or in a few states to nongovernment hospital with contracts with the state to provide such services.

In no other field of medicine could a competent person be admitted to a hospital over his objection. This occurs only in psychiatry and is the component of psychiatry that is social control. This social control function is the most fractious aspect of hospital psychiatry. It is this aspect of psychiatric hospitals that has been the brunt of antipsychiatry movements, whether they originate with psychiatrists themselves, for example, Thomas Szasz, R.D. Laing; religious groups; or individuals who label themselves "consumer survivors."

So engulfing had the social control function of the psychiatric hospital become, that until the early 1980s, simply being an involuntary patient at a psychiatric hospital meant one could be involuntarily medicated. The argument was a simple one: what was the purpose of holding a person in a hospital against his will if you could not treat him? This changed when, through litigation, the point was made that commitment is based on dangerousness, while the right to refuse treatment is based on competency (see, e.g., *Rogers v. Commissioner of Mental Health*, 390 Mass.489, 458 N.E.2d 308 [1982]).

The objection to the social control function of the hospital is hardly new. One-hundred and seventy-five years ago Elizabeth Stone protested her admission to the McLean Asylum; 150 years ago Elizabeth Packard made a career out her protestations; and 70 years ago actress Frances Farmer tried to rally the nation to support her self-proclaimed unjust involuntary admissions and treatment.

This week, in every state in the United States, there are individuals in various stages of civil and criminal commitment. There are also individuals being medicated over their objection. And what some believe is a glorious evolutionary step forward in mental health services and others think is a malevolent regression, a progressively larger percentage of involuntary treatment is taking place outside of hospitals, through AOT, mental health courts, conditional release, representative payeeships, leveraged housing, and probation.

So entrenched have these competing interests of social control versus autonomy become that each has their own set of slogans. Those in favor of

treatment over objection in a defined set of circumstance talk about "rotting with your rights on." Those in favor of free choice no matter what the circumstances chant: "Nothing about us without us."

There is one area where the both sides together object to the use of the psychiatric hospital as a social control agent—for individuals who do not meet the criteria for having a mental illness, or whose dangerous is not on the basis of a mental illness, or who are stuck in a hospital because they have no place to go—yet are committed to the psychiatric hospital. All states have their population of individuals who are there because their psychopathic behaviors land them in hospitals; individuals whose high profile crimes make them "political prisoners" and individuals who dangerous sexual behaviors means they must be locked up somewhere. The later situation is the basis for the Supreme Court decision in Kansas v. Hendricks (see Table 58.3–2).

It is perhaps the irony of the social control function of psychiatric hospitals that law enforcement cannot get individuals into hospitals who need to be there because district attorneys, forensic review boards, families, and victims fight to keep individuals in psychiatric hospitals who do not need to be there. The social control function is highly susceptible to stigma and prejudice.

Table 58.3–2.
Federal Government and Court Actions Defining the Role of Hospital Treatment over the Last Six Decades

1955	The Mental Health Study Act of 1955 (Public Law 182) calls for a nationwide analysis and re-evaluation of the human and economic problems of mental illness. It leads to the formation of the Joint Commission on Mental Illness and Health.
1963	President John Kennedy submits to Congress a "Special Message on Mental Illness and Mental Retardation" that calls for a "wholly new national approach" to those two health problems.
1960	In *Dusky v United States,* U.S. Supreme Court affirmed a criminal defendant's constitutional right to have a competency evaluation before proceeding to trial and setting the standard for determination of such competence. This has subsequently meant many individuals are sent to state hospitals every year for competency evaluations.
1964	*Dixon v. Weinberger*, filed in U.S. District Court of the District of Columbia, claims that patients at St. Elizabeth's Hospital have a statutory right to treatment and that those involuntarily committed under the 1964 Hospitalization of the Mentally Ill Act of the District of Columbia must be placed in the least restrictive setting consistent with suitable treatment.
1965	Medicare legislation is passed. It includes limited coverage for patients receiving active treatment in state hospitals in addition to those in general hospitals.
1966	The Social Security Amendments of 1965 (Public Law 89–97) adds Title XIX, Medicaid, to the Social Security Act. Medicaid funds psychiatric treatment in general hospitals for those under categorical assistance programs and who qualify as medical indigents, and it improves coverage for psychiatric illness under Medicare.
	In *Lake v. Cameron*, a U.S. court of appeals rules that an individual could not be committed to the hospital until hospital officials determined that there was no less-restrictive facility available to care for her.

In *Rouse v. Cameron*, a U.S. court of appeals finds that a criminal defendant who is acquitted by reason of insanity and involuntarily committed to a psychiatric hospital has a right, legally enforceable through habeas corpus, to adequate and suitable treatment.

1970 *Wyatt v. Stickney* is filed in federal district court in Alabama, addressing the issue of detention without treatment of involuntarily civilly committed persons. The court subsequently finds that three fundamental conditions are necessary for adequate and effective treatment in public psychiatric hospitals: A humane psychological and physical environment, enough qualified staff to administer adequate treatment, and individualized treatment plans.

1972 In *Lessard v. Schmidt*, a federal district court decides that under the due process provisions of the Constitution, persons facing involuntary civil commitment are guaranteed the full array of procedural safeguards formerly guaranteed only to individuals charged with a crime.

1973 In *Souder v. Brennan*, a federal district court finds that patient-workers are covered by the Federal Fair Labor Standards Act, entitling them to minimum wages and overtime compensation.

1974 In *Donaldson v. O'Connor*, the U.S. Fifth Circuit Court of Appeals rules that a person who is involuntarily civilly committed to a psychiatric hospital has a constitutional right "to such treatment as will help him be cured or to improve his mental condition." The U.S. Supreme Court issues its decision in this case on June 26, 1975, finding that "a State cannot constitutionally confine, without more, a nondangerous individual who is capable of surviving safely in freedom by himself or with the help of willing and responsible family members or friends."

1975 The first class-action suit on the right to refuse treatment is filed for Boston State Hospital patients in a case originally known as *Rogers v. Okin*. (Right-to-refuse-treatment cases were basically decided on state-by-state basis to the end of the century, with very different rulings among the states.)

1975 In *Drope v Missouri*, the U.S. Supreme Court rules when deciding whether to evaluate a criminal defendant's competency, the court must considered any evidence suggestive of mental illness, even one factor alone in some circumstances. Therefore, the threshold for obtaining a competency evaluation is low. When the issue is raised, the motion should be granted. This means even more individuals sent to the state hospital for evaluation.

1976 In *Tarasoff v. Regents of the University of California*, the California Supreme Court rules that "when a therapist determines, or pursuant to the standards of his profession should determine, that his patient presents a serious danger of violence to another, he incurs an obligation to use reasonable care to protect the intended victim against such danger."

1978 In *Rennie v Klein*, the U.S. Supreme Court rules that an involuntarily committed, legally competent patient who refuses medication has a right to professional medical review of the treating psychiatrist's decision. The Court left the decision-making process to medical professionals. This decision changed the long-standing practice whereby a committed patient could be treated over his object simply because he had been committed.

1979 In *Addington v. Texas,* the U.S. Supreme Court holds that the standard of proof in civil commitment hearings is "clear and convincing," a lower standard than "beyond a reasonable doubt."

1980 The Civil Rights of Institutionalized Persons Act allows the federal government to initiate actions against states whose public institutions, such as hospitals, prisons, nursing homes, and jails, deny residents their constitutional rights.

In *Suzuki v. Yuen,* the U.S. Court of Appeals for the Ninth Circuit rules that involuntary civil commitment solely on the grounds of danger to property is unconstitutional.

1981 In a 5-to-4 decision, the U.S. Supreme Court rules that inpatients of public psychiatric institutions are not eligible for Supplemental Security Income (SSI) payments granted to mentally ill patients in other settings.

1982 In *Youngberg v. Romeo*, the U.S. Supreme Court decides that a person in an institution has a constitutionally guaranteed "right to personal security," "a right to freedom from bodily

restraint," and the right to receive "such training as an appropriate professional would consider reasonable to ensure his safety and to facilitate his ability to function free from bodily restraints."

Congress enacts the Tax Equity and Fiscal Responsibility Act (Public Law 97–248), which sets the stage for a prospective payment system for Medicare.

1985 In *Ake v Oklahoma,* the U.S. Supreme Court rules indigent criminal defendants have a right to a competency evaluation. The potential pool of persons who can be sent to state hospitals for evaluation expands again.

1990 The Americans with Disabilities Act (ADA) is enacted to eliminate discrimination against disabled persons. Title II says, "No qualified individual with a disability, shall, by reason of such disability, be excluded from participation in or be denied the benefits of the services, programs, or activities of a public entity, or be subjected to discrimination by any such entity."

1991 The Patient Self-Determination Act, a part of the Omnibus Budget and Reconciliation Act of 1990, requires health care facilities that receive Medicare and Medicaid funding to provide information to adult patients about their right to make their own health care decisions, including the right to accept or refuse treatment and to execute advance directives about medical care.

1997 In *Kansas v. Hendricks*, the U.S. Supreme Court rules that sex offenders can be civilly committed because they "suffer from a volitional impairment rendering them dangerous beyond their control" and because "far from any premature objection, the confinement's duration is instead linked to the stated purpose of the commitment, namely to hold the person until his mental abnormality no longer causes him to be a threat to others."

1999 In *Olmstead v. L.C. and E.W.*, the U.S. Supreme Court rules that the ADA requires states to provide community placement for persons with mental disabilities if the state's treatment professionals have determined it is appropriate, if it is not opposed by the individuals affected, and if it can be reasonably be provided considering state resources and the needs of other disabled persons.

Publication of *Mental Health: A Report of the Surgeon General*

2000 The Ticket to Work and Work Incentives Improvement Act permits states to increase the level of income disabled persons can earn before they become ineligible for Medicaid and extends the period that disabled persons can be employed and the income they can earn before losing Medicare coverage.

Wyatt v. Sawyer (formerly *Wyatt v. Stickney*) settled.

The Drug Addiction Treatment Act allows office-based heroin treatment by permitting qualified physicians to prescribe take-home doses of buprenorphine.

Federal legislation authorizes $10 million over 4 years to establish up to 100 mental health courts.

Federal rules are issued establishing a national uniform standard for protecting the privacy of medical records.

2001 The Surgeon General promulgates a national strategy for suicide prevention: *National Strategy for Suicide Prevention: Goals and Objectives.*

The Health Care Financing Administration is restructured and renamed the Center for Medicare and Medicaid Services (CMS).

2002 The Department of Health and Human Services releases *Report to Congress on the Prevention and Treatment of Co-occurring Substance Abuse and Mental Disorders*.

2003 The President's New Freedom Commission on Mental Health puts out its report, *Achieving the Promise: Transforming Mental Health Care in America*.

2004 A federal district court in Oregon requires the state to eliminate a $250 copayment for hospital visits for the standard population of the Oregon Health Plan.

2005 The federal government, jointly through the Department of Health and Human Services (DHHS), the Department of Housing and Urban Development, the Department of Justice, the Labor

Department, the Veterans Administration, and the Social Security Administration, put out *Transforming Mental Health Care in America. The Federal Action Agenda: First Steps*. This starts a multiyear venture to alter the forms and functions of the mental health system in the United States.

2006 The 2006 Budget Reconciliation Act alters Medicaid rules, such that states can impose premiums and higher cost sharing on beneficiaries, as well as allows states to provide scaled-back Medicaid benefit packages. One consequence is transferring some Medicaid beneficiaries to the rolls of the uninsured, with hospitalization going from Medicaid reimbursement to free care.

The Substance Abuse and Mental Health Services Administration (SAMHSA) provides a training curriculum to reduce (or eliminate) the use of seclusion and restraint: *Roadmap to Seclusion and Restraint Free Mental Health Services*.

The CMS publishes final rules on the use of seclusion and restraint in the *Federal Register*. The new limits (previously there were none) are: Adults, 4 hours; children and adolescents age 9–17 years, 2 hours; and children younger than age 9 years, 1 hour.

Implementation of Medicare Part D.

2007 The Agency for Healthcare Research and Quality (AHRQ) of the DHHS reports that there is no evidence base for the off-label use of atypical antipsychotics.

SAMHSA, in *An Action Plan for Behavioral Workforce Development*, reports "an anemic pipeline of new recruits to meet the complex behavioral health needs of the growing and increasingly diverse population in this country."

The AHRQ, in *Care of Adults with Mental Health and Substance Abuse*, reports that 6% of all community hospital stays were primarily for psychiatric or substance use disorders and nearly 25% included such a disorder.

Federal judges in Wisconsin question diagnoses invented to civilly commit sex offenders after expiration of their criminal sentence. In *Brown v. Watters* the diagnosis was "paraphilia not otherwise specified-nonconsent"; in *McGee v. Bartow* the diagnosis was "personality disorder not otherwise specified with antisocial feature." Neither is a *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) diagnosis.

2008 The Paul Wellstone and Pete Domenici Mental Health Parity and Addiction Equity Act of 2008 (MHPAEA) amended the Public Health Service Act, the Employee Retirement Income Security Act (ERISA) and the Internal Revenue Code, to require group health plans and health insurance issuers to ensure that financial requirements (such as co-pays, deductibles) and treatment limitations (such as visit limits) applicable to mental health or substance use disorder benefits are no more restrictive than the predominant requirements or limitations applied to substantially all medical and surgical benefits.

2010 The Affordable Care Act was passed by Congress and then signed into law by President Obama on March 23, 2010. Titles I. Quality, Affordable Health Care for All Americans and II. The Role of Public Programs and V. Health Care Workforce have direct impact on psychiatric hospitals.

2012 U.S. Supreme Court rules in *National Federation of Independent Business v. Sebelius*on June 28, 2012, in a 5-4 ruling, that the Affordable Care Act is constitutional. The court defines the individual mandate as a tax and not a mandate and provides a choice for States to Opt-Out of Medicaid Expansion.

2013 A final regulation implementing MHPAEA is published in the Federal Register on November 13, 2013.

2013 Representative Tim Murphy (R-PA) introduces, on December 12, 2013, H.R.3717—Helping Families in Mental Health Crisis Act of 2013 which is the first comprehensive federal legislation addressing the needs of those with serious mental illness since President Kennedy's Community Mental Health Act in 1963.

2014 Representative Ron Barber (D-AZ) introduces, on May 2, 2014, H.R. 4574—The Strengthening Mental Health in Our Communities Act, the House Democrats' alternative to the bill filed by representative Murphy.

2014 U.S. Supreme Court Justice Ruth Bader Ginsburg files a dissenting opinion in *Burwell v. Hobby Lobby Stores, Inc.*, a decision that exempts employers from covering birth control (as required by the Affordable Care Act) if the employer objects on religious grounds. One of Ginsburg's queries was, could Scientologist employers not cover antidepressants on religious grounds?

2014 On April 1, 2014, President Obama signed into law the Protecting Access to Medicare Act (H.R. 4302), which includes a demonstration program based on the Excellence in Mental Health Act. This act (1) creates criteria for "Certified Community Behavioral Health Clinics," (2) provides $25 million that will be available to states as planning grants to develop applications to participate in the 2-year pilot, (3) stipulates that 8 states will be selected to participate in the 2-year pilot program, and (4) requires participating states to develop a Prospective Payment System for reimbursing Certified Behavioral Health Clinics for required services they provide.

Fiscal Rationale

In 1912, there was a debate in Congress on a government health insurance program. President Franklin Roosevelt almost established a federal health plan as part of the 1935 Social Security Act. Presidents Harry Truman and John Kennedy had health care proposals before Medicare and Medicaid passed during President Lyndon Johnson's term in office. However, before all that, President Franklin Pierce played a major role in the early eschewal of federal responsibility for the health care of persons with mental illness.

The individual most responsible for bringing the issue to President Pierce's desk was Dorothea Dix, a well-known reformer. On June 23, 1848, Dix delivered a Memorial Lecture to the U.S. Congress. Dix's subjects, as stated in her address, were as follows: "Allowing at the present time 22,000,000 inhabitants in the United States and supposing only one in every thousand to be insane or idiotic, we have then 22,000 to take charge of." She described the state they were in:

> a majority of whom are in needy or necessitous circumstances . . . destitute of appropriate care and protection . . . bound with galling chains, bowed beneath fetters and heavy iron balls, attached to drag chains, lacerated with ropes, scourged with rods, and terrified beneath storms of profane execrations and cruel blows . . . abandoned to the most loathsome necessities, or subject to the vilest and most outrageous violations.

Dix's remedy was hospitals: "No disease is more manageable or more easily cured than insanity; but to this end special appliances are necessary, which cannot be had in private families, nor in every town and city; hence the necessity for hospitals." Dix appealed to the legislators' sense of doing what is right: "Humanity requires that every insane person should receive the care appropriate to his condition." She articulated the social control function of the hospital by spelling out the civil and social obligation to consult and secure the public welfare: "First, in affording protection against the frequently manifested dangerous propensities of the insane." Furthermore, she made a powerful economic argument, indicating the insane and the community at large would benefit by "assuring seasonable and skillful remedial care, procuring their restoration to usefulness as citizens of the republic, and as members of communities."

Edward Jarvis best articulated the 19th-century position on the cost of care versus the cost of treatment that was fundamental to Dix's campaign:

> A man of twenty years of age, if sane, has an average life of 39.48 years, while if insane he has but an average life of 21.31 years if not restored to health. The average time for restoring to health the insane who apply for treatment upon the early symptoms of disease is twenty-six weeks. At $4 per week, which was the average cost in the three State Lunatic Asylums in Massachusetts for the past year, this amounts to $104, to which is added $30 for each patient, for the cost of rent or interest on the value of the hospital, etc., for six months, making an average cost of $134 for restoration to health. If not restored to health, the family or State must be at an expense of $156 a year for 21.31 years, and must also lose the patient's earnings for the 39.48 years which he would have made if well. The cost of the patient's support is estimated at $2,121, while the loss of his future labor, if he becomes insane at twenty years of age, is estimated at $2,665.37, making a total loss of $4,786.37 if not cured; while, if cured in the average time of twenty-six weeks at a cost of $134, there will be a gain to the family or to the State of $4,652.

Dix lobbied for her land grants bill through four presidential administrations. The bill was passed by both houses of Congress during Franklin Pierce's term. However, Pierce vetoed the bill. In his Veto Message on May 3, 1854, first he laid out the issues as he saw them:

> It cannot be questioned that if Congress has power to make provision for the indigent insane without the limits of the District it has the same power to provide for the indigent who are not insane, and thus to transfer to the Federal Government the charge of all the poor in all the States. It has the same power to provide hospitals and other local establishments for the care and cure of every species of human infirmity . . . The whole field of public beneficence is thrown open to the care and culture of the Federal Government.

Later in his Message, he explained the basis for his veto:

> If the several States, many of which have already laid the foundation of munificent establishments of local beneficence, and nearly all of which are proceeding to establish them, shall be led to suppose, as, should this bill become a law, they will be, that Congress is to make provisions for such objects, the fountains of charity will be dried up at home, and the several States, instead of bestowing their own means on the social wants of their own people, may themselves, through the strong temptation which appeals to states as to individuals, become humble supplicants for the bounty of the Federal Government.

From the veto by President Pierce into the early decades of the 20th century, the federal government was basically disinterested in the psychiatric and substance abuse populations. It eventually turned to the issues around the treatment of this population due to concerns about drug addiction. In 1914, the Harrison Narcotics Act allocated funds to study drug use. Subsequently, the Narcotics Division within the U.S. Public Health Service was created. It was renamed 2 years later the Division of Mental Health. In 1996, the federal government focused on mental illness with the passage of the National Mental Health Act, which established the National Institute of Mental Health (NIMH).

In 1989, the Omnibus Budget Reconciliation Act (OBRA) required the secretary of the Department of Health and Human Services to conduct a study of the IMD exclusion. The IMD exclusion dated from the 1950 Social Security Act Amendments, in which payments on behalf of those in IMDs

were excluded from old-age assistance. This exclusion continued unchanged until the enactment of Medicaid under the Social Security Act Amendments of 1965. For the first time states could use Federal Financial Participation (FFP) for a population in IMDs—in this case those 65 years of age or older. States could bill the federal government to help pay for the treatment in psychiatric hospitals of patients who were older than the age of 65 years. Other populations were not included, but Congress did expand FFP for services to persons with mental illness in general hospitals.

The 1965 changes to the IMD exclusion began to allow states to shift the cost of mental illness expenditures to the federal government. In a state hospital, the state bears 100 percent of the cost of care and treatment. The state cannot bill Medicaid. In any facility that is eligible for Medicaid reimbursement, each state pays considerably less than 100 percent, according to the FFP formula: Nonfederal percentage = 45 percent × (per capita state income) ÷ (per capita national income). Historically the range of federal participation has been between 50 and 83 percent—thus the fiscal incentive to move patients out of state hospitals.

An IMD is a facility with more than 16 beds. In addition, any one of the following defines an IMD: (1) the facility is licensed as a psychiatric facility, (2) the facility is accredited as a psychiatric facility, (3) the facility is under the jurisdiction of the SMHA, (4) the facility specializes in providing psychiatric/psychological care and treatment, or (5) the current need for institutionalization for more than 50 percent of all of the patients/residents in the facility results from mental diseases.

In 1971, Congress expanded Medicaid to include coverage of services rendered in intermediate care facilities (ICFs). In 1972, Congress expanded FFP for inpatient psychiatric treatment in IMDs to individuals younger than 21 years of age, so that now those younger than 21 and older than 65 years of age are eligible.

The IMD exclusion sets up a tension between the states and the federal government, each wanting to lower its share of the costs for psychiatric hospital treatment. Between 1972 and 1988, the federal government was busy with evaluating the proper application of the IMD exclusion by the states, disallowing certain states' practices, and defending itself in court. This culminated in the 1985 U.S. Supreme Court decision in *State of Connecticut Department of Income Maintenance v. Heckler* in which the Court unanimously found for the federal government, indicating that a hospital, a skilled nursing facility (SNF), or an ICF could be an IMD.

Thus, the IMD exclusion profoundly affects the role of the psychiatric hospital and the distribution of patients across types of hospitals. States would rather have persons with mental illness in community residential settings than in state hospitals, and in general hospitals rather than state hospitals. In both situations, the former means Medicaid payments; the latter means no Medicaid reimbursement.

No matter what the sector or who the payer, however, in the last quarter of the 20th century inpatient psychiatric treatment was getting more and more costly—hence the rise of managed care. Starting in the 1970s and continuing through the early 1980s, the principal methods for cost containment were actuarial manipulations designed to manage benefits. There was little regard for the effect these changes in benefits had on the indirect costs borne by beneficiaries, employers, and/or the community. Changes were made without consideration of their effects on the displacement of care onto the general medical sector. Modifications in benefit plan design included imposition of restrictions, exclusions, limitations, and penalties; provision of incentives; requirements for prior authorization; and retrospective denial of claims. This methodology is managing benefits.

Managing benefits changed into cost control through management of care, a methodology claimed to be more patient focused. By limiting authorization of expenditures to only those services deemed medically necessary and appropriate, delivered in the least restrictive and least intrusive treatment settings, and only by previously designated qualified practitioners, advocates of managed mental health care believed that proper care could be delivered to patients at the appropriate times, in designated settings, by the right type of provider, in skillfully titrated amounts, and at considerable cost savings. Techniques used to achieve this end included management through contracting, profiling, credentialing, and educating hospitals; organizing hospitals into a specialized, accessible, and interactive network of behavioral health care providers; using mandated standardized pretreatment assessment and treatment planning methods; and requiring the use of standardized forms, restricted formularies, and outcomes management.

Though not yet achieved, the more progressive goals of managed behavioral health care are disease management, demand reduction, health promotion, and wellness. Health maintenance organizations (HMOs) and other capitation-based arrangements have fiscal incentives to use these strategies, but both efforts and results have yet to be really impressive. Nonetheless, the techniques used mean that managed care has and continues fundamentally to affect the role of the psychiatric hospital.

The federal government sought further cost containment. The Tax Equity and Fiscal Responsibility Act of 1982 (TEFRA) led to new methods to control Medicare costs, most significant being diagnostic-related groups (DRGs) for reimbursement. With the end of cost-plus reimbursement and its replacement with reimbursement based on diagnosis, hospital profits for medical and surgical treatment began to decline. The behavioral health care industry was initially unaffected by DRGs, largely because psychiatric diagnoses were thought to lack sufficient power to predict the course of treatment. Thus, there appeared to be tremendous financial opportunities

available in the relatively unregulated behavioral health care market. These opportunities were short lived; the rise and fall of for-profit psychiatric hospitals were equally steep, as described earlier. With the application of DRGs to psychiatry, this fiscal advantage also dissipated. Thus, the federal government, through Medicare and Medicaid, fundamentally affects the role of the psychiatric hospital.

Although the modern era of managed behavioral health care began in the private sector, these principles and practices spread to the public sector. Medicaid Managed Care was initiated due to the spiraling costs of the Medicaid program. Between 1985 and 1993, Medicaid costs tripled and the number of beneficiaries increased by more than 50 percent.

Other Governmental Considerations

Although state governments most directly affect the roles of psychiatric hospitals—through state laws, regulations, licensure, inspections, and investigations—the federal government has profoundly changed the roles of psychiatric hospitals through federal legislation and court decisions. Table 58.3–2 provides a summary of these influences over the last six decades.

The federal government's influence can be examined through the example of the right to treatment. Much of the right-to-treatment litigation has focused on establishing standards of care and concomitant staffing patterns. In the 1940s, the APA maintained there should be no less than 1 psychiatrist for every 150 hospitalized patients, 1 graduate nurse for every 40 patients, and 1 attendant for every 8 patients. No state hospital of the day met all of the APA's standards.

The right to treatment was initially articulated by Morton Birnbaum, a lawyer and physician in 1960. There followed a series of lower-court cases: *Lake v. Cameron* (1966), *Rouse v. Cameron* (1966), *Nason v. Superintendent of Bridgewater State Hospital* (1968), *Wyatt v. Stickney* (1971), and *New York State Association for Retarded Children v. Rockefeller* (1973), the so-called Willowbrook case. Each of these is briefly explained in Table 58.3–2.

The U.S. Supreme Court decided three cases between 1975 and 1982 that might have established a right to treatment, meaning states that would be obligated to treat committed patients. In *O'Connor v. Donaldson* (1975), the Court found "A State cannot constitutionally confine, without more, a nondangerous individual who is capable of surviving safely in freedom by himself or with the help of willing and responsible family members or friends." In *Halderman v. Pennhurst State School & Hospital* (1977), the Court again did not reach the issue of a constitutional basis for a right to treatment or habilitation. In *Youngberg v. Romeo* (1982), the Court went the furthest it has to date when it held that persons with mental retardation who were involuntarily committed to institutions have "constitutionally protected liberty interests under the Due Process Clause of the Fourteenth

Amendment to reasonably safe conditions of confinement, freedom from unreasonable bodily restraints, and such minimally adequate training as reasonably may be required by their interests." Had the Supreme Court established a right to treatment, the roles of psychiatric hospitals might have been considerably expanded.

The major advances in the right to treatment in the 1980s occurred pursuant to the Civil Rights of Institutionalized Persons Act (CRIPA) of 1980. This act authorized the U.S. government to institute a civil action against any state whose officials, employees, or those acting on their behalf are "subjecting persons residing in or confined to an institution to egregious or flagrant conditions which deprive such persons of any rights, privileges, or immunities secured or protected by the Constitution or laws of the United States causing such persons to suffer grievous harm." Under this authority the Civil Rights Division of the U.S. Justice Department has been able to substantially bring the right to treatment closer to a reality for thousands of persons in state, county, or municipal psychiatric hospitals by applying the standards of *Youngberg* to negotiate consent decrees. A consent decree is a document filed with the court in which the two parties sign a binding agreement in lieu of litigation.

On July 26, 1990, the Americans with Disabilities Act (ADA) passed and established a "clear and comprehensive prohibition of discrimination on the basis of disability." Title II is of greatest interest because this title covers state and local government services and so includes public hospitals. Title II indicates "no qualified individual with a disability shall, by reason of such disability, be excluded from participation in or be denied the benefits of the services, programs, or activities of a public entity, or be subject to discrimination by any such entity." One regulation promulgated to operationalize this Act states "A public entity shall administer services, programs, and activities in the most integrated setting appropriate to the needs of qualified individuals with disabilities." This marks a shift from the long-standing standard, "least restrictive alternative," to the new standard, "most integrated setting." The ADA was seen not so much as a way to improve services within hospitals as a way to force states to move patients out of these institutions.

The hallmark Supreme Court decision to date applying the ADA to persons in hospitals is *Olmstead v. L.C.* (1999). The case involved two women who were in a Georgia state hospital despite the fact that treatment professionals had concluded each could be appropriately treated in community-based programs. The Court found that the "unjustified isolation . . . [of persons with mental disabilities] is properly regarded as discrimination based on disability." The basis for this finding was that "Institutional placement of persons who can handle and benefit from community settings perpetuates unwarranted assumptions that persons so isolated are incapable or unworthy of participating in community life." The

justices then made a leap to the conclusion that institutional confinement "severely diminishes the everyday life activities of individuals, including family relations, social contacts, work options, economic independence, educational advancement, and cultural enrichment." Thus, began the most recent wave of translocating persons from public psychiatric hospital to alternative settings. Apparently, general hospitals and private hospitals were deemed "in the community." So too, based on the most recent data, are jails and prisons.

FULFILLING THE ROLE

The hospital fulfills its role in the care and treatment of psychiatric patients in a prescribed way. Efficacious treatment derives from effectively performing each step.

Assessment

Assessments are done by individual practitioners of different disciplines. An admission assessment is conducted by a physician, preferably a psychiatrist. This assessment, done at the patient's presentation to the hospital, documents the chief complaint; the basis for admission and history of the present illness; relevant past psychiatric history, family history, and social history; a complete mental status examination; a substance abuse screen; and a risk assessment (suicide, homicide, fire setting, other). This assessment should lead either to admission or to nonadmission with an outpatient plan.

A nursing assessment is completed as soon after the patient's arrival on the ward as possible, but no later than 8 hours. The nursing assessment overlaps in part with the physician admission assessment but covers some areas in less detail and others in more detail. The nursing assessment includes a pain assessment, a falls risk assessment, skin care concerns, and special nursing care needs.

The third assessment that needs to be completed proximate with admission is the medical history and physical examination. This is done either by the admitting psychiatrist or by an internist, depending on the staffing of the hospital. Besides attending to a general medical history, particular attention needs to be paid to how medical disorders and physical findings might be affecting the psychiatric presentation.

All three of these assessments need to cover the areas of alcohol and substance use/abuse. Positive screens lead to an alcohol and drug abuse assessment, preferably completed by staff with expertise in this area.

Other disciplines need to complete their assessments prior to the interdisciplinary team (IDT) meeting at which the Treatment and Recovery Plan (TRP) is developed. These assessments include those by social work—the psychosocial assessment—and by rehabilitation services (often

inappropriately referred to as "activities therapy"). The psychosocial assessment needs to provide information from collateral sources when such information is necessary to complete the database, there are collateral sources to contact, and the patient has provided permission (release of information) to contact specific individuals. Some hospitals include a psychology assessment on all admission; others use psychologists who function as consultants, and psychology assessments are conducted only on referral. Dietician assessments are often done routinely; medical specialty assessments are done on referral.

Formulation

Traditionally, the weakest part of the process from assessment to intervention and one often left out entirely, the formulation needs to be seen as a fundamental part of the process. The formulation pulls the data together into a coherent picture of the individual. It is not a brief restatement of the facts of the case. The formulation takes the symptoms, which are the basis for an understanding of the *patient*, and adds significant historical information to provide an understanding of the *person*.

Leaving out or improperly constructing the formulation leads to the loss of important information that does not directly translate into diagnoses but is crucial for effective treatment planning. Formulations may be recorded as components of each assessment—for example, psychiatric formulation, nursing formulation—and then brought together at the IDT meeting, or they may be written at the IDT meeting by the psychiatrist drawing from all of the assessments.

Treatment Planning

Because treatment must commence at the onset of hospitalization, the Initial Treatment and Recovery Plan (ITRP) is, of necessity, a multidisciplinary process. The ITRP is initiated by the admitting psychiatrist and nurse, based on their assessments. Other disciplines add to the ITP as they conclude their assessments.

Whereas the ITRP provides the basis for directing treatment during the first few days of hospitalization, the rationales for specific interventions must be included in either the assessments or in the progress notes. For example, each medication ordered by the admitting physician must have a documented rationale. It is not sufficient simply to state that medications taken prior to admission are being continued, because this does not provide any basis for the medications. Stating that aripiprazole and clozapine, for instance, are being prescribed fails to justify polypharmacy without providing a basis beyond recording that these were the medications prescribed by the CMHC psychiatrist. Furthermore, any as-needed (PRN)

medication ordered at admission needs to have a rationale, one that is specific to the patient. Ordering lorazepam 2 mg orally for agitation and haloperidol 5 mg orally for severe agitation is not sufficient. Such orders are neither specific to the patient nor do they inform the nurse what the prescriber means by "agitation" and what he means by "severe agitation."

The TRP expands upon the ITRP and derives from an *interdisciplinary* process. The IDT is composed of professional and paraprofessional staff, as well as the patient. The patient, assisted by staff, is free to invite any other individuals to this meeting, for example, family members, friends, or advocate. The purpose of the IDT meeting is to *write* the TRP. It is not a time to sanction a TRP written before the meeting by one member of the IDT. The meeting uses the multidisciplinary assessments as the basis to create an interdisciplinary treatment plan.

The creation of the TRP follows an orderly process. The IDT establishes, with the patient as the lead, the problems, which in the inpatient setting are predominantly barriers to discharge. Other problems may be addressed, depending on the expected length of stay of the patient. For each problem, there is a long-term goal (LTG) and a set of short-term goals (STGs) or objectives. The goals are the patient's goals, not the staff's goals for the patient. Hence, problems and goals belong to the patient. For each STG, there is a series of interventions. Interventions are what the staff does, not what the patient does. Each intervention under an STG must specifically assist the patient to move toward achievement of that STG.

STGs need to be specific, measurable, attainable, realistic, and timely (often referred to by the acronym SMART). STGs are intermediate steps toward accomplishment of the LTG. Small steps that the patient reaches at intervals reinforce the patient and the staff.

Interventions need to specify the frequency of the intervention, the duration of the intervention, and the name of the intervener. For example, "Nurse Nightingale provides Medication Education Group, Tuesday and Thursday, 10:00-10:45 a.m."

Common errors in interventions include the following:

1. Writing job descriptions: "Nurse Nightingale will administer medication and monitor for side effects."
2. Failing to document intervener and/or duration: "Anger Management Group Wednesdays."
3. Including interventions unrelated to the STG, such as "Dr. Woodward will meet with patient Mondays, 1:00-1:20 p.m. to review concerns about weight gain from clozapine," when the STG is "Patient will have one five-minute telephone conversation per day with mother for three consecutive days without telling her mother to drop dead or piss off."
4. Using terms that communicate no specific intervention (and can often be dangerous to staff if done wrong) such as "encourage patient to . . . " or

"assist patient to . . . " If such interventions are used, the intervention must be explicit about how the "encourage" is to be done.

The ideal sets of interventions are clear, concise, and explicit. If the entire IDT were out sick one day, covering staff should be able to treat the patient by performing the interventions.

The TRP is the road map for the patient's treatment. Active treatment—a concept or phrase used by many certifying entities—is defined as that treatment found as an intervention on the TRP that moves the patient toward achievement of an STG that moves the patient toward achievement of an LTG that addresses one of the patient's problems. A simple rule when one is calculating active treatment hours for a patient is, "if it's not on the treatment plan, it's not active treatment."

Progress is recorded in progress notes. These are written pointedly addressing STGs. Each note needs to be labeled with the discipline of the intervener and the STG being addressed. Thus, there would be no nursing staff note reading "Patient ate well and slept well" unless eating and sleeping were problems on the TRP with specific LTGs and STGs.

The initial TRP is completed within a specified time frame, varying between 1 and 10 days and specified by the facility's policies and procedures. The TRP is reviewed through IDT meetings at which treatment plan reviews (TRPRs) are conducted. The TRPR builds on the TRP, uses progress or lack thereof noted in the progress notes, and modifies the TRP as needed. TRPRs also occur on a schedule. In units with short lengths of stay, the TRPR occurs from daily to every 3 days. In intermediate length of stay units, TRPRs occur weekly for 60 days, then every 2 weeks for 60 days, then monthly. In longer stay units, TRPRs may occur monthly after the TRP done at 10 days.

Besides occurring on a scheduled basis, TRPRs need to occur in response to a patient's clinical need. Many hospitals have thresholds that, when met, require a TRPR to be held within 1 business day. Such thresholds included (1) any episode of seclusion or restraints; (2) a specific number of episodes of seclusion or restraint or a specific number of hours of seclusion or restraint within a designated time frame; (3) the administration of any psychiatric medication PRN or a given number of PRNs within a specified time frame; (4) the initiation of 1:1 observation; and/or (5) any serious incident, for example, patient-on-patient assault, patient-on-staff assault, or suicide attempt.

The TRP needs to be comprehensive, or account for why it is not (either in the TRP or in the hospital's policies and procedures) in all but acute care settings. Thus, the TRP would be expected to address all of the patient's psychiatric and medical problems on longer-term units. A TRP could provide interventions for those problems that are impediments to discharge and address other problems as resources allow; this is often the

case on intermediate-length-of-stay units. A CTP could address only those problems that are impediments to discharge with the expectation other problems will be addressed in treatment after discharge; such an approach is often employed on short-term units. This does not mean that maintenance treatments will not be provided for acute or chronic problems that are not the focus of the hospitalization, such as antihypertensive medications, treatments for gastroesophageal reflux disease or constipation, and hypnotic medications.

There is a new emphasis on tying the hospital TRP to a community TRP for persons with SMI in systems of care (traditionally CMHCs, but now also health homes and other integrated care settings). In the person-centered approach, the community TRP starts with the individual's "life goals." Community clinicians, support and outreach staff (peer and nonpeer workers), and naturalistic resources are channeled toward assisting the individual to move ever closer to his life goals. Hospitalization is usually a detour on the journey toward one's life goal, so focusing on problems that are impediments to discharge is in the service of returning the person to the community to take up the pursuit of his individualized life goals. To do so effectively, the hospital TRP should record the life goals as anchor points.

Treatment

Treatment planning is necessary but not sufficient for effective treatment to ensue. Members of the IDT plus other staff need to provide integrated treatment that follows the plan.

Psychopharmacological treatment is a mainstay of contemporary inpatient treatment but must be prescribed (physician), dispensed (pharmacist), and administered (nurse) with awareness of contemporaneous interventions. Either initiating psychotropic medication or adjusting medication regimens is considered the sine qua non of inpatient psychiatry. Of course, not all admissions require medication, and distinguishing these patients from all others is an important function of the assessments and observations that are unique to the inpatient setting.

In prescribing medication, the attending psychiatrist must communicate the reasons for the medication and its side effects not only to the patient (obtaining informed consent before ordering the medication) but also to all members of the IDT. Hence, the importance of monitoring progress and informative progress notes accompanying each order.

PRN medications warrant particular attention. PRN medication transfers de facto prescription authority from physician to nurse because the nurse decides when and how much medication the patient will receive (within the parameters set by the physician). Unless the physician checks daily on the total dose of each PRN medication given, it is not possible for the physician to relate the patient's progress to the medication

administered. Hospitals have taken various approaches to PRN psychotropic medication, including eliminating them entirely; limiting the orders to short-term orders, for example, 3 or 5 days; or allowing PRNs only on admission units and not on other units within the hospital.

Well-written progress notes by the psychiatrist assist the nurse in writing useful nursing progress notes. Writing "patient remained calm and cooperative throughout shift" may convey no useful information if, for example, the patient is depressed with a recent suicide attempt and is externally calm and cooperates because it takes less energy and concentration to do so than not to do so. A physician progress note detailing the specific target signs and symptoms for which antidepressant X has been prescribed provides the foundation for the nurse to write progress notes that focus on those signs and symptoms. If the physician simply writes antidepressant X for "dysphoria" or "depression," progress notes by other staff members are likely to be equally uninformative.

Another function shared predominantly by the psychiatrist and the nursing staff (Registered Nurse [RN], Licensed Practical Nurse [LPN], Mental Health Technicians [MHTs]) is patient safety. Maintaining a safe milieu and maximizing the safety of each patient and staff depends on (1) active, individualized treatment, (2) levels of observation and privileges geared to the patient's level of risk, (3) prompt and skillful response to patient aggression, (4) modification of therapeutic interventions as the nature and/or level of risk changes, and (5) continuing staff education and training.

Level of observation and privileges serve the function of patient safety and should not be used as rewards for compliance with process variables like attendance at groups. When the level of observation is for the risk of harm to self, the most noteworthy harm being suicidality, the hospital needs a process by which increasing the level of observation, that is, more staff oversight, can easily be instituted by a physician or RN, but decreasing the level of risk can only occur on a written physician's order after a face-to-face evaluation. In some hospitals, this can only be done by the attending psychiatrist. Telephone orders and verbal orders should never be accepted for lowering the observation level.

In addition to medication, inpatient treatment involves individual sessions and group interventions. Individual psychotherapy is the exception these days, although this modality continues to be used in some public and some private hospitals. There are a few hospitals in which intensive psychotherapy is the mainstay of inpatient treatment. The programming of individual sessions with the social worker to focus on discharge planning is the rule. Individual sessions with nursing staff to practice skills taught in groups should occur at least through the day and evening shifts (and the night shift if appropriate to the patient's needs).

Group interventions fall under the heading of psychosocial

rehabilitation. In general hospitals, these groups occur on the unit. In state hospitals and in some private hospitals, these interventions are delivered off-ward in areas of the hospital often referred to as the "treatment mall." There are several advantages to setting up groups or classes in a centralized location, including the following:

1. Patients follow a variant of the "work order day"; patients, like staff, "commute" to where they spend their daytime hours; in the case of patients, they live in one place (the unit) and get their treatment in another location (the mall); lunch is often provided at the mall.
2. Pooling patients, and consequently pooling staff, means that a large number of different groups can be provided per hour, rather than having the same group occur simultaneously in multiple locations.
3. The issue of patients remaining in bed, watching TV, or participating in other diversions is handled by institutional policy and practice rather than day by day, case by case.
4. Safety of staff and patients is increased because there is more staff available for an emergency.
5. Professional and paraprofessional staff spend more time with patients because patients and staff are at the treatment mall during mall hours.

Newly constructed hospitals (see Table 58.3–1) are designed with accessible treatment mall locations. The use of perimeter security with significant freedom of travel for patients within the building eases access to mall-based treatment and maximizes patients' autonomy (see Fig. 58.3–5). One controversy surrounding the use of treatment malls at hospitals is whether or not the hospital can require all patients to attend the mall. Does the right to refuse treatment also mean the right to not go where treatment is provided? In one model patients have a right to refuse treatment, but patients do not have a right to determine where they are at the hospital at any given time. If this were a right, patients could refuse to remain behind any locked door. Patients must go to the treatment mall, but the hospital must provide a place for them on the mall if they refuse to attend the groups they are scheduled to attend. A corollary controversy in this model relates to the issue of whether staff can lay hands on a patient if the patient refuses to go to the mall. Staff can lay hands on a patient if there is an emergency, and leaving a patient on a ward with no staff because of the patient's refusal to leave the ward would constitute an emergency. In another model, where patients cannot be compelled to leave the unit for groups, hospitals have created units with and without an off unit requirement. There are benefits and drawbacks of each type of unit and absent safety concerns; a patient makes his choice based on his valuation of the different benefits of each type of unit.

Although there are no controlled studies of the operation and effectiveness of treatment malls, data collected at individual hospitals seem

to support (1) rapid adjustment of patients to a change to the treatment mall approach; (2) very low use of hands-on procedures to move patients; (3) decreased rates of seclusion and of restraint without accompanying increases in total daily dose of antipsychotic and/or antimanic medications or of benzodiazepines; and (4) improvement in patients' sleep with fewer doses of hypnotics. Most importantly, patients do seem to learn skills through the use of mall-based groups.

Clinicians doing hospital-based treatment, just like their colleagues doing outpatient treatment, need to be mindful of three contemporary concepts: recovery, evidence-based treatment, and trauma informed care. Practitioners of all clinical disciplines have struggled to achieve consensus definitions of these percepts. SAMHSA's definitions are as follows:

Recovery: A process of change through which individuals improve their health and wellness, live a self-directed life, and strive to reach their full potential.

Evidence-based: Demonstrating effectiveness in empirical research that meets a standard of scientific rigor as embodied in minimum review requirements, which include the stipulation that an intervention must have demonstrated one or more positive behavioral outcomes ($p \leq 0.05$) in substance abuse and/or mental health in at least one study using an experimental or quasiexperimental design.

Trauma-informed care: It is a strengths-based service delivery approach that is grounded in an understanding of and responsiveness to the impact of trauma, that emphasizes physical, psychological, and emotional safety for both providers and survivors, and that creates opportunities for survivors to rebuild a sense of control and empowerment.

A well-functioning psychiatric hospital would incorporate these principles into its therapeutic offerings by having expertise in and providing among other offerings: CBTp for psychosis; cognitive enhancement and restructuring therapy (CERT); cognitive restructuring for PTSD; cognitive therapy for psychosis (CT-R); dual recovery (mental illness and substance abuse); dialectical behavior therapy; family support and treatment; fire-setting treatment; grief therapy; illness management and recovery (IMR); individualized exercise plan (IExP); leisure skills development; medical care and treatment; mental illness and problematic sexual behavior treatment (MIPSB treatment); motivational interviewing and motivational enhanced therapy; person-centered approach; pharmacotherapy; positive behavioral support plan; readiness for change interventions (individual and group); sensory modulation; vocational rehabilitation; and wellness management recovery action plan

(WRAP). Behavioral interventions, generally under the direction of a psychologist with particular expertise in this area, need to be available at all hospitals. This is of paramount importance in hospitals that have units with intermediate- or long-stay patients. The behavioral plan is based on a functional assessment of the target behavior to be modified or eliminated. The plan provides a series of responses aimed at reinforcing some behaviors and extinguishing others. All direct care staff must be trained in the specific interventions to be used for a specific patient. Preferably, the hospital has a way to document such training and to ensure that any staff assigned to work with a patient who has a behavior plan is trained in that plan.

During hospital treatment, a major controversy has been patients' "right to smoke." It is unclear how this is a right. If it were, patients would also have a "right to drink." No one argues the latter, so why the former? Forbidding smoking on the unit has generally occurred at all hospitals. Moving that restriction to a designated area within the hospital was the next step. Patients can often be seen at the perimeters or in the courtyards of the hospital smoking. Many hospitals have progressed to prohibiting smoking anywhere in the building and some even prohibit smoking on the hospital grounds. Hospitals should neither be in the business of selling cigarettes nor use staff to purchase cigarettes for patients—a practice referred to as "making a cigarette run." Given that there is now a range of aids to stopping smoking—gum, patches, pills, support groups—these should be made available to patients and to staff. Nicotine replacements should be used as a transition to becoming nicotine free; too often they become permanent fixtures on the patient's pharmacologic plan. It was not that long ago that state hospitals received free tobacco from cigarette companies, purchased cigarette papers, and paid staff, and/or had patient groups whose focus was to roll cigarettes. The rolling machines had been purchased with state funds. Progress in smoking cessation needs to continue, particularly given the increased morbidity and mortality of persons with chronic mental illness. A role of the hospital should be to teach patients and support their efforts to maximize a healthy lifestyle. Wellness programs are being conducted at many hospitals and are well worth supporting.

Discharge Planning

The aphorism "Discharge planning begins at the time of admission" is, of necessity, particularly true today, given all of the pressures surrounding length of stay. Although the discharge process is primarily the responsibility of the IDT's social workers, it is a mistake to assume it is her or his task alone. Discharge planning is an interdisciplinary process.

Discharge planning is processed by the social worker interacting with the patient and IDT members until the TRP. At this point, the discharge plan becomes an integral part of the TRP. Whether discharge-related issues are identified as one of the problems on the TRP depends on the patient's specific circumstances. Discharge might be a problem if the patient is homeless, cannot return to the residence from which he or she was admitted, or is an illegal immigrant with no eligibility for entitlements. An often-missed problem related to effective discharge is recidivism, that is, the patient has multiple admissions, generally with short community tenure between them. Recidivism is often too quickly ascribed to noncompliance with medication without the IDT doing a thorough investigation of the etiology of repeated admissions. Noncompliance may well be a factor in any short time period between admissions, but this may also be accounted for by a number of other factors. Often ignored is the contribution to stabilization made by the structured environment of the hospital. Often commented on, but inadequately addressed, is the use of alcohol, marijuana, other street drugs, and other prescribed medication even in a medication-compliant patient. There is also the contributing factor of secondary gain—the hospital may be the locus of the best quality of life the patient has experienced for years, or even decades.

Discharge planning involves the establishment not only of sites of service and appointment times but also of efficacious linkage strategies. The steps that need to be taken to maximize the likelihood that the patient will actually make it to her or his first appointment with the outpatient psychiatrist are of paramount importance. Linkage also involves providing to the outpatient psychiatrist, outpatient therapist, and other appropriate personnel pertinent information in writing. A copy of the instructions given to the patient should reach the outpatient sites *before* the patient arrives for her or his first appointment; the discharge summary needs to follow shortly thereafter. So too does the TRP, so that the community can incorporate the work the hospital has done into the community TRP, just as the hospital incorporated the work the community had done into the hospital TRP. Phone contact from inpatient psychiatrist to outpatient psychiatry is advisable for any case seen as needing more than the usual written communications.

SPECIAL POPULATIONS

This section has focused on the role of the hospital in serving the general adult psychiatric population. The hospital serves many other populations, defined either by their demographics or by specific service needs.

Children and Adolescents

Twenty-one percent of U.S. children aged 9 to 17 years have a diagnosable

mental or addictive disorder causing at least minimal impairment, and 5 to 9 percent of children this age have a serious emotional disturbance that causes extreme functional impairment. Significant numbers of children and adolescents in need of treatment do not receive behavioral health services. When children's mental health services are unavailable, unaffordable, or inappropriate, many young people end up in the child protection or juvenile justice systems.

Children and adolescents represent approximately 7 percent of the total mental health inpatient population. However, children's services receive a disproportionally low fraction of what adults receive for inpatient services, despite the fact, that on average, children's inpatient treatment is about 1.5 times as expensive as adult inpatient treatment.

Although the number of available inpatient psychiatric beds decreased, the admission rates of children and adolescents to psychiatric hospitals increased over the last few decades. Between 1986 and 1997, the number of youth admitted to inpatient services increased by 143 percent and the rate per 100,000 youths increased by 119 percent. As the number of inpatient beds and specialized staff to care for children and adolescents with serious emotional disturbance has decreased, the number of families relying on hospital EDs for psychiatric services has increased. ED physicians report seeing a large number of children whose parents have simply run out of options for care.

Inadequate hospital-based and other services have created cohorts of labeled children. "Boarder kids" are children stuck for days, weeks, or even months in pediatric wards because there are no beds in a psychiatric hospital or ward. "Wait-list kids" wait months for case management or outpatient services. "Stuck kids" are in psychiatric hospitals but cannot leave because there is no place for them to go.

There are many factors that complicate the role of the hospital in the care and treatment of children and adolescents. Alcohol and illicit drugs are a major problem. Current alcohol use is 36.2 percent for 17-year olds, 19.9 percent for 15-year olds, and 6.5 percent for 13-year olds. Among youth ages 12 to 17 years, about 12 percent are current illicit drug users. Annual suicide attempts in 15- to 24-year olds have surpassed 1 million in the United States, and suicide is the third-leading cause of death for this age group. Age-specific mortality rates from suicide are 1.6 per 100,000 for 10- to 14-year olds, 9.5 per 100,000 for 15- to 19-year olds, and 13.6 per 100,000 for 20- to 24-year olds. Almost half of students with mental disorders drop out of grades 9 through 12, and of those dropouts, 73 percent are arrested within 5 years of leaving school. Children and adolescents with serious emotional disturbance often live in families with multiple risk factors and vulnerabilities, including single-parent households, poverty, and family history of substance abuse, violence, mental disorders, and/or felony convictions.

Although the challenges for families of children and adolescents with emotional and behavioral problems are great, best practices emphasize collaboration with families when coordinating care for the child. Inpatient facilities have placed an increasing emphasis on incorporating the family and other relevant support systems into a child's treatment plan.

Today, children and adolescents are likely to receive mental health services in what is referred to as "systems of care." Systems of care provide a spectrum of mental health and other necessary services organized into a coordinated network from community-based and least restrictive treatment settings and case management to intensive inpatient psychiatric care. Systems of care rely on "wraparound services." The values underlying systems of care include a focus on the individual child and family, the provision of services within the most normalized environment that meets the youth's need, the creation of partnerships with families, the use of a strength-based orientation, the creation of an environment of cultural competence, the provision of unconditional care, and the use of 24-hour institutional care at various points in time. Systems of care do not eliminate the need for inpatient level of care, but often shorten lengths of stay.

As the wraparound model appears to have evolved into a best practice in the care of the most difficult children and adolescents, it is important to note that inpatient hospitalization treatment is not a failure of the wraparound model but one of its service components. Thus, the hospital plays a key role in wraparound services.

A challenge that most states face is providing services to children with emotional and behavioral disturbances when they age out of the child system. The eligibility requirements for services in a state's adult system are many times narrower than the eligibly in the child system, so some transition age youth who have been receiving services for years are screened out, leaving them without care and treatment. A vulnerable time for a young adult is exacerbated by the states' need to restrict its eligibility pool for publically-funded mental health services.

Veterans

The veterans' hospital system was established after World War I when veterans were entitled to health care benefits and compensation. States were unable to handle the needs of this population, given that there were hundreds of thousands of U.S. solders "wounded not mortally" and uncounted numbers who suffered from neuropsychiatric conditions.

On his last day in office in 1921, President Woodrow Wilson signed into law a bill supporting $18.6 million for the establishment of hospitals for veterans. The years 1921 to 1923 saw the provision of more than 6,000 beds in new veteran's hospitals across the United States. From 1923 to 1945, there was considerable expansion of hospital beds. Following World War II, the VA was entirely reorganized. In the decades following World War II,

VA hospitals accounted for only a small percentage of the hospitalized population. Trends in bed use shifted, however, such that between 1955 and 1975, the number of VA inpatient episodes increased by 143 percent, whereas state and county mental hospitals decreased by 37 percent.

In the mid-1990s, the VA shifted its traditional focus on inpatient care and dramatically expanded its outpatient services. Between 1995 and 2001, the number of occupied annual inpatient psychiatry beds fell by 58 percent in VA hospitals, the length of stay decreased by 52 percent, and the number of veterans treated in the VA outpatient system increased by 27 percent. This shift, and the reorganization of the Veterans Health Administration (VHA) into 22 smaller, semiautonomous networks, may be contributing to the VA's apparent inability to meet the needs of veterans from combat in Afghanistan and Iraq. And that need is substantial. A nationally representative sample drawn from the National Health and Resilience in Veterans Study showed that the current and lifetime prevalence of PTSD in veterans was 4.8 and 8 percent, respectively. PTSD came from combat and noncombat situations and was associated with elevated risks of severe psychiatric disorders and suicide.

Efforts were initiated in 2006 to substantially improve the capacity of VA hospitals to meet the increasing psychiatric need of veterans. The VHA struggled to provide the necessary service. A 2010 report estimated that 18 veterans a day die by suicide and 950 suicide attempts occur each month among veterans receiving services through the VAH. Between 2010 and 1014, VA hospitals were the subject of scandals and problems, with systemic problems including turning away veterans who needed services and who then suicide, maintain secret waiting lists to create the appearance that delay in service was much shorter than it was, putting out false performance reports, covering up suicide attempts, and running facilities in which illicit drug dealing was routine practice. As one commentator said, "the VAH is a bright, shining example of misguided priorities and terrible mismanagement."

Veterans seek and/or receive treatment out of VHA settings for a number of reasons: The veteran is not service connected for a psychiatric disability, the veteran prefers treatment out of the VHA, the veteran is committed pursuant to a forensic status, or in some jurisdictions the veteran refuses voluntary admission and requires civil commitment. Thus, continuity of care can be particularly problematic as the veteran moves in and out of the VA, public, and private systems of care.

The challenges facing the VAH are significant. In 2014, there were 24 million veterans in the United States, about one-third of whom are enrolled in VA care. There are 21,000 mental health professionals to meet this need, but only 3,000 are psychiatrists. The expectation is that the Veterans Access, Choice, and Accountability Act of 2014 will improve the ratio of VA psychiatrists, non-VA psychiatrists, and other mental health clinicians

available to treat veterans with psychiatric disorders.

Individuals active in the military receive their psychiatric inpatient treatment in Department of Defense hospitals. Of major concern for this population is suicide. The U.S. Army suicide rate exceeds the civilian suicide rate with substantially elevated suicide rates following psychiatric hospitalization—an eightfold increase for 3 months following a psychiatric hospital discharge and a fivefold increase for 12 months after a psychiatric hospitalization.

Substance Abuse Comorbidities

Persons whose alcohol and/or substance use require hospital-based treatment fall into two categories: Those with so-called "straight substance abuse," meaning that there is no other mental illness that is the focus of treatment, and persons who are dually diagnosed with a mental illness and a substance use disorder both of which require active treatment.

Treatment for substance use in either population requires detoxification when such is necessary and then treatment initiating prevention of relapse and recovery. Relapse and recovery are lifelong enterprises that may or may not involve inpatient treatment. With the exception of detoxification of persons at high medical risk, all the services for persons with substance abuse or individuals dually diagnosed can be found at hospital and nonhospital loci of care.

Perhaps the major shift in the treatment of persons with dual disorders that occurred in the latter part of the 20th century was the movement from consecutive treatment to concurrent treatment. For decades, there was the belief that one could not address other psychiatric disorders until one had first addressed alcohol and/or substance abuse or dependence. Currently, efficacious treatment is considered to be treatment that addresses both at the same time.

Because the rate of alcohol and substance abuse is quite high in persons with other *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5), disorders, hospitals need to have expertise in substance abuse assessments and treatment at all levels of service. Many a diagnosis will be missed if the attending psychiatrist or the C-L psychiatrist is not thinking about the potential roles that alcohol and illicit drugs may be playing in the patient's presentation. The legalization of marijuana or medical marijuana in some states is presenting new dilemmas for psychiatric hospitals. It is too soon to tell how this will be dealt with in different states, and within one state, in psychiatric inpatients settings in different types of hospitals.

Geriatrics

Patients older than the age of 65 years and those deemed "functionally

geriatric" are treated in units with mixed-aged populations in some hospitals and on psychogeriatric units in others. The involuntary admission of elderly individuals varies greatly state to state, in that some state statutes prohibit the involuntary admission of persons with any form of "organic brain syndrome" as the basis for the commitment, whereas others do not.

Elderly patients have special needs that the hospital must attend to: (1) greater comorbidity with medical disorders; (2) increased likelihood of delirium; (3) possibility of their having another disorder that is confused with dementia, especially major depressive disorder; (4) greater need that all other medications they are taking be considered when the assessment is done and when psychopharmacologic recommendations are made; and (5) higher suspicion for impaired capacity to consent to treatment.

Of particular concern is the use of antipsychotic medication in elderly patients. In 2005, the FDA warned that second-generation antipsychotic medication was associated with an increased risk of death in older patients with Alzheimer disease and other age-related dementias. In 2008, the warning was expanded to include first-generation antipsychotics. Subsequently, a Harvard Medical School study of elderly, new users of antipsychotic medication showed that haloperidol had twice the mortality rate of the atypical antipsychotics, and among the atypicals, quetiapine had the lowest mortality rate. Another class of medications of concern is benzodiazepines, ubiquitous in their use in hospital settings to quiet agitated patients, including the elderly. A case-controlled study using Quebec, Canada health insurance data showed chronic use of benzodiazepines by elderly patients was associated with about a 50 percent increase in Alzheimer disease 5 to 10 years after a period of 90 or more days of use, with benzodiazepines with half-lives of greater than 20 hours carrying the greatest risk. Thus, caution should be used in the inpatient management of elderly patients by using benzodiazepines for longer than brief—up to 90 days—treatment.

Staff in any of the hospital services should consider the need for, and implement if necessary, a complete organic medical workup, formal cognitive assessments, and referral for follow-up services that are age sensitive.

Developmental Disabilities Comorbidities

Most states have deinstitutionalized persons with developmental disabilities/mental retardation at an even greater pace than their population with chronic mental illnesses. That means that former residents of developmental disability facilities who would not have been seen for hospital treatment now are.

Persons who present for services at hospitals with anywhere from mild to profound mental retardation or other developmental disabilities may be coming from home where they live with parents, from community

residential programs where they live with staff, or, in the case of mild mental retardation, from an independent living arrangement. In each instance, the person needs individualized services that are informed by his or her capacities. Especially important is the use of concepts and language the individual can comprehend.

Serving persons with developmental disabilities in the hospital has evolved in many different ways. In some hospitals, these individuals are "mainstreamed," that is, they receive services in the same areas of the hospital as all others. There are certain disadvantages to this approach, in that the essential skills to meet the needs of the population may be lacking. There are a few general hospitals that have specialty units to serve persons with developmental disabilities and even more state hospitals that do.

When the person with developmental disabilities presents for services at the hospital, it is most often due to unmanageable behavior. That is not to say that individuals with developmental disabilities do not become psychotic, depressed, or anxious; they surely do, and these conditions need psychiatric attention. However, a majority of persons dually diagnosed with a mental illness and mental retardation present because they can no longer be dealt with in the environment in which they live. Commonly the individual receives such diagnoses as impulse control disorder not otherwise specified, intermittent explosive disorder, or if adolescents or younger children, conduct disorder or oppositional defiant disorder.

Persons with developmental disabilities should leave the inpatient setting with a functional analysis of the problematic behavior that permits the outpatient setting to follow through with treatment that will facilitate habilitation. Often this entails the use of behavioral interventions. All hospital treatment of persons with developmental disabilities entails close collaboration with the team of persons providing all outpatient and residential services. Collaborative treatment is essential in the hospital's achieving successful outcomes with this population.

Medical Comorbidities

Psychiatric disorders complicated by or complicating medical disorders are a common occurrence. Psychiatric services are often required when there is a diagnostic question related to mentation or mood; when a patient is too "out of control" or his or her behavior is so "inappropriate" that management of the patient is not going well on the medical or surgical services; when the medical or surgical practitioner cannot communicate with the patient or cannot obtain informed consent; or when there is an ethical question about course of treatment.

There is perhaps no better example of the psychiatric hospital's role in treating persons with medical illness than HIV infection. There is a bidirectional relationship between severe mental illness and HIV infection; persons with psychiatric disorders are at higher risk of acquiring HIV, and

persons who are HIV positive have increased rates of psychiatric illness. The interactions between disorders and treatments are myriad. Psychiatric disorders impair judgment and heighten the risk of contracting HIV (e.g., mania in bipolar disorder) or lead more directly to increased risk (e.g., intravenous drug use). HIV induces, both psychologically and by direct effect on the brain, anxiety, depression, psychosis, and dementia. Antiretroviral medications can induce psychosis. Drug–drug interactions—drugs prescribed for HIV status, psychiatric status, and medical disorders due to HIV status—make treating the comorbid psychiatric disorders quite complex. Being HIV positive per se, the symptomatology of HIV, the psychiatric disorders that predated HIV-positive status, and the psychiatric disorders resultant from being HIV positive may all diminish compliance with both retrovirals and psychotropics.

The hospital plays a unique role in meeting the clinical needs of persons who are HIV positive. Although the general hospital is the mainstay of treatment for this population, the state hospital is not infrequently called on to provide care and treatment to symptomatic and nonsymptomatic HIV-positive individuals.

Although HIV infection has been used as an example, a comparable presentation could be made for scores of medical disorders. Some, such as systemic lupus erythematosus, temporal lobe epilepsy, and space-occupying brain lesions, are dramatic examples. On a more frequent basis, hospital-based psychiatric and medical services draw together to treat such conditions as cancer, renal failure, and trauma.

Psychiatry has known for over 150 years that individuals with SMI die younger than persons without these disorders. And the reason for this is still unknown. It is known that medical comorbidities can be significantly exacerbated by psychiatric medications. This is no better illustrated than by metabolic syndrome in persons taking some of the second-generation antipsychotic medications. It behooves the inpatient psychiatrist to work closely with his medical colleagues in the hospital, and others staff like dieticians and occupational therapists to create and monitor wellness programs for his patients.

A new service that has started to appear in a few state hospitals is hospice care. These services are provided to the state hospital patient who have spent some time in the hospital and without the patient needing to be transferred to another facility or even to change units within the hospital. The advantages to the patient are many, but the fundamental advantage in the patient's ability to remain in an environment he knows with staff he is comfortable with. It is important to have the patient's informed consent, or the guardian's is a guardian of the person is in place, for all services that will not be provided and those that will. In hospitals where this is done to the extent of full hospice services on site, the patients dies in his own room (it is generally not feasible to do this if the patient does not have a single

room) and this is processed before and after death with the other patients on the unit. Shortly thereafter it is beneficial to have a nondenominational memorial service in the hospital's chapel.

Deaf Individuals

In treatment as orally based as is psychiatric treatment, the clinical approach to persons who are deaf presents a unique set of challenges. Although in many states, deaf individuals who need psychiatric treatment secure that treatment within the hospital alongside all others with the addition of translation services, some states have a statewide deaf unit at one of its hospitals. Here, persons who are deaf can interact with staff without the imposition of a translator and can be in an environment that is sensitive to the deaf culture. There are a very few private hospitals that offer this service.

Deaf individuals present with the full range of psychiatric disorders. Being deaf does not protect one from DSM-5 disorders. Nor does it protect one from comorbidities such as mental illness/developmental disabilities and/or mental illness/substance abuse.

The range of the hospital's roles in treating deaf persons is no different than for hearing persons. To fulfill that role, hospital staff needs to be aware of, and sensitive to, the deaf culture. For this population, the state hospital-based deaf unit may be the least restrictive, most-integrated setting when inpatient treatment is required. In states with deaf units, that also require civil admissions only come from other hospitals, this restriction is waived for the deaf population who can be direct admits from multiple loci of care, including general hospital EDs.

Forensic Patients

Persons admitted to the hospital pursuant to the commitment of a crime are the states' responsibility and one that the state generally fulfills directly at state hospitals. There are a few exceptions when the state contracts out for these services.

Forensic patients are in the hospital basically for one of three reasons: (1) pretrial, for a determination of competency to stand trial and/or of criminal responsibility for the crime; (2) after a finding of being incompetent to stand trial, guilty but mentally ill, or not guilty by reason of insanity; or (3) jail or prison could not manage the inmate due to his behaviors as a result of psychopathology. Restoration of competency to stand trial is a uniquely forensic task, and the hospital needs to have specialty functions to accomplish this. Much of the rest of the clinical treatment of the forensic population is the same as that of the nonforensic population. Security on forensic units is generally much tighter than in other places at the hospital.

Often the role that the hospital is required to fulfill for many forensic patients is one that it does not play very often for other patients—housing forensic patients for years to decades beyond the time the patient needs hospital-level care. The degree to which this occurs is heavily dependent on the state commitment statutes and procedural handling of its forensic patients.

Although there is a clear dichotomy between forensic and nonforensic patients based on the state statute under which the patient was admitted, the clinical variation and treatment need to show no such distinction. Whether a patient is civil or forensic, especially for minor crimes, has more to do with the circumstances of the patient's initial encounter with the police than it does with his or her clinical presentation. The boundary is also blurred these days because of states admitting more persons at the end of a criminal sentence, especially those convicted of sexual offenses.

The hospital has a multiple roles with the forensic patient: (1) to meet the person's needs as a psychiatric patient, (2) to meet the state's needs to proceed with due process in trials, and (3) to maintain the public's safety in the face of those who break or are charged with breaking state or federal law. Hospitals are considerably more comfortable with the first role than with the other two.

With forensic patients, the judicial or quasijudicial systems control the admittance and discharge of patients. In many states, this contributes to both overcrowding at hospitals and to an ever increasing percentage of forensic patients in the hospital's census. It is an irony of current times that jails and prisons feel overwhelmed by inmates sheriffs believe should be psychiatric inpatients and psychiatric hospitals feel overwhelmed by inpatients psychiatrists asses to need jails and prisons.

OTHER HOSPITAL ROLES

This section has focused on the inpatient functions of the hospital, which comprise the service that is unique to it. The hospital fills a number of other roles, many of which are also performed in some fashion by entities that are not hospitals.

Emergency Services

Psychiatric treatment is provided on an emergency basis in hospital EDs (see Fig. 58.3–1). The arrangements under which this is done vary greatly. In community hospitals, the person presenting with a psychiatric problem is generally treated in the same fashion as all individuals—the same waiting area, the same examining rooms, sometimes the same physicians. In larger hospitals, all of these functions are often segregated into a designated area of the ED where patients are seen by nonphysician evaluators who consult with psychiatrists who may or may not see the patient. Like many other

hospital functions, crisis evaluation services have moved out of the hospital and to freestanding crisis services in some jurisdictions. Not uncommon is a hybrid model in which the hospital ED plays host to an outside crisis service. Here, the hospital performs medical screening evaluations.

The ED functions may include psychiatric holding beds, that is, the ability to keep a person in the ED for up to 23 hours, thus avoiding an admission. The ED may include crisis beds, a service allowing a short number of days that again avoids an admission to the psychiatric unit. Crisis beds are another service the hospital shares with nonhospital settings such as CMHCs, which offer freestanding crisis beds.

Psychiatric patients "stuck" in ED's awaiting transfer to an inpatient bed has become a nexus for consternation over inadequate inpatient beds. These patients, often called "boarders," can wait hours, days, weeks, or in some cases over a month during which time little is done for them other than room and board in the ED. In August 2014, the Supreme Court of Washington State found, In re the Detention of D.W., et al., found it unlawful, under Washington's involuntary treatment act, to board patients in ED's due to overcrowding of appropriate evaluation and treatment facilities.

Only about half the states have processes in place to systematically identify open beds for psychiatric patients who need admission. Even those states that can effectively search for bed availability are stuck with the inadequate number of psychiatric beds nationwide. A 2012, study by the Treatment Advocacy Center, "No Room at the Inn" demonstrated that not one state had sufficient numbers of public hospital psychiatric beds.

Step Down/Admission Diversions Services

Hospitals offer a range of services that function between inpatient and outpatient levels of care. Such services include day hospital, partial hospital, and night hospital. In treatment arrangements that are during the day, the individual attends a full day of active psychiatric treatment but lives outside of the hospital, for example, in his or her home, with family, or in a community residential program. In the night hospital program, the person leaves the hospital for school or work during the day but spends overnights at the hospital. All of these programs are also used as attempts at admission diversion, that is, to avoid inpatient hospitalization for this episode of illness. Step down programs and admission diversion programs are also offered by nonhospital entities, with the latter also offering respite beds. These have a longer length of stay than crisis beds and are not generally provided by hospitals.

Partial hospital programs, once enthusiastically endorsed by insurers as less expensive alternatives to inpatient treatment for their use as both alternatives to admission and step downs to decrease length of stay, have lost favor. There is a dwindling supply of such programs. Just between

2000 and 2001, the number of facility members of the National Association of Psychiatric Health Systems (NAPHS) offering partial programs decreased from 83 to 67 percent. Between 2003 and 2013, the number of hospitals offering partial programs decreased by 20 percent (from 508 to 410). There is expected to be further loss of partial programs if CMS decreases their reimbursement rate, as it is proposing to do.

Outpatient

Outpatient services are offered in more settings than any other service. Besides the hospital, outpatient services are found in CMHCs; group settings, either integrated with primary medical services or at their own sites; private practices; family services agencies; and hosted in locations such as shelters, specialty clinics, mental health residential programs, and mobile units. Payment for these services is most often by third-party insurers—private or government—with a copay by the patient. In larger metropolitan areas particularly, some outpatient providers have established practices that take no insurance.

The major challenge facing outpatient psychiatry at hospital locations is the high cost of delivering the treatment within hospital settings and the poor reimbursement rates. It has reached the point where expanding business in the outpatient department (OPD) is the last objective of the hospital because each new patient adds to the deficit.

On a more practical note, hospitals are seen as unfriendly places to the individual seeking outpatient psychiatric services. Parking is often difficult, far from the OPD, and expensive. Negotiating the corridors of the hospital is a challenge that many would prefer to avoid. In addition, the patient may have to go through a registration process that simply adds another layer of annoyance.

The prognosis for hospital-based outpatient services is not good. Often the victim of cherry picking by others (the most difficult patients are directed to the hospital OPD), the hospital psychiatric OPD is on the hit list of many hospital chief executive officers. One remedy may be hospital-based integrated clinics where outpatient psychiatry and medicine are collocated. Such attempts have been around for 40 years, but the momentum for such integration is accelerating.

Consultation-Liaison

Although many hospital executives would gladly replace the psychiatric inpatient service with more profitable medical-surgical beds and make much better use of the space devoted to the psychiatry OPD (which is often banished from the main hospital buildings anyway), the C-L function is usually highly valued. In part, that is because the C-L service directly affects the hospitals' medical and surgical services by evaluating patient's

capacity to consent, assessing cases of delirium and psychosis, and assisting with difficult dispositions. The C-L service can be invaluable in making differential diagnoses that will fundamentally alter treatment and disposition. Some have argued that it is because a hospital could not effectively function without C-L psychiatry that much of the rest of hospital-based psychiatry is tolerated. This may be a somewhat cynical overstatement, but it certainly has some elements of truth. A well-functioning C-L service is a fountain of goodwill for the psychiatry department.

Community Education and Patient/Family Support

One role of the hospital that is largely one of goodwill is the hospital's role as host to a remarkable array of self-help and support groups. Those that fall under the penumbra of mental health and substance abuse activities are frequent in hospitals; such groups are Alcoholics Anonymous, Narcotics Anonymous, and the National Alliance on Mental Illness. Less directly related to mental illness but using principles of support are groups centered on all manner of chronic conditions and issues, such as breast cancer, colostomy, and scleroderma. There are also groups for individuals in specific life circumstances, such as parents without partners and parents who lost a child to cancer.

Hospitals also play a community education role. Members of the psychiatry staff may provide substantive lectures geared to the lay public. These are different, yet complement the hospital's psychiatry grand rounds, which themselves are usually open to the public. Another form of education is informing the public about the services the hospital has to offer.

FUTURE DIRECTIONS

The challenges that face hospitals in the second decade of the 21st century are not new. Prior to 1950, virtually every problem and many of the solutions that define contemporary hospital psychiatry were noted in the professional literature. One need only read such sources as the *American Journal of Insanity*, *Alienist and Neurologist*, or state hospital annual reports to find them all.

Homelessness, the overpopulation of jails and prisons with persons with mental illness, the eschewal of persons with mental illness from any locale because that jurisdiction does not want financial responsibility for the person, an inadequate focus on treatment and overreliance on management, and a propensity to not spend tax money on persons with mental illness are all conditions Dorothea Dix found in the 1840s when she began her lifelong work of reform. Samuel Woodward, APA's first president and the first superintendent of what is now the Worcester Recovery Center and Hospital (Figs. 58.3–4 and 58.3–5) would have recognized them all.

The loss of the person in meeting the acute needs of the patient, the reliance on modern technologies for diagnoses that has diminished one-to-one time with patients, and the general sense of the dehumanization of psychiatry and medicine in general were noted by William Allison White in 1925. White remarked in his APA presidential address that "the introduction of these highly technical methods has been accomplished by a corresponding lack in development, at least, if not actual loss, of any adequate dealing with the patient as an individual or as a human personality."

Even hospitals bending to the dictates of payers to minimize costs is not new. More than 125 years ago Kirkbride lamented that "it will be a sad day for these institutions, and still sadder for the patients in them, when the rivalry of hospitals and their offices shall be, rather to discover for how little inmates can be kept, than to secure what is best, and most thoroughly promotes the great objects for which they were established."

State hospitals are disappearing by design. Whether that is the result of thoughtful or ill-conceived planning is a matter of debate. General hospital psychiatry programs, however, are disappearing through a thoughtless process of survival of the fittest.

Reimbursement and operating margins for psychiatric services lag behind those of other hospital-based medical services. The diminishing financial returns from psychiatry have led hospital management consultants to recommend converting psychiatric beds to higher-margin medical and surgical beds. Even to remain fiscally viable now, psychiatric hospital inpatient revenues need to cross-subsidize emergency, consultation, and outpatient services.

Today, psychiatrists generally fail to acknowledge those times when the psychiatric hospital is a forerunner or role model for the rest of psychiatry if not the rest of medicine. One of the foci of contemporary medicine is the integration of medicine and psychiatry, or medical and mental health services. As practitioners in psychiatry and in medicine focus on methodologies to integrate care and treatment, they need look no further than the public psychiatric hospital, which has been an integrated care organization for over 100 years, and still is a fine example of integrated care and treatment. Outpatient integration, it seems, is mimicking business as usually at the state hospital but without its walls.

Attributes of a state hospital that contribute to its high degree of integration include:

- Psychiatric and medical services collocated
- An integrated psychiatric and medical treatment plan
- A single, shared medical record, now an electronic medical record in many institutions
- Ease of communication among a patient's physicians and between those

physicians and other disciplines

- Case or care management integrated into treatment
- Professional and paraprofessional staff assisting patients to follow through with psychiatric and medical recommendations in an integrated housing and care model
- On-site wellness programs, for example, dietary, exercise, organized leisure
- Other health promotion activities, for example, weight loss, smoking cessation, treatment of substance abuse
- Transportation to any off-site medical appointments
- Workforce development, for example, student placements, pre- and postdoctoral internships, residency rotations
- Paid time off for staff education
- On-site dental, podiatry, optometry, radiology, phlebotomy, and neuropsychiatry services
- Peer supports
- Referrals to community and social supports
- Services for all independent of the ability to pay
- Funding supports not only direct service but time for collaboration
- Unitary billing system
- Transition services for relocation provided and funded
- Interfaces with vocational services
- Provision of in vivo training, for example, bus riding, banking, using the library
- On-site hospice care with direct care staff the patient is already familiar with the state psychiatric hospital, as an integrated care system, should have outcome measures that reflect this. The current, common outcome measures fail to take this into account and currently include number of assaults patient on patient and patient on staff; number of serious assaults; number of episodes and time in any form of seclusion or restraint (manual, mechanical, chemical); two or more antipsychotic medications at discharge; five or more psychiatric medications prescribed; time out of hospital on unsupervised passes; and timeliness of all manner of documentation. Many of these measures are open to interpretation, especially what a facility chooses to label as an episode of restraint. What about improvements in health and wellness as outcome measures?

Virtually no knowledgeable commentator claims that the system of care and treatment for mental illnesses can be sustained without the roles played by psychiatric hospitals. At the same time, too few informed people are working on methods to interdigitate the hospital's roles into the fabric of an integrated system of care, one that looks less like Figure 58.3–1 and

more like one that achieves effective outcomes, through a person-centered approach, with fiscal management that does not compromise the very care and treatment psychiatrists are attempting to deliver.

▲ 58.4 Mental Health Services Research

CASSIS L. HENRY, M.D., AND LISA B. DIXON, M.D., PH.D.

The imperative for mental health services research arises from some basic and alarming facts. Over half of the persons with mental disorders receive no mental health treatment. For those who do, the vast majority—approximately 75 percent—do not receive treatment that can be judged of good quality by evidence-based standards. Those outside of the health services research field, such as clinicians and other stakeholders, may not see how mental health services research can improve the substandard quality of mental health care. In fact, they may not even understand what health services research is. The Association for Health Services Research broadly defines it as:

> The multidisciplinary field of scientific investigation that studies how social factors, financing systems, organizational structures and processes, health technologies, and personal behaviors affect access to health care, the quality and cost of health care, and ultimately our health and well-being. Its research domains are individuals, families, organizations, institutions, communities, and populations.

This chapter reviews the specific scope of mental health services research and illustrates through several case studies how such research addresses critical questions that arise in the routine provision of services, laying the groundwork for improving the quality of mental health care.

THE SCOPE OF MENTAL HEALTH SERVICES RESEARCH

Clinicians seek to address identified clinical problems, disorders, and diseases. Clinicians turn to biomedical research to answer two basic questions: (1) What is known about the nature of this problem? (2) What can be done to remedy it or alleviate the suffering associated with it? Research answers to the first question derive from *basic sciences research*, whether biological (e.g., What neural pathways are affected in bipolar disorder?), behavioral (e.g., How do organisms respond to different types of reinforcement schedules?), psychological (e.g., How do negative automatic thoughts affect mood?), or sociological (e.g., What are the pathways to homelessness?). Research answers to the second basic question arise from *clinical research* involving well-controlled treatment trials designed to determine efficacy and safety, as well as from the more or less systematic trial and error of clinical experience. Broadly, the basic and clinical sciences deal with knowledge needed prior to the initiation of routine care. In other words: What is the health problem, and what treatments might relieve this problem? *Health services research* questions, however, arise once clinical services get underway. Clinicians have

extensive exposure to the basic and clinical sciences during their training but may have little or no exposure to, and hence little understanding of or appreciation for, the value of health services research.

What kinds of questions do mental health services researchers ask? These questions can be divided into two general categories—*clinical services research* and *service systems research*. Like clinical research, *clinical services research* focuses on "front-line" clinical issues and uses individual service recipients (patients, families) as the participants and units of study. Examples of questions asked by *mental health clinical services research* include the following: How effective are antidepressant agents in producing illness remission among typical patients with major depression seen in routine office practices? What considerations influence individuals to seek treatment and to agree to complete a course of prescribed treatment? What range of treatments for persons with schizophrenia are "evidence-based?" Do persons with substance abuse and mental illness have better outcomes when they receive care from integrated addiction mental health teams or programs with parallel services? What are the effects of a routine depression screening measure in primary care on detecting and treating major depression in such settings?

Mental health services system research examines questions at the service system level and typically uses aggregated service components (providers, treatment agencies, state mental health systems, etc.) as the units of study. Examples of questions asked by service systems researchers include the following: How many persons with severe mental illness who are being treated in a public mental health system have access to routine primary care? Does this differ between two states with different Medicaid policies? What are the various sites in a city where homeless persons with severe mental illnesses receive services, and are these coordinated? What are the effects of a decision by Medicaid to cap the total number of prescribed medications that recipients can receive? Do restricted formularies for antipsychotic medications reduce overall costs? Do they affect quality? Do local mental health authorities improve coordination, continuity, and quality of care for high-need patients?

Given this broad scope of mental health services research, it is also helpful to note what it does not include (Fig. 58.4–1). The distinction has already been mentioned between basic and clinical research on one hand and mental health services research on the other. The interface between clinical research and clinical services research begins at the transition between treatment efficacy and treatment effectiveness studies. *Efficacy studies* examine the outcomes of treatments within narrowly defined samples of patients who are carefully selected to control for variables that might interfere with determining a treatment effect (e.g., the exclusion of patients with comorbid substance abuse or medical disorders). Efficacy study designs attempt to maximize internal validity. *Effectiveness studies*

examine treatment outcomes among more inclusive, diverse, and "typical" clinical populations. External validity assumes a more important role. Generally, effectiveness studies only occur after treatment efficacy has been established. Mental health services research, while somewhat distanced from the efficacy studies with which many clinicians are familiar, is still *research*, using standardized scientific procedures to answer specific research questions to generate new knowledge that is generalizable beyond the system being evaluated. It should be distinguished methodologically from routine activities undertaken by service systems and service agencies to monitor policy implementation, program or system administration, or quality assurance.

Figure 58.4–1 illustrates the distinction between basic and clinical research and health services research, the flow between these larger research domains, and depicts various activities conducted within health services research. For example, one way in which clinical practice is affected by services research occurs as the results of clinical efficacy trials and effectiveness trials are applied to routine practice—a form of "translational research." Given that a primary goal of basic and clinical research is to inform clinical practice, when a body of scientific knowledge has accumulated, it should be adopted into clinical practice. However, this translation does not happen as it should; the gaps between existing scientific knowledge about treatment efficacy and effectiveness on one hand and routine clinical practice on the other have been referred to collectively as the "quality chasm" in medical care, encompassing both access and quality.

A major question for mental health services research then, is how to promote the adoption of scientifically validated treatments (evidence-based practices) and, by doing so, bridge the "quality chasm." One response has been the development of evidence-based practice guidelines, variously referred to as evidence-based practices, evidence-based treatment recommendations, or "best practices." The identification of evidence-based best practices is critical to examining current practice patterns, evaluating their quality, identifying areas in need of improvement, and ultimately identifying areas in which current treatments fall short. The methodology for developing such evidence-based practice guidelines emphasizes the results of efficacy and effectiveness research, augmented by expert opinion when research evidence is underdeveloped in essential areas.

FIGURE 58.4–1. The relationship between basic and clinical research and health services research.

Once a set of research-based best practices has been identified, health services researchers can ask a variety of questions about how current practices compare to best practices, including variations in practices across treatment settings, practitioners, and patient subtypes, as well as the relationship to such factors as insurance coverage, health policies and regulations, and cultural diversity. Such research can also examine patterns in outcomes of care across different kinds of services and relate these to patterns in the implementation of evidence-based practices. Such studies are essentially descriptive, but they allow comparisons of actual practices to standards of care.

Identifying gaps between actual and best practices can lead to developing health services interventions to improve care. Such interventions fall into one of two general categories. *Supply side* interventions focus on individual providers or service programs. These interventions seek to change the care offered in some way. Some examples of supply side interventions include provider education and training programs, systematic feedback to providers regarding their current practices, consultations to agencies about implementation of best practices, financial incentives to alter practices, and so on. *Demand side*

interventions focus on the demand for services and are directed at changing patient behavior. Examples of such interventions include educating patients about best practices, training patients in how to advocate for themselves in health settings, and providing service vouchers to patients to enable them to select services that they identify as most helpful.

Both supply and demand side interventions can occur at distinct levels involving individual providers and patients, local service agencies, local or regional service systems, and local, regional, or national policies. *Shared decision making* is a strategy that involves both supply side and demand side approaches at the level of the individual patient–provider interaction. *Policy-level interventions* occur at the level of a system of care with the intention of changing patterns of service delivery—for example, changing the services covered by insurance, creating local mental health authorities to improve the coordination and outcomes of treatment in a given locale, mandating the integration of mental health and substance abuse services, or offering Medicaid care through a coordinated and managed "health home."

Such interventions, however, are not in themselves health services research. Rather, health services research evaluates the effects of such interventions on a range of outcomes, including patient outcomes, changes in patterns of care, and costs. In health services research, the interventions must be clearly defined, the fidelity of their implementation closely monitored, and the outcomes measured in a standardized form. Research designs to minimize threats to internal and external validity—for example, randomized clinical trials—are critical, as in clinical research. The research questions, although based on the specific interventions, focus on knowledge that can be generalized to other settings. As in other areas of research, findings from any phase of health services research optimally feed back to raise new research questions.

Recent work has focused on methodologies for implementation research, a burgeoning domain of health services research that attempts to understand how effective interventions fail to lead to improved patient care. Studies of implementation problems in carrying out interventions at the level of systems or individual clinical care depend upon various conceptual frameworks but generally acknowledge the need to study factors including (1) the structural, political, and cultural context as well as internal organization of the settings in which the intervention will take place, (2) characteristics of the individuals involved, (3) the process of implementation of the intervention, and (4) the nature of the intervention itself. Such research takes a pragmatic approach, seeking to understand how real-world conditions affect the implementation of the evidence-based practices for which clinical and other research has established evidence of efficacy and effectiveness.

The following "case reports" concretely illustrate the application of mental health services research to critical questions that arise in the routine provision of services.

Case 1: Treatment of Depression in Primary Care Settings

Depression is one of the most common mental disorders and accounts for a staggering amount of disability worldwide. Over the last several years, there have been substantial improvements in methods for diagnosing depression and a broad range of efficacious treatments for depression exist, including antidepressant medications and evidence-based forms of psychotherapy. A number of evidence-based practice guidelines have been developed, so the opportunities to effectively diagnose and treat depression are substantial.

Given the state of diagnostic and treatment methods for depression, how successful is The United States in treating depression? This health services research question raises some basic epidemiological queries. How many people suffer from depression? Do they seek treatment and where? What treatments do they receive? The most comprehensive estimates of the prevalence of mental disorders derive from the Epidemiologic Catchment Area (ECA) Study and the National Comorbidity Survey (NCS), which estimated the 1-year prevalence of major depressive disorders at 6 to 7 percent. The vast majority of depressed individuals (about 80 percent) contact a health care provider over a 1-year period, but only about 25 percent receive any appropriate treatment for depression. Most patients (about 80 percent) who visit a health care provider for depression see a primary care provider; only about 20 percent of patients with depression visiting a health care provider see a mental health specialist. Among such patients with a treatment contact for depression, 80 percent of those treated in primary care received no appropriate treatment for depression (pharmacotherapy or counseling). The opposite prevailed in mental health treatment settings, where most patients (nearly 90 percent) received an appropriate form of depression treatment. Such data illustrate the challenges in providing quality care for individuals with depression. Most persons receive no depression treatment (despite some contact with a health care provider). Most of those who do receive some treatment receive inadequate care. The predominant opportunity for the treatment of depression is in primary care. How can clinicians and administrators address these problems in access to and quality of depression care? How can mental health services research assist in these efforts?

Health services researchers have examined interventions targeting providers (the supply side of care), individuals affected by depression (the demand side), and policies. By far the majority of health services research in this area has focused on the supply side through attempts to change provider management of depression, especially primary care providers,

who see most of the patients with depression. Such research has approached the under-treatment of depression in primary care with different interventions of interest. For example, a multicomponent health care system-level intervention called "collaborative care" structures depression treatment in primary care settings by using case managers who educate and follow patients, track outcomes, and adjust treatments for patients who are not responding, consultation and decision support for primary care providers by mental health specialists (psychiatrists or psychologists) and the use of technology-based resources to support the system. Numerous randomized controlled trials on collaborative care for depression have demonstrated meaningful effects on depression symptom improvement, adherence, response to treatment, remission and recovery from depression, as well as satisfaction with care. However, only a small effect has been established on patient quality of life, including functional status.

A second health services research approach has studied the implementation of quality improvement (QI) programs for managed primary care settings with the goal of increasing the percentage of clinically depressed patients receiving appropriate depression care by national guidelines. The QI intervention consists of four components: institutional commitment of in-kind resources, training of local clinical leaders to implement interventions (cognitive behavior therapy, pharmacotherapy), training of local treatment staff, and patient identification. In one 12-month study, depressed patients in QI intervention clinics were more likely to receive counseling or medications, visit a mental health specialist, have a remission from the depressive episode, and retain employment than depressed patients in "control" clinics. Researchers have evaluated another approach in "behavioral health labs" that improve screening and detection of depression in primary care settings. All three of the above depression treatment models demonstrate the potential for improving depression care in primary care settings through "supply side" interventions. Major challenges remain, however, in promoting the widespread adoption of these approaches.

Far less research on depression care has been conducted on demand side interventions with patients, although one can certainly argue that even the predominantly supply side interventions just reviewed increase demand by educating patients about their symptoms of depression and about the value of treatment. Negative attitudes about depression and its treatment among the general population can deter persons from seeking help. Such negative attitudes arise from personal health beliefs, social norms and stigma, as well as from prior negative experiences with help-seeking. True demand side interventions are aimed at directly increasing the likelihood that individuals with depression will seek and participate in effective treatment. Such demand side interventions focus on awareness of

the signs and symptoms of depression, self-assessment for these signs and symptoms, the effectiveness of treatment, and skills in seeking help. Some common examples of such efforts include National Depression Screening Day campaigns, free depression screenings at employee health fairs, free pamphlets in physician offices and clinics, anti-stigma campaigns through the media, and direct-marketing media campaigns on depression, such as those currently put forward by pharmaceutical companies. Health services research that examines the effects of such programs remains sparse, and little is known about the effects of these types of demand side interventions.

A third domain of intervention to improve detection and treatment for depression in primary care is that of policy, system organization, and financing approaches. A prime example of this type of intervention is the current effort to promote health insurance parity for the treatment of mental disorders. Inadequate insurance coverage for the treatment of a mental disorder poses major barriers to treatment. The federal Affordable Care Act (ACA) enacted in 2010 expands coverage of mental health and substance use disorders by including benefits for such disorders in the Essential Health Benefits required of all new small group and individual market insurance plans and by applying federal parity protections more broadly, requiring insurance plans to cover treatment for mental health and substance use disorders at parity with medical and surgical benefits; a projected 62.5 million individuals will benefit by access to these federal parity protections. In addition, the ACA provides states a new option for organizing care in their Medicaid programs: "health home" services for Medicaid beneficiaries with severe chronic conditions who can benefit from enhanced coordination and management of physical and behavioral health care as well as long-term community-based services and supports. The "health home" model aims to improve the quality of health care and the patient experience while providing more cost-effective care. Health services research on service organization and financing seeks to answer critical questions about the effects of policy interventions such as parity laws and "health homes" on issues including the quality and experience of behavioral health care—such as depression care—delivered through reorganized systems.

Case 2: Services for Families of Persons with Schizophrenia

During the second half of the 20th century, clinical research on families in the treatment of individuals with schizophrenia dispelled early assertions that disturbed family relationships play a major role in the etiology of the disorder. Instead, research led to the recognition that families provide major support networks for most persons with this disorder, and that they need education and support to enable them to engage as partners in care. The potential advantages of engaging and educating families optimally was

suggested by early studies linking high levels of "expressed emotion" among families to greater likelihood of patient relapse after hospital discharge. Research spanning from the 1970s to the 1990s clearly established family psychoeducation (FPE) as an evidence-based practice in the care of individuals with schizophrenia. The Schizophrenia Patient Outcomes Research Team included FPE as a treatment recommendation, stipulating that patients who have ongoing contact with their families should be offered a family psychosocial intervention that lasts at least 9 months and includes education, support, and some training in problem-solving skills. Other statements of best practices also include a recommendation for FPE. FPE was found to reduce relapse rates, improve medication adherence, reduce symptoms, and improve functional outcomes for individuals with schizophrenia. Specifically, more than 30 randomized clinical trials showed that relapse rates for individuals receiving FPE were 25 to 50 percent lower than those observed for individuals receiving standard individual services.

In line with the health services research framework (see Fig. 58.4–1), investigators have examined the prevailing patterns of practices as they relate to families with regard to both access to any services and more specifically access to evidence-based practices consistent with the FPE model. A variety of studies conducted in community settings and in Veterans Administration facilities has shown that not only is FPE rarely offered, but in fact a far lower standard of family contact with clinicians occurs in the majority of cases. Chart reviews, clinician interviews, and consumer interviews all have produced the same conclusions. Thus, major problems in the access to and quality of family-oriented services exist.

Following the health services quality-of-care framework, researchers have undertaken efforts to improve practices by disseminating FPE. Supply side approaches have been the most common. Numerous initiatives to disseminate FPE have been attempted throughout the country. The New York State Office of Mental Health (OMH) mounted an impressive effort to implement programs at 35 different sites throughout the state and provided extensive training. Although numerous family groups were started and the potential benefit was large for those families and patients who participated, OMH decided not to continue the project because only a small number of families and patients throughout the state actually received the program. The Substance Abuse and Mental Health Services Administration included FPE as part of an effort to disseminate evidence-based practices by creating toolkits that include informational resources for all stakeholders, a workbook for practitioners, and a fidelity scale. The implementation phase of this project resulted in limited selection of FPE as a practice to disseminate and limited penetration of FPE in those sites that selected FPE.

The marginal success of these dissemination initiatives for this

evidence-based practice demands greater understanding of how to influence changes in practice. Research must strive to understand and overcome observed roadblocks to dissemination of family services, whether these roadblocks exist on the supply side among providers and service systems or on the demand side among patients and their families. Such roadblocks can take many forms. In identifying such barriers, health services researchers seek critical points for intervention to improve dissemination. For example, practitioners may be unaware of the value of the intervention, or they may lack the skills to deliver it. Families may be suspicious of such services as a result of unpleasant experiences based on older family therapy models. Payment systems may not provide support for the programs. However, even the FPE demonstration projects that had the capacity to overcome most or all of these barriers failed substantially to affect dissemination. In such a case, health services researchers have at least two other strategies at their disposal. The first is to develop more inventive dissemination strategies. The second is to decide that a modified or new evidence-based practice is needed—one that is more acceptable to providers, patients, and service systems.

This first task of developing more inventive dissemination strategies requires re-evaluating the barriers to dissemination. Such barriers exist at the disparate levels of patient and family, providers, administrators, and payers. Supply side strategies, such as providing higher rates of reimbursement for providing FPE, as well as more intensive and targeted training for providers, could be successful. Health services researchers investigate these strategies by using qualitative methods to interview providers and payers where FPE initiatives have already been started to determine whether they think that increased rates of payment or training would help. Strategies under study also target barriers to FPE at the consumer and family levels, thus focusing on developing the demand for FPE. A new approach called Recovery Oriented Decisions for Relatives' Support (REORDER) uses a shared decision-making process to structure patients' exploration of whether they want to include families in their mental health care. REORDER is personalized by attending to patient preferences for family involvement, focusing on the mental health recovery goals of the patient, and exploring how family members could join with the patient to meet those goals. The REORDER clinician begins by working with the consumer to identify pros and cons of family involvement and then uses education, support, and decision-making exercises to assist and empower patients to meet their goals. A randomized trial showed that this approach markedly increased rates of family contact with clinicians while it also increased a measure of recovery among participants assigned to the REORDER condition.

The second strategy to address difficulties in implementing FPE is to develop new evidence-based practices or to test revised models of FPE that

attempt to reduce barriers to implementation. For example, a meeting of family researchers and practitioners identified the need to determine the critical ingredients of FPE so that a simpler and briefer model could be tested. The National Alliance on Mental Illness Family to Family Education Program may provide a second approach. This program is not a clinical service, but is peer-driven. Trained family-member volunteers teach this manualized 12-week program in weekly 2- to 3-hour sessions. The program provides information about mental illnesses, treatments, medication, and rehabilitation. Participants also learn self-care, mutual assistance and communication skills, problem-solving strategies, and advocacy, and develop emotional insight into their responses to mental illness. Although the program does not aim to reduce patient relapse, it may provide some benefits to families. Notably, the program had been widely disseminated in spite of the dearth of systematic research demonstrating its effectiveness. After its dissemination, a partnership between health services researchers and NAMI conducted three sequential studies including a randomized trial have provided evidence that the program is helpful to families—in improving family functioning, coping, empowerment, and knowledge. This demonstrates that in the pursuit of dissemination of evidence-based practices, health services researchers may tackle the challenge of conducting research on existing practices that are in wide use but as yet relatively unstudied.

Case 3: The Continuing Saga of the New Antipsychotic Medications

The quest for a better antipsychotic medication spawned considerable enthusiasm, investment in new product development, and basic and clinical research during the last quarter of the 20th century. The net result was the introduction of several "second-generation" antipsychotic medications that by 2006 accounted for nearly 90 percent of all prescriptions for antipsychotic medications in the United States and nearly two-thirds of such prescriptions in the United Kingdom. This market growth was driven in part by a growing body of clinical trials, predominantly funded by pharmaceutical companies, reporting efficacy and safety advantages of the second-generation antipsychotics compared to the older agents. These reported advantages included a lower risk of extrapyramidal side effects, greater effect on negative symptoms and cognitive impairment, lower relapse rates, and greater safety and tolerability. The use of these agents grew exponentially and accounted for dramatic increases in pharmaceutical costs in the care of individuals with schizophrenia.

By the early 21st century, the major remaining issue seemed to be the relative efficacy and tolerability of the competing second-generation agents. Thus, two major, government-sponsored trials were launched on the relative effectiveness of the second-generation agents. These were the

Clinical Antipsychotics Trials of Intervention Effectiveness (CATIE), sponsored by the National Institute of Mental Health (NIMH), and the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study (CUtLASS 1), sponsored by the U.K. National Health Services Technology Assessment Program. Due to continuing concerns about the substantially higher costs of the second-generation agents and lingering questions about the results of industry-sponsored trials, both of these studies included comparisons with first-generation agents. The details of these studies are not within the scope of this section on health services research, but the main and consistent findings across both studies were that, contrary to study hypotheses, the second-generation agents in general showed little or no superiority over the first-generation agents on multiple outcome measures. The CATIE study found that although olanzapine had a somewhat longer time to discontinuation, it also had markedly worse metabolic side effects. Although much debate continues regarding the strengths and limitations of these effectiveness studies compared to the body of earlier efficacy trials, this evolution of research on antipsychotic medications illustrates several salient points and challenges for health services research.

As noted in Figure 58.4–1, the interface between standard clinical research and health services research is often where efficacy meets effectiveness. CATIE and CUtLASS are two large multisite effectiveness trials contradicting a large body of prior efficacy trials, well after those efficacy trials have had their effect on routine practice. The current discussion provides a good opportunity to further clarify the distinction between efficacy and effectiveness. There is a common misunderstanding that the types of outcomes measured determine this distinction. For example, in most efficacy studies the primary outcomes are "clinical," that is, symptom reduction and rates of side effects. The primary outcome for the CATIE trial was time to discontinuation of the assigned medication, and for the CUtLASS trial the primary outcomes were quality of life, participant satisfaction, and costs of care, in addition to symptoms and adverse effects. However, such outcomes could also be used for efficacy trials; the types of outcomes measured cannot be used to distinguish efficacy from effectiveness. Rather, the primary distinction between efficacy and effectiveness trials is that the former emphasize *internal validity* of a comparison in order to isolate effects attributable to the interventions studied—for example, active drug versus placebo or comparison of two active treatments. Efficacy trials typically restrict their samples narrowly to reduce "extraneous" variation due to factors other than the compared treatments. Because the samples are restricted, external validity or generalizability is reduced to achieve high internal validity. In contrast, effectiveness trials seek to determine the effects of treatments in more heterogeneous samples that represent the population of patients who might be treated. CATIE and CUtLASS are effectiveness trials because of

their multisite sampling of "typical" patients in various clinical settings. The CATIE and CUtLASS studies are thought to be more generalizable than the efficacy trials that preceded them, and they might therefore have greater effect on practices and policies.

A health services researcher always tries to understand the population and the system of care to which a particular study might generalize. Although CATIE and CUtLASS are more broadly reflective of persons with schizophrenia who are receiving treatment than were the previous efficacy trials, it is important to note that CATIE and CUtLASS too have restricted generalizability. The CUtLASS trial restricted its sample to patients of age 18 to 65 years with schizophrenia spectrum disorders who were assessed to have an inadequate response or adverse effects to their current medication. They were therefore deemed to be candidates for a medication change. CATIE had a somewhat different set of inclusion criteria: Age 18 to 65 years, schizophrenia diagnosis, able to take oral medications, no history of serious adverse reactions to the proposed treatments, more than one schizophrenia episode, no history of treatment resistance, not currently pregnant or breast-feeding, and no serious and unstable medical condition. For both studies, the mean age of the participants was 40 to 41 years, and for both samples the average length of illness was about 14 years. In addition, for both studies patients were willing to try a medication change. With regard to treatment settings, the 1,493 subjects in CATIE were drawn from 57 clinical sites in the United States, including 16 university clinics, 10 state mental health agencies, 7 Veterans Affairs sites, 6 private nonprofit agencies, 4 private practices, and 14 mixed systems of care. The 227 subjects of CUtLASS were drawn from 14 community psychiatric services in the English National Health Service. Practicing clinicians can rapidly recognize the limitations of even these broad CATIE and CUtLASS samples with regard to generalizability to their own patients and practice settings.

Given this current state of knowledge about effectiveness, safety, and patterns of use of the various antipsychotic medications, then, what further questions can health services research help to answer? There are many issues, but two key ones relate to formulary guidelines and how clinicians and patients will make choices regarding an antipsychotic agent, given the relative advantages, risks, and costs associated with the various agents.

It is not surprising that the results of CATIE and CUtLASS, essentially showing equivalence of effectiveness among most agents and differences in costs and adverse effects, have rekindled the debate about drug formulary policies. This debate is framed on one end by those who advocate to "fail-first" on a less expensive agent before a more expensive medication can be tried. On the other end are those who advocate for an open formulary that allows free choice by physicians and patients. This perspective argues that individual response cannot be predicted from the existing research and that, given apparent equivalence of effectiveness and variable safety

considerations, it is probably more cost-effective in the long run to allow individual patients and their physicians to decide what medication is best. This individualized approach may prove less costly, given that symptom reduction and avoidance of adverse events may be enhanced. Health services research can be brought to bear on such questions.

The formulary policy debate is one of supply side interventions at a systems level. Such interventions can be defined according to differing levels of restrictions to access to the various antipsychotic agents. These could include the "fail-first" use of cheaper agents before access to a more expensive agent is allowed, a "preferred drug list" that would make available all of the first-generation agents and a limited number of second-generation agents (based on cost), and a completely open formulary. The key health services research questions are how different formulary policies affect patient outcomes (symptoms, adverse events, drug discontinuations) and costs (medication costs, total mental health care costs, total health care costs) in large systems of care.

In the wake of the CATIE and CUtLASS studies, health services researchers also seek to understand decision-making processes in the selection of an antipsychotic agent. Given the results of CATIE, one might expect to see at least some changes in patterns of care, including increased use of the older agents and increased use of clozapine (based on evidence from efficacy trials, as well as CATIE, that clozapine is helpful in treatment-resistant schizophrenia). What has actually happened? In the United States, since the publication of CATIE and CUtLASS, the use of olanzapine has declined, perhaps due to the finding of associated metabolic risks. The use of first-generation agents has continued its slow downward drift. The use of clozapine has remained unaffected. Prescriptions for two other second-generation agents, quetiapine and ziprasidone, have grown modestly. There is little or no evidence that these large effectiveness studies have had substantial effects on practices. One obvious explanation for this apparent lack of response to the results of CATIE and CUtLASS in patterns of medication use is that there has been insufficient time for such effects. A health services researcher might seek to describe the patterns over a longer period of time, to understand the decision processes underlying such changes, and to assess the effects of interventions to bring about the desired widespread changes in practice.

Descriptions of patterns of antipsychotic utilization over time can be achieved by analyzing prescription claims data from large payers—especially Medicaid, but also Medicare Part D and commercial insurance carriers. Analysis of such large databases permits the ascertainment of overall prescription rates for the various antipsychotic agents and hence estimation of their changing market shares. Such analyses also permit examination of the association of a limited but important set of patient characteristics, including age, gender, race, and primary diagnosis, with

types of medications. These observations allow examination of issues such as disparities in access to various agents among subgroups. Similar analyses can identify the clinically questionable use of certain agents among patient groups known to be particularly at risk of certain adverse effects, patterns of "off-label use," and differences in prescribing patterns across insurance plans with different levels of formulary coverage. This type of *health services utilization research* is primarily descriptive but is used to focus on more specific research questions or hypotheses to be tested in *interventional services research*. For example, an observation in a utilization research study that a significant number of patients are being prescribed more than two antipsychotic agents simultaneously could lead to a utilization review intervention study that questions such practices and requires justification in individual cases. The effect of such a utilization review intervention on prescribing practices could be evaluated. Another intervention might involve identification of patients who are prescribed a second-generation agent that is known to have metabolic side effects and who are also prescribed medications that indicate a metabolic risk, such as cholesterol-lowering, antihypertensive, or hypoglycemic agents. Identifying such patterns could lead to an intervention to change prescribing practices. These two examples illustrate the type of supply side interventions at the provider level which can be developed in response to services research data drawn from the system level.

Health services researchers are also increasingly interested in interventions that influence interactions between individual patients and their providers. If the goals of antipsychotic therapy are to reduce psychotic symptoms with the least risk and to maximize the quality of life and functioning, how do clinicians and patients evaluate and negotiate the decision about what medication to use? To what extent do they incorporate evidence from clinical trials and practice guidelines into their decisions? What other sources of information do they use? How do patients and physicians ascertain and weigh individual risk factors? How do costs factor into their calculations? A variety of research techniques can be applied to these questions, including structured questionnaires, qualitative interviews, and direct observation of patient and physician interactions. As better understanding of these patient–physician decision processes emerges, interventions can be designed to facilitate improvements in care. Studies of shared decision making, a nonpaternalistic model of how patients and clinicians make medical decisions together, have shown that both physicians and patients in psychiatric settings have generally positive attitudes toward the approach. However, in practice, shared decision making is incomplete or less frequent compared with what occurs in general medicine settings. Researchers have begun to identify barriers and facilitators to shared decision making and to evaluate interventions to promote this process by preparing both professionals and patients to

engage in it, including through the use of decision aids and support systems. Knowledge about how physicians and patients obtain and weigh scientific information can lead to information being presented in better, more user-friendly and relevant formats. It is essential to evaluate changes not only in the processes of decision making and treatment—for example, increases in the use of shared decision making or greater consideration of risk factors in these conversations—but also associated changes in outcomes, symptom relief, reduction in adverse effects, patient function and quality of life, and physician and patient satisfaction. There is limited empirical evidence to date about the outcomes associated with the use of shared decision making in mental health, although researchers have found in patients an increased feeling of involvement in and positive attitude toward treatment as well as increased self-awareness.

OVERVIEW

Pressures are mounting to ensure that the fruits of biomedical research translate into treatments and services. Mental health services research has substantial power to both inform and to advance this process. In the end, all mental health services research can be summarized in three questions. Do persons with mental health needs have access to treatment? Is the treatment they receive of adequate quality, incorporating the latest in scientific knowledge? Does the treatment offer good value—that is, good outcomes for the resources expended? These questions are posed by the field in such a manner as to maximize generalizability and to identify subgroup variations. These questions must also be asked within systems concerned with health care and social policy to inform clinical care and maximize the benefit to individuals—the ultimate goal.

Mental health services research, necessarily interdisciplinary, must consider how social factors, financing systems, organizational structures and processes, health technologies, and personal behaviors affect access to health care, the quality and cost of health care, and ultimately health and well-being. Health services researchers work closely not only with biomedical colleagues, but also with investigators from other scientific disciplines (sociology, anthropology, psychology, economics, education, and political science) and with service system and policy leaders to implement and evaluate changes.

Much of biomedical science tends to be occupied with internal validity—the strength of the claim that the experimental manipulation causes the outcome. This leads to the desire to control all potentially confounding variables, but it reduces external validity. External validity, or generalizability, lies at the center of the translational process and health services research. At the same time, generalizability encompasses sensitivity to variations among subgroups of patients, taking into account demographic and cultural differences in disease, health care beliefs, and

behaviors and access.

Moving forward, mental health services research faces several challenges. First, while the advance of "evidence-based practices" embodies the principle of translating scientific knowledge into practice, more attention must be given to the complementary principle of "practice-based evidence." In essence, how can one inform the directions of science through evidence that emerges from clinical practice and experience? Second, challenges for treatment systems and for research seeking to identify and promote "best practices" arise from the growing diversity of US culture. Third, the field needs a better understanding of how to implement system changes and to disseminate best practices. For this the field must look beyond the traditional medical and social sciences to such disciplines as marketing science. Fourth, research designs that treat service providers as research subjects require careful consideration to ensure the protection of human subjects that have not been traditionally addressed by institutional review boards.

Finally, major challenges exist in the juxtaposition of the comparatively slow progress of science with the needs of practitioners, planners, administrators, and policy makers, who must respond quickly to the needs of patients and systems of care. The Recovery After an Initial Schizophrenia Episode (RAISE) project of the NIMH provides a current example of a multidimensional partnership serving to hasten the translation of scientific findings to practice. The NIMH funded two RAISE projects to study the effectiveness and implementation of evidence-based coordinated specialty care programs for young adults experiencing the onset of nonaffective psychosis. Attention to policy and practice while these research studies were being conducted led to the relatively rapid expansion of resources for evidence-based programs as part of the mental health block grant in 2014. For health services research to remain relevant, new models of partnership will continue to be needed—models that provide timely information in an iterative and collaborative manner among all stakeholders.

▲ 58.5 The Psychiatric Hospitalist

BARRY H. GUZE, M.D., AND ANGEL CIENFUEGOS, M.D.

INTRODUCTION

Over the last quarter of a century, the American health care delivery systems, and other systems around the world, have adopted an inpatient treatment model called by most the "hospitalist model." As opposed to the nonhospitalist traditional models, these are medical providers who are part of inpatient programs in medicine, pediatrics, surgery, and now mental health, in which the medical care is provided. The hospitalist is a specialist in inpatient treatment, based in an inpatient facility or hospital. This type of practice specializes in acute and serious illness rather than chronic ambulatory medicine and health maintenance. They are knowledgeable about comorbidities in acute and critical clinical presentations. The number of hospitalists has been growing consistently and it has been suggested that the generalist who cares for patients across the full continuum of care may be a vanishing breed.

Traditionally, patients have been cared for in the hospital by their prior primary care physicians, in most cases family practitioners or general internists in a "Continuity of Care" model. In a recent transformation in many parts of the United States, when patients are hospitalized their care is now more likely to be provided by a hospitalist. In especially complex cases in which multiple consultations where subspecialists are required, it is the hospitalist who coordinates care. When the patient is discharged, he or she returns to the care of the primary care physician and routine follow-up by other medical specialties. This change parallels the change of practice patterns in psychiatry, in which, in many instances, a separate psychiatrist may care for a patient while admitted for inpatient treatment. Historically, these individuals in psychiatry have been called unit directors or ward chiefs of large state mental institutions. However, in their current role, they are the psychiatric parallel of the hospitalist found in medicine and pediatrics. In both cases, outpatient physicians relinquish the care of hospitalized patients to inpatient specialists.

The development of the hospitalist model has occurred similarly for

medicine and psychiatry in the context of the changing role for acute care hospitals. As both medicine and psychiatry become more ambulatory in orientation, inpatient institutions have been moving away from their central role in health care. They are becoming specialized institutions for acutely ill patients. Generally, the level of severity of illness in the inpatient setting has continued to increase as well as the number of comorbidities. Although the hospitalist model was widely accepted previously in Canada and the United Kingdom, the first modern hospitalist program was established in the United States in 1994, overcoming the opposition of many primary care physicians who objected to the model because of the disruption in continuity of care. In any case, it was a fact that inpatient care had become an economically inefficient use of their time.

The hospitalist has emerged in response to the increasing complexity of care associated with hospitalized patients. These individuals, with time and training, develop significant experience with the acutely ill patient. They develop an understanding of continuity and coordination of care since part of their responsibility is to work on the "hand-off"—the patient's transition from outpatient to inpatient and, after treatment, back again to the prior outpatient physician.

The initial growth in the number of hospitalists occurred because leaders at health maintenance organizations (HMOs), some hospitals, and medical groups believed that they would lead to a reduction in inpatient costs without a reduction in patient satisfaction or quality of care. Recent estimates indicate that the current number of hospitalists in the United States is nearly 30,000. In 2010, 57 percent of US hospitals had hospitalists on staff including 87 percent of hospitals with a number of beds equal to or above 200. Approximately 80 percent of Veterans Affairs hospitals currently have hospitalists. Membership in the Society of Hospital Medicine (SHM), the professional organization for hospitalists, is about 6,000.

Because hospitalists have become common at the major teaching hospitals in the United States, they have also become a major provider of instruction to medical students and residents in internal medicine and pediatrics. These two groups now receive much of their inpatient education from hospitalists working in their role as attending physicians.

THE DEFINITION OF HOSPITALIST PHYSICIANS

Robert Wachter, MD, MHM coined the term "hospitalist" in the *New England Journal of Medicine* in 1996. **According to the SHM, this is a** medical specialty dedicated to the delivery of comprehensive medical care to hospitalized patients. Practitioners of hospital medicine include physicians and nonphysician providers who engage in clinical care, teaching, research, or leadership in the field of general hospital medicine. In addition to their core expertise managing the clinical problems of

acutely ill, hospitalized patients, hospital medicine practitioners work to enhance the performance of hospitals and health care systems by attending to all patient care needs during hospitalization; being mindful of quality and process improvement techniques; collaborating, communicating, and coordinating with all physicians and health care personnel; caring for hospitalized patients; and ensuring safe transitioning to the community, all the while emphasizing the efficient use of hospital and health care resources.

Hospitalists should be physicians who have general inpatient care as the primary focus of their professional activities, which include clinical care, teaching, research, or administration. Hospitalists typically spend more than 25 percent of their time working in hospital settings. Commonly they are internists taking the place of primary care physicians in providing inpatient care. Many hospitalists become involved in clinical-administrative tasks in addition to patient care responsibilities. Commonly these include quality improvement efforts and peer review. Academic hospitalists may explore issues such as outcomes research that explores the cost and quality of inpatient care. Many lead the development of new inpatient educational programs for house staff and medical students. Most hospitalists work in community hospitals; a smaller number work in teaching hospitals. In those academic settings, their responsibilities expand to include teaching medical students and residents.

In general medicine, most hospitalists have been trained as internists. There is no separate training program for hospitalists, although some residency tracks and 1-year fellowships have begun to emerge. Such residency tracks typically focus on training in inpatient medicine as well as hospital-oriented quality improvement, patient safety, and end-of-life care. Fellowships usually focus on providing future academic hospitalists with the research skills they will need in areas related to inpatient care.

Hospitalists are usually salaried physicians with defined work hours. They care for patients with complex medical illnesses, rather than the chronicity found in outpatient practice. Many of them have interests in health systems and want a chance to improve the quality of services and control costs associated with inpatient practice. The increasing complexity of medical care demands greater specialization. In many settings, the expectation for physicians to have expertise in both inpatient and outpatient medicine is increasingly regarded as unrealistic. Supporters of the hospitalist movement emphasize the benefits of a specialized knowledge base. Hospitalists specialize in inpatient care, allowing primary care physicians to focus on ambulatory care. A consequence of the increase in the number of hospitalists has been a proportionate increase in the number of “office-only” physicians as well.

Hospitalists in academic settings are on-site experienced physicians. Their presence helps hospital wards to run more smoothly, which increases

patient and nursing staff satisfaction. Such individuals are usually familiar with ward dynamics. They also often have a good relationship with the ancillary staff, appreciate their contributions, and have long-term commitments to the hospital. Such involvement facilitates the management of clinical situations and therefore prevents them from evolving into significant problems. Moreover, these individuals generally have a breadth of clinical knowledge and experience from working in hospitals. Thus, they are skillful in the expeditious treatment of the seriously ill, comfortable in managing multiple minor inpatient problems, and familiar with consulting various medical and surgical specialists. These attending physicians are also best positioned to provide the supervision that interns and residents need when managing acutely ill inpatients. Due to their inexperience and rapid turnover, interns and residents benefit from the support that a responsible physician provides when making major medical decisions.

It has been suggested that the minimum amount of inpatient work expected of a hospitalist is 25 percent of their practice. This minimal amount allows the hospitalist to become experienced in the management of common inpatient conditions. Relationships with care providers in affiliated disciplines can also develop more easily with this degree of availability. Such individuals are often more likely to commit to enhancing the hospital by participating in quality improvement efforts and helping to control costs.

There are two common models of hospitalist care. The most common consists of full-time inpatient physicians who practice as a group. In the second model, a group of physicians rotate responsibility for inpatient care. The rotational periods vary, depending on the practice of the group. This method allows a group to maintain skills in both inpatient and outpatient practice. It can, however, produce frequent periods of discontinuity in outpatient care.

The use of the hospitalist model may be voluntary or involuntary depending on how managed care organizations choose to transfer care when a patient is admitted for inpatient treatment. Commonly under the involuntary model, the outpatient physician is not permitted to write orders and is relegated to visiting the patient in the hospital. In contrast, many physicians voluntarily transfer responsibility for the care of their patients to hospitalists, cardiologists, or specialists in intensive care medicine. For example, it is common for primary care physicians to transfer care of their patients to intensivists (physicians specializing in intensive care) when their patient is admitted to the intensive care unit (ICU). In a similar manner, geriatricians working in nursing homes commonly transfer care to internists when their patients are admitted to the hospital. Although not all hospitalists may have the same degree of interest or ability in studying patient outcomes or developing practice guidelines, most of them participate in these organizational activities.

ROLES OF THE HOSPITALIST

The predominant role of the hospitalist is to take care of hospitalized patients. Over the years inpatient care has become more and more specialized and has gained in complexity and, while the number of hospitalized patients has decreased, the acuteness of their conditions has risen. Simultaneously, the scrutiny of the length of stay (LOS) and associated hospital costs are increasing. It is common to see hospitalists involved in projects to reduce LOS and cost of admission. Generally, reports show that inpatient care of medical patients by hospitalists reduces LOS and hospital costs. Hospitalists are able to respond more rapidly to changes in a patient's condition because they tend to be readily available and control the timing of treatments and consultations.

The hospitalist is also the receptor for inpatient admissions. Increasingly, outpatient physicians prefer to transfer hospital care to a specialist. Common reasons for this preference include the convenience of uninterrupted outpatient work, the convenience of not making rounds in the hospital, and a lack of expertise or comfort with the acuteness of illness and clinical skills associated with inpatient work. There is also some desire to avoid the intensive scrutiny associated with providing care to hospitalized patients. Similarly, hospitalists provide pre- and postoperative medical care to surgical patients. Their availability allows the surgeon to be in the operating room all day and ensures that the patient receives appropriate medical care. Many health care systems are having hospitalists become the physician of record for nonmedical inpatients with medical comorbidities.

An analogous situation has long existed with ICUs. Most ICUs are closed, meaning that they use dedicated critical care physicians who accept the patient from the generalist on the ward and transfer care back to them when the patient leaves the unit. These physicians have the skills, abilities, and availability to care for the critically ill patient, and because of these skills they have improved outcomes and efficacy.

In many specialties, including critical care, oncology, bone marrow transplantation, cardiology, infectious diseases, and psychiatry, the hospitalist model is common. The attending physician is dedicated to inpatient service. In academic centers, this may be for multiple rotations throughout the year or full time.

An additional role for hospitalists is providing physician participation in hospital management. Commonly this occurs by their joining in quality management operations, the development of hospital policies and procedures, management of the formulary, participation in credentialing activities, peer review, and utilization management. They also care for outpatients, often in a consultative role. Some hospitalists participate in follow-up clinics in which patients are seen once or twice following discharge. Such outpatient activities, however, represent only a small

fraction of their time.

Hospitalists also play a role in communication. Most systems expect the hospitalist or their designee to contact the primary care physician within 24 hours of admission and to ensure that either a summary letter or the discharge summary is sent to the outpatient clinician at discharge. They also transfer clinical information from the outpatient care physician to the inpatient provider on hospitalization and the subsequent transfer of information back to the outpatient care physician by the hospitalist on discharge. This "hand-off," also known as "warm hand-off" in cases when the communication is verbal, is symbolic of the transfer of clinical responsibility that occurs on hospitalization. The hospital-based physician assumes responsibility for diagnosis and management. For this reason, most hospitalists believe that there is an obligation to validate the diagnosis. This is, in essence, the provision of a second opinion about diagnosis and subsequent management. Much has been written about the hand-off. It is one of the two controversies of the model (the other controversy being obligatory use of hospitalists). The disadvantage of the hand-off is obvious: Important information can be lost and result in discontinuity. There may also be patient dissatisfaction because of the assignment of a new physician.

The hand-off can also be viewed as producing one of the strengths of the hospitalist model. It results in the patient being under the care of a physician in the hospital throughout the day. This individual reacts to clinical data in real time. He or she is the coordinator of inpatient care. However, some surveys show that patients are at least as satisfied with the care from hospitalists as they are with care from their primary care physician. The data suggest that patients may be willing to trade familiarity for availability. It is also noteworthy that many hospitalized patients do not have primary care physicians, especially among the uninsured. In some systems where hospitalists are introduced there is an increase in patients' satisfaction with their outpatient physician, suggesting that the improved ability to focus on their outpatients is a benefit of this model for the primary care physician.

Hospitalist systems that focus on inpatient–outpatient communication have fewer difficulties. Commonly, programs fax the discharge summary to the outpatient clinician on the day of discharge. Some programs fax daily progress notes as well. Increasingly, programs have a continuity clinic in which patients may be seen once or twice soon after discharge to ensure stability before the patient reappears at the primary care physicians' office.

THE PSYCHIATRIC HOSPITALIST

It could be argued that psychiatry was the first of the medical disciplines to adopt the hospitalist model on a large scale. Paradoxically, however, full-time inpatient psychiatrists have never called themselves hospitalists.

Psychiatric hospitals and asylums date back to the early Middle Ages. The most available career opportunity available to doctors treating the mentally ill was working in a hospital until the rise of psychoanalysis. The career choice was to focus on working in a publicly supported state mental hospital or a private psychiatric hospital. Those physicians resemble what are now considered to be hospitalists.

With the advent of antipsychotic drugs and the trend for deinstitutionalization during the 20th century, psychiatry, along with numerous other disciplines, adopted the model of continuity of care, in which physicians follow their ambulatory patients both in outpatient settings and while hospitalized. Outpatient psychiatrists admitted and followed their patients in the event of a needed inpatient stay.

As the field has expanded and the effect of third-party payers has restructured the profession, the proportion of hospitalists has declined while the absolute number has increased. One of the earliest surveys of career areas for psychiatrists dates to 1953; it noted the role of psychiatrists working full time in hospitals. Later surveys in the 1960s, 1970s, and subsequent years noted that the percentage of psychiatrists working in mental hospitals was decreasing. In 1965, for example, roughly 30 percent of psychiatrists worked in hospitals, but by 1979 this had dropped to less than 14 percent.

One of the problems that nonhospitalist-based psychiatry has shared with other medical disciplines is that the admission and care of their patients while admitted was very disruptive of their careers as academicians, teachers, and researchers. The role of unit director or ward director has been a traditional role in psychiatry. At one time, these individuals were relatively junior psychiatrists who, in academic settings, would attempt to succeed in the traditional triad responsibilities of research, patient care, and teaching. In any setting, academic or not, these individuals are the epitome of the psychiatric hospitalist. Their job functions are highly congruent with the descriptions of hospitalists noted earlier.

In 2010, one of the hospitals of the Veterans Affairs Healthcare System transitioned its mental health inpatient units from nonhospitalist or continuity of care (nonhospitalist based) to a hospitalist-based model of care. This change resulted in an increase in the total number of discharges and a decrease in the number of readmissions within 30 days. Surprisingly, patients discharged by hospitalists were more likely to follow up with after care appointments. This is important considering the statistically increased incidence of suicide after an inpatient stay.

As it is with other medical disciplines, one of the expectations from a financial standpoint is that psychiatric health care delivered by hospitalists will decrease the LOS as well as the cost. It may also facilitate care of patients with medical comorbidities, since medical consults are readily

available and hospitalists are likely to be more familiar with interacting with medical and surgical disciplines. In a modern institution, psychiatric hospitalists cover on-call and consult responsibilities. Psychiatric hospitalists are familiar with assessing and treating agitation, acute states of the most severely mentally ill patients, including psychotic and mood disorders. They are also comfortable with protocols to assess and treat withdrawal from alcohol and other substances a well as with keeping up with the legal requirements of involuntary admission.

Psychiatric hospitalists spend most of their time on inpatient units. They carry a significant share of resident and medical student training. Trainees working with hospitalists are frequently more satisfied with the amount of time and dedication they get from their attending physicians, which normally are part of the clinical faculty of the associated academic institution. These faculty members are expected to be educators in addition to clinicians and are not subjected to the same publication and funding expectations of research faculty. The inpatient units are the center for education and training during the first years of residency and offer the appropriate diversity of clinical presentations providing students with the appropriate amount of learning material.

Psychiatric inpatient units are environments where multidisciplinary approaches involving psychiatrists, nurses, psychologists and social workers are more frequent than in many outpatient settings. Co-management of psychiatric and medical problems will also be particularly common for these practitioners making them more familiar with interacting with medical consults and more apt to treat these comorbidities more effectively. For similar reasons, they will be better qualified to assess appropriateness for transfers from medical to psychiatric units.

HISTORY OF THE MODERN HOSPITALIST MOVEMENT

The Modern Hospitalist Movement was born in the United States in the 1990s. The argument still continues between followers of the "Continuity of Care" model and the hospitalist model. Several factors led to the change. For the outpatient clinician, the arrangement frees them from the disruptive burden of seeing a small number of inpatients. It allows them to focus on their area of expertise: outpatient practice. It avoids disruptions in the outpatient schedule that can occur when inpatient rounds are a daily responsibility. For the hospital and third-party payers, the model reduces inpatient expenditures with similar clinical outcomes. This model does not adversely affect patient satisfaction with care or trainees' satisfaction with their educational experience. Although this practice pattern may benefit hospitals or group practices, its professional fees are not usually sufficient to make the program self-supporting. To remain viable over the long term, these programs require support from the programs such as hospitals or group practices that benefit from the efficiency rendered by these

programs.

Under the traditional model for inpatient care, outpatient physicians made hospital rounds early in the morning and again at the end of the day. There could be calls from the emergency room or the hospital. The calls would, at times, interrupt outpatient practice and interfere with the efficient treatment of outpatients. Many clinicians noted a decline in office productivity when they were obliged to make hospital rounds for a small number of inpatients.

A significant factor that led to the development of hospitalists was the desire to focus on efficient outpatient treatment and to allow inpatient treatment to be provided by those who would give it full-time attention. This allows outpatient physicians to avoid the frequent interruptions, paperwork, and preauthorizations associated with inpatient care.

The acuteness and diagnostic complexity of inpatients have been increasing over the last several decades. With the increase in acuteness and complexity have come newer treatment modalities and procedures associated with inpatient care. Those who only infrequently care for inpatients have found it increasingly difficult to remain current in these treatment methods. Part of the appeal of the hospitalist movement has been that it frees outpatient physicians of the responsibility to remain current with treatments they would only rarely use.

In England and Canada, the early recognition of the benefits of focusing on either ambulatory or inpatient care led very early on in this process to distinction of outpatient and inpatient physicians. The term “hospitalist” was first used to describe this concept in the United States by Wachter and Goldman.

In academic medical centers, hospitalists have become a third career pathway in addition to the prior pathways of clinical educator and clinical researcher. The development of the clinical educator was due to the need to care for outpatients and to teach students and residents at ambulatory care sites. How an individual physician spends his or her time is highly variable and tends to depend on the needs of the institution and the skills and experience of the individual physician. Time is typically divided among providing direct care to outpatients, supervising students and residents in providing ambulatory care, and various scholarly activities. Many also spend several months each year attending on an inpatient unit, during which time outpatient responsibilities are reduced. Educational activities may include responsibility for specific courses in the medical school curriculum or the teaching of specific knowledge or skills, for example, in patient examination. Most academic medical centers expect their clinician teachers to do scholarly work to meet standards for promotion. These activities commonly include developing new educational programs, writing review articles or case reports, or conducting research in medical education along with presentations at scientific meetings.

In Europe and Canada, there have long been specialists in inpatient general medicine who have been active in urban hospitals. A clear demarcation between inpatient and outpatient practice is new in the United States. In the United Kingdom, the consultant physician would take over care from the general practitioner when the patient was admitted to the hospital.

The increasing use of such hospitalists was initially spurred on by the emphasis on efficiency that came with the rise of managed care. The managed care environment stimulated the development of the hospitalist model in the United States. The emphasis on efficiency and cost containment took precedence over continuity of care.

Until the 1970s, most primary care was provided by a general practice physician who was not board certified in any particular specialty. Most medical care at that time was provided in a hospital setting. In the inpatient setting, the general practitioner was often assisted by the internist, who was often more experienced in inpatient medicine. By the 1980s, family practice had emerged as a specialty and came to define the general practitioner. The role of the internist in inpatient practice was diluted by the rise of medical specialists who could assist the general practitioner with inpatient care. Until the mid-1990s, hospitalists were uncommon in general medicine in the United States. Rare examples of hospitalists in the United States before the 1990s were called house doctor, hospital rounder, or inpatient manager. By the 1990s, however, general internists and family practitioners had begun to focus on outpatient care and had a progressively smaller role in inpatient care. Internists began to manage inpatients, and intensivists emerged to manage ICUs. Emergency departments began to be staffed by specialists in emergency medicine.

Although multiple forces were responsible for this change, two major factors were predominant—cost pressures on hospitals and physicians, and the increasing acuteness of inpatients. The shift of most medical care to the ambulatory setting resulted in most physicians having little ongoing experience with inpatient care. Practice effects meant that those who did large volumes of inpatient care had superior outcomes.

Many felt that the hospitalist model conflicted with the traditional notion of a generalist who would treat patients in both inpatient and outpatient settings and in so doing provided treatment that was less fragmented and more holistic.

THE STAGES OF HOSPITAL CARE

It has been suggested that hospital care in the United States has gone through four stages. In the first stage, all inpatients were cared for by their primary care physicians. This worked best when the acuteness of illness was low and most practitioners had large numbers of inpatients, cost was not as important as it is today, and hospitals were adjacent to practitioners'

offices.

The second stage occurred when these conditions no longer existed. Specifically, hospitals are no longer nearby, acuteness of inpatients is significant, costs are managed, and inpatient care has a significantly higher degree of complexity. Furthermore, outpatient offices are busy due to the shift of care from inpatient to ambulatory. At this point, physicians may form a group to rotate responsibilities for inpatient care. This system introduces an inpatient–outpatient discontinuity. The compensation for this is the enhanced availability of the inpatient physician.

A third stage is the development of voluntary hospitalists who are dedicated inpatient physicians paid by the hospital, medical group, or managed care company. Under this model not all inpatient care is provided by hospitalists. Primary care physicians retain the opportunity to manage their patients when they are admitted to the hospital.

A fourth stage is the mandatory hospitalist stage. At this point, all inpatients are cared for by hospitalists. This model is more common when there is strong institutional control of physicians. When there is a loose affiliation between the hospital and primary care providers (PCPs), the relationship is more likely to be at stage three if outside physicians wish to retain control of their patients.

BENEFITS FROM THE USE OF HOSPITALISTS

There has been more than a decade of research in benefits and disadvantages of hospitalist care. Most of this body of research demonstrates that hospitalists are efficient providers of care while lowering LOS and total hospital costs without lowering quality of care. Hospitalists are more efficient in hospital resource utilization than physicians who spend the majority of their time practicing in ambulatory settings. Many factors are believed to contribute to the improved efficiency of hospitalists. These include the practice effect of their familiarity with common inpatient conditions and with the hospital system. They are also more available to acutely ill patients and may respond more promptly to changes in their clinical state or changes in laboratory data.

Ambulatory care physicians experience a significant benefit from the presence of hospitalists. Hospitalists allow outpatient-based clinicians to attend to their patients without the disruption in their schedules that can result from the unpredictable demands associated with caring for acutely ill patients in the hospital. Furthermore, many ambulatory care-based clinicians may lack the familiarity with the inpatient management techniques that they had when they were trainees.

For the typical internist, the inpatient census is small. However, this small number of patients typically requires more effort than in the past because the patients tend to be more acutely ill and their care more complex. Furthermore, the pace of hospital work has also quickened, and

physicians are under pressure to minimize LOS, making the emphasis on efficiency even greater. Conditions that were once an indication for inpatient admission are now commonly treated in the outpatient setting, be that the office, the home, or the nursing home. The result is that outpatient practice is also more acute and demanding, making the disruptions of providing care for some inpatients also more challenging. Hospitalists may also shorten a patient's stay in the emergency department by being available throughout the day to admit a patient. An experienced hospitalist usually becomes comfortable caring for acutely ill patients with a variety of medical conditions. In some cases, this may result in a decreased use of laboratory studies and consultative services. This may also contribute to a reduction in the cost of inpatient care.

Because most primary care physicians spend decreasing amounts of time caring for inpatients, many feel they have lost some of their skill in inpatient care. This reduction has occurred both because fewer patients are admitted and because LOS is shorter. With fewer inpatients, there are less interruptions in a tightly scheduled day of outpatients. What emerges is an increasing split between inpatient and outpatient practice.

Acting as case managers, hospitalists reduce inpatient resource utilization, resulting in a shorter LOS and a lower cost of inpatient care without a reduction in quality of care or patient satisfaction. The reduction in resource utilization is likely a practice effect combined with the ready availability of hospitalists for diagnostic and management decisions. They coordinate and integrate care for their assigned patients, generating and reviewing clinical data, and facilitate access to subspecialty services. Since they are more readily available, they generally have more time to communicate with patients and their families as well as with the PCPs. The rapid increase in the number of hospitalists in the United States suggests that all these factors bring significant benefits to hospital health care.

There are a large number of uninsured patients in the United States. When they present in the emergency department seeking admission, there usually is no primary care physician with whom they have a prior relationship. Therefore, there is no outpatient physician available to manage their inpatient care. An increasing role for hospitalists is to provide care for these patients. Many office-based physicians feel that providing inpatient care is not cost-effective. The poor reimbursement for hospital visits is a common reason that many no longer provide hospital care. More and more outpatient physicians are also seeing sicker patients. Their volume of inpatient work has also increased.

Good communication between inpatient and outpatient physicians has also enhanced the acceptance and perception of benefits of this model. A key aspect of communication is the prompt delivery of a discharge summary to the outpatient physician.

Hospitalists also work with surgeons to provide primary inpatient care

to surgical patients in the pre- and postoperative periods. These combined hospitalist–surgeon teams have been associated with reductions in postoperative complication rates with no significant difference in cost or LOS.

Hospitalists improve the efficiency of inpatient care while maintaining or enhancing the quality of care. Their expertise comes from familiarity with the management of common inpatient conditions. Efficiency consists in reductions in resource use, usually measured as average LOS and hospital cost. This occurs because hospitalists are familiar with clinical pathways, are experienced in the planning of post discharge care, and are available throughout the day to respond to changes in diagnostic data or clinical condition.

Hospitalists relieve office-based physicians of the unpredictable demands of hospital practice. Patients are no longer kept waiting, and physicians no longer have the inconvenience of recurrent trips to the hospital. Outpatient physician productivity increases following the removal of inpatient responsibilities. Outpatient physicians are more reliably available in the office. They are not interrupted by hospital calls or the need to leave abruptly to see acute inpatients. They are able to expand their outpatient hours because they no longer make inpatient rounds. Their workday is more predictable. Another issue is that the number of acute care hospitals is diminishing and with them the relative percentage of patients admitted to the hospital.

Hospitalists standardize the quality of inpatient care. In many academic medical centers, there has been a concern about the wide range in inpatient abilities found in community-based clinicians. Many programs have worried about granting these physicians admitting privileges or opportunities to participate in the teaching service. Using a hospitalist system allows both the community-based physicians and the outpatient academic faculty to enjoy the same quality of inpatient care that is provided by hospitalist faculty.

Hospitalists produce clinical science with an emphasis on outcomes research, quality assessment, and quality improvement; clinical trials to improve treatment or diagnosis; and the development of clinical guides and pathways. They have been found to have better performance in measures of patient satisfaction, particularly with the discharge process, and they are recognized as leaders in issues of patient safety.

There is a positive correlation between experience and quality of care in a number of areas in medicine and surgery. When implemented, the hospitalist model has resulted in fewer but more appropriate specialty consultations, lengths of stay, and hospital costs. Due to their familiarity, hospitalists develop good working relationships with ancillary hospital staff, including discharge planners, nurses, consulting specialists, and outpatient physicians. Retention and recruitment improve in the

hospitalist system.

HOSPITALISTS AS CLINICIAN-EDUCATORS

Large academic institutions are the leaders in hospitalist-based care. In these institutions, one of the hospitalist functions is training of residents and medical students. Some are considering or implementing hospitalist fellowships. This means house staff receive training by those with expertise in hospital care. Throughout the day, there is an expert readily available with whom to confer about patient management. There is improved teaching and expert guidance. Hospitalists provide role modeling to trainees for careers in hospital work. They provide teaching effectiveness, knowledge of relevant subject matter, discussion of pathophysiology, emphasis on cost-effectiveness, and timely and effective student feedback.

The effect of hospitalists on academic medical centers may broaden the separation between researcher and clinicians. The researchers will focus further on research and obtaining grants. The clinician-educators will concentrate on clinical work and teaching. With the group of clinician-educators, there will be an added subdivision, with some focusing on outpatients and others on inpatients. Hospitalists may bring relief to the residents' on-call duties by covering for clinical needs.

Several studies have also found that hospitalists improve the educational experience for medical students and house staff. Because the faculty supervisors are skilled and experienced in modern inpatient care, they provide more effective teaching and oversight. Generally, when academic programs have evaluated the teaching abilities of hospitalists there has been enhanced satisfaction by students and residents when compared to prior models. Some trainees have also noted a reduction in workload associated with the hospitalist model. House staff report that hospitalists are more effective teachers.

Many academic medical centers have hired hospitalists as clinician-educators. This need has arisen because primary care physicians are able to spend very little time in the hospital. This results in less time with trainees for educational activities. The expectation is that hospitalists will devote more time to education, performance feedback, and supervision. This expectation has been supported by resident evaluations of teaching which rate hospitalists higher than traditional attending physicians, who briefly rotate onto the teaching service.

Clinical research done by hospitalists has traditionally consisted of studying the hospitalist movement. This has included studies of the efficiency, cost, and quality of hospitalist-run services, including inpatient–outpatient communication. Research has begun to expand to include prevention of nosocomial infections and hospital quality assessment, including medical error and pain management, health services and outcomes research, and ethics. Newer areas also include clinical trials that

focus on conditions common to the hospital, and genetic epidemiology. Since the advent of the modern hospitalist is a relatively new occurrence, there is probably insufficient mentorship at the moment. Improving mentorship may increase academic productivity among hospitalists.

DISADVANTAGES AND OBJECTIONS TO THE HOSPITALIST MODEL

Most objections to the use of the hospitalist model come from the fact that it introduces a purposeful disruption of continuity of care. Each patient transition increases the risk of medical errors and adverse events. In many cases, the hospitalist has no previous knowledge of the patient, making a problem for continuity of care. Hospitalists may be inclined to order more diagnostic tests to establish a baseline status that is already known to the primary care physician. They may also be unaware of a patient's and family's wishes regarding advance directives.

There are two potential models for the hospitalist system: voluntary and closed. In a closed system, only hospitalists have admitting privileges, and ambulatory care physicians are excluded. An open system allows both groups to admit their patients. Concerns have been raised that a closed system may engender bad feelings among community physicians. A potential disadvantage of the hospitalist model is that outpatient physicians will lose their skills in treating inpatients. It is clear, however, that by focusing on outpatient care they can be expected to improve their skills in that area.

Hospitalist expertise is based on the amount of time spent in inpatient care. Some studies point to the fact that improvements in quality occur after years of practicing this model. However, some of these physicians for different reasons, including possibly avoiding burnout, choose to practice part time, which will limit their acquisition of experience and knowledge. It has also been argued that the driving force for this movement has been decreasing costs rather than improving quality.

Inpatient specialists often hold higher levels of medical certification than some hospitalists with no formalized training in hospital medicine. In addition, subspecialist consultants may be apprehensive that hospitalists, due to their familiarity with common inpatient conditions, may produce fewer consultations. A reduction in consultations would be associated with a lower cost of care. Because of the severity of illness in hospitalized inpatients, consultations will continue to occur.

During the transition from outpatient to inpatient and again with the transition back to outpatient status, there is a risk of poor communication between the treating clinician and the receiving clinician. An aspect of this coordination of information flow is the risk of fragmentation of care and the loss of a care coordinator who has comprehensive knowledge about the patient's health. One study found that communication between PCPs and hospitalists leaves significant room for improvement with more than half of

the PCPs not provided with a discharge summary, while almost one quarter had no knowledge that their patient had been admitted. Most likely due to a decreased LOS, patients are also discharged quicker and sicker than before. With appropriate phone calls, and copies of discharge summaries and letters, it is possible to minimize this problem and avoid a significant loss of medical information. This process is unquestionably facilitated by the implementation of electronic medical records.

Generally residents have been very satisfied with the quality of teaching provided by hospitalists, ranking them higher than traditional attending physicians. However, because of their greater expertise in patient work, it can also be expected that hospitalists will threaten the autonomy of residents since they tend to have an increased physical and intellectual presence on the wards.

Evidence suggests that patients accept hospitalists without significant difficulty. Generally they are satisfied with the quality of care and do not perceive significant differences between hospitalist care and that provided by their outpatient clinician or traditional ward attending physicians. It has been suggested that patients may be willing to trade the familiarity of the outpatient clinician for the enhanced availability of their hospitalist. It has also been suggested that patients may no longer be as emotionally bound to their physicians. Many patients have no regular outpatient physician. Furthermore, in the current insurance environment many patients switch health plans and providers with relative frequency.

Increasingly, training programs in psychiatry, medicine, and pediatrics emphasize ambulatory care. This raises questions about the adequacy of preparation of recent graduates for inpatient attending. Training programs may need to be revised to provide appropriate preparation for the hospitalist role.

PROFESSIONAL ORGANIZATIONS

The National Association of Inpatient Physicians (NAIP) was founded after Robert Wachter, MD, MHM, coined the term “hospitalist” in 1996, followed by the commencement of NAIP’s first annual meeting in 1998. NAIP changed its name to the SHM in 2003. SHM continues to be the only medical society devoted entirely to hospitalists and the hospital medicine movement. There is no analogous professional organization for psychiatrists.

SPECIALTY TRAINING AS A HOSPITALIST

Increasingly, training programs are geared toward providing only enough inpatient training so that graduates are capable of caring for acutely ill outpatients. Special tracks may develop to provide adequately trained hospitalists from different medical disciplines. These programs would focus on developing clinician-teachers with the skills and knowledge necessary

for inpatient practice. Sufficient outpatient experience would be provided so the hospitalist would comprehend what level of severity can be managed in the outpatient clinic. In medicine, tracks exist at both the resident and fellow levels.

As training of hospitalists becomes more common, one emerging possibility is the development of two types of residencies. One would emphasize ambulatory care and the other would focus on hospital-based care. This would evolve by the use of different tracks for residents. In psychiatry, this separation would be expected to occur after the first 2 years, which usually emphasize inpatient and consultative work.

FINANCIAL, POLITICAL, AND ORGANIZATIONAL ISSUES

In many hospitals, the reimbursement for inpatient care is such that revenues from hospitalist services are insufficient to provide for the costs of physicians to staff the hospitalist program. In many cases, the benefits to the hospital or, in the academic medical center, to the training program are sufficient to justify additional program support. In academic programs, the training and service obligations are often thought to justify the additional cost.

The willingness of ambulatory care physicians to forgo inpatient care has been heavily influenced by the relatively low compensation. Many have realized that they can increase their clinical income by substituting relatively higher-paying outpatients for the lower-paying inpatients and avoiding the unreimbursed commutes to the hospital.

The low rate of reimbursement for inpatient care complicates implementation of the hospitalist model. Low reimbursement along with a payer mix that often includes uninsured patients means that few hospitalist programs can support themselves solely on professional fees. Further complicating the picture is the fact that clinicians are reimbursed a single professional fee each day despite commonly interacting with the patient several times a day and also working with allied professional staff and families. The net result is, commonly, a significant shortfall in the revenue needed to pay hospitalist physicians at a rate commensurate with community norms for other physicians. Generally hospitals are able to generate about 60 to 80 percent of their salaries by fee-for-service billings and/or capitation dollars. Because of the benefits they provide to hospitals, practice groups, and other sponsoring agencies, these groups commonly supplement the shortfall in professional fee income.

The hospitalist model will have an effect on a hospital's income. Cases that are paid on a per diem basis may produce less income because of the shorter LOS that occurs with hospitalist attending physicians. In a capitated case rate in which the hospital is paid according to diagnosis-related groups or when a medical group is paid on a contract rate, there are clear benefits from the reduced lengths of stay and reduced use of ancillary

tests associated with hospitalists. In such situations, the savings that result from the use of hospitalists may exceed the salary support provided by the institution. This significant savings is the rationale for supporting the salaries of hospitalists.

To avoid the perception of a conflict of interest, most institutions avoid paying hospitalists for reducing the utilization of services. However, many programs have created incentives related to outcomes measures and patient satisfaction.

HOSPITAL MEDICINE AS A NEW SPECIALTY

Fellowships are currently very limited. Typically they focus on training clinical educators and provide a curriculum on teaching theory, curriculum development, and evaluations methods and opportunities to strengthen teaching skills, along with opportunities to receive feedback about teaching activities. Some also provide instruction on research methods and encourage clinical research activities.

In many institutions, hospitalist positions are staffed by recent graduates and are intended to be transient. In these settings, the opportunities for long-term career development are unclear. In contrast, academic settings that intend to develop a stable cadre of hospitalists provide protected time for promoting scholarly activities and to work on improvements in the hospital system.

Traditionally, academic medical centers have been challenged in attempting to recognize the contributions of clinician-educators. It is these accomplishments that are the basis of being rewarded with promotion through the professorial ranks. Customary measures of accomplishment include publications and grants, along with other objective evidence of regional, national, and international recognition. The challenge has been to apply these assessment standards to the provision of clinical care or teaching ability. Traditionally, teaching capabilities have been assessed by peer and student evaluations. More challenging is the assessment of clinical excellence.

Hospitalists, similar to emergency medicine physicians and critical care specialists, are site-defined specialists. That is, their area of expertise is not defined by an organ or procedure but by where they deliver care. As such, they care for patients with a variety of illnesses and ages within that location.

In medicine, there are other attributes associated with a subspecialty. There is a large group that identify themselves as hospitalists. There is a professional society with regular meetings. There is a clinical textbook. Clinicians agree that there is a core skill set and body of knowledge.

FUTURE DIRECTIONS

Many of the changes noted in the medical community are applicable to

psychiatry. Outpatient providers are becoming unfamiliar with treating acute cases of agitation and severe mental illness as well as complications of the abuse of substances and legal requirements for involuntary inpatient treatment. Moreover, similar forces are influencing the practice of inpatient psychiatry. Patients are sicker and there is significant pressure to decrease LOS. In addition, the oversight on hand-offs and development of after care plans for treatment and safety are also currently growing.

The hospitalist movement is rapidly growing in psychiatry, medicine, and pediatrics. In the latter two areas, where the numbers are more clearly known, the number of hospitalists is larger than those in many board-certified subspecialties. The hospitalist movement, similar to prior trends in emergency medicine and critical care medicine, has a defining environment and a correspondingly separate body of knowledge and skill set.

Hospitalists can be expected to have an increasing role in improving care for hospitalized patients. Due to their extensive familiarity with the workings of the hospital, they are able to identify system problems. They are able to work with administrators and nurses to assure that necessary equipment is available and proper protocols are in place to facilitate quality care.

Hospitalists have developed related research areas. Typically, these are outcomes-oriented studies that focus on hospital care. Examples include quality of care, cost containment, resource utilization, and LOS. Such studies are typically conducted by academic hospitalists at university medical centers.

Currently, the term hospitalist does not refer to a subspecialty. In medicine, there are increased efforts to make the hospitalist a subspecialty with residency requirements and board certification. The future may see similar trends in psychiatry. Currently, there is a subspecialization in psychosomatic medicine or consultation liaison psychiatry. The same forces that led to this process may lead to the establishment of the psychiatric hospitalist subspecialty.

Unresolved questions about the future of the hospitalist movement remain. For example, should hospitalists be exclusively inpatient providers, or should there have some component of outpatient or consultative work? Should all inpatient care be delivered by hospitalists, or is there also a role for outpatient clinicians in the inpatient setting? How will hospitalists be compensated, and who will employ them? What is the optimal training to be a hospitalist?

As the acuteness of inpatients increases, more and more the demands of the job resemble those of emergency medicine department attending physicians or intensive care specialists and less those of outpatient primary care clinicians. Whereas current compensation for inpatient and outpatient physicians is similar, it can be expected that compensation for hospitalists

will also increasingly resemble that of intensivist or emergency medicine physicians.

Unique to psychiatry, there is a certain lack of recognition of the hospitalist physician as a differentiated area of practice. In other areas of medicine, the hospitalist role is widely recognized. Despite a long history of the hospitalist role in psychiatry, a role that dates back to the origins of the profession, few psychiatrists who work predominately in a hospital setting would consider themselves hospitalists. They are more likely to call themselves unit directors or ward directors. As the recognition of psychiatric hospitalists increases, a further appreciation of the similarities and differences between psychiatric hospitalists and hospitalists in other areas of medicine can be expected. One can imagine, for example, that the activities of colleagues in other areas of medicine will provide guidance for improving the career path for hospitalists, starting with fellowships and progressing through various levels of seniority following training.

Under recognized and poorly characterized, psychiatric hospitalists could be at the forefront of interactions with third-party payers that seek to alter the nature of psychiatric hospitalization. Improved recognition of their role, clarity of their training pathway, and identification of the stages of professional career development will promote this career pathway to trainees and ensure that there are well-trained individuals providing expert inpatient care.

▲ 58.6 Psychiatric Rehabilitation

RADU V. SAVEANU, M.D., ROSIE E. CURIEL CID, PSY.D., AND DAVID LOEWENSTEIN, PH.D.

AN OVERVIEW OF PSYCHIATRIC REHABILITATION

Psychiatric rehabilitation was once thought of as merely a series of psychosocial interventions that were aimed at augmenting psychopharmacological approaches. It is now recognized that true psychiatric rehabilitation is extremely integrative, involving an interdisciplinary approach. Importantly, the goal of psychiatric rehabilitation is not merely the remission of symptoms but helping the patient to assume their highest potential for the most independent and meaningful function within the community. Optimal psychiatric rehabilitation employs a person-centered approach with a focus on individual dignity, goal attainment, and a collaborative therapeutic relationship. There is also an emphasis on marshaling necessary environmental supports that will improve the efficacy of interventions within the home environment, community, and place of vocation. These community supports may involve professionals, paraprofessionals, natural community supports, or environmental modification.

Successful psychiatric rehabilitation is accomplished by a comprehensive understanding of the patient's (1) psychiatric condition, (2) treatment regimen, (3) social supports, and (4) contextual cues in the environment and an understanding of a patient's strengths as well as his or her limitations.

Psychiatric rehabilitation is not only limited to severe mental illnesses (SMIs) such as schizophrenia, bipolar disorder, or schizoaffective disorder but also extends to persons with treatment resistant major depression, severe anxiety disorders, and substance abuse (alone or comorbidly). Instead of a focus on remission and symptom control, there has been an increasing emphasis on improving the long-term outcomes of persons with SMI and incorporate constructs as increased autonomy, well-being, financial independence, and quality of life. Many persons with schizophrenia may obtain control over positive symptoms such as

hallucinations and delusions but still have to deal with negative symptoms that have adverse effects on communication, initiative, and interpersonal interactions. Neurocognitive symptoms of schizophrenia have been implicated in reduced ability to function in the home, workplace, and the community. However, theses cognitive effects extend well beyond issues with memory, processing speed, and executive dysfunction. Indeed, some of the greatest difficulties with community functioning are related to deficits in social cognition including perception and processing of affect, knowledge of social rules and conventions, inferring another person's intentions as well as attributing causality for positive or negative outcomes. For example, someone with paranoid schizophrenia may have a particularly difficult time properly inferring another person's motivations and intentions. Further, there may be difficulties with attributional biases in which negative outcomes are attributed to external causes with poor insight into one's role in certain events. Lack of insight into one's own processes and misinterpreting the emotions and intentions of others can lead to isolation, lack of meaningful interpersonal contact, difficulties dealing with others in the community, and problems with interacting with others in the workplace.

Psychiatric rehabilitation strategies are increasingly holistic, respect the autonomy of the individual in decision making, and specify incremental, graduated goal attainment with the goal of optimal function in the community. Since functional outcomes and quality of life are such important aspects of psychiatric rehabilitation, it will be important to precisely define different aspects of these different outcomes.

REHABILITATION IN THE MEDICAL CONTEXT

In the past, there was sometimes a disconnect between the concepts of medication management and/or treatments (e.g., ECT) and the concept of psychiatric rehabilitation. The former was associated with a medical model and emphasis on somatic approaches versus while the latter was associated with psychosocial treatments such as social skills training, vocational remediation, and building environmental supports. The medical model was seen as quite distinct from psychiatric rehabilitation, the latter rooted in a behavioral approach. However, with the increasing recognition that many psychiatric disorders need to be conceptualized as chronic conditions with waxing and waning of symptoms over time, there is little doubt that there is a need to integrate both medical and psychosocial approaches. For example, a significant issue in treatment of schizophrenia and bipolar affective disorder is noncompliance with medication management. As a result, a major focus of many current psychiatric rehabilitation approaches is to focus on adherence to medical treatments and medication regimens as a primary focus of psychiatric rehabilitation. This is typically done using advanced therapeutic and behavioral techniques as well as the use of

technological innovations in medication management and electronic reminders. There may also be an emphasis on cognitive and behavioral training with regard to prospective memory, or "remembering to remember an intended action." Further, it is well accepted that medication compliance is likely going to be higher with concomitant efforts to build supports in the environment, prepare the individual to deal with environmental stressors, and to promote a physical and emotionally healthy lifestyle. For example, an individual with severe obsessive-compulsive disorder (OCD) may be prescribed specific medications to help them manage their condition, but this can be augmented by two empirically supportive cognitive-behavioral strategies that have been used to effectively treat OCD (graduated exposure and response prevention). However, OCD symptoms may also be exacerbated by stress. Therefore, treatments may also focus on assertiveness training, social skills training, and enhancing both social and environmental supports. This increasingly more integrative approach requires the coordination of a number of health care disciplines.

UNIFYING CONCEPTS OF REHABILITATION AND TREATMENT

It is now clear that the most successful approaches to psychiatric rehabilitation involve the *integration* of medical and a variety of psychological and psychosocial approaches. As described below, psychiatric rehabilitation is more person-centered. That is, instead of a more paternalistic model in which the patient adheres to the wishes of treatment providers, there has been a greater emphasis on shared decision making on behalf of providers, patients, and their families. This person-centered approach not only provides greater shared collaboration and decision making between the patient, family and treatment team but also provides shared decision making that increases the probability of investment and compliance. This individualized approach to treatment also emphasizes targeted goals that are unique for an individual patient with the appropriate admixture of therapies that are specific to the person's needs. It is of essential importance for both the patient and the treatment team to (a) identify targeted short-term and long-term goals that are operational and obtainable; (b) plan a sequence of interventions and supports that are appropriate to an individual's stage of recovery; (c) build in social and environmental supports, stress inoculation, coping strategies, and other continuing therapies that will reduce the chances of relapse; and (d) to continue a collaborative treatment milieu between the patient, family, and care providers that provide the greatest opportunity for mutual respect and decision making. The shift from doing something for the patient to collaborating in their recovery and well-being means that treatment becomes educational as well as treatment focused.

PSYCHIATRIC REHABILITATION AND INCORPORATION OF PERSON-CENTERED

RECOVERY MODELS

As in other fields of medicine, psychiatric rehabilitation has adopted the notion that individualized and collaborative methods of care improve the prospects for recovery. The traditional view of the psychiatrist as the sole, responsible, and authoritative clinician has been replaced with the model the multidisciplinary or interdisciplinary team approach. The *person-centered* approach builds upon this by actively engaging the patient and their family in shared decision making regarding medication and incorporates their personally relevant goals and unique psychosocial circumstances into the formulation of treatment plans.

The person-centered approach is in line with a more optimistic vision for the long-term *recovery* of the seriously mentally ill as it offers opportunities to generate higher levels of motivation by patients. These progressive changes in ideology have mostly been championed through the leadership of federal, state, and local agencies. Many training programs are more cognizant about teaching emerging practitioners about the person-centered, recovery-oriented mode of service delivery, which is expected to continue to intensify and develop in the coming years given that this approach is expected to strengthen the therapeutic alliance, promote greater motivation and collaboration, and achieve better outcomes.

HOW CAN RECOVERY BE DEFINED?

Sustained recovery refers to long-term abstinence or remission of symptoms and normal psychosocial functioning. It refers to a measurable set of processes, stages, and outcomes that are grounded on mediating and moderating variables that facilitate its attainment and maintenance. That is, recovery is an outcome of the process of recovering.

Individuals can take many pathways to recovery, depending on the varied factors that influence the process, such as personal attributes, social environment, continuity and quality of treatment, and subjective experience.

Examples of attributes and experiences that may be associated with individuals who are progressing toward recovery include hope, destigmatization, empowerment, self-acceptance, insight, awareness, collaboration with professionals, sense of autonomy and self-control, and participation in self-help and patient-run programs. Subjective experiences and attributes not only can mediate the process leading to recovery, but they also can sustain recovery. For example, a treatment or self-help program may engender a feeling of empowerment, which can be instrumental in motivating a person to sustain treatment and rehabilitation until recovery can be achieved. Once recovery has been achieved, empowerment may be even more firmly experienced through improved functioning and mental and emotional stability.

Similarly, having hope for future improvements in quality of life may be reinforced by the enthusiasm and collaborative alliance embedded in a therapeutic relationship. Many patients who have written first-person accounts of their recovery have pointed to the importance of a long-term relationship with a practitioner who refused to give up hope for the patient's ultimate improvement and recovery. Hope can serve to fuel motivation for change and for active participation in clinical services or self-help, which are stepping stones toward recovery. Subjective experiences of empowerment and hope continue to grow after a state of recovery is attained, contributing to further strengthening and protecting individuals from stress-induced relapse. Encouragement and hope also enhance efficacy expectations that empower the individual to assume greater control and responsibility over their lives.

EMPIRICALLY BASED MODELS OF PSYCHIATRIC REHABILITATION

Psychiatric rehabilitation has evolved substantially over the last several decades. Previous descriptions of interventions used in psychiatric rehabilitation included sole descriptions of token economy and other reinforcement programs for long-term patients in psychiatric hospitals, client-centered identification of personal goals, and various sheltered and segregated work and social programs in the community. Comprehensive services that incorporated personally meaningful adjustment to daily living in normal community settings were nonexistent.

Over 50 years of intervention research has led to the expectation that even patients with the most severe mental disabilities can gain from empirically validated, behavioral interventions to improve their daily, and community functioning. Evidence-based therapies are now in widespread use in psychiatric rehabilitation.

Fulfillment of these expectations for therapeutic improvement has been facilitated by political advocacy, destigmatization of mental illness, and self-help activities of consumer organizations such as the National Alliance for the Mentally Ill, the Schizophrenia Fellowship, and networks of mental health clients. In 1991, the Americans with Disabilities Act was signed into law, requiring equal employment opportunities and reasonable employer accommodations for workers with mental illness.

Recovery is now more than ever a realistic goal for many persons with mental disabilities with enduring biological vulnerabilities such as schizophrenia; however, it is necessary that the full range of evidence-based biopsychosocial services be available in a continuous, comprehensive, coordinated, consumer-oriented, and competently delivered system of care. Despite the field of psychiatry producing a wide array of evidence-based treatments and services, public and private funding has eroded for organizing and delivering these services with high fidelity.

Despite the many challenges that are confronted in the field of psychiatry, opportunities to offer effective rehabilitation to persons with mental disabilities have never been better than at the present time. With that in mind, psychiatric rehabilitation is confronted with the major challenge of fiscal limitations, inadequate resources, and poor coordination.

MAKING EVIDENCE-BASED TREATMENT AND SERVICES ACCESSIBLE

There have been increasing efforts to reduce the barriers to effective dissemination and promote the adoption of evidence-based practices (EBPs) in psychiatry using a package of user-friendly treatments in the form of "toolkits" that are designed to make the collection of evidence-based treatments more accessible to clinicians. These efforts such as the project implementing EBPs have mostly been sponsored by federal, state, and foundation agencies. Standardized guidelines for the application of the evidence-based treatments are provided in workbooks that are included in the toolkits, as are training materials and procedures to provide means for assuring that the treatments will be used with the highest levels of fidelity.

The EBP project was conducted in three phases. The first phase focused on developing the kits, which are now available from the Substance Abuse and Mental Health Services Administration (SAMHSA) website: http://mentalhealth.samhsa.gov/cmhs/communitysupport/toolkits/. In the second phase, pilot demonstrations using the kits at 50 sites in 8 states were completed in 2007. The toolkits contain implementation resource information as well as information on how the EBPs are related to improving the functioning, quality of life, and recovery of patients. The third phase focused on a broad national dissemination of the kits. Given the over $2 billion allocated by public health authorities to make EBTs available, and the substantial implications to science and practice, evaluations have been and are currently being carried out to measure the success of the toolkits. A review conducted by Barlow and McHughs found that the studies evaluating the efficacy of dissemination and implementation programs are limited; however, efforts are continuously being made to improve these procedures. At the time of this review, critical components that facilitated the adoption, competence, and sustainability of EBTs were unclear.

At present, SAMHSA provides a plethora of toolkits with EBTs for various disorders free of charge, many of which are available on DVD or digital download at http://store.samhsa.gov/list/series?name=Evidence-Based-Practices-KITs.

The ultimate purpose of the EBP toolkits—"to promote the implementation of evidence-based psychosocial treatments in routine mental health settings"—is a goal that has great potential to improve the lives of people with serious mental disorders. However, implementing and

directly monitoring fidelity to the model can be a costly and time-consuming process. A balance needs to be achieved between monitoring the accurate implementation of each EBP while promoting dissemination of the EBPs in a way that allows the adopting agencies to tailor the innovation to fit the specific function, mission, patient population, local resources, and other contingencies they face. Continuous quality improvement has been used effectively as an approach to implement EBPs at community-based settings.

At the level of the community agency implementing EBPs, specific expectations for clinician performance and ongoing program evaluation, as well as a culture change is required to implement and sustain the provision of EBPs. Thus, evaluating the cost-effectiveness of the EBP toolkits using a longitudinal time frame and a methodology that captures the organizational characteristics and the total expenditures to the systems of care in using the EBPs for the patients within their catchment areas is essential to the long-term viability of these programs.

With improved and more reliable methods of diagnosis and symptom and functional assessment and an empirically validated definition of recovery, the population and needs of patients requiring psychiatric rehabilitation are becoming better defined. Methods for determining readiness for rehabilitation also have been validated, enabling administrators and practitioners to be more efficient in their use of rehabilitation programs and resources. Because of its growing technology and its conceptual and empirical base, psychiatric rehabilitation has attracted an interdisciplinary group of practitioners and investigators whose work has contributed to its evolving scope and stature as a subspecialty of the mental health and rehabilitation professions.

The challenges to community-based care for persons with serious and chronic mental illness have been met partially by new initiatives at the *clinical* and *policy-making* levels. New interventions have been designed and validated, such as psychoeducational and behavioral family therapies, social skills training, cognitive-behavioral therapy (CBT) for medication-resistant psychotic symptoms, intensive case management models for assuring continuing care, supported housing, and employment services. At the level of psychiatric politics, consumers and families have become empowered by the advent of peer-directed self-help organizations; the use of the mass media for education of the public about mental disorders and the possibilities for recovery, including noted political, sports, and entertainment figures going public with their mental disorders and successful treatment; legislative lobbying, assertive advocacy, peer support, and involvement in treatment by families; efforts to gain parity in funding for mental health services; and the Americans with Disabilities Act.

Despite advances in assessment and treatment, the implementation of psychiatric rehabilitation in the public sector has been frustrated by

inadequate funding and resources, lack of trained personnel, limited dissemination of the new technology, insufficient affordable housing, unattractiveness of voluntary treatment, and a lack of administrative and financial integration of state and local community mental health and substance abuse services. The consequences of those system-wide problems have meant that too few individuals with mental disabilities are receiving state-of-the-art services and too many thousands are living on the city streets or in jails and prisons.

REHABILITATION IN THE PRODROMAL, ACUTE AND STABLE PHASES OF SEVERE MENTAL ILLNESS

Effective treatment and rehabilitation of persons with mental illness require clinical services that are linked to the phase of their disorder. For most stress-related, recurring, and disabling mental disorders, the following phases are relevant for practitioners' initiating and/or adjusting their treatment:

- Motivation and engagement in treatment
- Prodromal
- Acute
- Stabilizing
- Stable
- Recovery
- Refractory

There is broad-based variability in the manner in which individuals experience a particular phase in that no two individuals experience any phase in the same way. Individual differences influence each phase in terms of severity, duration, degree of disability, resolution, course, and boundaries. The following experiences depict two persons with schizophrenia in the *stabilizing phase*. This serves to exemplify the need to adapt treatments to individual diversity within a particular phase of illness.

Mr. F, a 23-year-old male was admitted for involuntary psychiatric hospitalization after he locked himself in his dorm room refusing others entry because he was afraid that someone was out to harm him. When persons entered the room he was in the bathtub rocking back and forth and talking incoherently. After 5 days of stabilization, he was released from the hospital and returned home to his family but was still very anxious about being alone, difficulties with voices in his head telling him he was "doomed" and he was extremely concerned that his movements were being monitored. Because he was resistant to oral medications (he thought they might be tampered with and might harm him), he was prescribed an injectable antipsychotic, which helped to stabilize his symptoms. Upon returning to school, he completed a semester taking a reduced course load and living at home. However, during the next semester, he insisted on taking a full course load and started to use marijuana and other drugs to help to manage the resultant distress. He began to feel very hypervigilant and felt that others in his class were judging him critically. This further reduced his concentration and he started doing poorly in class setting up a vicious cycle where he was readmitted with extreme paranoia and had to again drop out of school. At this point, treatment became integrative and, in

addition to adjusting his psychiatric medications, he received supportive psychotherapy and was engaged in several cognitive-behavioral and skills-building training that provided him ongoing support and structure. He learned to be more assertive and comfortable in his interactions through assertiveness social skills training and relaxation/stress management techniques, which greatly helped his coping skills. Mr. F eventually returned to school, earned his degree and is currently in a supportive work program.

Ms. L, age 32 years had persistent obsessions and compulsions that increasingly became worse, particularly when she was promoted from an associate to a partner in a prestigious law firm. She became increasingly convinced that she was going to succumb to a terrible disease and washed her hands hundreds of time per day because she was afraid that germs on her skin would contaminate her or that she could pass them to other people. She started to avoid touching door handles, pens that others had touched, and even refused to shake hands with new clients. She had a new child who was 9 months old and was terrified that he would become ill and would wash him many times at night and disinfect his playroom. She fired several nannies because she feared that they would pass illnesses to the child and the family. She got into more constant fights with her husband who thought that she was being unreasonable and increasingly had difficulties with depression and generalized anxiety. She was admitted when the partners called a meeting with her to discuss their concerns about her performance and she became extremely anxious and acutely suicidal.

Following discharge from the hospital 3 days later, she was placed on a combination of Luvox and other psychotropic medications and immediately referred to a therapist who focused on CBT approaches. It took several weeks before she was adequately stabilized to engage in interventions for OCD (graduated exposure and response prevention). In addition, couples' work with the patient and her husband was conducted by another therapist that helped the husband better understand her illness, support her behavioral homework, and helped the couple better communicate. OCD can involve a waxing and waning of symptoms. As a result, Ms. L, who is now back to work, is involved in maintenance therapy where she sees her behavioral therapist 2 times a month, but more frequently if needed.

These two examples illustrate the need to conceptualize the treatment of these two individuals into several components (a) stabilization; (b) dealing with ongoing acutely psychotic, mood, or anxiety symptoms; (c) using the therapeutic alliance to provide the maximum motivation for treatment; (d) using integrative therapeutic support to augment and strengthen the possibility of positive treatment results; (e) ongoing assessment and strategies aimed toward relapse prevention; and (f) reinforcement and maintenance of gains.

The framework for phase-linked treatment and rehabilitation is depicted in Figure 58.6–1. It should be noted that EBPs are the backbone of services generally found to be useful for patients as they traverse the various phases of their disorder. There is considerable variability in how fast each individual moves from one phase to another. Some may even skip a phase, becoming stable within 1 week of an acute relapse, without the gradual stabilization of symptoms and functioning that is more frequently the case. People also move back and forth between phases as stressors impinge on their vulnerability and the individual has not compiled sufficient protective factors. The process is not nearly as linear as shown in the Figure 58.6–1.

PRODROMAL PHASE

Early identification, engagement, and treatment are the mainstays of this phase, which may be associated with individuals who are at risk of their first episode of SMI or are experiencing the warning signs of a recurrence of their disorder. Preventive interventions for young people at high risk of developing a psychotic illness remain in the early stages of development. The sensitivity and specificity of identifying the early signs of a developing psychosis have not been fully validated; moreover, psychosocial and pharmacological interventions have not been empirically documented as effective in averting schizophrenia or other psychotic disorders when provided to young people with what may appear to be prodromal signs and symptoms.

FIGURE 58.6–1. Multidimensional framework for phase-linked treatment and rehabilitation.

PRODROMAL SIGNS AND SYMPTOMS PRIOR TO THE FIRST EPISODE OF SCHIZOPHRENIA

Youth who are possibly moving toward their first episode may be experiencing sleep problems, strange, unusual, unwanted, and intrusive thoughts, or depression, irritability, hypomania, or anxiety. Other prodromal signs and symptoms include ideas of reference, paranoid worries and fears, significant social and emotional withdrawal, suspiciousness, apathy and loss of drive, disturbances of attention and concentration, functional deterioration, odd behavior, perceptual

abnormalities, and derealization. These young people almost always refuse to accept professional intervention, preferring to think that their condition is transient and will dissipate without psychiatric treatment. Of course, the stigma of mental illness is a major deterrent to obtaining treatment.

For these individuals and their families, a patient, nonconfrontational stance is desirable. Because it is not even certain that they are moving to an acute episode, it is necessary to monitor the presenting symptoms and how they might be interfering with the individual's current life. Then, depending on the specific problems that are interfering with the individual's reaching his or her goals, the psychiatrist points out that treatment may very well help to overcome the obstacles to progress toward these goals. This approach is called *motivational interviewing* and represents a strategy for engaging patients in treatment. It may be necessary for the practitioner to ally with the family so that the latter can join in the motivational enterprise. The treatment approaches to this early, developmental phase of schizophrenia are delineated in Table 58.6–1.

SYMPTOMS PRODROMAL TO A RELAPSE

Because each psychotic episode places the individual at greater risk of prolonged psychosis, disability, and refractoriness to treatment, prevention of relapse has been assigned a high priority. It is often the case that the individual with recurrent illness does not recognize or acknowledge his or her symptoms; in this case, it is best to simply work on building a relationship with the patient that will eventually pay dividends for active treatment once trust has been achieved.

If possible, prior to a recurrence, the practitioner should provide illness management services that include training in recognizing and monitoring early warning signs of relapse together with developing an emergency plan for preventing full-blown relapse. This educational effort is important because repeat episodes of schizophrenia, major depression, bipolar disorder, and other SMIs carry a poorer prognosis and a higher risk of:

- More frequent acute episodes in the future
- Higher likelihood of nonadherence to treatment
- Greater difficulty treating each successive episode
- More serious disruption of social, occupational, educational, and family roles
- Greater likelihood of stigma and family isolation
- More frequent involvement of police, involuntary admission to hospital, homelessness, or jail
- Considerably greater financial and emotional burden for the family.

Table 58.6–1.

Interventions for the Prodromal Phase of Schizophrenia in Young Persons Not Yet Diagnosed with the Disorder

1. A psychoeducational approach is directed to the patient, family, other caregivers, primary care physicians, school counselors, and staff at college counseling centers. The psychoeducation must be keyed to the particular needs, readiness, and role of the individuals who are in a supportive relationship with the individual who is experiencing the prodromata to a serious mental illness. Outreach and liaison with "gatekeepers" to mental health services—primary care physicians, clergy, schoolteachers, school counselors—is important for mental health facilities and solo practitioners to mount a successful effort in identifying young individuals at high risk of a serious mental disorder. There should be ongoing liaison, education, and consultation with the family and referring professionals and agencies.
2. Nonstigmatizing, age-appropriate, culturally congruent services should be offered in a youth-friendly, nonclinical environment.
3. Specific treatment for symptoms and behavioral problems that are interfering with the young person's goals and functioning should be adopted:
   a. Motivational interviewing.
   b. Stress management.
   c. Cognitive-behavioral therapy or interpersonal therapy for anxiety and depression.
   d. Cognitive-behavioral therapy for prepsychotic symptoms.
   e. Supportive relationship that permits open discussion of the young person's concerns, worries, symptoms, and progress toward goals.
   f. Antipsychotic medication at low dose for symptoms that do not respond to psychosocial interventions and continue to impede the young person's functioning.
4. There should be frequent re-evaluation of the patient's clinical status to determine whether a schizophrenia prodrome is actually operating.

EARLY INTERVENTION AND RELAPSE PREVENTION

One component of illness management is teaching patients and their families to recognize the prodromal signs and symptoms of relapse, monitor them, bring them to the attention of the mental health provider, and follow through with their emergency plan to avert relapse.

An acute episode of illness including relapse for persons who have had previous episodes frequently follows prodromal signs and symptoms. This holds for mood disorders as well as disorders within the schizophrenia spectrum. Regardless of where a patient resides during an acute episode of illness—crisis home, family home, inpatient unit, or partial hospital—the major task of the facility and staff is to mitigate overstimulation and provide a safe, secure, supervised, and predictable environment. This is accomplished by offering clear expectations for daily activities, a posted schedule of daily events, discharge criteria, standards for each privilege level, and a structured routine and treatment environment. Staff experienced in working with acutely ill patients offer individualized, clear expectations for behavior and low task demands that are not unnecessarily burdensome but are flexible in terms of how much social interaction is prescribed. In addition, the staff should offer low-key planned and scheduled activities, orientation, and guidance on the rules of the facility by posting visual aids on the bulletin board and white boards. One staff

member should be designated for helping each patient conduct problem solving and offering supportive therapy at all hours.

In this phase, pharmacological and behavioral treatments of acutely ill patients are predicated on stabilizing or eliminating symptoms and improving cognitive status so that the patient can move toward focusing on the development of skills and utilizing the social and professional supports that will help him move into the next phase of treatment.

Most patients in the acute phase can begin learning illness management skills. During the acute phase, it is essential to customize skills training and support to symptomatic and cognitively impaired individuals; thus, in educating, it is very important to use strategies such as motivational enhancement, repetition, responsive reading, modeling, role playing, and problem solving. It is also necessary to be flexible in using relevant and culturally appropriate communication in educating patients about the value of medication.

CONTINUITY OF CARE FROM HOSPITAL TO COMMUNITY

Patients are rarely sufficiently stabilized by the time they are discharged due to increasingly shortened inpatient hospital stays. Unfortunately, continuity of care offered on most discharge plans consists of providing the patient and family members with the contact information of providers or available community mental health centers who will accept persons with serious and persistent mental illness. Predictably, numerous studies have confirmed the frequent lack of follow-through from inpatient to outpatient care.

Many obstacles stand between inpatient care and the fluid provision of and engagement in outpatient services. First, the patient is struggling with persistent psychotic, anxiety, or depressive symptoms after discharge from inpatient care. These symptoms, as well as cognitive deficits common in serious mental disorders, interfere with the patient taking the initiative to set up an aftercare appointment. When hospital clinicians fail to involve family in psychoeducation regarding their loved one's illness and need for continuing care, family members may have the mistaken belief that definitive treatment has been completed in the hospital and fail to encourage follow-up services. They may even suggest that their relative discontinue medication because they are not aware of the prophylactic value of pharmacotherapy and may have the mistaken belief that antipsychotic medication is addictive.

Numerous ways have been used to promote continuing care. These include having a representative of the community mental health center visit the inpatient unit and be introduced to the patient nearing discharge. The two can spend a little time together, enough for the patient to understand the importance of outpatient care, obtain clear directions to the facility, and become comfortable with the familiarity of shifting treatment to another

agency. In a reciprocal fashion, patients may be accompanied by a staff member to make a visit to the community agency where outpatient services will be provided. The same familiarization will reduce anxiety and increase the likelihood of follow-through. Providing transportation from the patient's home to the aftercare facility almost always increases attendance and participation.

Being that this is an era of person-centered, recovery-oriented services, there are training programs, such as the Community Re-Entry Module, that empower patients to learn skills and attitudes that support continuity of care. Some of these skills taught by this training program include: connecting with the community, planning a daily schedule, making and keeping appointments and managing medications. These skills will allow the patient to take responsibility for making the connection with outpatient services.

In this continuity of care program, family members are involved in the training as much as their schedules permit. A randomized, controlled study comparing the continuity in reaching outpatient services for inpatients who participated in the Community Re-Entry Module versus those who received standard discharge planning by a social worker showed that more than 80 percent of the individuals participating in the module succeeded getting to an outpatient facility after leaving the hospital, compared to only 37 percent of those receiving standard discharge. This study confirms the capabilities of patients with schizophrenia to take responsibility in maintaining their treatment.

During the acute phase of treatment, some common patient responsibilities include such functional and symptomatic outcomes as engaging in independent self-care and personal hygiene without prompting, socializing with peers without hostility or social withdrawal, voluntarily accepting medication, and learning the reasons why medications are being prescribed—both for dampening the current symptoms that led to hospitalization and for prophylactic purposes to reduce risk of relapse. The patient and doctor review specific behavioral progress being made toward the goal on a daily basis, which is the cornerstone of motivation, hope, and shared decision making. Most inpatient units have "level systems" that are used to provide incentives to patients to take more responsibility for their self-care, reliability, participation, and inappropriate behavior. Level systems can be customized to meet the individual needs of specific patients by using tokens, credits, or points superimposed on the level system. Another way to motivate patients to reach their goals and discharge readiness during the acute phase of illness is to use therapeutic contracts. Therapeutic contracts invite collaboration in that both parties describe their goals and responsibilities for the inpatient period of treatment.

The psychiatrist and other staff must ensure that the patient is familiar

with and has a plan for reaching follow-up care as an outpatient. As discharge approaches, the responsible psychiatrist should reach out to the family and invite them to attend a psychoeducation meeting with the psychiatrist present to answer questions and give feedback on how their relative is progressing. Having the family present with the psychiatrist and treatment team during a psychoeducational meeting in the acute phase of illness provides opportunities to acquire another source of information about the patient's disorder and disability. Family members can at times be more reliable assessors, and many of them keep written records or diaries of the course of illness, medications, and responsiveness and side effects to the illness. Home visits seldom occur in the current era; however, this can provide considerable information about the quality of life of the patient prior to hospitalization, thereby enabling more accuracy and clinical acumen to be brought to bear on the diagnosis, treatment experiences, and social functioning of the patient.

STABILIZATION PHASE

As previously mentioned, stabilization of symptoms and cognitive deficits almost always continues after acute discharge into the stabilization phase. Most of the considerations noted previously in the acute phase are continued in the outpatient sector; hence, the treating psychiatrist has the responsibility for ensuring that continuity of care is actualized.

STABILIZATION OF SYMPTOMS WITH MEDICATION

Once discharged, it is likely that the patient will stay on medications. Monitoring symptoms using quantitative scales such as the Brief Psychiatric Rating Scale (BPRS), the Positive and Negative Syndrome Scale (PANSS), or the Target Symptom Scales during regular appointments can help the prescribing practitioner make informed decisions regarding changes in type or dose of medication.

The use of a quantitative rating scale for the informed use of medications is illustrated by the stabilization of the patient in the following case, a young woman with schizophrenia. Responsiveness to medication is also affected by the emotional climate in the family, which needs to be considered by the prescribing psychiatrist.

Ms. R, a 28-year-old female had two previous hospitalizations for relapse of persecutory delusions, each of which responded fully to antipsychotic medication. After being discharged from the hospital following her second hospitalization, her delusions were substantially improved; however, she reported feeling "numb and disconnected" from others. During the first month of outpatient visits, her psychiatrist gradually titrated up her medication, with evidence of stability in that her delusional symptoms did not reoccur. However, regular ratings using the PANSS showed that her negative symptoms were worsening. After a family conference, it became clear to the psychiatrist that Ms. R's parents did not understand the impact that negative symptoms could have on Ms. R's daily functioning despite the lack of active psychosis. As a result, they were pressuring her to return to work. The stress associated

with their lack of education about her illness was reverberating within the family, adversely affecting both Ms. R and the parents. The psychiatrist scheduled a series of weekly and then biweekly educational sessions for Ms. R and her parents that gradually lowered the "emotional temperature" of the family household, resulting in Ms. R receiving the assistance that she needed in order to actively seek out vocational rehabilitation.

ILLNESS MANAGEMENT

During the stabilization phase, learning illness management skills including gaining a more solid understanding of the role of medication can be very useful. This includes skills such as how to communicate assertively with the psychiatrist about side effects or lack of symptom reduction. Supportive treatment sessions are provided on a weekly or biweekly basis with invitations to the family or other caregivers to participate in the training sessions for illness management that focus on medication and relapse prevention. UCLA offers a Social and Independent Living Skills (ILS) training with modules that offer training on key skills including illness management. The modules are composed of a prescriptive clinician's manual or guide, a videocassette for demonstrating the skills to be learned, and a patient's workbook, containing practice exercises and monitoring forms. Skills are learned by using a combination of focused instructions, videotaped demonstrations, role-played rehearsals, social and videotape feedback, problem solving, and practice in the natural environment through in vivo exercises and homework assignments. Patients proceed through each skill area in a specific sequence of learning exercises and activities. The training procedure emphasizes the "discovery learning" method as opposed to expository or didactic teaching.

COLLABORATIVE RELATIONSHIP WITH PATIENT

The development of a collaborative and therapeutic relationship, with a foundation based on the elements described in the earlier discussion of engagement, is essential if the patient is to remain in long-term treatment and make progress toward his or her personal goals. Personally relevant goals are motivating for the patient's participation in the stabilization, stable, and recovery phases of treatment. Depending on the needs and desires of the patient, these goals can be connected to such areas of functioning as self-management, friendship and intimacy, work or school, family relations, residential status, recreation, financial, and spiritual needs. The psychiatrist and other mental health professionals working with the patient must help the patient set incremental, stepwise goals that will bring the patient closer to his or her overall personal goals. Thus, as symptoms and cognitive impairments stabilize, the patient may benefit from weekly social skills training that gives the patient opportunities to learn from social modeling, role-play practice, and homework assignments to facilitate achieving short-term goals that are on the pathway to overall goals. For example, a man in his 30s who has reached the recovery phase of

schizophrenia may have a personally relevant goal to find an apartment and live independently. With the guidance of the skills trainer, he may proceed through a series of steps, including the following:

- Learning and demonstrating the ability to engage in medication self-management and other ILS required for living in an unsupervised residence.
- Through problem solving training, identifying various ways to locate apartments that are for rent, generating options.
- Evaluating the pros and cons of each identified apartment—for example, costs, location, and availability of public transportation.
- Practicing in the group how to ask questions assertively about the apartment with the property manager or owner, then applying the skills practiced to the real-life situations.
- Reviewing the advantages, disadvantages, and feasibility of each apartment and making a provisional choice with second and third preferences.
- Practicing (in the group setting) how to request a loan from parents to help subsidize the rent, then carrying out the request with parents.
- Practicing (in the group setting) finalizing and signing a lease agreement with the property manager, then doing it in real life.

Once the individual settles into an apartment, there are many more related goals, including furnishing the apartment, meeting neighbors, identifying and engaging in social events available in the community. Once the individual is successfully established in the apartment, he or she may again set new personal goals such as making friends and finding a part-time job.

Each success that patients experience in moving deliberately toward their overall goals brings greater self-confidence, hope, and positive expectations. These successes also reinforce the therapeutic relationship with the psychiatrist and other mental health professionals who are assisting the patient. As therapeutic relationships strengthen, so does the willingness of patients to confide in their treaters.

INVOLVING FAMILIES IN STABILIZATION

Because of the important role families play in facilitating or impeding improvement in patients with major mental disorders—including schizophrenia, mood disorders, disabling anxiety or somatoform disorders—it is vital, for rehabilitation efforts, to include them in planning, monitoring, and promoting stabilization. In fact, as noted in the description of the engagement and acute phases of illness, mobilizing families as partners in the treatment enterprise is relevant for all phases, including stable and recovery periods.

Relatives and other caregivers can be involved in sessions that are organized either for individual families or multiple family groups, with goals limited to psychoeducation or, more extensively, teaching skills in communication and problem solving, coping with persistent symptoms, and implementing relapse prevention plans.

In the stabilization phase, patients should be involved in family sessions as their symptoms and cognitive impairments permit. It is essential that family services be fully integrated with other treatment modalities being offered to the patient, such as social and vocational rehabilitation and medication management. Multidisciplinary integration is accomplished most effectively through regular consultations and interactions among all those responsible for the patient's services. Communication among mental health providers can be initiated and led by the psychiatrist through phone calls, case conferences, and team meetings and email. Families can also benefit from participation in peer-related services offered by local National Alliance on Mental Illness affiliates that include Family-to-Family seminars, Share and Care Meetings, educational lectures, and annual statewide and national conferences.

Contacts with families should continue indefinitely because they often serve as the most important continuous thread of support that weaves together the various phases of illness. It is now well established that patients living with relatives who learn coping skills from behavioral family management have two to three times fewer relapses than patients who are treated with medication and case management alone.

STABLE PHASE

Patients are considered stable when their symptoms no longer interfere with everyday activities. This does not mean that their symptoms are in remission, although they are usually rated as "moderate," "mild," or "very mild" on the BPRS. Some patients are able to participate in work, school, social, and recreational activities in normative settings even when delusions and hallucinations are present on a daily basis. Psychological interventions can displace symptoms, as when patients are actively engaged in conversations or tasks that shift their attentional capacity from isolated self-preoccupation by using eye contact, questions and answers related to current and future plans, and CBT. Cognitive functioning can also be improved by cognitive remediation (CR) in this phase of treatment.

Incremental steps toward long-term, person-centered goals continue in the stable phase. Progress toward goals can be promoted by participation in training programs that use behavioral learning principles to assure generalization of skills learned in skills-training sessions that take place in clinical settings. The key to generalization is for clinicians, family members, or peers to promote opportunities and encourage, as well as reinforce the use of skills in the natural environment.

VOCATIONAL REHABILITATION

During the stable and recovery phases, patients may be able to begin job seeking or return to school. Although supported employment (or supported education) is the most popular evidence-based service for vocational rehabilitation, it is not the only occupational goal that is clinically relevant. A wide variety of vocational and educational activities can be compatible with the stable and recovery periods of functioning. Before some patients are ready for work in competitive jobs, they inevitably need to transition through work-related activities short of regular jobs in the community. At the same time, it is important to recognize the value of supported employment because patients with mental illness who gain jobs in the competitive sector can work half-time or more in competitive lines of work, and can gain satisfaction with their renewed or achieved status as workers.

However, not all individuals with mental disabilities wish to participate in supported employment. Approximately half of those with disabling forms of schizophrenia, mood disorders, and personality disorders do not engage in supported employment. Moreover, supported employment is not always associated with increased self-esteem, quality of life, global functioning, or reduced psychiatric symptoms. There are alternative ways to lead a working life, including an array of opportunities that can be viewed as prevocational in nature such as volunteer opportunities and on-the-job training.

Various work circumstances can lay the groundwork for recovery. The value of including the full spectrum of work activities as relevant to rehabilitation is illustrated by the findings from an evaluation of 49 consumers who participated in a range of prevocational endeavors. A study found that patients who participated in a wide range of work-like settings improved their social functioning scores on the Colorado Client Assessment Record. Ratings can range from 1 (*normal functioning*) to 9 (*clearly disabled*). When seeing themselves as self-directed agents contributing purposefully to their own, patient-centered work goals, patients can make progress toward independence and self-sufficiency in a variety of ways as they are able to see themselves working toward recovery.

RECOVERY PHASE

As noted earlier, recovery does not mean “cure”; rather, patients in this phase are empowered to live meaningful and satisfying lives, having reached many of their overall goals that bring them into normal community settings and interactions. In this phase, patients are more autonomous and self-directed in their choice of person-centered goals and taking steps and garnering resources to achieve their goals. They are equal partners with their professional providers of services, making decisions and serving increasingly as their own case managers. They often assume paying jobs as

peer-counselors and peer-advocates in addition to joining with mental health professionals as active proponents of public education and political action for decreasing stigma and improving funding for mental health services in their states and communities.

Recovered patients are capable of managing routines, work, school, independent living, and illness self-management without direct supervision by relatives or mental health professionals. That being said, it is strongly recommended that recovered persons sustain their connection to mental health services, even if this consists of only occasional "check-ins" with their treatment providers given the increased vulnerability to relapse and stress sensitivity often experienced by individuals that have experienced serious mental disorders. Refresher courses for patients' emergency plans to implement relapse prevention are one mechanism to extend recovery for longer periods of time.

ASSESSMENT IN PSYCHIATRIC REHABILITATION

The assessment of persons with SMI involves a comprehensive assessment of a number of important domains with specific well-validated tools. The goal of any good assessment is to render an accurate diagnosis and then to suggest areas that can be targeted with specific interventions. The key to a comprehensive assessment of SMI is a thorough assessment of symptoms (both positive and negative), including the nature, frequency, intensity and duration of particular symptoms. It should be noted that the management of certain symptom clusters (e.g., reduction of hallucinations and/or delusions) but not others (e.g., apathy, social cognition, and interpersonal skills) may not be specifically addressed by specific pharmacological and behaviorally based treatments. In addition, reduction of symptoms is not analogous to a "cure" for most individuals since neurocognitive and behavioral deficits in conditions such as schizophrenia may persist after symptomatic relief of positive symptoms. A number of symptom rating scales include the PANSS, the BPRS, and the Scale for the Assessment of Negative Symptoms (SANS). These instruments can provide useful and important information on symptom dimensions and provide a common basis by which to come to inform clinical and research diagnosis as well as to assess outcome.

As with many assessment instruments, interpretation of these measures depends on the operationalization and validity of specific symptom constructs as well as their ability to designate which cluster of symptoms belongs to a particular psychiatric condition. It is important to take into account the fact that many psychiatric syndromes have overlapping features, and differences in symptom presentation can be a function of the stage of illness, time of onset of a psychiatric episode and the context and environment in which the patient is assessed. Further, many persons with SMI have comorbid psychiatric and medical disorders such as co-

occurrence of alcohol and substance abuse disorders. Further specific endocrine, metabolic and neurological disorders may produce symptoms that mimic psychiatric symptomatology.

One of the big challenges in the field is that controlled clinical trials often use relatively stringent inclusion and exclusion criteria that do not account for all of the comorbid psychiatric conditions, medical conditions, polypharmacy, and important mediating factors such as compliance, supported employment services (SES), environmental supports, and cross-cultural issues. As a result, it is increasingly important to ensure that findings obtained from placebo-controlled, randomized clinical trials generalize to persons in different medical, hospital and community mental health settings. While controlled randomized clinical trials may possess internal validity, the true test of an intervention is effectiveness in real-world community settings.

NEUROCOGNITIVE SYMPTOMS

Cognitive assessment is important in SMI, particularly in schizophrenia, given the number of impairments associated with the disorder. Neurocognitive deficits are thought to be a core feature of schizophrenia and often include emotional processing, perceptual disturbances, attention, sensorimotor integration, executive function, context processing, social perception, processing speed, and working memory. While pervasive cognitive deficits can vary in degree of intensity among individuals with schizophrenia, a substantial number of persons with bipolar disorder (up to 40 percent) may have completely normal cognitive profiles. A tremendously positive development in schizophrenia research has been the development of the Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS) Consensus Cognitive Battery (MCCB) for the assessment of schizophrenia. The MCCB has not only been successful in research on schizophrenia but has also been able to differentiate Bipolar 1 and Bipolar 2 patients from controls. It has been recommended that because of the more subtle nature of cognitive deficits in schizophrenia, additional tests that should be considered (besides the MCCB) include the California Verbal Learning Test-II (CVLT-II). In addition, the Wisconsin Card-Sorting Task, Trails B and the Stroop Color-Word task are all measures that should be considered.

An interview-based assessment of cognition specifically for schizophrenia is the Schizophrenia Cognition Rating Scale (SCoRS). The SCoRS assesses cognitive functioning based on interviews with both patients and their caregivers. The assessor then incorporates both sources of information to determine a final rating. Performance on the SCoRS scores has been found to be associated with both actual performance on cognitive tests and measures of real-world functioning.

The problem with any neuropsychological assessment is that there are

many factors in SMI other than underlying putative brain damage that may contribute to poor performance. For example, poor motivation, sedation and other cognitive effects of medications, social anxiety, paranoia or hypervigilance and interactions with the test examiner may have significant effects on test outcome. In some settings, attention and motivation to perform may be so low that the neuropsychological battery with the Tests of Malingering and Memory (TOMM) or Green's Word Memory Test (WMT) is augmented. It is important that any neuropsychological assessment that is performed is not in the acute stages of SMI. The authors find it much more helpful to conduct neurocognitive evaluation after ample stabilization has occurred. There is a tendency to think that neuropsychological testing taps orthogonal, independent cognitive domains but deficits in memory and measures of verbal fluency may all be related to generalized cognitive slowing, attentional deficits and reduced speed of processing. While there have been attempts such as the National Institute of Mental Health (NIMH) initiative (Cognitive Neuroscience Treatment Research to Improve Cognition in Schizophrenia [CNTRICS]) aimed to develop measures derived from cognitive neuroscience, with explicit links to known neural systems and psychopharmacology, the field is still hampered by a locationist notion of the brain where function is thought to occur in specific brain regions (e.g., amygdala) rather than distributed networks of neuronal activity that involve multiple brain regions. This highlights the importance of relating neurocognitive function to functional measures such as fMRI and PET in order to identify working neural networks in the brain.

SOCIAL COGNITION

There is increasing evidence that negative symptoms have an impact on both social competence and social outcomes, but do not exert an influence on social cognition. However, social competence and social cognition have significant effects on real-world social outcomes. The Result of the Expert Panel and Rand Survey has identified four major domains of social cognition that includes (a) emotional processing, (b) attributional style/bias, (c) social perception, and (d) Theory of Mind (ToM)/mental state attribution. Measures that the committee agreed upon for final inclusion in the battery to assess the aforementioned domains included the abbreviated version of the Ambiguous Intentions and Hostility Questionnaire (AIHQ), Bell Lysaker Emotion Recognition Task (BLERT), Penn Emotion Recognition Test (ER-40), Hinting Test, abbreviated version of Relationship Across Domains (RADs), Reading the Mind in the Eyes Test, The Awareness of Social Inferences Test (TASIT), and the abbreviated version of the Trustworthiness Test.

Recently, as part of the Social Cognition Psychometric Evaluation (SCOPE) study, it was shown that the BLERT, a test of affect recognition

and Hinting Task (ToM) had the highest psychometric properties among a number of social cognition tasks under study and were recommended for use in clinical trials. Those with intermediate psychometric properties included the ER-40, TASIT and Eyes Test which were recommended for further study. In contrast, the AIHQ, RADs test, and Trustworthiness Task had considerably poorer psychometric properties and caution was urged in the use of these measures.

COMMUNICATION AND SOCIAL SKILLS

Deficits in metacognition, the ability to construct complex ideas about oneself and others and the ability to respond to social and psychological challenges underlie many of the communication and social skills deficits found in schizophrenia. This mismatch between perceptions of oneself and the world and communication with others in the environment can cause considerable difficulties for an individual with schizophrenia. Impaired communication and language skills have been identified as common in schizophrenia and it has been shown that persons with schizophrenia have greater social skills deficits than those with major depression or bipolar disorder. Those with schizophrenia appear to have social skills deficits that are intermediate. Social skills training is based on behavioral principles of modeling; shaping, rehearsal, and positive reinforcement are all important parts of successful training paradigms. It should be noted that social skills training has advocated for helping an individual interact with his/her world. Both social cognition and negative symptoms carry the most variance in explaining real-world social outcomes. This suggests that targeting both social cognition and negative symptoms may be as important as teaching social skills to individuals. The problem with both social skills and expressive and receptive communication deficits in schizophrenia is that there is a complex interaction between social perceptions, integration of thinking about self and others and behavioral outputs that can all serve to produce negative outcomes that effect social, vocational and community life. It is likely that the most effective approaches are going to have to focus on the complex interplay between individual perceptual and social cognition deficits, how these interact with more complex metacognitive processes and help modify behavioral repertoires that will foster optimal real-world functioning.

ASSESSING FUNCTIONAL OUTCOMES

Broadly speaking, the goal of any psychiatric rehabilitation or remediation effort is to enhance and support optimal functioning in the environment. However, there are different types of function, including interpersonal communication, ability to manage one's household affairs, managing one's finances, community affairs and working in a vocational setting. These broad areas of functioning have considerable overlap. For example,

managing one's household affairs may involve arranging for transportation to the bank or supermarket and understanding bus, train or subway routes. There are important decisions to be made on how to prioritize income, making sure that income is used for food, housing and medication before it is allotted for other purposes. Persons pay bills, must interact and effectively communicate with others and meet daily responsibilities in the community and the workplace. Every individual is different and understanding the individual's psychiatric condition, treatment regimen, adherence to treatment, natural social supports, contextual cues in the environment, and an understanding of a patient's strengths as well as his or her limitations is critical to helping the individual achieve optimal functioning within the community. This requires assessment techniques that allow for appropriate targeted interventions and remediation strategies. Proper assessment allows for optimal treatment and psychiatric rehabilitation. The reader will notice that these are not two distinct entities but rather a continuous effort to promote wellness and to maintain optimal function in many environmental contexts.

A critical distinction is the distinction between *functional capacity* and *functional performance*. Functional capacity refers to the ability and the underlying skills required to successfully perform activities that support independent living in the community. *Functional Capacity* can encompass a wide range of activities such as (a) the ability to count money or balance a checkbook, (b) having sufficient social cognition to understand implicit rules regarding social interactions or behaviors, (c) adequate social skills to successfully navigate a work or community environment, (d) requisite cognitive abilities such as intellect, memory, reasoning, language abilities to engage in meaningful home, community or occupational activities. If a person does not possess adequate functional capacity (requisite skills required for independent or even assisted living), then the focus of psychiatric rehabilitation has to be on attempting to build and foster those skills that will result in the greatest independence and quality of life. *Functional Performance,* while often dependent on underlying functional capacity, refers to the actual ability to consistently perform a variety of skills in a way that maximizes autonomy, quality of life and the ability to cope with real-world demands. Functional performance then represents the actual performance of the individual in interpersonal, social, financial community, and vocational domains.

Individuals with a psychiatric condition such as bipolar disorder may have excellent underlying financial capacity, intellectual skills, social cognition and awareness and be able to live independently and to be gainfully employed. However, because of waxing and waning of symptoms, there may be certain periods where they may fail to adequately manage their manic, depressive or mixed episodes and may mismanage finances, have difficulties meeting the demands of home, work or family and be

incapacitated despite their premorbid high levels of functioning. Individuals with schizophrenia may have intact financial and adequate cognitive skills to manage to work and live independently in some settings. However, persistent difficulties with negative symptoms and social cognition can lead to problems that may negatively affect their ability to support themselves and their families. Primary and comorbid substance abuse can radically affect a patient to make poor choices and to allocate financial resources to their addiction or dependency, thus threatening their living situation. Psychiatrists are confronted with the sad reality that many homeless and socially impoverished individuals have underlying psychiatric conditions and lack proper supports that could substantially improve their well-being and quality of life.

The distinction between functional capacity and general real-world functional performance is critical in that these constructs dictate the approaches that one will take toward assessment and subsequent management. Skill-building and other approaches to help increase functional capacity may be critical (i.e., individual or small groups social skills training). However, the effectiveness of these approaches can only be seen when it forms the building blocks to enhance functional performance (i.e., generalizing social skills training to real-world community and/or occupational settings). Thus, assessment of functional capacity and real-world performance are critical elements in psychiatric rehabilitation. Functional capacity and performance can further be subcategorized with regard to particular domains such as cognitive, financial skills and judgment, social cognition, social skills, and judgment that affect individual autonomy and quality of life. Further, specific types of functional skills required for everyday living may pertain to specific domains such as caring for one's self in the home, successfully interacting with the community, or learning and maintaining job specific skills. This suggests that functional assessment strategies need to be tailor-made for each individual and display reliability (consistency of measurement) and validity (assessing the construct that needs to be measured).

TYPES OF FUNCTIONAL ASSESSMENT

Functional assessment can be employed in a number of ways. The most direct method of assessing functional capacity is direct observation of the patient performing behaviors in the clinical setting. One widely used measure such as the Performance-Based Skills Assessment (UPSA) developed by investigators at the University of California directly assesses the individual's functional capacity with regard to finances, communication skills, household chores, transportation, and planning recreational and other activities. The advantage of such a measure is that it is easy to administer, has demonstrated reliability and validity and can provide direct and quantifiable information on functional capacity. Knowledge of deficits

in functional capacity can be critical for initial assessment as well as response to treatment. However, performance-based assessment may not always map on the individual's performance in the community. In this case, a qualified informant can provide essential information based on repeated observations of the individual in the context of different environmental supports and contextual cues. In this context, a reliable collateral informant, whether it be a friend, relative, or knowledgeable professional can provide essential information that may simply not be available by performance-based functional assessment. However, quality of the informant matters. If a collateral informant has little opportunity to observe the patient, has a cognitive psychiatric disability themselves or self-serving biases, their report may be of little value in providing useful functional information. While it is always important to obtain and respect the individual's evaluation of their real-world functional performance, it is important to note that in schizophrenia and other neuropsychiatric conditions such as Alzheimer disease (AD) and other neurodegenerative disorders, reports are often positively biased (i.e., the patient often reports a much higher level of functional performance than may actually be the case). Anosognosia or the "inability to appreciate what one does not know" is a neuropsychological condition that is seen in traumatic brain injury (particularly within the right hemisphere), AD and in psychotic disorders such as schizophrenia.

As a result, it is often very useful for the clinician to compare the report of the patient and reliable informant and to also use performance-based functional assessment tools and rating scales.

FUNCTIONAL ASSESSMENT SCALES

In addition to the UPSA, the performance-based measure of functional capacity, a study also notes important scales for functional capacity such as the ILS and Test of Adaptive Behaviors (TABS). Everyday functional rating scales selected by the RAND expert panel include the Independent Living Skills-Survey (ILSS), Specific Levels of Functioning Scale (SLOF), Life Skills Profile (LSP), Birchwood Social Functioning Scale (SFS), Social Behavior Schedule (SBS), and Heinrichs-Carpenter Quality of Life Scale (QLS).

The most widely employed measure of functional capacity, the UPSA is a particularly compelling scale of functional capacity that has shown correlations of 0.6 to 0.7 with neurocognition in a number of studies. It includes simulations of everyday activities of daily living such as: communication (i.e., dialing the telephone to schedule a physician appointment, obtaining and dialing a number from a telephone operator); comprehension/planning (reading and planning a recreational outing); finance (counting currency, making change, and paying a bill); household management skills (e.g., shopping for grocery items), and transportation

(using a bus schedule in planning a trip and understanding charges and obtaining information). Some versions of the UPSA include a medication management subtest and are referred to as the UPSA-II. There is also an abbreviated version of the UPSA that focuses on communication skills and finances which is called the UPSA-B.

The SLOF relies on self or informant reports but is especially useful when employed by a high contact clinician. The scale taps the following domains, Participation in Community and Household Activities, Interpersonal Relationships, Work Skills, Self-Care, Physical Functioning, and Socially Acceptable Behavior subscales.

The UPSA has the advantage of being an objective performance-based functional measure and is preferable to self-reports of patients who often overestimate their abilities or questionable informants. Critics of the UPSA maintain that the UPSA measures tap functional behaviors but that they are more psychometrically similar to cognitive measures. There are contextual cues in the real-world environment that dictate functional real-world functional performance apart from demonstrating capacity in contrived clinical and laboratory settings. Measures such as the SLOF are most effective when used with informants but may in some cases be susceptible to reporter biases. The SLOF and other functional rating scales are typically most effective in the hands of a high contact clinician who knows the patient well and can weigh informant and patient reports against his/her own clinical judgment. While the SLOF has been extensively validated with schizophrenia patients, studies have shown that 64 percent of bipolar patients evidence deficits in one or more SLOF domains. The UPSA-1, UPSA-II, or UPSA B has been employed with a large number of patient groups including those with major depression, bipolar disorder, and schizophrenia. Importantly, the instrument has also been employed in diverse cultural and language groups.

Other scales important in psychiatric rehabilitation include the Maryland Assessment of Social Competence (MASC), a structured role-play designed to assess social skills. Other scales use time-sampling techniques consisting of numerous observations of patient social behaviors, such as the Time Sample Behavioral Checklist (TSBC) or Clinical Frequencies Recording System (CFRS), or Staff-Resident Interaction Chronograph (SRIC) but are usually only appropriate for institutional and residential treatment settings since these involve extensive ratings by staff members.

COGNITIVE REMEDIATION IN COMMUNITY AND OCCUPATIONAL FUNCTION

Neurocognitive deficits are core features of schizophrenia and moderate to severe cognitive impairments are present in the vast majority of cases. The most commonly used measures are memory scales such as the Rey Auditory Verbal Learning Test (RAVLT) or CVLT-II. Executive function is often measured by the Wisconsin Card Sorting Test (WCST) or Trails B

(although this measure taps many aspects of neurocognitive function) or measures of the DKEFS. Digit symbol of the WAIS-IV is a good measure of processing speed as is Trails A. Examples of widely used neurocognitive batteries include the MATRICS MCCB, the Brief Assessment of Cognition in Schizophrenia (BACS), and Repeatable Battery for the Neuropsychological Assessment of Schizophrenia (RBANS).

Meta-analyses have shown that CR in schizophrenia has robust effects of cognitive outcomes but there is little evidence that there is an effect on functional skills and abilities. However, when combining CR with functional skills training, better results in community living skills occurred than with functional training alone. An important review indicated that poor neurocognitive function had significant effects on vocational and occupational status within the community setting. Subsequent investigations revealed that CR plus SES enhanced positive employment outcomes whereas other studies have not shown such effects. An important issue is whether training specific cognitive abilities such as memory, attention, and executive skills are as effective as directly training specific functional and occupational skills. The notion is that training component cognitive abilities in the hopes that they will generalize to specific real-world behaviors may be less important than directly training target behaviors of interest.

As an example, consider an adult with schizoaffective disorder who is working in a supported occupational setting. One approach might be to train specific cognitive component abilities in the hopes that they will generalize to work setting. An alternative approach that the authors favor would be training those skills required for job-related performance. For example, CR strategies would specifically target actual job-related activities such as organization, strengthening procedural memory for certain rote activities, and employing strategies to monitor performance. This targeted functional training would involve the cognitive aspects of the skills related to employment but directly integrate this training in an integrated manner and in a manner that would more likely generalize to the employment setting.

REHABILITATION OF SOCIAL COGNITION

There has been an increased interest in moving beyond merely framing core features of schizophrenia in terms of positive and negative symptoms and neurocognitive impairment. There has been emerging evidence that deficits in social cognition can also be considered core and stable features of schizophrenia. Social cognition pertains to the perceptions, beliefs, and interpretation of other people's behaviors. Poor social cognition can significantly impair a person with SMI to appropriately respond to others in their environment. Green and others concluded that there were five major aspects of social cognition. *Theory of Mind* generally refers to an

individual's ability to infer the beliefs and intentions of others. *Social Knowledge* consists of the understanding of rules and conventions that underlie social behavior and guide social interactions. *Social Perception* is the ability to recognize general rules concerning roles and societal rules. *Emotional Processing* involves the experiencing and use of emotions and has been linked with emotional intelligence. Finally, *Attributional Bias* involves attributing causality to both positive and negative outcomes. Each of these components is critically important in understanding how an individual relates to others in the community and their vocational performance. It should be noted that deficits in social cognition are not only observed in those with schizophrenia but also individuals with bipolar disorder and to a lesser extent, those with major depressive disorder.

There is increasing evidence that social cognition accounts for far more variability in community function than neurocognitive abilities.

A recent meta-analysis of studies on social cognition revealed that social cognitive training procedures have relatively large effects on emotion recognition, small to medium effects on measures tapping Theory of Mind effect, and no effects on attributional bias or social perception. One of the most important findings in this study is that these kinds of techniques have a moderate to large effect on community functioning. However, there may be less of an effect on higher-order social cognitive skills. This has led to the development of more real-world–computerized tests using virtual reality such as the RC2S which involve navigating a computerized character through situations that involve emotional processing and learning contextual cues.

COGNITIVE BEHAVIORAL THERAPY

CBT is a type of psychotherapy based on principles of conditioning, learning, and cognition. As applied to schizophrenia, CBT engages patients collaboratively, challenging their interpretations of events or experiences. It is thus often used to assist patients in developing more realistic alternatives to delusional and paranoid thinking. It can also be used to help patients to develop less stressful attributions for hallucinations. For example, rather than accepting that the voices that he or she hears are omnipotent, omniscient, and must be obeyed, behavioral experiments can be set up to allow the patient to test this hypothesis and replace these thoughts with more realistic ones. In many cases, the reduction in anxiety that accompanies modified attributions regarding voices leads to a reduced frequency and intensity of hallucinations. In the case of negative symptoms, CBT is often used to challenge anhedonic beliefs, schedule activities, and administer self-rewards for increasingly engaging in pleasurable activities. CBT works best with patients who are willing to actively participate in treatment, often as the result of distress from symptoms and/or at least minimal insight into the abnormal nature of their

experiences.

A meta-analysis of CBT for schizophrenia conducted in 2001, including seven randomized, controlled trials, showed that CBT produced large clinical effects on both positive and negative symptoms. CBT as an adjunct to routine clinical care also resulted in significant additional benefits compared with routine clinical care plus supportive therapy. An updated review of 17 clinical trials testing the efficacy of CBT for schizophrenia conducted in 2004 showed that CBT results in better outcomes on specific measures compared with routine care or supportive therapies in a variety of settings (e.g., day-treatment programs and long-stay inpatient programs) and across some special patient populations (e.g., relapse-vulnerable patients, older adults with schizophrenia, and individuals with comorbid substance abuse or anxiety disorders). Researchers conducted a meta-analysis of 14 studies including 1,484 patients, and found that compared to other adjunctive measures, CBT showed significant reduction in positive symptoms. The specific symptoms alleviated with adjunctive CBT include delusions, distress, or delusions related to auditory hallucinations, paranoia, and negative symptoms. Improvements in distress related to auditory hallucinations and delusions were maintained at follow-up.

In addition to problems uniquely associated with psychotic disorders, various forms of CBT are effective for addressing generalized anxiety, panic, social anxiety, depression, obsessive-compulsive symptoms, and substance abuse. These problems often co-occur with chronic psychotic disorders, and there is no reason to believe that CBT interventions are any less effective in treating them in people with schizophrenia than in the general population.

An issue when considering CBT for psychosis is that, to succeed, patients must have at least some motivation to reduce or eliminate their symptoms. Patients who are thus motivated typically demonstrate good treatment responses, whereas unmotivated patients often do not respond or drop out of treatment. Another challenge is to find ways to engage first-episode patients in CBT. Often, more supportive efforts are needed to engage first-episode patients in the treatment system prior to initiating CBT.

SOCIAL LEARNING AND SOCIAL SKILLS TRAINING

The social learning program (SLP) is a comprehensive, integrated set of learning-based techniques (typically including a token economy) and skills-training activities. In most cases, an SLP is delivered within the context of a residential facility, usually for patients with severe and chronic behavioral disabilities. A key feature of the SLP is that all staff members on all shifts are trained to structure their interactions with patients in specific ways during all waking hours. Research indicates that SLP is the most effective

form of inpatient treatment for people with schizophrenia, including the so-called "treatment-refractory" patients. The SLP has demonstrated effectiveness with a wide range of people with disabilities in a variety of settings (e.g., state and private hospitals and maximum security forensic hospitals). The components of the SLP form an extremely positive teaching environment that assists clients in developing adaptive behaviors and skills relevant to successful return to the community. Contemporary versions of this approach incorporate skills-training technologies, psychiatric rehabilitation techniques for engaging clients, CBT, vocational rehabilitation, cognitive rehabilitation, and substance abuse treatment.

A guiding assumption of the SLP is that all persons with severe mental disorders, no matter how severe the impairments, can learn new behaviors and skills and therefore progress to less structured environments. To promote behavior change and skill acquisition, the SLP incorporates a wide variety of techniques based on fundamental learning principles. Differential reinforcement forms the basis of many of the procedures of the SLP. Staff at all levels and disciplines are highly trained and carefully supervised in the timely and consistent delivery of verbal praise, positive social attention, and material reinforcement for adaptive behaviors and the application of extinction or response-cost techniques for bizarre, aggressive, or rule-violating behaviors. Effective SLPs deliver much more positive reinforcement than extinction or response cost. The result is a highly reinforcing, positive, and supportive environment.

Although most comprehensive SLPs include some sort of token economy or point system to deliver feedback and behavior-related consequences, some use individual behavioral contracts, contingency management plans, or social reinforcement alone. However, in all well-designed SLPs, specific objectives and goals of clients are individualized, as are the specific interventions for assisting them with acquiring the skills necessary to accomplish these goals/objectives. Another key feature of all effective SLPs is that, as patients begin to demonstrate improvements in behaviors, there is a planned and systematic withdrawal of tokens or points and an emphasis on generalization training so that clients will be able to apply acquired skills and knowledge successfully in "real-life" community settings under more natural, primarily social reinforcement conditions.

An effective SLP is based on a wealth of data that are generated during all waking hours by all staff, using a number of observational rating procedures (described in the section on assessment). The availability of data on all critical behaviors (e.g., grooming, attendance at groups and activities, social contacts, and aggressive behavior) allows for sophisticated data-driven treatment planning. Moreover, the ability to demonstrate specifically to patients why their privileges or other consequences of their behavior are occurring and what needs to change and by how much to receive different consequences is a powerful tool. In effect, this type of

data-driven system serves to instill responsibility for behavior change in the patient, instills a sense of agency and mastery regarding behavior change, and reduces the institutionalized and dependent attitude that staff arbitrarily determine privileges, which is so often found in state hospital settings. Moreover, as demonstrated in a recent study, patient satisfaction with treatment is often high in SLPs.

Given the complexity, specificity, and range of procedures involved in the SLP, staff training is of paramount importance. All staff members are involved in extensive initial and ongoing training, using both didactic instruction and in vivo practice. Competency-based supervision is provided through regular performance feedback, using observational data on staff—patient interactions and structured supervisory observations.

Another important feature of SLPs is the focus on the generalization and maintenance of gains after program discharge. As patients acquire skills and develop goals for community living, they are provided with opportunities to apply these skills and pursue their goals in community settings. After discharge, declining contact aftercare is provided. Some SLPs arrange to train staff at community residential facilities to maximize the maintenance of gains after discharge.

SLPs have traditionally been provided on long-term treatment units. Recently, however, modifications of the full program have been tried in other settings, such as acute inpatient units and community-based residential settings for outpatients with SMI, with demonstrated success.

GENERALIZATION TRAINING

Recently, efforts have been made to improve the generalization of skills training gains in the community. One method, called in vivo amplified skills training (IVAST), uses specially trained case managers who routinely and frequently conduct additional training sessions in participants' environments. These sessions help patients to perform and practice their new skills in their community residences. An initial study of IVAST found that patients receiving the intervention achieved higher levels of interpersonal problem-solving skills, significantly greater social adjustment, and better quality of life over a 2-year period than participants with skills training alone.

A second procedure for promoting generalization involves engaging the people already in the patient's life, including residential care staff, peers, and relatives. People from these groups are selected by patients based on the criteria of cooperativeness, accessibility, and familiarity with the patient's environment. The intervention consists in structured meetings between the patient and the chosen supporters to review the use of the new behaviors, explore the causes of problems in successful performance of the behaviors, and problem solve around how to be more effective. No constraints are placed on the frequency or duration of a pair's meetings.

Evaluations of this procedure have found that participants who received both the skills training and the added support improved their interpersonal and community functioning during training and continued to improve during the 18 months following training. In contrast, those without support lost some of their improvements during the follow-up.

These data have two important implications. First, including specific interventions for generalization can help to improve patients' outcomes. Second, use of these procedures should become a practice standard, given that loss of skills is likely without them. Finally, recent developments in Medicaid reimbursement strategies have begun to shift part of the responsibility for providing care to community residences. This macro-level development provides clinicians and researchers with the opportunity to develop and apply integrated approaches to closing the gaps between the skills acquisition, performance, and generalization aspects of skills training. However, this inevitably means that more attention will have to be paid to training community residence staff on how to deliver interventions correctly.

ILLNESS/WELLNESS MANAGEMENT SKILL TRAINING

Gaining the ability to manage one's psychiatric illness is central to the rehabilitation and recovery perspective. In the rehabilitation and recovery literatures, skill training in illness/wellness management has gradually been differentiated from related social and living skills approaches, reflecting a growing recognition that specialized skills are needed to self-manage psychiatric disorders, comparable to skills needed to self-manage physical conditions such as diabetes. People learn about the episodic and persistent symptoms of their illness, the relationship between symptoms and functional impairments, pharmacological means and other techniques (e.g., relaxation and stress management) for controlling symptoms, drug side effects, identification of "warning signs" of an impending relapse, and various other aspects of their disorder and its management. Behavioral skills indirectly relevant to disorder management include, for example, the assertive skills necessary for dealing with the doctor and the doctor's receptionist in getting an appointment for a medication visit.

Several developer groups have packaged illness/wellness management skill training materials for testing and dissemination. A number of original studies and reviews confirm the effectiveness of skill training focused on illness/wellness management for improving adherence to treatment in people who live with SMI. The SAMHSA has produced two packages for public dissemination that fall under this category, Illness Management and Recovery, and Medication Management Approaches in Psychiatry. Both packages include materials for all participants in the illness/wellness management process, including the person in recovery, physician, other service providers, family, and friends.

Illness/wellness management training for people with schizophrenia benefits from relapse-prevention and related techniques. Well known for its application in substance abuse, many of the techniques of relapse prevention are well suited to the episodic nature of the lived experience of people with schizophrenia, the role of stress in precipitating psychotic symptoms, and the important role of the recovering person in managing those episodes. The original application of relapse prevention is also of interest, given that people with schizophrenia often have substance abuse problems as well. There have been no controlled trials of the unique contribution of relapse-prevention techniques to disorder management in schizophrenia, although they are frequently incorporated into psychiatric rehabilitation programs. Peer involvement is especially relevant to illness/wellness management.

SUPPORTED EDUCATION

Supported education prepares people with psychiatric disabilities to achieve educational goals in an academic setting. It addresses ways to overcome obstacles related to achieving educational success, such as improving academic skills and problem solving, bolstering self-confidence, and engaging in career development. Several models of supported education exist. Mobile support is one type that has been found beneficial. In this approach, a counselor meets one-on-one with a student to tailor an individualized plan to maximize academic success. This may include assistance in accessing services already in place in the educational setting, help with locating and using school social and recreational services, preparatory coursework, case management support, ongoing support and check-in meetings at the local student center, study support and visits to the campus library, linkage support to other campus services, and individual counseling (didactic, supportive, and/or exploratory). Other models of supported education include didactic group meetings in a classroom setting focusing on study skills, supportive group meetings, and the provision of standard study guides. Evidence from these programs suggests that distress levels are higher in people with schizophrenia than in other students. This should lead to further efforts to introduce stress management techniques into supported education activities for patients with schizophrenia.

SEX EDUCATION

Many individuals with serious mental illness aspire to and achieve meaningful education, work, and enjoy mutually supportive family and intimate relationships. The topic of intimacy and sexuality has been given the least attention in this population by mental health professionals. Surveys have discovered that 60 to 70 percent of adults with serious mental illness report being sexually active in the last year, with approximately 30

percent reporting two or more partners.

Clearly, sex education should be an integral part of a comprehensive rehabilitation program. The current impetus for increasing patients' sexual knowledge derives in part from the alarmingly high rates of HIV infection and AIDS found among individuals with serious mental illness. Not surprisingly, the majority of sex education programs have been designed to increase patients' awareness of the risk of HIV and AIDS, dispel misinformation and stereotypes, and provide the knowledge and skills needed to decrease their chances of becoming infected. Emphasizing teaching techniques that use procedural learning and memory can mitigate any cognitive disabilities that may impact learning. In psychiatric rehabilitation, implicit or procedural learning is enhanced by video and live demonstrations, termed social modeling. Other techniques that build on procedural learning and memory are role playing, interacting with a computer as in computer games, using pictures and attractive graphics to amplify written information, and engaging in repeated practice.

These educational methods can also be used for sex education programs that have broader goals than simply teaching persons with serious and persistent mental illness how to reduce their chances of becoming infected by HIV. Some of the educational objectives that comprise more ambitious and enlightened efforts in this realm include the following:

- Increasing patients' knowledge and comfort about sexuality
- Encouraging patients to identify and clarify their values and attitudes about sexuality
- Informing patients about alternative methods of birth control
- Teaching patients decision-making skills regarding sexual activity
- Overcoming medication-related sexual dysfunction and preventing deterioration or cessation of sexual activity
- Improving intimacy skills
- Imparting basic HIV and AIDS education
- Instructing patients in proper condom use.

COMORBID SUBSTANCE USE DISORDERS

The field of psychiatric rehabilitation is confronted with the need to identify and treat substance use disorders as epidemiological data show high prevalence rates among individuals with concurrent SMI. Substance use disorders have been associated with medication nonadherence, underachievement, decreased work productivity, poor health, neuropsychological impairment, social dysfunction, and violence, among other negative biopsychosocial effects. Prospective studies have shown that treatment outcomes, hospitalization rates, housing stability, and functional status, are worse among patients with dual disorders. Studies have also shown that problems related to substance use tend to persist over the long

term among patients with SMI. Lifetime treatment or help-seeking behavior is uncommon, particularly among those with psychiatric comorbidity, thus clinicians are admonished to be proactive with assessing for substance use disorders to mitigate the negative impact on successful recovery and community adjustment.

Historically, individuals with SMI such as schizophrenia and co-occurring substance use disorders received treatment for one disorder, but were excluded from the other. Eventually, distinct and parallel treatment programs emerged; however, treatment outcomes were poor using this model. As a result, integrated treatment models combine substance abuse and mental health interventions in one clinical program. It is now commonplace that facilities offer outpatient dual disorders interventions as well as integrated residential treatment programs. In integrated treatments for patients with dual disorders, mental health treatments and substance abuse treatments are brought together by the same clinician, or team of clinicians, in the same program to ensure that the patient receives a consistent explanation of illness and a coherent prescription for treatment rather than a contradictory set of messages from different providers. Integrated treatment aims to improve collaboration between treatment providers, to eliminate the patient's burden of attending two separate programs, and to remove financial and other barriers to access and retention. Comprehensive programs have frequently included not only standard mental health interventions, such as medication monitoring and support services, but also assertive outreach to engage patients in treatment; intensive case management; and individual, group, and family substance abuse counseling. Research efforts are still being made to test and refine individual components and combinations of integrated dual diagnosis treatments. As with all treatment, effective interventions targeting substance use should be individualized to address personal factors and stage of motivation.

TOWARD MORE INTEGRATIVE MODELS OF CARE

It is readily apparent that current psychiatric rehabilitation extends far beyond previous psychosocial models that were added to medication management and other somatic therapies. Psychiatric rehabilitation today is an active, integrated, and person-centered enterprise, which presupposes a strong therapeutic relationship, trust, and cooperation between the patient, family, and multidisciplinary treatment team. Excellent treatment is predicated by using state-of-the art and empirically validated assessments. While neurocognitive deficits may be pervasive in many types of schizophrenia, persons with bipolar or unipolar affective disorder may have less but still significant impairment in this area. In some cases, comorbid substance abuse disorders can further impair already pre-existing cognitive deficits. Equally important is the accurate assessment of

functional capacity (based on performance based tests) and most importantly, real-world functional performance. Functional performance cannot be limited to merely higher- and lower-order activities of daily living but must encompass also social and vocational function. There is also increasing evidence that deficits in social cognition and meta-cognition create considerable stress for individuals with schizophrenia beyond typical memory impairments, slow cognitive processing, and other neurocognitive deficits. As previously discussed, there is ample literature to suggest that improving communication skills, enhancing social skills, and behavioral goal attainment are all effective means to help the individual cope with stressors that might increase the likelihood of relapse. This chapter has focused on empirically oriented approaches that can help in these efforts. As previously mentioned, it is of essential importance for both the patient and the treatment team to (a) identify targeted short-term and long-term goals that are both operational and obtainable, (b) plan interventions and build supports that are appropriate to a person's stage of recovery, (c) build coping strategies and stress management techniques that will reduce the chances of relapse, and (d) foster a collaborative treatment milieu involving the patient, family, and care providers.

Every person with SMI is a unique individual. While evidence-based approaches can provide guidance in selection of the best instruments and interventional tools, this can never be done in isolation and without knowledge of the person's strengths, weaknesses, resources, and unique personality and environment. The best chances for optimal recovery and stabilization are through a multimodal approach that encourages adherence to medication and targeted treatment goals, stress management and coping techniques, as well as developing optimal environmental supports. SMI conditions are like many chronic conditions that need constant attention and management.

However, unlike many physical ailments, persons with SMI still have to manage additional stigma and lack of understanding afforded those which chronic medical and neurological conditions. The most effective interventions will be those with most-empirical support, targeting the many different aspects of deficits in SMI (including but not limited to social isolation, deficits in social cognition, problematic meta-cognition, functional and vocational deficits, as well as problems with communication and social skills). However, focusing solely on these targets without recognizing the importance of contextual cues and social supports risks fragmenting care.

There needs to be continued emphasis on more integrated and comprehensive models of care. Patients deserve no less.

▲ 58.7 A Sociocultural Framework for Mental Health and Substance Abuse Service Disparities

MARGARITA ALEGRíA, PH.D., KIARA ALVAREZ, PH.D., BERNICE A. PESCOSOLIDO, PH.D., AND GLORISA CANINO, PH.D.

INTRODUCTION

The Institute of Medicine (IOM) defined disparities in health care as "racial or ethnic differences in the quality of health care that are not due to access-related factors or clinical needs, preferences, and appropriateness of interventions." Responding to an important gap in that view, *The 2003 National Healthcare Disparities Report (NHDR)* expanded the definition to include differences in access associated with patient race, ethnicity, income, education, and place of residence. Although these reports strengthened public concern about glaring discrepancies in patterns of health service use and outcomes for racial and ethnic minorities in the United States, there has been limited progress in disparities reduction. Most of these disparities continue to be associated with the patient's race, ethnicity, and income profile and are a lost opportunity to eradicate the augmented age-adjusted mortality and increased burden of disease for ethnocultural populations. Despite the attention focused on health services disparities, particularly in view of demographic projections suggesting that ethnic/racial minorities will become the majority of the US population by 2044, there are a lack of strategic approaches that provide guidance for understanding the policy, social, and cultural factors that account for these disparities. Without frameworks and models, implementing the science-to-services translation called for by National Institutes of Health is difficult.

To date, numerous conceptual models have attempted to chart the potential causes of mental health and service disparities. Most of these models are based on the understanding that disparities in mental health and mental health care result from multiple factors, have no single underlying cause, and are not necessarily caused by same mechanisms across racial/ethnic groups. However, the majority of these models also link the existence of disparities to broader social, political, and economic inequality, as well as systemic racism, discrimination, and the historical subjugation of minority populations in Western society. Additionally, some frameworks detail a small set of factors related to a particularly important possible mechanism, while others seek to provide an overview of a broad range of possible causal mechanisms.

For example, some researchers have put forward models of health disparities based on the idea that residential segregation leads to differential exposure to environmental risk factors, particularly those that

affect psychosocial stress. Structural factors such as tax incentives and zoning laws affect the types of industries in minority neighborhoods, which may lead to increased exposure to environmental pollutants and lower neighborhood quality of life. Limited private and public investment in low-income areas can also result in poor quality housing stock and insufficient health infrastructure, leading to poor living conditions and reduced access to care. Physical (noise, pollution) and psychosocial conditions (social disorganization, crowding, discrimination, economic deprivation, and crime) in the neighborhood may augment allostatic load and damage health over time through what has been called the "weathering hypothesis."

Other scholars argue that the fundamental causes of disparities have to do with macrosocial factors such as historical, political, economic, and legal conditions, which are closely linked to the distribution of wealth, opportunities, and power. Intermediate conditions such as the built environment (i.e., community investment, public safety, enforcement of local rules, quality of education, and civic engagement) interact with the individual to cause stressors (i.e., violent crime and financial uncertainty) or buffers (like social integration) that can lead to differential health behaviors and mental health outcomes.

More focused theoretical models explore potential causes of disparities in a single area that may play an outsize role in causing disparities. One such model analyzes the effects of employment and work on health. Employment affects socioeconomic status, the types of conditions in which individuals spend much of their time, the type and quality of health insurance and other benefits available to individuals and their families, stress levels, and the regularity or irregularity of one's work schedule. All of these factors combine to impact how likely a person is to get sick over both the short and long term, whether and where an individual will seek care, the quality of care received, and the ability to continue with treatment (particularly if the individual is not allowed significant time off of work). Historically, the authors argue, minority individuals have been more likely to work in jobs that are low status, have lower pay and benefits, are physically demanding, and expose workers to stressors or even dangerous environments or substances.

Finally, some models center more closely on individual factors and life stresses that are caused by ethnicity/race and socioeconomic status, as well as community context, gender, and age. These may be connected with biological and psychosocial factors that increase or decrease vulnerability to stress, and consequently impact health behaviors, access to treatment, and mental health outcomes. In these models, disparities result from a complex interaction of race/ethnicity, poverty, gender, and minority status with social circumstances (i.e., supportive social relationships and family networks) and an individual's responses to those circumstances (i.e., optimism and personal agency), which impacts psychosocial reserve

capacity and cognitive-emotional processes.

There is clearly a great deal of overlap between the theoretical models discussed above, with most differences between models being merely variations in scope and emphasis. These different frameworks have accelerated disparities research by identifying some areas for research and intervention. However, they still largely fail to offer coherent, empirically based platforms upon which to develop public policies, systematic guidelines, professional training, or restructuring of health care systems to reduce service disparities. Building from past work and the theoretical literature reviewed above, this chapter outlines a culturally informed framework for mental health and substance abuse service disparities which integrates both the IOM and NHDR definitions of disparities by focusing on ethnic and racial differences in access to and quality of care. Although specifically designed to addresses mental health and substance abuse service disparities, the basic framework could be tailored to other health problems as well. In an effort to integrate sociocultural elements with the IOM and NHDR understandings of disparities into a health service disparities frame, a definition of the word *disparities* is necessary. Rather than utilizing the less-restrictive definition put forth in the NHDR of "any differences in service use among populations," the authors define disparities as *racial and ethnic differences in access, health care quality or health care outcomes that are not due to clinical needs or the appropriateness of treatment*. Patient preferences are also included as potential sources of disparities since they do not stem from "undue differential treatment on the basis of race and ethnicity." Patterns within the health care system influence racial and ethnic minorities' preferences in treatment, and patient-level factors linked to race or ethnicity inform minorities' preferences in treatment. As such, "undue differential treatment on the basis of race and ethnicity" may be operating through preferences. Thus, preferences cannot be disentangled from people's available options in care or from health literacy factors and can contribute to disparities.

This approach to understanding disparities in service delivery emphasizes that cultural processes refer not only to race/ethnicity as a particular set of values, norms and beliefs, but also to the circumstances and experiences leading to a group's social, economic and political status. Culture creates repertoires that structure human actions. In order to understand the relationship between culture and health, one must reject a simplistic view of culture or cultural difference and view cultural processes as a fundamental thread connecting communities, health systems, providers, and patients. The sociocultural framework (SCF) requires going past the use of sociodemographic categories as proxies for culture and moves toward understanding the cultural repertoires available to patients and how cultural scripts influence service disparities.

At the same time, the authors take into account cultural variation in the

prevalence of psychiatric disorders, expecting that these differences may be related to differences in exposure to risk and protective factors, the intensity or meaning ascribed to risk factors, the threshold at which a behavior is considered pathological, or the extent to which an environmental risk factor is mediated by genetic factors. In order to avoid inappropriate attribution of cultural factors influencing service disparities in minority communities, the authors adopt an approach that directs attention to life conditions and lack of resources that limit opportunities and affect the psychological development and well-being of minorities.

The Sociocultural Framework

As depicted in Figure 58.7–1, the SCF has three essential elements—systems, domains, and mechanisms. Two key systems that produce disparities are the health care system and the community system. Each operates at three domains or levels—the societal level (larger policy or environmental contexts), the organizational level (formal organizations or lay sectors), and the individual level (provider or patient). At each level, these domains interact or interface to produce mechanisms of inequality and bias that cumulate to disparities in health, health care, and quality of life.

FIGURE 58.7–1. The sociocultural framework for the study of service disparities.

While the SCF for mental health and substance abuse service disparities emerged from the IOM disparities framework examining the role of the health service system in creating disparities, the SCF update expands the role of other policies and neighborhood characteristics in influencing disparities in health care. The authors follow the IOM's *Unequal Treatment* report in focusing on three domains or levels within the health care system: **(1) federal and economic health care policies and regulations at the state and federal level; (2) the operation of the health care system and provider organization; and (3) provider/clinician-level factors.** These domains are depicted on the left-hand side of Figure 58.7–1.

However, the SCF extends the IOM framework by adding the parallel focus on how the community system may differentially impact access to services or quality in services by considering the role that community, neighborhood characteristics, family, friends, and individual level factors play in ethnic and racial minority individuals' referral, entry, and retention in mental health or substance abuse services. These additional domains or levels are drawn from utilization, "take-up" or help-seeking models and include **(4) the environmental context, specifically social and economic forces affecting ethnocultural populations; (5) the operation of the community system, including family, friends, and the lay sector; and (6) patient-level factors.** These domains are depicted on the right-hand side of Figure 58.7–1.

The six domains depicted in the center of the framework impact mental health and substance abuse service disparities for ethnocultural populations through the six main mechanisms listed in the center portion of Figure 58.7–1. These include **(1) failure of health care markets, institutional bias, limited financing, and lack of ancillary services, leading to decreased access and quality of mental health care and substance abuse services; (2) differential pathways into mental and substance abuse health care, leading to differential experiences of treatment, no treatment, or inadequate treatment; (3) poor patient–provider interaction, leading to miscommunication, clinical uncertainty, low therapeutic alliance, stereotyping, and clinical errors; (4) mismatches in mental health and substance abuse service offerings and minorities' needs, leading to resistance or lack of compliance in health care and under-treatment; (5) lack of community trust and erroneous expectations of services, leading to disengagement and poor collaboration in treatment; and (6) limited workforce availability and training of mental health and substance abuse service providers to treat ethnic and racial minorities, leading to reliance on informal or poorly trained providers.**

In sum, at each level, the health care system and community forces interact to produce mechanisms that lead to differential health care outcomes in mental health and substance use care, including greater illness severity and diminished quality of life. The domains are linked by and through these mechanisms. Further, nowhere in the SCF is the nature and operation of "culture" partitioned in a separate box. All mechanisms and domains are set within a shaded region which represents *culture*. Every aspect of onset, recognition, identification, treatment, and outcome is embedded within a larger cultural frame (that includes the culture of medicine) that influences service delivery options and decisions as well as the culture of the patients shaping the lay community. It operates at all levels, serving as an overlay at each community and health care system level and is intimately involved in how domains at the same level interact to produce mechanisms of inequality. The following text discusses how the interaction at each domain may operate to impact mental health and substance abuse service disparities. Concrete examples of how the six main mechanisms may produce disparities are provided. Because service disparities result from the interaction between the domains at each level, some overlap occurs in the authors' descriptions. Furthermore, the chapter brings in concepts and findings not specific to mental health and substance abuse care as appropriate, to help identify potential leverage points to reduce disparities. Finally, the chapter acknowledges that the mechanisms linked to access may be different than those leading to poor quality of care or differential outcomes in treatment. Similarly, while a framework sets the parameters and foundations for explaining disparities, more theoretical work must be done on the SCF to create testable models for understanding the challenges which lead to mental health and substance abuse service disparities for diverse ethnic and racial groups.

HEALTH CARE SYSTEM DOMAINS

Federal, State, and Economic Policy

Federal, state, and economic policies impacting health and mental health care have the potential to create, exacerbate, or reduce health disparities. Due to their over-representation in government-sponsored programs, ethnocultural populations may face additional challenges as a result of state and federal regulations aimed toward cost control. For example, state differences in implementation of the Patient Protection and Affordable Care Act (ACA), the Children's Health Insurance Program (CHIP), and federal financing of Medicaid payments all have a disproportionate effect on minority populations. Each is discussed, in turn, below.

Affordable Care Act and Medicaid Expansion. A key provision of the ACA is the expansion of Medicaid to include adults with incomes up to 138

percent of the federal poverty level ($16,104 for an individual or $27,310 for a family of three in 2014), in order to increase the number of Americans who are insured. However, as a result of the Supreme Court ruling on ACA provisions, individual states are allowed to decline the Medicaid expansion. As a result, more than 4 million Americans are uninsured due to a coverage gap. They do not qualify for Medicaid in their state, but do not earn enough to qualify for the insurance tax credits available to those making 100 percent of the poverty level or above. Since minorities tend to be over-represented among the poor, the flexibility of states to set their own eligibility criteria has implications for minorities' access to and quality of care. An estimated 4 in 10 uninsured African Americans fall into the coverage gap. Latinos, who have the highest percentage of uninsured when compared to other racial/ethnic groups, are also affected. The percentage of uninsured Latinos dropped from 36 to 23 percent after the enactment of the ACA, according to a 2014 survey by the Commonwealth Fund, but rates of uninsured Latinos remained unchanged in states that had not enacted the Medicaid expansion.

Immigrants of all backgrounds face particular challenges under current health insurance laws. Those who are lawfully present are subject to a 5-year waiting period for Medicaid and CHIP, as well as exclusions from these programs for some classes of immigration status. States may waive the waiting period for pregnant women and children, but not all states choose to do so. Undocumented immigrants are further disadvantaged, as they are not eligible for Medicaid at all, are not eligible for tax credits used to make private health insurance more affordable, and are not eligible to purchase health insurance via the federal health insurance exchange.

Lack of access due to not having insurance serves as a potential mechanism promoting service disparities. Not surprisingly, it has been argued that expanding insurance coverage for minorities would reduce disparities. However, knowledge about health care insurance options limits access even for the insured. For example, low-income and Spanish-speaking Latinos who are potentially eligible for insurance via health care marketplaces are much less likely to know about them when compared to high-income and English-speaking Latinos.

Low Reimbursement Levels and Provider Shortages. A major challenge in service provision for low-income populations is ensuring the availability of providers who accept Medicaid patients. In 2011, 31 percent of physicians surveyed stated that they would not accept new Medicaid patients, compared to 18 percent who stated they would not accept new privately insured patients. There are lower rates of psychiatrists accepting Medicare, Medicaid, and noncapitated insurance when compared to other specialties, and rates are decreasing over time. In 2009 to 2010, only 43.1 percent of psychiatrists accepted Medicaid and 55.3 percent accepted

noncapitated insurance, compared to 73 percent of physicians from other specialties who accepted Medicaid and 88.7 percent who accepted noncapitated insurance. Rates among psychiatrists represented a 19.5 percent decrease since 2005 to 2006. This limitation seriously restricts the available pool of providers willing to serve minorities, who are disproportionally represented in Medicaid services. Low participation of physicians is particularly concerning, given the expansion of Medicaid to an estimated 17 million people under the ACA.

Low reimbursement rates, payment delays, and billing requirements have been noted as a primary reason for not taking Medicaid patients in physician surveys. Systemically, providers within organizations serving large numbers of Medicaid patients may experience high expectations for productivity in order to make services financially feasible, which can increase provider burnout. There may also be a need for providers to spend additional time coordinating care for more vulnerable patients. The implementation of accountable care organizations (ACOs), which bring together groups of providers and provide more flexible payment structures to incentivize positive outcomes, may be beneficial in reducing health care disparities. Expansion of safety-net providers such as community health centers (CHCs), another provision of the ACA, is another avenue by which health disparities may be reduced. However, the long-term sustainability of CHCs is partially dependent on the revenue that they can continue to generate from patients, which is more challenging in states with high proportions of uninsured patients.

Children's Health Insurance Programs. CHIP is designed to make free or low-cost health insurance available to children without insurance but who are ineligible for Medicaid. As such, it plays a crucial role in reducing access barriers that create health service disparities among minority youth. In the first 10 years after CHIP was implemented, rates of uninsured children dropped from 30 percent of Latino children to 20 percent, 19 percent of black children to 12 percent, and 17 percent of Asian, Native Hawaiian, and Pacific Islander children to 12 percent. A study of CHIP implementation in New York found that pre-existing racial/ethnic disparities in access, unmet need, and usual source of care between white, Latino, and African-American youth were virtually eliminated during the first year of enrollment. However, racial and ethnic minority children continue to be less likely to be enrolled in health insurance when compared to white children, even when eligible for CHIP.

In 2009, the Children's Health Insurance Authorization Act (CHIPRA) established provisions aimed at reducing health disparities, including providing outreach grants to increase enrollment, increasing federal matching rates for interpreters and translators, providing federal funding for medical care for immigrant children in states that waive the 5-year

insurance waiting period, establishing quality of care measures to track health outcomes for children, and including specific provisions addressing health concerns that disproportionately affect low-income children and children of color. Across states that enacted the additional CHIPRA coverage for immigrant children, health insurance rates for this population increased by 14.5 percent and unmet health need decreased significantly.

Mental Health and Substance Abuse Parity. Laws aimed at achieving parity between insurance benefits for general health conditions and insurance benefits for mental health conditions have been enacted in various ways since 1996. In 2008, the Mental Health Parity and Addiction Equity Act (MHPAEA) was passed, and the ACA subsequently expanded the reach of the act to more types of insurance plans. The MHPAEA does not require plans to offer specific mental health benefits, but rather to ensure that the benefits offered are equal to those offered for other health conditions. Implementation of the law has been a complex process, resulting in final regulations being issued in 2013. While parity provisions are a promising step forward in access to care, it remains to be seen how the enactment of current regulations may or may not impact health service disparities.

National Standards for Cultural and Linguistically Appropriate Services. Policies can directly address issues relevant to minorities. The National Standards for Cultural and Linguistically Appropriate Services (CLAS) were published in 2000 by the Department of Health and Human Services (DHHS) and revised in 2013. The CLAS standards provide guidelines for health care organizations addressing three areas: governance, leadership, and workforce; communication and language assistance; and engagement, continuous improvement, and accountability. These standards have been used to shape service delivery systems, as well as by some states to propose or pass legislation. Organizations are urged to provide trained interpreters, as well as linguistically and culturally adapted medical forms for non-English speakers. While the CLAS standards are not a federal law, failure to meet language access recommendations may be a violation of Title VI of the Civil Rights Act of 1964, which prohibits discrimination in organizations receiving federal funding. DHHS-funded organizations must provide meaningful access to services to non-English speakers, including trained interpreters.

Policy Supporting Innovation. Policy changes can also facilitate the use of innovative strategies to address health disparities. In 2013, the Centers for Medicare and Medicaid Services adopted a regulation change allowing states to choose to reimburse for physical and mental health services provided by unlicensed providers, as long as a physician or other licensed

practitioner has recommended the service. This opens a possibility for states to fill in gaps in service availability by engaging providers such as community health workers and other lay providers. The use of lay providers to deliver mental health services has been successful in several major studies carried out in low- and middle-income countries, and may be applicable in under resourced communities within the United States.

Technology used to track delivery of patient care and implement quality measures is another promising avenue via which to reduce health disparities. Advances in health information technology (HIT), including electronic medical records (EMR), have been a critical component of national health policies. The ACA calls for improved reporting requirements, while CHIPRA has promoted the development of standard quality measures as a way of tracking and addressing health care needs. The IOM noted in a 2009 report that more detailed information on racial, ethnic, and linguistic background should be included in data collection efforts, in order to target efforts to eliminate health service disparities. Combining detailed data collection with quality measures allows identification of gaps in care for specific groups and to respond with specific programmatic improvements.

In sum, the larger parameters of a society shape the health care system. At the federal and state level, specific policies on health care, as well as economic policies and regulations, create a set of market forces. In turn, the nature of these policies interacts with community context to impact ethnic and racial minorities in the health care system. Both the intended and unintended consequences of these policies on health care organizations are described next.

Operation of the Health Care System and Provider Organization

As a result of the system level factors described above, health care systems face differential costs and opportunities associated with treating ethnic and racial minority populations. As noted above, reimbursement by the state or the federal government holds a central role in shaping provider burden, service design, workforce diversity, and organizational climate of health care organizations.

Cultural and Linguistic Competency in the Operation of the Health Care System. Health care policies designed to encourage cultural and linguistic competence, such as the CLAS guidelines, are expressly designed to counter discrimination. Yet the ways in which a policy is implemented impacts client care. Language barriers for non–English-speaking immigrant groups create major challenges in access to care. In one study alone, language barriers between provider and patient accounted for a $38 increase in charges for testing, and increased length of stay in the emergency department. Patients who speak a different language from their

providers report worse outcomes and higher drop-out rates, and may experience misdiagnosis or poor treatment based on misunderstandings in assessment. However, even the use of interpreter services by competent providers has been shown in some instances to result in lower quality care. At the same time, improving linguistic competence within a system results in additional costs and time investment. Health systems may be reluctant or simply unable to cover these resources. Furthermore, even if willing, individuals may not be readily available or trained to fulfill the required services. Policy efforts such as state legislation based on the CLAS standards may be beneficial in reducing health disparities, but resources and training must be available to health care systems to finance and implement organizational change.

Integrated Health Care. The integration of behavioral health services into the primary care setting has been advanced as a strategy to improve behavioral health outcomes for minority populations, given studies that indicate that members of racial and ethnic minority groups are more likely to seek mental health care via their primary care providers (PCPs). At the same time, there is still limited data available on how to best implement high-quality behavioral health services for minority populations in primary care. Studies have found that PCPs are less likely to detect mental health concerns among racial and ethnic minority patients than white patients. The pressure to treat behavioral health challenges in the time-limited setting of primary care, in addition to constraints in specialty care options available for PCP referral, may result in situations in which clients are offered lower quality services or do not follow up on treatment. One study found that Latino primary care patients diagnosed with depression were more likely to follow up on and complete treatment via medication alone, despite the majority of the patients expressing a preference for psychotherapy over medication. These patients were able to access medication directly via their PCP, but may have experienced challenges in accessing therapy services. Research on models of integrated and collaborative care, as well as their impact on specific racial and ethnic minority populations is needed in order to explore how this approach may or may not reduce health service disparities.

In other ways, the design of health care systems and services contributes to disparities. When health care organizations do not offer effective treatment for behavioral health problems, issues such as alcoholism, substance dependency, or posttraumatic stress disorder affect health status directly and compound other health problems indirectly. Further, offering a service-level spectrum, whereby good quality health services are offered for services that attract the healthy, but poor quality services are offered for the sick or those with chronic conditions (labeled adverse selection), tends to discourage use and hinders good outcomes.

Organizational Climate and Institutional Racism. Outcomes research has demonstrated that the climate of attitudes and beliefs and culture (actual behaviors) in the provider organization toward ethnocultural populations affects the receipt of quality care. Ethnic and racial minority patients might be viewed as less "appealing" to the health care providers if they are thought to present with a disproportionately greater risk of requiring more intensive treatment. For example, minorities may come to mental health and substance abuse care at higher levels of illness severity and terminate treatment early. In a capitated managed care environment, these factors might make ethnic and racial minority individuals less attractive to the health care system. In addition, these patients may also require referrals and networking with other social and service agencies—work for which the health care provider is not compensated. These hidden costs could have an effect on the desirability of treating ethnic and racial minority patients that may translate into negative attitudes, or what has been labeled institutional racism. Use of evidence-based strategies for organizational change, such as the ARC (Availability, Responsiveness, Continuity) intervention model, may be an avenue by which to change organizational attitudes. In this model, "change agents" are trained to educate providers, advocate for systems-level change, provide implementation data and feedback, and facilitate communication within the organization and with the broader community.

Design of Services for Minority Groups. While the evidence is inconclusive on whether the lack of targeted services for diverse patient populations plays a central role in service disparities, a meta-analysis showed that culturally adapted interventions were four times more effective than those not targeted to specific cultural groups. Further, interventions conducted in the client's native language were twice as effective as those conducted in English. Yet, structuring for racial and ethnic concordance, or matching between patient and provider is one area of heated debate. Race concordance for African Americans has been associated with higher patient participation in decision making and greater satisfaction with care. Patient–provider matching also tends to improve retention of clients and intervention outcomes and may increase entry and adherence to treatment. If this is, indeed, the case, professional services in culture-specific clinics might be a tool for providing better services to ethnic minorities. However, there is limited evidence on whether or not they reduce service disparities. While ethnic similarity may facilitate retention in therapy, it may have only a minor role in therapy outcomes. Similarly, physician's race concordance with patients does not appear to be associated with either use or quality of care, only with preventive care.

Clients are likely to respond to the therapy in ways that are consistent with their cultural socialization regarding care. Therefore, culture most

likely defines the options perceived to be available, useful, and/or desirable manifestations of the therapist and client roles. Patient preference for one theoretical orientation over another might characterize members of cultural groups. Researchers hypothesize that therapists and clients who are ethnically similar may be more analogous in terms of problem perception and attitudes about coping and treatment goals. As a result, these coinciding factors may improve the effectiveness of therapist/client interactions.

This is not to say that all racially/ethnically concordant patients and providers will share the same attitudes and beliefs. Research has demonstrated that *cognitive* match between patient and provider is most important, with evidence of this significance persistent even after controlling for ethnic match and the client's language preference. These findings have implications for practice/training and for the need to assess discrepant orientation and treatment ideas.

Provider-Level Factors

Use of Guideline Concordant or Evidence-Based Treatment. Providers' reluctance to adopt evidence-based treatments (EBTs) when serving minorities has been well-documented, leading to service disparities. The question remains as to whether the deviation from EBT is greater among providers who serve primarily ethnic and racial minorities or whether providers are less likely to provide EBT to their minority clients. Evidence has been found for both; clients who are poor or African Americans and Latinos have been found to be less likely to be offered the more rigorous or intensive care options provided to those who were more advantaged, but also facilities serving mostly ethnic and racial minority patients were less likely to offer evidence-based care. However, many health care institutions do not provide sufficient support for providers to adopt quality behavioral health care within the pressures for productivity.

Research examining the use of medical procedures across chronic illnesses, such as depression, has consistently found a lack of referral of minorities for EBTs when compared with non-Latino whites, even when minorities meet clinical appropriateness criteria for EBTs and when age, gender, and insurance status are controlled. Although longitudinal studies examining changes in trends for disparities in EBT among Medicare managed care patients indicate that racial disparities in EBT have declined for some illnesses, for mental health care the gap in EBT for minority patients remains.

Provider's Attitudes and Perceptions: Uncertainty, Stereotyping, and Bias. Providers seldom receive training in how to motivate minority patients to voice their treatment concerns or preferences. Providers display fewer patient-centered behaviors, are less receptive to question asking, and tend

to demonstrate greater verbal dominance with minorities than with white patients. This can lead to miscommunication or misunderstanding between the patient and provider, resulting from cultural or language differences, that contributes to uncertainty. If providers are more effective in understanding and delivering appropriate services to their nonminority patients, treatment and outcome disparities could result. Uncertainty may also enter the clinical encounter when providers experience ambiguity concerning the diagnostic implications of clinical symptoms, signs, or tests due to atypical symptom presentation, or when the provider has incomplete information about the efficacy of a therapeutic intervention. In part, these problems result from the under-representation of minorities in clinical trials which establish the efficacy or effectiveness of EBTs.

Stereotyping of ethnocultural patients by health care professionals has also been identified as a potential source of service disparities. Various studies have revealed how providers may hold preconceptions about patients based on their group membership, resulting in provider stereotypes. While stereotyping may stem from unconscious bias, reflecting limitations in cognitive mechanisms, the effects on disparities are real nonetheless. Categorizations such as race, age, sex, and socioeconomic status are overgeneralizations. For example, providers tend to see black patients as less educated than non-Latino white patients. Further, psychiatrists characterized African-American patients who were indistinguishable from white patients in sociodemographics and clinical data (except for race) as "less articulate, competent, introspective, self-critical, sophisticated about mental health centers, and psychologically minded" and consequently less able to profit from psychotherapy. Finally, provider-based biases have also been posited as negatively influencing clinical decision making. As a result, both over and underdiagnosis could result from these stereotypes and negative biases.

Overdiagnosis occurs when appropriate behaviors in one culture are interpreted as pathological by a professional from another culture. These can simply result in more severe diagnosis attached to individuals as their social and cultural distance increases. In more extreme cases, certain cultural or religious beliefs and practices common among Latinos and African Americans accept, and sometimes encourage, visual and hearing perceptions of supernatural experiences, which are often interpreted by professionals from another culture as pathological hallucinations. In an epidemiological study in Puerto Rico, 13 percent of the population reported some kind of hallucination. Yet a qualitative analysis of these symptoms by trained local psychiatrists revealed that they occurred mostly in the context of religious or spiritualist experiences, and were not pathological. Incorrectly diagnosing a psychotic disorder where none exists could result in inappropriate hospitalization, or in the use of potentially dangerous antipsychotic medication. Not surprisingly, recent epidemiological and

clinical research has raised questions about the relationship between the endorsement of psychotic symptoms and the diagnosis of psychotic disorders among culturally diverse groups.

Underdiagnosis occurs when clinicians ignore genuine manifestations of mental illness, misguided by a misinterpretation of cultural sensitivity. A growing body of research suggests that the absence of cultural and contextual information contributes to an elevated probability of misdiagnoses and inappropriate treatment formulation. Several studies have documented that minority patients were more likely to report that their provider did not discuss end-of-life care, and were less likely to receive recommendations for how to quit smoking or engage in diet and exercise. Providers may unintentionally or intentionally dismiss minority patients' concerns or may not communicate about health promotion, psychoeducation, or early screening for mental disorders. Only one-quarter of Latinos surveyed in the National Latino and Asian American Study reported ever being asked about alcohol or drugs. Fewer than 20 percent of Latino patients reported ever being asked about emotions, nerves, or mental health problems. This limited inquiry may lead to missed opportunities for early identification of mental health or substance use disorders and lack of referral to specialty services.

Clinician Training in Cultural Responsiveness. While cultural responsiveness training has been offered as a solution to the problems described above, it is not an integral part of the education of many health professionals. Health care personnel typically have limited training in cross cultural formulation and cultural humility, leading to a lack of concordance in defining the problem and treatment goals. There is also evidence that providers signal their expectations about patients' outcomes and whether they believe there will be improvements, which may be related to actual patient health outcomes. For example, health care professionals may communicate lower expectations of treatment outcomes for socially and economically disadvantaged patients, which could discourage minority patients and lead to poor outcomes and low treatment retention.

THE COMMUNITY SYSTEM

Environmental Context

Neighborhood context influences both individual health and health behaviors. Residing in socioeconomically disadvantaged neighborhoods has been linked to poor health outcomes, due to structural factors (e.g., increased exposure to pollutants and decreased access to health-promoting spaces such as parks and playgrounds); limited access to health care facilities and health care providers; poor quality of available health care; stress related to poverty and neighborhood violence; and decreased social

connectedness. At the same time, recent studies demonstrate that the effects of neighborhood context vary for different groups.

In two studies investigating neighborhood effects on substance use and on depression and anxiety symptoms in a nationally representative sample, neighborhood affluence actually resulted in increased risk of substance use disorders for Asians and African Americans, and increased risk of depression for African Americans. Latinos living in neighborhoods with high Latino/immigrant concentration had decreased risk of alcohol use disorder, but increased risk of anxiety disorders. Neighborhood context may affect groups differently based on other contextual factors; for example, Asians and African Americans residing in affluent neighborhoods may experience more discrimination and feel a greater sense of social isolation. Latinos residing in predominantly Latino/immigrant neighborhoods may experience protective factors of social cohesion, reduced exposure to daily discrimination, and increased sense of collective identity, but may also be subject to increased stress due to residential segregation and to the collective impact of anti-immigration policies on neighborhood cohesion.

The geographical area in which minority populations live helps to create a social context which, in itself, fosters a lack of connection with treatment systems and the dominant culture. Geographical segregation continues, perhaps even at greater levels than would be expected for minority populations. Members of immigrant groups have a variety of experiences with resettlement depending on the time period in which they arrived in the United States, the context of entry, and the political and social climate toward the particular group at the time. Thus, the social context and the geographical context are often intertwined and overlapping for ethnocultural populations. This impacts health on multiple levels, from prevalence of particular conditions to access to and use of mental health and substance abuse services.

Operation of Community System and Social Networks Sectors

While it is difficult to draw a clear line between the environmental context and the community, the difference is important. While the larger social context can shape lower levels of social organization, the community is often seen as representing the "small worlds" of individuals—that is, the actual nature of social ties that individuals have in a geographic area as constituting their "community of meaning." With regard to health and health care, the neighborhood and local social networks are seen as key.

Level of Social Cohesion and Neighborhood Violence. Community systems differ dramatically in a series of characteristics that both can facilitate the use of services and offer protection against health problems. In the SCF, community is defined as "a group of people with a similar

cultural origin and diverse characteristics that are linked by social ties, share common perspectives and engage in joint action in geographical locations or settings." Community social cohesion may play a role in health disparities by influencing factors that affect service outcomes. For example, there is evidence that organized and cohesive communities are able to ensure that state budget cuts do not affect their community and this in turn allows them to maintain increased access to funding for health and education.

Social Capital and Social Networks. Service systems working with ethnocultural families need to consider the important role of extended family as a possible source of support or burden in treatment. Another important component is the effect that family and social networks may have on inhibiting or facilitating help-seeking. Mexican American and African-American adolescents are more likely than whites to turn to relatives or family members to obtain health care. Thus, in strong and tightly meshed family networks, such as those of most Latinos, African Americans and Asians, individuals may initially be discouraged from seeking professional health services. It is only when family support systems are lacking, or become ineffectual in handling a crisis, that some culturally diverse families will seek professional help. Some investigators have suggested that informal care providers, such as self-help groups and religious leaders, reduce seeking of professional help and may be related to service disparities; others argue that they are an important referral source to formal services. Innovative strategies that leverage the influence of community networks, such as programs to promote HIV education and testing in African-American churches, are a way to embed health care services in the settings in which individuals and families naturally seek help.

Individual Factors Other than Need or Clinical Appropriateness

General Education. Number of years of schooling is directly linked to the development of effective capabilities that influence subsequent life conditions that have an effect on health, including economic welfare, healthy lifestyles, and full-time employment. Higher rates of education have been shown to positively impact mental health by increasing one's resources to cope with adversity or increasing a sense of control over one's destiny. Low educational attainment is not only a strong predictor of poor mental health and substance abuse outcomes for children but remains significant for mid-age and older cohorts.

Health Literacy and Numeracy. Health literacy is a skill involving both oral and written communication that may or may not be related to educational attainment. It is a twofold concept that includes the

individuals' basic literacy skills and the application of those skills within the health care system. A related concept, health numeracy, involves not only understanding of mathematics but also of quantitative concepts such as "reduce/increase." The IOM has highlighted that health literacy is not solely an individual skill; rather, it results from the interaction between individual capacity and the demands of the health care system. Health literacy may indirectly create barriers to health care use by inhibiting access to care due to a patient's inability to register for health insurance; difficulty in interpreting coverage benefits and rules; avoidance or delays in accessing health services due to the inability to adequately fill out forms in physician offices or difficulty following directions to service facilities. Once individuals with poor health literacy enter care, they face disparities in health outcomes associated with literacy limitations, with people who read at lower levels being 1.3 to 3 times more likely to experience adverse health outcomes than individuals with high literacy levels. Patients with low health literacy are also more likely to report poor health, have an increased risk of hospital admission, and have incomplete understandings of their health problems and treatment. In one nationally representative study of US parents, almost a third had below basic health literacy. The strongest predictors of basic and below basic health literacy were level of education and English proficiency, followed by being Black or Latino, being born outside of the United States, and reporting low income.

Negative Provider Stereotypes. Patient views of providers may prove to be influential factors in causing disparities for ethnocultural populations. For example, some literature suggests that individuals who hold strong negative stereotypes of physicians are more likely to delay care or only seek treatment once symptoms become severe or impede daily functioning. Therefore, if delays in treatment are due in part to negative stereotypes, service disparities in illness prevention or early intervention may emerge. Negative stereotypes of physicians may result from patients' own history of negative treatment in care or the distrust many minorities feel toward the health care system.

Patient's Competing Needs. Some ethnic and racial minority patients may come from low-income backgrounds with complex social needs. Lack of access to paid sick leave, inflexible work scheduling, irregular hours, lack of transportation or unreliable transportation, and difficulty obtaining childcare all pose additional challenges to utilizing health care services. Studies have found that these barriers account for both missed appointments and lack of follow through on specialty referrals.

Problem Recognition and Characterization of Mental Health and Substance Use Problems. Disparities in health care among some racial and ethnic

minority children appear to be linked to parental knowledge of available treatments. For example, it has been reported that there are significant differences between African-American and white parents in their knowledge of attention-deficit/hyperactivity disorder (ADHD). In one study, only 36 percent of African-American parents reported that they knew some or at least any information about ADHD, compared to 70 percent of whites. There is also evidence that different ethnocultural groups in the United States have varied perceptions of what is considered a mental health problem in their offspring. In one study, Latino and African-American parents rated their adolescents' mental health and life satisfaction as better than their non-Latino white counterparts and overall perceived fewer emotional or behavioral problems in their children. These differences existed even after adjusting for clinical need of the child, child's level of impairment, and sociodemographic characteristics of the parents. Thus, while lack of knowledge about a problem may lead to health disparities, it is also possible that different perspectives on a situation may lead to different patterns of seeking care.

WHEN HEALTH CARE SYSTEMS AND COMMUNITY SYSTEMS MEET: MECHANISMS PRODUCING DISPARITIES

Taken together, disparities arise when disadvantages in the health care system interact with those in the community. At each level or domain, the SCF suggests that six fundamental mechanisms produce disparities for ethnocultural populations. These are represented as the center stream in Figure 58.7–1. While they link with causes of disparities, they also suggest points of intervention. They represent potential leverage points for systems, providers and patients to change the health care system, existing policies, clinical training, and community programs. Below, each interface between community and treatment systems is explored.

1. **Failure of health care markets, institutional bias, and limited financing, leading to decreased access to and utilization of mental health and substance use services.** State and federal regulations aimed toward cost control also contributed to the increase in the number of uninsured or underinsured. For example, individuals are typically excluded from Medicaid as states respond to increased costs by enacting more stringent eligibility criteria. Yet expansion of public insurance programs and subsidized private plans to low- and middle-income individuals offered under the ACA can increase access to care. Nonetheless, some minority groups may confront other hurdles to getting insurance such as lack of citizenship or documentation status or may still have difficulty paying for subsidized coverage, leading to lack of insurance or underinsurance. While health insurance coverage facilitates access, it is not a sufficient condition for ensuring behavioral health care, since lack of

available appointments is a serious barrier to mental health and substance treatment. The low number of mental health and substance use providers accepting Medicare and Medicaid reduces access to quality care for low-income and vulnerable populations. However, other factors such as increased health maintenance organization (HMO) penetration, augmented provider supply, and the presence of a community mental health center in neighborhoods of color have been shown to reduce service disparities.

2. **Differential pathways into services leading to differential experiences of service, delayed utilization, no service, or inadequate service.** Language barriers can lead patients to drop out of care, opt for alternative services, or delay care. Inaccuracies in assessment can also result in mistreatment or misdiagnosis of minority patients. There is mounting evidence that minority patients receive lower quality treatment and receive treatment for a shorter period of time. For example, white youth are more likely than minority patients to receive adequate care following a major depressive episode, while minority youth are less likely to be prescribed psychotropic medications, even after adjusting for need factors. Equally importantly, the larger cultural context determines how similar social networks can facilitate or delay treatment. Competing demands on time from work and child care for minority parents may constrain minority families from engaging in treatment, given more urgent matters.

Thus, differential pathways into services may represent a key mechanism leading to service disparities among racial/ethnic minorities, with lack of patient problem recognition, differential referral and treatment by providers, and barriers to care serving as potential precipitating factors to disparities. Further, it is likely that an individual's first service contact may not be with a specialty professional, but rather with a formal or informal gatekeeper provider who has a powerful role in determining whether and where to refer a patient for further treatment. Factors that may influence a provider's perception of a patient's need for referral include the providers' familiarity with and links to health service resources, the provider's perception of the clients' willingness to accept mental health services, and organizational boundaries that limit the gateway providers' time or resources. Improved behavioral health screening for Medicaid-eligible minority youth and adults has proven to decrease disparities in access. Augmenting caregiver's resources for accessing services and improving child outcomes, or engaging families to attend their first intake therapy session have also been shown to increase access and reduce disparities in families of color.

Other pathways result in disparities that may have both short- and long-term effects. For example, Latino and African-American children are over-represented in the juvenile social service sectors. They receive fewer

therapeutic services compared to clinically comparable white children, and remain longer in services. As a result, data analytics are being used to detect patients at risk of receiving lower quality care based on demographic and illness related factors, and payment systems used to incentivize providers for providing high-quality care to these patients. Nonetheless, there is considerable debate over the utility of pay-for-performance measures in achieving specific goals at the level of hospitals and the health system as a whole. ACOs may help eliminate disparities by rewarding health care systems for efficient use of resources and positive outcomes and penalizing them for inefficiency and poor results.

3. **Poor patient–provider interaction leading to miscommunication, clinical uncertainty, low therapeutic alliance, stereotyping, and clinical errors.** Patient–provider match and expectations for the visit are important in determining treatment outcomes. However, attempts to address research documenting problems arising from poor patient–provider interaction have inadvertently produced additional problems. Ethnocentric models of health service delivery may overpathologize minority behaviors that differ from those of the majority culture. Racial and ethnic minorities report being treated with disrespect or being looked down upon more often (14.1 percent of blacks, 19.4 percent of Latinos, and 20.2 percent of Asians) than non-Latino whites (9.4 percent). The critical link to disparities lies not only with what happens in the clinical encounter but with the resulting effects on the patient's utilization of health care and on the advice they offer to others in their lay network. For example, patients who reported being treated with disrespect were less likely to go for a routine physical exam within the least year, to have received optimal care for a chronic condition, and to have followed their doctor's advice.

Patients may also have different expectations of treatment and provider behavior that impede effective communication. A number of studies have reported that differences in race and ethnicity between patients and their providers can present barriers to effective communication and partnerships for care. Disparities resulting from barriers to effective communication between racially/ethnically mismatched patients and providers include discordance in the understanding that patients and providers have regarding disease causation and effectiveness of treatments, significantly lower reports of physician participatory decision-making styles by minority patients as compared to nonminority patients, and lower rates of receiving preventative and necessary medical care among blacks with nonblack physicians compared to blacks with black physicians. These examples demonstrate that patient–provider match and expectations for the visit are important in determining treatment outcomes.

4. **Mismatches in mental health and substance use service offerings and minorities' services needs and living**

circumstances, leading to drop out and low or no service use. Services disparities have been linked to higher disability and greater disease burden in minority populations. One of the mechanisms by which service disparities take place is through the mismatch of services to the patient's needs. As described earlier, there is substantial evidence of the potential for clinicians to stereotype—that is, to incorrectly assign a classification or social categorization, particularly when the patient's request is ambiguous. Under such conditions, clinicians may inadvertently incorporate attitudes and beliefs from prior clinical encounters or common stereotypes. This may lead clinicians to disregard individual data and consequently mismatch services to needs. This mismatch of services to needs can result in decreased utilization of and access to health services and health resources as well as differential outcomes in health, and greater disease burden. In the absence of cultural and contextual information that supplants stereotypes, there is an elevated probability of misdiagnoses and inappropriate treatment formulation. Ethnocultural populations are more likely to have nonconcordant psychiatric diagnoses in psychiatric emergency services and to be undetected for mental health disorders in primary care. More general literature on disparities shows that symptom presentation varies across racial and ethnic groups and can differ from what most clinicians are trained to expect. Yet, minorities are less likely to be offered "talking therapies" such as counseling, and tend to be prescribed higher drug dosages than their white counterparts.

Dissimilarities in the typical conditions in which many minority populations live as contrasted to their providers (i.e., including poverty, lack of economic opportunity, food insufficiency, inadequate housing, social exclusion, low access to educational opportunities, and unsafe neighborhoods) can lead to social inequality that needs to be tackled by the health care system. As such there has been a call for health equity research that prioritizes multilevel interventions, addressing structural and contextual factors at the community, organizational, and individual levels. Multilevel interventions to amplify social connection in minority neighborhoods could increase behaviors that have a positive or protective effect on health such as exercise, expansion of social networks, and better problem solving.

5. **Lack of community trust and erroneous expectations of services, leading to disengagement and poor collaboration in health care service systems.** Local perceptions of health services affect utilization and depend on prior experience with the provision of services, and the efforts that the local service system has made to understand and adapt to the cultural and need demands of its clientele. For example, qualitative analyses of an Afro-Caribbean community revealed that their experience of mistreatment and social exclusion by health professionals reverberated on future utilization and on community sentiments toward

the mental health system. Other studies found that the level of community mistrust of health care providers was associated with a decreased likelihood of using health care. For example, African-American families report fearing that their children would be institutionalized and express this fear as an important reason for not taking their children to treatment. These findings, as well as those of others, reveal that insufficient accessing of services increases with repeated negative contacts with the health system or with a lack of trust in key gateway providers such as teachers. Thus, community-held beliefs may prove to be strong influential factors in the production of health service disparities for ethnocultural populations.

6. **Limited workforce availability and training of service providers to treat ethnic and racial minority youth, leading to reliance on informal or poorly trained providers.** The disproportionately low geographic supply of providers, particularly multilingual service providers, in communities with ethnic and racial minorities as compared to nonminority communities is producing a failure of the market to provide more and better quality care to minorities. For example, communities of color have been found to be four times more likely to have a shortage of providers, regardless of community income. Low reimbursement rates from public and private payers can lead to a shortage of services and provider burnout. Health care organization arrangements for distributing providers to minority Medicaid beneficiaries have also been suggested to be influential in service disparities. Merely 7.8 percent of psychologists, 12.9 percent of social workers, and 21.4 percent of psychiatrists are from racial/ethnic minority groups. Medicaid beneficiaries, particularly those with limited English language skills, may have a difficult time competing for physician services if physicians have a high caseload of privately insured patients.

Communities with high proportions of black and Latino residents were four times as likely as non-Latino whites to have a shortage of physicians regardless of community income. In parallel, health care services available through the Indian Health Services vary widely across tribes. The Indian Health Services partially offsets the lack of insurance for some uninsured American Indian and Alaska Natives (AIANs), but important needs are left unmet. This is problematic since AIANs were more than two times as likely to be uninsured than non-Latino whites. These findings have led to conclude that elimination of racial/ethnic health disparities is an issue of distributive justice which entails redistributing valuable material resources and opportunities to those in the lower echelons of society.

In sum, the interaction of health care system and community level factors produces a mismatch in cultures—not only the culture of medicine and the culture of everyday life but also in the mismatch of dominant culture ideas and those that may be unique to ethnocultural populations.

Oftentimes, the beliefs of both patients and providers are based on generalized cultural beliefs and do not cut through those prejudices to get to individualized care. Equally important, both actual experiences and a family's, provider's, or community's experiences can produce a view of treatment that limits the receipt of effective care.

FUTURE DIRECTIONS: RESEARCH AND INTERVENTION

The SCF is intended to help conceptualize and carry out research directed at eliminating ethnic and racial disparities, to assist in the training of health and social agency personnel, and to supply service planners and policy makers working hypotheses, initially, and a science-base, eventually, on how to intervene and eliminate service disparities. As evidenced from the authors' review of extant theory and research, traditional service models should be restructured in order to reduce service disparities for ethnocultural populations. The six posited mechanisms that produce disparities form a foundation for rethinking intervention strategies as (1) increased client/patient activation/empowerment; (2) information exchange between client and provider, between systems and communities addressing social networks rather than individuals alone; (3) new and/or different policies to increase access to services; (4) better treatment matching; (5) restructuring of service systems to reduce reliance and action based on stereotypes, prejudice, and clinical uncertainty.

1. **Patient activation,** defined as learning the knowledge, skills, attitudes, and self-awareness necessary to have greater decision making and efficacy in health care behavior, has been associated with improved health behaviors such as exercise, disease self-management behaviors such as adherence to drug regimens, and an array of health outcomes including improved mental health. There is evidence that patient activation enables patients to take charge of their health behavior, elicit more information from their provider, achieve greater satisfaction in the clinical encounter and better outcomes, and increase engagement and retention in care.
2. **Information exchange** is based on a dialogue between patient and provider or between community and health service system so that the provider learns about the social context (i.e., where patients live, what they do, what matters to them, their social position, and their environment and cultural perspective of the patient). There is evidence that information exchange promotes a more egalitarian view of the information needed for a patient-centered encounter and to structure treatment recommendations or proposed behavioral changes acceptable in the patient's daily lives. If service use and provider action depends on a social influence process as well as individual predispositions as has been documented since the 1970s, then understanding and using effective diffusion methods is likely to be more effective and efficient.

3. **Policies** include decisions by organizations such as routinely providing assistance to patients in communicating with their providers, or regulations by governments or public authorities such as deciding eligibility criteria for Medicaid services. An example of a policy change could be a new requirement that interpreter services be readily available in the clinical encounter if English is not the primary language of the patient. Also, mapping shortage areas where few mental health providers accept public insurance programs to provide additional incentives (i.e., higher reimbursement rates) for providers to offer care in those areas could be a policy to reduce disparities.

4. **Better treatment matching** includes the provision of linguistically appropriate services as well as treatment and outreach options that are socioculturally compatible with the circumstances of the target population. There are three basic criteria on which to judge whether there is treatment matching of services: the treatment/services are based on cultural values of the groups of interest; the strategies involved in the treatment/services are congruent with the culture and context of the particular ethnic/racial group; and the components of the service/treatment strategy are based on the expectations and behavioral preferences of the ethnic/racial groups. It is argued that the treatment matching of the services/treatments with the patient/community is necessary for quality improvements to be institutionalized and sustained by the service organization and acceptable to the community.

5. **Restructuring of services** involves organizational change to better accommodate the needs of clients. Settings that are accessible to communities and which they trust (i.e., community-based organizations and churches) might be more acceptable as settings for health or mental health service delivery or outreach. Changing stereotypes, prejudices, and uncertainty in provider–patient relations includes creating interventions to change preconceived ideas of either the patient or the provider that may adversely affect the communication or interaction in the clinical encounter.

As research that addresses the complexity of the multiple levels and two major domains that produce health and health care disparities evolves, efforts to eliminate disparities can be more tailored and effective. The goal of the SCF is to help stimulate the research and policy thinking that can foster change for health care systems and communities.

▲ 58.8 Criminalization of Persons with Serious Mental Illness

H. RICHARD LAMB, M.D., AND LINDA EDNA WEINBERGER, PH.D.

The enormously increased presence of persons with serious mental illness in the criminal justice system is one of the great problems of the day. As a result, mental health professionals and society have become much more concerned about the number of persons with mental illness in jails and prisons, as well as the treatment provided to these persons both in such facilities and after release. These issues are relatively recent. Reports of large numbers of persons with mental illness in US jails and prisons began appearing in the 1970s, a phenomenon that had not been reported since the 19th century.

For the purposes of this section, the focus will be on persons with serious mental disorders; that is, schizophrenia, schizoaffective disorder, bipolar disorder, and major depressive disorder. This section discusses the definition of criminalization of such persons and how criminalization came about, the extent of criminalization, the role of the police with regard to persons with mental illness, and the characteristics that are often found in persons with mental illness who have been arrested. The difficulties in treating this population both before incarceration and after release are addressed, including the relationship between serious mental illness and violence and the problems presented by persons who are not able to

recognize that they have a major mental illness. The section presents a summation of ways that have been proposed to reduce criminalization. These ways include the following: increased community mental health services that are effective and appropriate to treat persons who are or are at risk of becoming criminalized; better coordination among the police, courts, and mental health professionals; mobile crisis teams; increased mental health training for police officers; and diversion programs for offenders with serious mental disorders to prevent them from entering the criminal justice system, as well as transferring those who are already arrested into the mental health system. The necessary components of treatment for such persons will be discussed. These include having clear goals of treatment and practice; establishing a close liaison between treatment staff and the justice system; understanding the need for structure; having a focus on managing violence; and appreciating the crucial role of case management, appropriate living arrangements, and involving family members. Finally, the section ends with a brief discussion of recently enacted criminal justice efforts to decrease the total number of persons incarcerated, and recommends possible strategies to reducing the criminalization of persons with serious mental illness.

MAGNITUDE OF THE PROBLEM

The US prison population, including both federal and state prisons and county and city jails, was 2,145,100 inmates as of December 31, 2015. The percentage of jail and prison inmates assumed to be seriously mentally ill (schizophrenia, schizoaffective disorder, and major depressive disorder) has generally been estimated at about 16 percent. Using these numbers yields an estimate of 343,216 incarcerated persons with serious mental illness in jails, and state and federal prisons. The actual number may be somewhat higher or lower, depending on the accuracy of the percentage. These figures represent a substantial number of persons with serious mental illness in jails and prisons.

Moreover, research has shown that approximately one-fourth of persons with serious mental illness in the community have a history of at least one arrest. The association between serious mental illness and arrest is a widespread phenomenon that has affected both the mental health and criminal justice systems.

Ms. G was a 28-year-old single woman who was diagnosed with schizophrenia at age 22. Prior to her diagnosis she had a chaotic childhood and adolescence. Her mother abused alcohol and often left her alone in their apartment for days at a time. Ms. G was placed in multiple foster home placements where she frequently eloped, looking for her mother. Attempts at reunification were always unsuccessful due to the mother's continuing neglect and Ms. G's increasing disruptive behavior. At age 18, Ms. G was no longer a ward of the court and she began living with her 23-year-old boyfriend. She tried to work at fast-food restaurants but found the demands of the job increasingly stressful. She also started to experience paranoid ideas about her coworkers with whom she often fought and heard voices telling her that they

wanted to sexually molest her. On one occasion, when she was 20, she got into a fight with her manager and threw his glasses so hard against the wall that they broke. The police were called and Ms. G was arrested.

During her incarceration, the jail personnel did not recognize that she had a mental illness. She was given probation with no requirement that she obtain psychiatric treatment. She continued to live with her boyfriend until he said she could no longer live with him because of her constant hallucinations and delusions about him. She was now homeless and without money. One day, she walked into a grocery store and stole a loaf of bread and a package of sliced turkey. She was apprehended by a security guard and the police arrested her. During this incarceration she was identified as having a mental illness and was treated with antipsychotic medication in jail. Ms. G received probation but this time was to attend psychiatric outpatient treatment. She went to the community mental health clinic once but did not attend again because she did not believe she had a mental illness and refused to take any medications.

Shortly thereafter, Ms. G got into a fight with another homeless person and stole his blanket in front of several bystanders who called the police. This led to another arrest where she spent a few months in jail and was again given probation with a condition of outpatient psychiatric treatment. Following her release she attended outpatient treatment at a mental health clinic for several weeks. Initially, she took her medications which resulted in a dramatic improvement of her symptoms. However, several weeks later Ms. G stopped taking her medications, wherein her symptoms returned and she became very threatening to the staff. The court was informed of this and she returned to jail. Prior to her release from jail, Ms. G was encouraged to return to her previous outpatient clinic for treatment. Sometime later, Ms. G, appeared at the clinic but the intake team concluded that her history of nonadherence to psychiatric medications along with her past violent behavior could make her a problem in management beyond the capabilities of the clinic.

A few months later, Ms. G was arrested outside a department store for having stolen a sweater and pushing a customer out of her way. At this time, she was charged with petty theft with priors and assault, which was a felony. The judge believed he had no option but to send Ms. G to state prison. Criminalization was now confirmed.

Most outpatient mental health treatment facilities are not structured to successfully treat persons like Ms. G and, as described in this section, community mental health staff is often reluctant to try.

DEFINING CRIMINALIZATION

Many factors come into play in determining why a person with mental illness is arrested rather than taken to a psychiatric hospital.

Generally, persons who are thought to have committed a felony are arrested and brought to jail regardless of their mental condition. The criminal justice system, charged by society with the responsibility for removing from the community persons accused of committing serious crimes, sees no alternative but to first place the person in custody in a secure setting and then arrange for psychiatric treatment, if necessary. If the person is thought to have committed a serious crime, the police and the criminal justice system generally do not want to place this person in a psychiatric hospital, because such persons may well pose a number of problematic issues that cannot be treated and managed adequately by the mental health system and thus place society at risk.

Examples of this may be a person with schizophrenia who was found by the police in possession of a loaded gun; he was brandishing the weapon and threatening others because he believed that they were poisoning him. Another person with untreated bipolar disorder was arrested after he drove

his car erratically on the street and onto a sidewalk full of pedestrians because he wanted to be recognized for his race-car-driving skills.

For persons charged with misdemeanors, the situation is more complex. In 1972, the term "criminalization of the mentally ill" was first used. It was observed that persons with mental disorders who engaged in minor crimes were increasingly subject to arrest and prosecution. Later, many authors applied the concept of criminalization to persons with mental disorders who were arrested for serious crimes. The distinction between arrest and incarceration of persons with mental illness who have committed minor offenses and those who have committed serious offenses is an important one.

This section takes the position that the term criminalization should be used primarily in connection to persons with serious mental illness who are arrested and incarcerated for minor offenses instead of being placed in the mental health system. However, it should be acknowledged that many persons with serious mental illness who commit serious crimes and enter the criminal justice system might not have engaged in such behavior if they had been receiving adequate and appropriate mental health treatment at that time.

Concern about the inappropriate placement of persons with serious mental illness in the criminal justice system is not new. As far back as 1939, researchers in Europe advanced the thesis that a relatively stable number of persons are confined in any industrial society. Using prison and mental hospital census data from 18 European countries, they found an inverse relationship between prison and mental hospital populations. They theorized that if one of these forms of confinement is reduced, the other will increase. According to this theory, when prison populations are extensive, mental hospital populations will be small, and vice versa. Thus, if there is room in prisons and a shortage of hospital beds, many persons with mental illness who come to the attention of law enforcement might well be directed to the criminal justice system. Recent research in South America is compatible with this hypothesis. As will be seen in this section, this has happened in the United States and other countries; the census of state hospitals has dropped precipitously while the number of persons incarcerated in the criminal justice system has risen to record proportions.

One of the major concerns in present-day psychiatry is that placement in the criminal justice system poses a number of important problems and obstacles for the treatment and rehabilitation of persons with serious mental illness. Even when quality psychiatric care is provided in jails and prisons, the inmate/patient still has been doubly stigmatized as both a person with mental illness and a criminal. Furthermore, jails and prisons have been established to mete out punishment and to protect society; their primary mission and goals are not to provide treatment. The correctional facility's overriding need to maintain order and security, as well as its

mandate to implement society's priorities of punishment and social control, greatly restrict the facility's ability to establish a therapeutic milieu and provide all the necessary interventions to treat mental illness successfully.

CAUSES OF CRIMINALIZATION

A number of factors have been cited as causes for persons with mental illness being placed in the criminal justice system. The most common ones are deinstitutionalization and the unavailability of intermediate and long-term hospitalization in state hospitals for persons with serious mental illness; more formal and rigid criteria for civil commitment; the lack of adequate support systems for persons with serious mental illness in the community, as well as the difficulty such persons coming from the criminal justice system have in gaining access to community mental health treatment; persons with co-occurring disorders of a serious mental illness and a substance abuse problem being caught up in the war on drugs (being arrested and incarcerated on the basis of the use, sale, and possession of drugs); and a belief by many law enforcement personnel that deviant behavior can be dealt with more quickly and efficiently within the criminal justice system than in the mental health system.

Deinstitutionalization

Beginning in the late 1950s, the inclination to provide hospital beds declined precipitously. This was because of the introduction of psychoactive medications; the development of more efficacious community treatment interventions; the creation of federal programs (e.g., SSI, SSDI, Medicaid, and Medicare), which would fund community treatment and housing for persons with mental illness; the influence of the civil rights movement; and the high cost of institutionalizing persons with mental illness. For example, in 1955, when the number of patients in state hospitals in the United States reached its highest point, 559,000 persons were institutionalized in state mental hospitals out of a total national population of 165 million (339 beds per 100,000 population). By 2016 (as a result of hospital closures and bed eliminations), the number of persons in state mental hospitals dropped to 37,679 for a population of approximately 324,000,000, or 11.7 beds per 100,000 population. This rate is similar to that found in 1850 when persons with serious mental illness received little care and concern. Their plight led to the beginning of the movement, spearheaded by Dorothea Dix and others, to provide more humane care by treating persons with serious mental illness in hospitals. In some states today, such as California, the ratio is even less; that is, there are fewer than 2 state hospital beds per 100,000 population, excluding forensic patients.

Deinstitutionalization has thus been viewed as setting the stage for

increasing numbers of persons with mental illness entering the criminal justice system. It must be remembered that the community mental health system was developed in the 1960s and 1970s for persons with mental illness who had more moderate needs. While deinstitutionalization held the promise of persons with serious mental illness being able to live successfully in the community, that hope was not achieved for a sizeable number of individuals. Part of its failure was attributed to a lack of planning before or during deinstitutionalization as well as a lack of adequate funding. As a result, communities were not able to provide a sufficient community care system (i.e., housing, medical and psychiatric care, social services, and social and vocational rehabilitation) for the formerly hospitalized patients. Despite this, the majority of deinstitutionalized patients were able to adapt successfully in the community; however, this was not the case for a considerable minority who were arrested and placed in jails and prisons or who became homeless (between one-fourth and one-third of homeless persons have a serious mental illness). Some of these individuals presented challenges in treatment—such as not seeing themselves as mentally ill, not taking their medications, abusing substances, and in many cases, becoming violent when stressed. Many of these persons needed highly structured care to replace that which had been provided to them, albeit imperfectly, in psychiatric hospitals. The flawed implementation of deinstitutionalization would thus appear to be a significant factor accounting for the migration to jails and prisons of many persons with mental illness who otherwise could have been treated with more adequate services in the community or in a hospital. The criminal justice system had become by default a safety net for the mental health system.

Restrictive Civil Commitment Criteria

Many believe that more formal and rigid civil commitment criteria have contributed not only to deinstitutionalization but also to an increased number of persons with mental illness in jails and prisons. In 1969, California's then-novel civil commitment law, the Lanterman-Petris-Short Act, went into effect. Within a decade every state made similar modifications in their commitment codes. Such a rapid and complete consensus among legislatures is virtually unprecedented. More important, it reflected a nearly universal view that past inattention to the rights of persons with mental illness needed to be corrected.

In effect, the new civil commitment laws resulted in three major changes. First, the laws modified the substantive criteria for commitment from more general criteria that simply embodied concepts of mental illness and need for treatment to more specific criteria that embodied either dangerousness to self or others resulting from mental illness or the incapacity to care for oneself. Second, the laws changed the duration of

commitment from indefinite and extensive periods to specific and brief periods. Third, the new laws explicitly provided that persons civilly committed have rapid access to the courts, to attorneys, and, in some cases, to jury trials; this access ensured the kinds of due-process guarantees to civilly committed persons that criminal defendants had obtained over the previous decade.

These procedural safeguards and clear commitment standards resulted in fewer, as well as shorter, commitments. Consequently, many individuals with mental illness who otherwise would have been civilly committed by family or others were now left to reside in the community where they might not have been able to care for themselves and control their impulses. Thus, some of these individuals might well have committed criminal acts and entered the criminal justice system.

Lack of Adequate Community Support Systems

Another factor that both leads to and perpetuates the criminalization of persons with serious mental illness is the lack of adequate support systems in the community. An essential part of support systems for these persons is the availability of community treatment resources. Moreover, the type of community mental health resources available may not be suitable for all of the population to be served.

The availability, or lack of availability, of treatment resources in the community has three important aspects. First, in most jurisdictions, mental health treatment, housing, and rehabilitation resources are insufficient to serve the very large numbers of persons with serious mental illness in the community. For instance, case management has come to be viewed as one of the essential components of an adequate mental health program. However, the mental health system is ill prepared to provide quality case management services to all persons with serious mental illness who require it, including those leaving jails and prisons.

Second, community mental health resources may be inappropriate for some of the population to be served. For instance, persons with mental illness may be expected to come to outpatient clinics when the real need for a large proportion of this population is outreach services, in which mental health professionals go to see patients where they live. In addition, some service providers may lack the ability to provide the degree of structure required by many persons with serious mental illness. The issue of structure will be discussed later.

Third, persons with mental illness who have been in jail may not be able to gain access to community treatment even when it is available. Many of these persons have been described as resistant to treatment, dangerous, and seriously substance abusing, characteristics generally not considered desirable by most community mental health agencies and staff. Furthermore, because many of these agencies may not have the capability

to provide the needed structure, limit setting, and security and safety for staff necessary to treat these persons successfully, their reluctance to treat them may be appropriate.

A large proportion of persons with mental illness who commit criminal offenses are found to be highly resistant to psychiatric treatment. They may refuse referral, may not keep appointments, may not be adherent with psychiatric medications, may not abstain from substance abuse, and may refuse appropriate housing placements. There is evidence that many of these persons suffer from a disorder called anosognosia (a biologically based inability to recognize that one has a mental illness, and thus a biologically based lack of insight). This is discussed in greater detail later.

Thus, the mental health system finds offenders with mental illness extremely difficult to treat and may be hesitant to serve them. This reluctance may extend to virtually all areas of community-based care, including psychiatric treatment, therapeutic housing, social and vocational rehabilitation, and general social services. Moreover, many offenders with mental illness can be intimidating because of previous violent and fear-inspiring behavior. Treating this group is very different from helping passive, formerly institutionalized patients to adapt quietly to life in the community. Community mental health professionals are not only reluctant, but may also be afraid to treat them, especially when measures are not adopted to ensure staff safety. As a consequence, these persons are left for the criminal justice system to manage. However, there are outpatient facilities in which structure is provided, security personnel are present and thus staff are protected, and mental health and criminal justice staff collaborate closely; under such circumstances, many of these persons are successfully treated.

The Role of the Police

The police play an important role in the criminalization of persons with serious mental illness, and this will be discussed in the context of the more in-depth exposition of the police and mental health that follows.

Police and Mental Health. Since the advent of deinstitutionalization and the exodus of persons with mental illness into the community, law enforcement agencies have had an increasingly important function in the management of persons who are experiencing psychiatric crises. The rationale for the police to intervene in the lives of persons with mental illness derives from two common-law principles: the power and the authority of the police to protect the safety and welfare of the community, and the state's paternalistic or *parens patriae* authority, which dictates protection for citizens with disabilities who cannot care for themselves, such as those who are acutely mentally ill.

The police are typically the first responders in the community to urgent

situations involving persons with mental illness. They provide services 24 hours a day, 7 days a week. Consequently, they play a major role as a mental health resource. They are responsible for either recognizing the need for the treatment of an individual with mental illness and connecting the person with the proper treatment resources or making the determination that the individual has committed a type of illegal act for which the person should be arrested. This responsibility thrusts them into the position of primary gatekeepers who determine whether the individual will enter the mental health or the criminal justice system.

With respect to persons with mental illness, police in all states have the power to transport persons for psychiatric evaluation and treatment when there is probable cause to think that they are a danger to themselves or to others because of their mental condition. As a result, law enforcement officers have assumed the role of "street-corner psychiatrist" by default. It would appear that many officers have grown accustomed to this role and consider it one of their duties; however, other officers do so reluctantly, and some do it with resentment. A major problem with having to fulfill this role is that the police have little training in performing this kind of triage. This lack of training is one of the factors that has played an important part in the criminalization of persons with mental illness. The training of law enforcement officers is discussed later in the subsection entitled *Diverting Persons with Mental Illness from the Criminal Justice System*.

The police have a great deal of discretion in the exercise of their duties, including determining what to do when they encounter a person with acute mental illness in the community. In most cases, the police use informal tactics, such as trying to "calm" the person or taking the person home. This practice has been referred to as "psychiatric first aid." In situations that cannot be handled informally, the police may have to take persons with mental illness to hospitals or to jails.

In some cases, however, public policy limits the police officer's discretionary power. For instance, if the person with mental illness is alleged to have committed a major crime, the disposition is clear—that person is taken to jail because of the seriousness of the offense.

Often, the interaction between the police and the person with mental illness is initiated by citizens. In such cases, the citizens' demands also may come into play and limit the discretion of the police. For example, many retail stores have a policy that anyone caught shoplifting should go to jail, and store managers are instructed to make a citizen's arrest and call the police without exception. In another kind of situation, people who have just been assaulted by a person with psychosis frequently are not inclined to be sympathetic to their assailant, even when mental disturbance is evident. The result may be an angry citizen who insists on having the person arrested and taken to jail.

Police and Criminalization. As discussed previously, the police play an important role in the criminalization of persons with serious mental illness. Even when the police consider the behavior of a person who has come to their attention to be the result of a mental illness, they may encounter a number of problems and irritants when trying to place the person in an inpatient psychiatric facility. For example, there may be long waiting periods in psychiatric emergency rooms during which police officers cannot attend to other duties. Mental health professionals may question the judgment of the police and refuse admission, or they may admit for only a brief hospital stay a person who just a short time before constituted a clear menace to the community.

However, the police are well aware that if they arrest a person with mental illness, that person will be dealt with in a more systematic and predictable way under the criminal justice system. The individual will be taken into custody; it can be hoped that the person will be seen by a mental health professional attached to the court or in the jail and will probably receive psychiatric evaluation and treatment. Thus, arrest is a response with which police are familiar, one over which they have more control, and one that they believe will lead to an appropriate disposition.

Although a person with mental illness suspected of committing a serious crime will most certainly be arrested and transported to jail, a number of factors in addition to those just mentioned have been proposed to explain why a person with serious mental illness suspected of committing a minor offense is arrested rather than taken to a hospital. A person who appears mentally ill to a mental health professional may not appear so to police officers, who, despite their practical experience, have not had sufficient training in dealing with this population and are still laypersons in these matters. In addition, mental illness may appear to the police as simply alcohol or drug intoxication, especially if the person with mental illness has been using drugs or alcohol at the time of the interaction with the police. Moreover, in the heat and confusion of an encounter with the police and other citizens, which may include forcibly subduing the person with mental illness, signs of mental illness may go unnoticed. Furthermore, studies have shown that the occurrence of violence at the time of a police encounter increases the chances that the person with mental illness will be taken to jail.

Another instance is when law enforcement officers may charge persons with mental illness with a misdemeanor and take them to jail if they think that no other appropriate alternatives are available, a practice that has been referred to as “mercy booking.” Thus, the scarcity of psychiatric inpatient beds and/or limited community mental health services may be a factor contributing to the criminalization of persons with serious mental illness.

MENTAL ILLNESS AND VIOLENCE

In countries that experienced mass deinstitutionalization since the late 1960s, a number of studies have shown that persons with serious mental illness were more likely to commit criminal offenses, and even more likely to commit violent offenses, than the general population. This growing body of evidence demonstrates a relationship between mental illness and violence, primarily among persons who do not take their medications and are psychotic. Substance abuse has also been shown to increase the risk of violent behavior, particularly in combination with serious mental illness. Thus, nonadherence to medication, acute psychosis, and substance abuse account for most of the increased violence of persons with serious mental illness. For instance, one study examined persons with serious mental illness in the United States who had been arrested over a 10-year period, and found that more than one-third were arrested for violent crimes (assault and murder), and more than one-fifth were arrested for drug offenses.

The relationship between serious mental illness and violence is most easily seen in relatively nonviolent societies, such as in Scandinavia. The Scandinavian countries maintain centralized case registries that record comprehensive data on everyone born in the country or who immigrates there. Included in this wealth of data are psychiatric registers and national police registers. In Denmark, the psychiatric registry includes data such as admissions to psychiatric wards, dates of admission and discharge, and discharge diagnoses. There is also a national police register that records all arrests and convictions, as well as information on all criminal proceedings. These registers allow for the computerization and analysis of the data.

For instance, it was found that males in Denmark with a serious mental disorder who were admitted to a psychiatric hospital by age 44 years represented only 5 percent of the total population of males but were responsible for about 30 percent of all the violent offenses committed by males. Likewise, female mental patients in Denmark constituted about 5 percent of the female population but were responsible for 50 percent of all the violent offenses committed by females.

In another Danish study, the risk of violent offending was found to be 4.6 times higher for male subjects with schizophrenia and 2 times higher for those with affective psychoses than for male subjects who were never admitted to a psychiatric ward. For female subjects with schizophrenia, the risk was 23.2 times higher, and for those with affective psychoses, the risk was 3.9 times higher, than for female subjects who were never admitted to a psychiatric ward.

Similar findings were noted in Sweden in a study that examined all 15,117 individuals who were born in Stockholm in the same given year. They were evaluated through case registries 30 years later to determine how many were diagnosed with a serious mental illness and were convicted of a violent crime. It was found that 15 percent of the men and 6 percent of

the women who had a major mental disorder were convicted of a violent offense. A recent study of persons with mental illness in Sweden who were prescribed antipsychotics or mood stabilizers, found that violent crime dropped by 45 percent for those receiving antipsychotics and 24 percent for those receiving mood stabilizers.

It has been asserted that violent behavior by a subgroup of persons with serious mental illness increases community stigmatization and rejection of persons with mental illness generally. These violent episodes, often highly publicized, may result in the association of mental illness with violence in the public's mind. Such stigmatization can result in reluctance on the part of the public to support funding for adequate mental health services for persons with mental illness. Moreover, there may be less tolerance for integrating persons with mental illness into community housing and finding them appropriate employment. It will be difficult to reduce the stigma of mental illness and its consequences until the violence of this subgroup is addressed. Furthermore, to safeguard the welfare of persons with serious mental illness, as well as the safety of the public, mental health professionals and society must not ignore the evidence that mental illness is associated with some increased risk of violence.

Although there is a subgroup of persons with serious mental illness who are violent, it is extremely important to take into consideration data that demonstrate that an even larger group of persons with serious mental illness are the victims of violence. For example, in a review of studies of violent victimization, 35 percent of persons with serious mental illness had been victims of violence within the last year. For persons with serious mental illness, their victimization by violence tends to receive less public attention than the violence that is perpetrated by them.

Anosognosia

Anosognosia is a biologically based inability to recognize that one has a mental illness, and thus is a biologically based lack of insight. Researchers have identified various parts of the brain (e.g., ventricles, frontal and temporal lobe subregions, medial temporal and inferior parietal regions, and subcortical structures) where damage is likely to result in anosognosia. Impaired insight may be mediated by deficiencies in conceptual organization and the lack of flexibility in abstract thinking. Generally, lack of insight that one has a serious mental illness is one of the risk factors for violence in persons with schizophrenia, thus demonstrating a relationship between poor insight and violent behavior.

The importance of anosognosia is demonstrated by a study investigating 907 adults who met the criteria for psychotic and affective disorders and received public mental health services. This study found that 26 percent of these persons with serious mental illness reported being arrested or violent in the last year. These individuals were significantly more likely to deny

needing psychiatric treatment.

Overall, these findings suggest that many of the people who are most in need of psychiatric treatment are the least likely to believe that they need it. Treatment nonadherence is a key barrier to implementing evidence-based interventions. Several studies confirm that treatment involvement is related to lowered risk of arrest and violence in persons with serious mental illness by reducing their psychiatric symptoms and substance abuse. Interventions to improve insight and treatment adherence in this population are warranted and needed.

SOME CHARACTERISTICS OF PERSONS WITH SERIOUS MENTAL ILLNESS WHO ARE INCARCERATED

It is known that there are very large numbers of persons with serious mental illness in jails and prisons. What is known about them in terms of their criminal histories and legal status, the psychiatric services that they use while incarcerated, and the challenges that they might present in psychiatric treatment after release?

Two studies attempted to answer these questions. The first was a retrospective study of inmates with serious mental illness who were arrested and placed in a large, urban county jail. It should be noted at the outset that these findings do not necessarily represent what one would find in a similar study conducted in state and federal prisons, or even in other jails. This study revealed that 76 percent of these inmates required and received psychiatric inpatient care or its equivalent for part of their time in jail during the current offense. Clearly, a large number of people with serious mental illness are receiving their acute psychiatric inpatient treatment in the criminal justice system rather than the mental health system.

With respect to these inmates' history before the current arrest, at least 92 percent were known to be nonadherent to psychiatric medications, 94 percent had prior arrests, 72 percent had prior arrests for violent crimes, and 76 percent were known to have a history of substance abuse. Given these data in addition to the fact that three-fourths of these inmates required inpatient psychiatric care in the jail, it would appear that the jail had acquired the responsibility of handling many persons with serious mental illness who were among the most difficult and expensive to treat.

Another study conducted on individuals who had a serious mental illness and were transferred from jail to a psychiatric inpatient unit found that 75 percent had a history of physical assault in the community, 72 percent engaged in substance abuse, and 78 percent were generally nonadherent to medications. Findings revealed that poor insight into illness and nonadherence to medications were associated independently with violence toward others.

That such large percentages of persons in both studies had a history of

being nonadherent to psychiatric medications suggests that treatment on re-entry into the community should include such measures as evaluation and supervision by mental health courts, assertive community treatment (ACT), and assisted outpatient treatment (AOT) (see later discussion). Moreover, short-term, intermediate-term, or long-term hospitalization may be needed for many.

It was observed in these studies, as it frequently is in jails generally, that a number of persons with serious mental illness are arrested when it appears that their offending conduct was due primarily to their illness. The nature and circumstances of the offense suggest that these persons should have been psychiatrically hospitalized instead of being taken to jail. The following two cases serve to illustrate this point.

A person with psychotic symptoms and a previous diagnosis of schizophrenia was walking in circles, talking to himself, and then urinating outside a grocery store; he was arrested and charged with indecent exposure. Another person with manic and paranoid symptoms was panhandling at a gas station and yelling that a customer was stealing his money, whereupon he pushed this customer and others. The attendant at the gas station called the police who arrested him for assault. These individuals would probably have been better served if they had been taken to a psychiatric hospital and placed under the jurisdiction of the mental health system rather than being arrested and placed in jail. Incarcerating such persons in settings where it is difficult to provide good treatment, such as jail, does not appear to meet the needs of society by protecting society from dangerous people. Moreover, efforts to reduce the possibility of recidivism by these persons can generally be accomplished by treatment and management within the mental health system.

Using Cognitive Behavioral Therapy to Address Antisocial Characteristics

Some professionals have attributed criminal acts by many persons with serious mental illness primarily to the individual's criminal characteristics. These professionals believe that while there are incarcerated individuals who may have serious mental illness, many of them are in correctional facilities largely because of their antisocial attitudes, and a lack of problem solving and self-control skills that contribute to their criminal behavior. Consequently, a primary intervention suggested to reduce recidivism is to focus on the antisocial cognitions of these persons.

Indeed, a number of persons with serious mental illness in the criminal justice system may have antisocial tendencies, often to the extent of justifying a diagnosis of antisocial personality disorder. While cognitive behavioral therapy (CBT) may be a necessary component of the treatment regimen for many such offenders in reducing their recidivism, if such persons' thinking and judgment are impaired by their untreated psychotic and manic symptoms they may not be able to profit from CBT

interventions. Therefore, if CBT is to be effective, it should be combined with psychiatric treatment.

Diverting Persons with Mental Illness from the Criminal Justice System

With the very large and increasing number of persons with serious mental illness found in jails and prisons, there have been large-scale efforts to divert these persons from the criminal justice system to the mental health system. Diversion before the person is actually booked into jail, or pre-booking diversion, is exemplified by large-scale efforts to create community mobile crisis teams of police officers and/or mental health professionals. In addition, coordination between police and mental health professionals, as well as mental health training for law enforcement officers, may help in reducing arrests.

Diversion after booking takes a variety of forms. These include specialized mental health courts that handle exclusively offenders with mental illness. Mental health consultation to other courts may also assist the judge by offering recommendations for treatment in lieu of incarceration.

Mobile Crisis Teams. Psychiatric emergencies have been managed effectively in communities in which close formal liaisons between law enforcement and mental health agencies have been established. These arrangements have helped to facilitate the resolution of crises of persons with mental illness in the field without the need to resort to hospitalization or incarceration. When resolution in the field is not possible, the existence of these liaisons increases the number of persons with mental illness who are referred to the mental health system rather than jailed, thus reducing criminalization. For those who need psychiatric hospitalization, these relationships tend to increase the rate of acceptance by hospitals.

Different strategies have been developed to provide a mobile team of police, mental health professionals, or both to respond in the community to persons with mental illness who are in crisis. The following are two of these strategies that are used most commonly.

An increasing number of jurisdictions use sworn police officers who have special and extensive mental health training to provide crisis intervention services as part of crisis intervention teams (CIT programs) and to act as liaisons to the mental health system. This approach is often referred to as the “Memphis model” because it was developed in Memphis, Tennessee. These specially trained officers may deal with mental health emergency situations on-site or act as consultants to the officers at the scene. This model places a heavy reliance on psychiatric emergency services that have agreed to a no-refusal policy for persons brought to them by the police. Although this strategy has a close liaison with mental health, it does not require the actual participation of mental health professionals in

the field.

Another model that some jurisdictions use deploys teams composed of both specially trained sworn police officers and mental health professionals employed by the local community mental health department. These teams have been shown to be effective in resolving emergency situations in the community involving persons with mental illness and in diverting them to the mental health system rather than to the criminal justice system. An advantage of this model is that the mental health professionals on the team may have access to the person's documented mental health history. Having such data available is an important factor that can help the team better understand the person's mental condition and make more informed decisions.

The major goals of both of these specialized mobile crisis teams are to resolve the crisis and to reduce criminalization. Studies that have evaluated such teams found that they had arrest rates ranging from 2 to 13 percent (with an average of less than 7 percent), in contrast to an arrest rate of 21 percent for contacts between nonspecialized police officers and persons who were apparently mentally ill. This finding lends credence to the idea that a specialized response lowers the incidence of inappropriate arrests.

Regardless of whether police officers act as part of a team with members of the mental health system in dealing on-site with emergency situations, or police officers acting on their own in dealing with these situations, it is imperative that they obtain all available information about past police contacts with the individual when mental illness is thought to be present. Such information may include aspects of the person's actions during previous police contact, such as suicide attempts and violence, and how the previous contact was resolved.

A crucial part of developing and maintaining any specialized mobile response team is that a rigorous and ongoing evaluation of the program must be conducted. For instance, response times—the time from the call to the arrival of the team on the scene—should be measured on a routine basis. If response times are too long, police officers in the field tend not to call on the mobile teams. The teams' arrest rates, in addition to the mental health alternatives they choose, need to be evaluated regularly to be sure that appropriate dispositions are being made and that mental health facilities are cooperating with these efforts.

Increased Coordination and Need for Training. From the standpoint of the police, it is clear that officers need and want rapid on-site assistance from mental health professionals when they are called on to deal with difficult or complex situations involving persons with mental illness who are acutely psychotic, behaving bizarrely, or exhibiting violent behavior, or for persons who have attempted suicide or made a suicide gesture. Similarly, mental health professionals who are working as members of

psychiatric emergency teams without police support may feel ill equipped to handle such individuals in the field. Thus, it has become increasingly apparent in recent years that when persons with mental illness in the community are in crisis, neither the police nor the emergency mental health system alone can serve them effectively and that it is essential for the two systems to work closely together.

Training of Police. Most police departments provide some type of officer training in mental illnesses; however, training in how officers should respond to persons with mental illness who are in crisis is less common. Moreover, mental health training is needed for all police officers, not just for those who are part of the specialized mobile crisis teams.

Training for police officers about mental health issues and individuals with mental illness should begin in police academies as a regular part of the curriculum. This training should focus on enhancing the understanding of mental illness by law enforcement personnel. Furthermore, it should aim at increasing their knowledge about such mental health issues as how to recognize mental illness, how to handle violence or potential violence among persons with mental illness, what to do when a person is threatening suicide, and when to call the specialized mobile crisis team. In addition, information should be provided as to what mental health resources are available, both inpatient and outpatient, and when a person should be arrested and incarcerated as opposed to being taken to a mental health facility.

For the training to be successful and relevant, trainers should come from both the mental health and criminal justice systems. Trainers from the mental health system should be persons who have experience with crisis intervention in the field and/or in crisis centers, as well as knowledge and field experience relating to the criminal justice system. These mental health professionals must understand and appreciate the challenges and risks that law enforcement officers experience every day in the field. However, trainers from the criminal justice system already have credibility with their trainees and knowledge about such issues as officer safety and enforcement protocols that noncriminal justice system persons would not have.

Another important issue to consider when law enforcement officers come into contact with persons who have mental illness is how the individual perceives the officers. Persons with mental illness may have negative attitudes toward the police; they may be fearful of police, believing that the officers do not listen to them, and may use force against them. Such perceptions can lead to dangerous escalating interactions. Consequently, the attitudes and behaviors of both the officer and person with mental illness have an effect on the outcome of their contact. Understanding how persons with mental illness may perceive law

enforcement officers, particularly if they had a previous negative experience with police, is essential.

It needs to be emphasized that mental health training should be an ongoing process, not only for police officers in special mental health crisis teams but also for all police officers.

MENTAL HEALTH SERVICES AFTER ARREST

To reverse criminalization, it is extremely important to identify persons with mental illness as quickly as possible after they have been arrested and placed in jail. A facility may routinely screen all incoming detainees for serious mental disorder. Initial screenings may be conducted by custody personnel who notice the inmate engaging in odd or bizarre behavior. Medical/psychiatric questionnaires have also been used in many correctional institutions as a screening device. Such questionnaires consist typically of less than 20 questions aimed at identifying inmates who may need psychiatric care. Those individuals who endorse items on the questionnaire or who appear to have a mental illness may then be seen by a clinician for a more extensive evaluation to determine what type of housing and/or mental health treatment they should receive while incarcerated. Even more important, if the person is one who should have been treated in the mental health system in the first place, discharge planning should begin as soon as possible after arrest.

Given the large numbers of persons with serious mental illness who are arrested, jail administrators should be encouraged to negotiate programmatic relationships with mental health agencies to provide multidisciplinary teams of clinicians to work in the jail setting. These teams should include psychiatrists so that psychoactive medications can be prescribed. The teams should be established inside jails to provide short-term crisis intervention, treatment, referral to a psychiatric hospital if necessary, and discharge planning. Such information can be useful in helping the judicial system make decisions concerning the person's legal disposition.

Mental Health Courts. Post-booking diversion strategies are being used increasingly by special courts called mental health courts. The first mental health court that received national attention was established in Broward County, Florida, in 1997, and since then, the number of mental health courts in the United States has increased greatly. Initially, these courts were set up to hear cases of persons with mental illness who were typically charged with misdemeanors. In recent years, these courts have increased their purview to serve persons with mental illness charged with felonies. In mental health courts, all the courtroom personnel (i.e., judge, prosecutor, defense counsel, and other relevant professionals) have experience and training in mental health issues and available community resources. These

mental health courts have a particular set of characteristics: they hear specialized cases involving defendants with mental illness; they use a nonadversarial team of professionals (e.g., judge, attorneys, and mental health clinician); they are linked to the mental health system that will provide treatment; and they use some form of adherence monitoring that may involve sanctions by the court.

Underlying the concept of mental health courts is the principle of therapeutic jurisprudence, which emphasizes that the law should be used, whenever possible, to promote the mental and physical well-being of the people it affects. The concept of therapeutic jurisprudence operates on the belief that the application of the law can have therapeutic consequences. It should be emphasized that therapeutic jurisprudence does not diminish the importance of public safety, which is fully taken into account by the court.

In a system characterized by therapeutic jurisprudence, people with serious mental illnesses charged with crimes may be diverted into programs designed to address their treatment and service needs rather than simply being incarcerated with their treatment needs being neglected. Even individuals with serious mental illnesses convicted of serious crimes can be provided with humane and appropriate treatment while incarcerated. Generally, mental health courts facilitate linking offenders with serious mental illness to appropriate needed services and supports on discharge from jail in order to enable them to successfully re-enter their communities.

Mental health courts were developed as a strategy to divert persons with mental illness from the criminal justice system into the mental health system. When offenders with mental illness are booked into jail, their case is usually handled by mental health courts in one of two ways. In the first situation, the prosecution of their cases may be postponed by the judge so that they may be involved in a specified treatment program run by the mental health system. If they successfully complete the program, their criminal charges are dismissed, and the individuals are no longer under the jurisdiction of the criminal justice system. If they fail to complete the treatment program successfully, the charges are reinstated, and the criminal proceedings resume. In the second case, the offender with mental illness offers a plea of guilty or *nolo contendre,* which is accepted by the court. The person is sentenced (e.g., sentenced to 180 days in jail, which may be held in abeyance) and given probation, which includes treatment by the mental health system as a condition of probation. If the person is nonadherent with treatment or other probationary conditions, probation may be withdrawn and the sentence imposed. There is evidence that these types of jail diversion may reduce recidivism for persons with serious mental illness.

The mental health court system works in a collaborative effort to devise and implement a treatment plan that includes medications, therapy,

housing, and social and vocational rehabilitation, all in an effort to address the individual's mental illness and reduce the risk of recidivism. Research has suggested that a factor contributing to reducing recidivism and improving clinical outcomes is when the court and mental health personnel work as a "team" to coordinate and provide services. Clearly, the quality of services plays an influential role in the success of mental health courts. However, there may be unforeseen limitations of these programs with respect to available resources. That is, there are often insufficient community psychiatric treatment, rehabilitation, and housing capabilities in the existing mental health system to accommodate those persons with mental illness who are diverted from the criminal justice system. Another issue that has already been discussed is that many community resources are not appropriate, adequate, or willing to serve a large proportion of those who are diverted from the criminal justice system. Not surprisingly, there is research evidence that this lack of appropriate resources to which diverted persons can be referred results in recidivism.

Another problem resulting from the services recommended by these courts for offenders with mental illness is the possibility that they might be provided at the expense of programs for persons with mental illness who have not committed crimes. When this happens, an undesirable situation may be set up whereby committing a crime offers the patient with mental illness the best chance of getting psychiatric treatment.

These specialized mental health courts have been given high priority because they appear to be part of the answer to the problem of criminalization. However, for these diversionary programs to be truly effective and not overwhelm the already existing limited budgets of the departments of mental health, the treatment to which the courts have referred the offender with mental illness should be funded by additional monies. These monies could come, at least in part, from savings in the criminal justice system, which would no longer have to incarcerate and treat these persons.

The Importance of Mental Health Consultation to the Court. Consultative arrangements with mental health professionals may help to correct a problem that involves the computerized criminal histories, or "rap sheets," available to the court of persons with serious mental illness. Criminal justice personnel, such as prosecutors, probation officers, and parole officers, access the person's criminal history. It is important to consider what effect this may have on the court's decision making regarding the disposition for the individual when there is no mental health input. These computerized criminal histories seldom include a narrative as to what really happened during the previous arrests. Even when a person with serious mental illness commits nonserious offenses, a series of them can result in a lengthy computerized criminal history for the individual. Thus,

when such individuals subsequently appear in court, they may look like habitual criminals when their criminal histories are accessed.

By providing mental health evaluation and consultation it may become clearer in these instances that these are persons with serious mental illness who were not receiving adequate treatment and who repeatedly acted in an inappropriate and/or aggressive manner when stressed, which caused them to come to the attention of law enforcement officers and be arrested. An example would be a woman with a history of bipolar 1 disorder who has a history of arrests for crimes including disturbing the peace (playing loud music throughout the early morning hours), destroying public property (defacing doors in a county building), resisting arrest for disorderly conduct (screaming at her neighbors in the middle of the night), and hitting a man on the bus whom she falsely believed was making sexual overtures toward her. Her most recent arrest was for throwing rocks at her neighbor because she mistakenly believed he was spying on her while she was taking a shower. Without the input of a mental health professional to evaluate this individual, the judge might believe that she should be incarcerated instead of referred to a hospital or other psychiatric treatment. Thus, this person with serious mental illness would continue to be criminalized.

OUTPATIENT TREATMENT TO REVERSE OR PREVENT CRIMINALIZATION

To decriminalize persons with serious mental illness, it is necessary to find ways to help them become stabilized outside of jails and prisons and, to the extent possible, not enter the criminal justice system at all. Thus, the community treatment of persons with serious mental illness who are or may become offenders has developed into an increasingly important and urgent issue. There are greatly increased numbers of persons with serious mental illness who find their way into the criminal justice system, are released into the community, and unfortunately, revolve back into the criminal justice system.

A study examined all persons (N = 79,211) who were incarcerated in one state's prison system during a 1-year period. Ten percent were diagnosed as having major depressive disorder, bipolar disorders, schizophrenia, or nonschizophrenic psychotic disorders. Twenty-one percent of these inmates with serious mental illness were currently incarcerated for a violent offense. These inmates also had a statistically higher percentage of assault, robbery, and property offenses than the inmates who had no psychiatric disorder. In addition, the inmates with serious mental illness were far more likely to have a history of incarceration than those without a serious mental illness. As a result of this study's findings, the authors acknowledged that there was a need to not only develop programs to treat persons with serious mental illness in correctional facilities but also to find effective alternatives to incarceration in the community, including pre and post-booking diversion programs, increasing discharge planning or

continuity of care programs, drug and alcohol screening and treatment, and access to psychiatric inpatient treatment.

The purpose of this section is to review community treatment of persons with serious mental illness who without treatment have been or might become criminalized, and to discuss the principles of treating this population as viewed generally by clinicians who conduct such treatment. This includes those who specialize in forensic mental health care. In addition, because such large numbers of persons with serious mental illness have become criminalized and then released into the community, many mental health professionals who previously may not have been involved in treating offenders with mental illness are now finding themselves with treatment responsibilities for this population.

Probably, many criminalized persons with serious mental illness can be treated at mainstream mental health clinics on their release from jails and prisons. This is exemplified by nondangerous persons with psychosis who are arrested for minor crimes, such as disturbing the peace or not paying for a meal in a restaurant, and who are taken to jail rather than the more appropriate disposition of taking them to a hospital. Another example would be individuals with serious mental illness who committed felonies and were sent to prison but are nondangerous, such as a person with bipolar disorder who was sentenced to prison for forging checks.

However, it must be recognized that there are many who are discharged from correctional institutions who have multiple problems that cannot be adequately treated in traditional community-based facilities. An example of this would be persons with serious mental illness who have a history of dangerousness; placing such persons in a traditional community clinic often results in exacerbations of their illness and acts of violence that lead to rehospitalization or reincarceration. For these individuals, it is important to have special, highly structured clinics staffed by professionals who understand dangerous offenders with mental illness and their treatment. Moreover, adequate security in such clinics is essential; this should include metal detectors, the presence at all times of trained security personnel, and emergency alarm buttons within easy reach of the mental health staff. These clinics may be in the mental health system, with the patients' treatment monitored by the criminal justice system (e.g., court and/or department of probation), or the clinics may be an actual part of the criminal justice system (e.g., run by parole departments).

Treatment of Co-Occurring Disorders

It is estimated by professionals and other personnel in the criminal justice system who are knowledgeable about incarcerated persons with serious mental illness that at least three-fourths of them also meet DSM-5 criteria for substance use disorders. Clearly, if treatment after release is to be successful, both the mental illness and the substance abuse must be

addressed. These services should be integrated in the community, and it is generally held that the same clinical personnel should provide and coordinate both mental health and substance abuse treatments. Treatment of co-occurring disorders very frequently needs to be a long-term process.

Assisted Outpatient Treatment

Another important treatment modality that is available in almost all of the states is AOT, often called outpatient commitment. AOT is a court-ordered civil commitment in which the patient is not under the jurisdiction of the criminal justice system. Rather, AOT is initiated by the mental health system to ensure that persons with mental illness and a history of hospitalizations or violence participate in services in the community that are appropriate to their needs. AOT is for persons with mental illness who are capable of living in the community with the help of family, friends, and mental health professionals but are resistant to psychiatric treatment, including medications. Without such treatment, they may relapse and become violent and/or dangerous to themselves and require hospitalization. Because of these characteristics, this population is also prone to be arrested, incarcerated, and criminalized. To prevent decompensation, which may result in hospitalization or criminalization, and to help these persons stabilize in the community, such at-risk individuals are ordered to participate in outpatient psychiatric treatment, with their progress closely monitored by the court.

When AOT is successful, it is because there is usually a requirement that it be accompanied by an intensive and proven form of community treatment, such as ACT or forensic assertive community treatment (FACT). ACT is a community-based program with mobile mental health treatment teams that provide an array of treatment, rehabilitation, and housing services that are available 24 hours a day. FACT is similar to ACT but also includes legal leverage via collaboration with the criminal justice agencies, in an effort to reduce recidivism. The goal of ACT and FACT is to help persons with serious mental illness stay out of the hospital and develop skills for living in the community. It should be noted that AOT, ACT, and FACT are evidence-based practices; that is, they have been shown to be effective, using scientifically valid studies.

There are many who believe that the widespread use of AOT would reduce the criminalization of persons with serious mental illness because it mandates treatment for individuals who otherwise are likely to be arrested and enter the criminal justice system.

Challenges of Mandatory Outpatient Treatment

Individuals in AOT with serious mental illness, as well as those who have committed criminal offenses, represent a challenge to outpatient clinicians.

The problem lies not only in ensuring safety to the community but also in working with individuals who may be resistant to treatment.

A large proportion of persons with serious mental illness who commit criminal offenses have a history of being highly resistant to psychiatric treatment before their involvement in the criminal justice system; this is also true for persons who are considered to need AOT. They may have refused referral, may not have kept appointments, may have been nonadherent with psychoactive medications, and may have refused appropriate housing placements. Many have anosognosia and are not able to recognize that they have a mental illness.

For many offenders with mental illness, problems of resistance may continue after release from incarceration, which can place them at risk to the community. This is a fact that the treating professional must always keep in mind.

The mental health system finds many resistant persons with mental illness extremely difficult to treat and is often reluctant or unable to serve them. The reluctance becomes even greater after these persons have committed offenses, become involved in the criminal justice system, and are referred to community agencies. The disinclination to serve these persons extends to virtually all areas of community-based care, including therapeutic housing, social and vocational rehabilitation, and general social services. Many offenders with serious mental illness are intimidating because of previous violent, fear-inspiring behavior. Treating them is very different from helping submissive, nonthreatening, formerly institutionalized patients to adapt quietly to life in the community. Thus, community mental health professionals not only are reluctant but also may be afraid to treat offenders with mental disorders. In addition, professionals may work in treatment facilities that do not adequately provide for staff safety, do not possess the authority and leverage of the criminal justice system, and do not provide treatment interventions with adequate structure for this population. The reluctance to treat potentially dangerous persons in such treatment facilities may be warranted. Another issue related to mental health professionals' reluctance to treat such individuals is their belief that they do not have adequate training and experience in risk assessment to ensure public safety. As discussed later, outpatient programs need to increase their ability to treat persons who do not see themselves as having a mental illness and/or have a potential for dangerous behavior.

Another important obstacle to receiving outpatient treatment for persons with serious mental illness who are in AOT or are offenders is that community mental health resources may be inappropriate. For instance, these persons may be expected to come to outpatient clinics, when the real need for many in this population is for outreach services where professionals come to them.

As discussed later, a crucial part of the treatment of these persons with serious mental illness is adequately and appropriately structured and supportive, therapeutic housing arrangements.

When the Criminal Justice System Is Involved

When the criminal justice system is involved in the outpatient treatment of offenders with serious mental illness, a need exists for a clear understanding of the criminal justice system's perspectives and goals. These perspectives and goals include an emphasis on concerns about public safety, control of violence, extensive use of authority, and close cooperation between the mental health and criminal justice systems.

There are a variety of circumstances under which offenders with mental illness in the community remain under the jurisdiction of the criminal justice system. One such group consists of individuals given probation by the court that includes a condition of outpatient treatment, with the possibility of being sent to jail or prison if they are nonadherent to treatment. Another consists of individuals released from prison who are referred for treatment by their parole officer with the understanding that failure to comply may result in a revocation of parole and return to custody.

Treatment under the Jurisdiction of the Criminal Justice System

For those offenders who are mandated by the court or an agent of the criminal justice system (probation officer, parole officer) to attend outpatient treatment, the criminal justice system retains jurisdiction over the individual. In such situations, both the offender with mental illness and the therapist must satisfy legal requirements, such as regular attendance and periodic progress reports. The patient must comply with legal restrictions, such as abstinence from drugs and alcohol. Therapists who treat such individuals are often asked to provide reports to the court, probation officer, or parole officer on the patient's treatment, including issues such as attendance, diagnosis, progress, and prognosis.

Both the criminal justice system and forensic clinicians generally expect that offenders with mental illness given treatment will gain some understanding of the role of their psychiatric disorder in past and potential future dangerous behavior, and that they will avoid behavior or situations that might increase the risk of criminal activity or deterioration in their clinical condition. Moreover, both society and the criminal justice system expect that treatment will be conducted under conditions that can, to the greatest extent possible, ensure safety to the community.

Thus, a balance must exist between individual rights and public safety. However, it has been argued that courts place a greater emphasis on the potential dangerousness of the offender with mental illness than on the individual's rights. In so doing, the courts place the burden on the offender

to demonstrate that he or she no longer poses a danger to the community. Consequently, the person's risk of violence, to a large extent, dictates whether such an individual will be placed into and remain in the community.

Outpatient treatment for offenders with serious mental illness is not designed to make presently dangerous individuals nondangerous. Rather, the criminal justice system presumes that offenders with mental illness placed in outpatient treatment will not be dangerous to others while under supervision and treatment in the community. A primary concern in outpatient treatment of these individuals is to assess any changes in mental condition that may indicate violence and to reduce potential threat of harm. Therefore, features that contribute to a patient's risk of harm are addressed first in treatment. The psychiatrist must assess dangerousness and incorporate this assessment into an intervention strategy. Thus, outpatient clinicians must have as great as possible an understanding of each patient's potential for violence as a function of his or her history and psychiatric condition. Moreover, the clinicians should feel comfortable and qualified to engage in such assessments.

In contrast, in nonforensic psychiatric treatment of nonviolent persons with serious mental illness, the primary focus is usually on alleviation of symptoms. Clinicians who treat offenders with mental illness need to recognize that they have assumed responsibility not only to the patient but also to society in ensuring the patient's safety to the community. This responsibility is not as central when clinicians are treating nonoffenders.

Identifying a Treatment Philosophy

To work effectively with this extremely difficult group of psychiatric patients, both those in AOT and those who are offenders, the necessity of identifying and articulating a treatment philosophy of both theory and practice should be emphasized. This philosophy, as already mentioned, should strike a balance between individual rights and public safety and use treatment services that take both into account. A reality-based treatment philosophy is needed, one that includes clear treatment goals, with attention paid to goals expressed by the patient; a close liaison with the court or other criminal justice agency monitoring the patient, including access to each patient's database from the criminal justice and mental health systems; and an emphasis on structure and supervision.

The importance of psychotropic medications for this population with serious mental disorder, most of whom have problems centering on control, cannot be overemphasized. In many cases, if adherence is to be ensured, the patient must live in a community facility in which each dose is dispensed by staff.

A clear conception of the clinical uses and therapeutic value of authority appears to be a cornerstone of successful community treatment for persons

with serious mental illness in AOT or for those who are offenders. When treatment is effective, the staff is not ambivalent about the use of authority. They are comfortable about insisting consistently and reasonably that the imposed conditions be followed, monitoring patients' adherence with prescribed psychiatric medications, and monitoring patients to detect the use of alcohol or illegal drugs. They have no problems with insisting that patients live in appropriately structured and supportive residential settings, to the extent needed by each individual, as a condition for remaining in the community. They are willing to rehospitalize patients in community facilities promptly at times of crises and are willing to recommend revocation of patients' community status and return them to the court with the opinion that community treatment is no longer appropriate.

It is also important to emphasize the legal and ethical aspects of treating persons under the jurisdiction of the court. Before persons in AOT and offenders with mental illness are asked to consent to outpatient treatment, they should be apprised of all the conditions and limitations that will be imposed on them, why they will be imposed, and what will happen if they do not comply. Areas to be addressed include limits to confidentiality, with respect to both past and present treatment and criminal history, and conditions under which such information must be shared with criminal justice and mental health system personnel; supervision and monitoring by various authority figures, such as probation or parole officers, judges, therapists, and case managers; mandatory adherence with treatment and other imposed conditions; and residence in an appropriate living situation. The patient must understand that nonadherence with the terms and conditions may result in revocation of outpatient status. It is also imperative that the treatment staff understand fully the patient's legal status and conditions for community placement and agree to monitor and uphold them. Staff members must accept their role as agents of social control.

Treatment Goals

Generally, mental health professionals believe that community treatment of persons with serious mental illness who are in AOT and/or have been offenders should focus on stabilization of the illness, enhancement of independent functioning, and maintenance of internal and external controls that prevent patients from acting violently and committing offenses. It is hoped that patients will share these goals. Patients should at least have the goal of avoiding involvement with the criminal justice system. Important points for discussions between the clinician and the patient are the patient's understanding of which behaviors and symptoms are of concern, why they are of concern, what is expected of the patient both by the clinician and by the supervising court or criminal justice agency, and how the treatment can help the patient to meet these

expectations.

Even patients with severe psychiatric symptoms may be able to understand these elements of treatment and adopt appropriate attitudes toward treatment. Thus, a full resolution of symptoms is not always needed for treatment to be viable in a community setting. For some persons with long-term, serious mental illness, total elimination of symptoms is not a realistic goal. Rather, the primary prerequisite for safe and effective community treatment may be patients' ability to understand and accept their clinical needs and the system's legal requirements and to demonstrate adherence.

Liaison between Treatment Staff and the Court

An essential aspect of the treatment of offenders with mental illness, especially those under the jurisdiction of the criminal justice system and of persons in AOT, is a close liaison among treatment staff and the court, the district attorney's office, the departments of probation and parole, and the patient's counsel. At the core of the liaison is a complete and relevant database, which is fundamental in understanding the extent of the patient's problems, determining whether outpatient treatment is appropriate for the patient, and developing a treatment plan. The database should include arrest reports, computerized criminal histories ("rap sheets"), hospital records, evaluations by court-appointed psychiatrists or psychologists, results of psychological testing, probation reports, and records from previous hospitalizations, outpatient treatment, and incarcerations.

A successful liaison requires open, frequent, and continuing contact between the treatment staff and the various aforementioned personnel in the legal system. In addition, all must respect each other's perspective and accept that they are all working toward the same goals. Together, the mental health and legal systems lend their expertise in developing and modifying the most effective community treatment program for patients. Both must accept that such a program cannot be effective for certain individuals who need hospitalization or are too dangerous and thus are not appropriate for outpatient treatment.

The Need for Structure

Usually, patients referred for mandatory outpatient treatment lack internal controls; they need external controls and structure to organize them to cope with life's demands. For instance, mental health professionals who treat this population generally believe that staff should insist that patients' days be structured through meaningful, therapeutic activities such as work, day treatment, and various forms of social therapy. Another basic element of structure for this population is that treatment is mandatory and under the jurisdiction of the court.

What effect does involuntary treatment have on persons with serious mental illness? Adherence has been shown to increase when persons with serious mental illness are required to undergo involuntary treatment. Adherence is important because it has been demonstrated that persons with serious mental illness who do not comply with treatment present an increased risk to themselves and to the community. Thus, treatment nonadherence may in and of itself result in rehospitalization or incarceration.

For offenders with mental illness, the criminal justice system tends to view outpatient treatment or conditional release programs as provisional; such programs are not regarded as the right of the offender with mental illness. Thus, the courts are not obliged to grant this form of treatment; if granted, the courts allow the state to quickly and easily revoke it. The possibility of revocation of outpatient status gives the treatment staff powerful leverage to ensure adherence to the treatment conditions.

Finally, it is essential that staff understand and accept the therapeutic value of structure and their use of authority if community treatment of offenders with serious mental illness is to be successful.

Management of Violence

A major focus of therapy should be on high-priority issues such as the need for the patient to control impulses and inappropriate expressions of anger. Persons whose violence is rooted in a major mental illness often experience their violence as a frightening loss of control. Because their violent acts often occur in the context of psychosis, they tend to perceive a clinician who is not aware of their destructive potential as unable to protect them. They tend to establish that knowledge by testing the clinician for limits. The clinician must be continuously alert and firm in order not to risk being perceived as uncaring and unable to protect the patient from his or her destructiveness. Treatment contracts made by the psychiatrist and the patient that deal with expectations and consequences openly and from the beginning provide a helpful structure for working with these potentially violent patients.

Persons with serious mental illness, especially those with histories of violent behavior, generally need continuous rather than episodic care. Thus, regular monitoring is needed, especially when symptoms are absent or at a low ebb, in order to deal with individual and situational factors that may arise and result in violence.

Persons with serious mental illness who have been hospitalized or incarcerated frequently enter outpatient treatment while they are still taking medication and may for the first time in years find themselves symptom free, in control of their violent impulses, and able to function in the community. After a while they may believe that they can succeed without medication; they discontinue its use, decompensate, and perhaps

engage in violent behavior. Thus, for this population of persons with serious mental illness, a large number of whom have problems involving control and violence, the importance of continued adherence to antipsychotic medications and medications for bipolar and depressive disorders cannot be overemphasized.

In addition, behavioral, cognitive, and psychoeducational techniques emphasizing anger management have been widely used and have been successful in the treatment and management of violence.

Integrating Treatment and Case Management

The purpose of case management is to help patients obtain the services that they need in a timely manner and for as long as they need them. Almost all of these patients need the basic elements of case management, which starts with the premise that each patient has a designated professional with overall responsibility for his or her care.

The case manager formulates an individualized treatment and rehabilitation plan with the patient's participation. As care progresses, the case manager monitors the patient to determine whether he or she is receiving treatment, has an appropriate living situation, has adequate funds, and has access to vocational rehabilitation. The treatment plan emphasizes helping the patient to deal with practical problems of daily living. In addition, the case manager provides outreach services to the patient wherever he or she is living, whether alone, with family, in a board-and-care home, or in another residential setting.

Outreach services may take the form of assertive case management. An assertive case management program deals with patients on a frequent and long-term basis. It takes a hands-on approach that may necessitate meeting with patients on "their own turf" or even seeing a patient daily. This form of contact and familiarity with the patient helps the case manager anticipate and prevent a significant decompensation. Low caseloads for case managers of potentially violent persons with mental illness—probably not more than ten cases—have been recommended, as has 24-hour-a-day, 7-day-a-week availability. Many violent acts and arrests occur during evenings, nights, and weekends, when traditional treatment programs are closed.

Patients who perceive the case manager as mainly an agent of the court and whose primary intention is to make them "toe the line" will be less likely to form a positive relationship with a case manager. They may be guarded and defensive in their interactions. They may also feel a need to portray themselves in a good light, even though they have problems for which they need help. Therefore, case managers, in addition to enforcing the terms and conditions of the court and the treatment, need to be persons who will go beyond this role to secure and provide services and support. It is crucial that patients see the case manager as their advocate to further

their treatment and rehabilitation, particularly when agencies in the criminal justice system are dealing simultaneously with them in more coercive or authoritarian ways.

Case managers may experience considerable stress in working with patients in mandatory outpatient treatment. They may feel, with some justification, that they are in danger if they work with persons with serious mental illness who have been violent in the past or if their work requires visits to high-crime areas, where many persons with serious mental illness live. Additional problems may include unusual working hours, which may disrupt their family and social relationships, and lack of upward career mobility.

Therapeutic Living Arrangements

Survival in the community for the majority of persons with serious mental illness appears to depend on an appropriately supportive and structured living arrangement. Such an arrangement can often be provided by family members. In many cases, however, the kind and degree of structure the patient needs can be found only in a living arrangement outside of the family home with a high staff–patient ratio, dispensing of medication by staff, enforcement of curfews, and therapeutic activities that structure most of the patient's day.

Some patients need a great deal of structure and supervision in their housing situation, others need only a minimal amount, and most fall somewhere in between. The treatment staff member assigned to the patient or the patient's case manager must decide whether a particular living arrangement has the appropriate amount of structure to meet the patient's needs. However, it is important to first discuss the suggested living arrangement with the court or the responsible agent in the criminal justice system and obtain his or her approval.

A consideration for all patients who move from a closed or locked setting such as a hospital, jail, or prison is the patient's ability to handle transition. It is generally not advisable for persons who have been hospitalized or incarcerated for a long time to then be placed in the community in a living situation with little or no structure. Such individuals are frequently unable to cope with the immediate stress and demands of these arrangements, and they either decompensate or commit subsequent offenses.

For many persons with serious mental illness, it is helpful to release them to graduated lower levels of structure—for example, from a hospital or prison to a locked community facility to a halfway house and, when they are ready, to family or independent living. In the graduated release process, close attention must be paid to patients' coping skills and need for monitoring.

Working with the Family

The role of family members or significant others can be critical in the treatment of offenders with mental illness or for those in AOT. The treatment team should determine whether these individuals were the victims of the patient's aggression, whether they have maintained contact with the patient, and whether they are interested in continuing such contact. The team should also learn whether other social support systems are available while the patient resides in the community. Social support can be an extremely important part of community treatment for persons with mental illness. Assessing problems that may develop between the patient and family members or significant others is essential if contact between them is anticipated.

Another important consideration is the family members' needs for guidance and support, especially when they have been victimized by the patient. Clinicians should help them in understanding the patient's mental condition, teach them to recognize symptoms of decompensation, demonstrate methods for self-protection, and explain the patient's current legal situation.

Moreover, family members should be involved in support groups to help them during crises. In self-help programs, they can benefit from the experience of other families in similar situations.

Cultural Competency

It is important that mental health professionals understand the roles that ethnicity, race, culture, gender, and age play in how mental illness manifests. Equally important is an understanding of the kinds of treatment and how treatment is presented that will be acceptable to these groups. Only then can the mental health system provide to racial, cultural, and ethnic minorities and persons of all ages and both genders services that are appropriate for their needs and ones to which they will be responsive.

Pitfalls

Mental health professionals must understand their potential liability for the actions of their patients on community status who are prone to violence. They need to be aware that in some states, courts have imposed on therapists a duty of care that extends to foreseeability of harm. Moreover, the litigious nature of society adds further pressures, stress, and risks. Treating clinicians may be held accountable for patients' suicides, assaults, homicides, and other crimes, even when treatment was mandated, sound, and met the professional community's standards of care. In both public agencies and private practice, malpractice insurance coverage must be adequate so that clinicians feel comfortable, personally and professionally, in undertaking the treatment of persons with serious mental

illness who need mandatory outpatient treatment.

Another important concern of those clinicians involved in the community treatment of offenders with serious mental illness, especially persons who have committed high-profile crimes, is the possibility of notoriety and unfavorable publicity. Clinicians may fear that if patients commit further sensational crimes, their professional reputation will suffer and their facility may receive negative media coverage.

Twenty-Four–Hour Structured Inpatient Care

Not all persons with mental illness can be treated effectively in the community. There is a substantial minority of persons with serious mental illness who need the structure and support of acute, intermediate, or long-term care in a hospital setting or a highly structured, locked 24-hour care community facility. It is important to identify high-risk patients so that scarce community treatment resources are used for those most likely to succeed and for those who are least likely to incur the high costs of lengthy hospitalization or rearrest for serious offenses.

It is essential to facilitate access to hospital care for patients who need it. In the early years of deinstitutionalization, many believed that if the counter-therapeutic practices that had been exposed in some state psychiatric hospitals could be eliminated, this would simultaneously eliminate the need for hospitals altogether. However, experience has shown that some persons with serious mental illness require hospitalization, and some may need it for an extended period of time. This may be true even in communities that offer a complete array of excellent and integrated community-based services.

It is important to acknowledge that the community is not necessarily the most benign treatment site for all people with mental illness at all times. Access to hospital care for those who need it for as long as they need it is absolutely essential to the success of deinstitutionalization and the reduction in criminalization for this population.

For those persons with serious mental illness who do not require a setting as highly structured as that of a locked psychiatric hospital but who are not ready for an open community setting, intermediate care facilities have proven extremely valuable. An example is the institutes for mental disease (IMDs) in California. IMDs are locked, private, community intermediate care facilities with a moderate but lesser degree of structure than that found in long-term psychiatric hospitals, such as state hospitals. The facility provides very close medication supervision, with many patients receiving their medication in either liquid or crushed form. The staff–patient ratio is high, with at least 27 hours of activities a week for each patient. These activities include group therapies, therapeutic, social, and recreational activities, and instruction in activities of daily living.

Intermediate care facilities have been used widely for both civilly and

criminally committed patients. These intermediate care facilities have helped to stabilize persons who might well have been criminalized; for those persons coming from jails and prisons, they might well have prevented recidivism.

Decarceration of Jails and Prisons

Imprisonment rates in the United States have increased 500 percent over the past 30 years; currently, the United States has the highest rate of incarceration in the world. This has resulted in prison overcrowding and great financial costs. Consequently, many efforts are underway currently to decrease the number of persons imprisoned. Some of these are reductions in state and federal sentences for less serious crimes, including drug offenses; the use of alternatives to prison, by means of diversion programs; offering early release to prisoners who participate in rehabilitation programs; and legal mandates to reduce prison overcrowding.

Beginning in 2009, the number of prisoners in US prisons and jails dropped slightly each year. The greatest reduction in prisoners was in California, which exemplifies many of the factors that led to decarceration. In the case of *Brown v. Plata*, the US Supreme Court in 2011 found that overcrowding in California's prisons resulted in a violation of prisoners' constitutional rights, and upheld an order to significantly reduce the number of state prisoners. Legislation known as "Public Safety Realignment" was enacted that year which used two primary methods to reduce overcrowding, costs, and recidivism. The first method focused on reducing admissions to prison, by having many nonserious, nonsex, and nonviolent felony offenders serve sentences, generally of 3 years or less, in county jail instead of prison. The second method focused on having fewer prisoners return to prison; that is, inmates who previously were released on state parole were now released under county probation, to be supervised and provided services by county agencies. If they violated their conditions of probation (but without committing a new crime), they could not be returned to prison but could be placed in jail.

"Realignment" became effective on October 1, 2011. At that time there were 143,710 state prisoners. By January 4, 2017, the number had been reduced to 114,000, a reduction of 29,710 state prisoners. Persons with serious mental illness may account for a sizeable number of those released. As mentioned previously, recent studies estimate that approximately 16 percent of persons in prisons have a serious mental illness. If this percentage holds for the 29,710 reduction in state prisoners, then approximately 4,754 (29,710 × 16%) fewer persons with a serious mental illness are incarcerated in California prisons.

States across the nation are addressing the financial costs and effectiveness of incarceration for those currently in prison. Relying on local jails instead of prisons to incarcerate offenders is also likely to result in

high costs and overcrowding conditions in the jails, and lead to releasing the least dangerous jail inmates for more serious offenders. As a result, arresting persons with serious mental illness who commit or are alleged to commit nonserious, nonsex, and nonviolent crimes and placing them in jails may become less common than in the past.

Consequently, the era of the criminalization of large numbers of persons with serious mental illness may be ebbing in both state prisons and jails. The criminal justice system will not be able to absorb the great numbers that they did formerly. As a result, during decarceration the mental health system may be expected to assume the care and treatment for far more persons with serious mental illness. Some of these individuals may be among the most difficult and expensive to treat, as well as at great risk of decompensation and/or reoffense. If, however, society gives a high priority to successfully treating and reducing the hundreds of thousands of persons with serious mental illness who are currently in jails and prisons, or who are being released, or who are at risk of being arrested, some similar problems encountered during deinstitutionalization may be able to be avoided.

Some Possible Strategies

The list of problems is formidable, but they can be resolved. There would need to be a very large increase in the number of community mental health services, including ACT and FACT teams and intensive case management; co-occurring disorder programs; administration of antipsychotic medications and mood stabilizers (especially important in reducing arrests for those who have problems involving control and violence); crisis response teams; appropriately structured and supportive housing; vocational rehabilitation; social rehabilitation; availability of acute care in the community; access to acute, intermediate, and long-term inpatient care when needed; more flexible civil commitment laws; and AOT when indicated. Many of these interventions are evidence-based practices. With a sufficient amount of all of these services being made available, the number of persons with serious mental illness being criminalized should drop significantly.

With the large numbers of persons with serious mental illness who first come to the attention of law enforcement officers, the opportunity to enter the mental health system should be given to those who are appropriate for diversion. Toward this end, there needs to be many more mobile crisis teams, such as CITs of specially trained police officers, who can find alternatives other than arrest and incarceration for such persons in crisis. There should also be increased education and training on mental illness and available mental health resources for law enforcement officers in general. Diversion after arrest may be accomplished in mental health courts, where persons with mental illness are sent to the mental health

system to obtain treatment in lieu of incarceration. It needs to be emphasized that pre and post-booking diversion can be effective only if there are adequate and appropriate mental health resources to which persons with serious mental illness can be diverted.

For those persons with serious mental illness who enter and remain under the jurisdiction of the criminal justice system, creating a successful treatment program for them is a difficult task that demands the input and cooperation of correctional and mental health professionals who are knowledgeable and accepting of the tenets of both the criminal justice system and mental health treatment. A close liaison among such varied professionals helps to maximize a successful outcome for offenders with mental illness. These persons should be provided with appropriate treatment while they are incarcerated and after they have been released into the community. Moreover, all such programs should be evaluated independently to determine which are effective and which are not, to ensure the best possible use of scarce resources.

Finally, a significant increase in mental health services, ranging from outpatient treatment and case management to highly structured 24-hour care, would no doubt result in far fewer persons with serious mental illness committing criminal offenses. There is an enormous stigma attached to people who have been in jails and prisons or in a forensic hospital. Such persons have been categorized as both mentally ill and as offenders, which makes it extremely difficult to place them in community treatment and housing.

In this time of decarceration, psychiatrists are poised to provide persons with serious mental illness the mental health treatment and supportive social services that were inadequately provided previously for so many, and thus led to their decompensation and criminal behavior. If the goals of reducing the criminalization of persons with serious mental illness are to be accomplished, the mental health and criminal justice systems must be provided with all the necessary resources and funding to identify and treat these individuals in the most appropriate setting. It cannot be emphasized enough that the criminal justice system should not be used as a substitute for the mental health system.

59 Psychiatric Education

▲ 59.1 Graduate Psychiatric Education

GEORGE ALAN KEEPERS, M.D.

Over the last 100 years, the education of physicians in the specialties of medicine has evolved from informal, unsystematized training of variable length and content into the highly regulated residency training programs that constitute the normal educational path for medical school students throughout the United States today. At times gradual, the development of these programs was changed dramatically by the influence of the Flexner report which resulted in the standardization of both undergraduate and graduate medical education and the adoption of a residency training model begun at Johns Hopkins University. Today, graduate medical education is undergoing another disruptive episode of evolution championed by the ACGME, the organization responsible for the accreditation of all residency training programs in the United States. In the past, training programs were standardized around the processes and contents of their clinical and didactic curriculum. The Accreditation Council on Graduate Medical Education's (ACGME) competency movement and its more advanced elaboration, the Milestones Project seek to use measures of the intermediate and final outcomes of residency training to judge the adequacy of training and of training programs.

This textbook has always covered the subject of psychiatric training but each author has developed the topic in a somewhat different fashion. In earlier editions, the role of the American Board of Psychiatry and Neurology in influencing training programs was emphasized by Lester Rudy and subsequently by Steven Scheiber. James Eaton, in contrast, emphasized the historical development of the field and the influence of the National Institute of Mental Health (NIMH) in providing funding and direction for the development of high-quality training programs. Most recently, Larry Faulkner reviewed the major organizations that influence psychiatric training programs, provided an overview of the organizational structures that regulate and determine the processes and content of

training programs, and addressed issues in psychiatric education that were then relevant.

At the time of the previous edition, as Faulkner noted, psychiatric educators faced a number of controversial issues, which he reviewed in some detail. Some of these issues have been resolved while others continue to be very actively discussed by psychiatric educators. The interference of service requirements in residency with residents' educational activities has been effectively eliminated by ACGME regulations which limit work hours, require protected time for education and incorporate residents' judgments regarding this issue into the Accreditation Council on Graduate Medical Education (ACGME) Psychiatry Residency Review Committee's (PRRC) evaluation of training programs.

Conflict in the training curriculum between biological psychiatry and psychotherapy education has been reduced by the field's consensus regarding the importance of both and by the specification in the PRRC's Program Requirements (PRs) and residency training milestones (discussed below) of specific training requirements in both areas. The conflict between resident support and resident evaluation has also been softened by recent developments. Academic medical centers are increasingly developing resident support systems which exist outside of departmental structures. The movement toward competency-based education embodied in the milestones supports a developmental rather than summative or judgmental approach to residency training. Nonetheless, balancing the provision of specific feedback based on high expectation while maintain a positive, nurturing environment for residents remains a challenge.

While ABPN certification following residency remains nominally voluntary, two developments in the field have pressured residents and programs toward 100 percent participation in certification. First, many, if not most, health systems are now requiring American Board of Medical Specialties (ABMS) specialty certification as a condition of credentialing. Secondly, the PRRC's PRs, which took effect in July of 2015, require that programs maintain a 70 percent pass rate on the certification examination for their graduates.

One issue raised in the previous edition remains a significant area of controversy. The limitation of duty hours and reduction in the clinical responsibilities assigned to residents has had the unintended consequence of reducing residents' continuous contact with patients and delays their maturation as independent practitioners. It is even uncertain as to whether the reductions in work hours has led to the intended improvements in patient safety because of the multiplication in transitions of care required in the new paradigm. The ACGME is currently studying this issue.

This chapter adopts an historical approach to the topic of Graduate Psychiatric Education (GPE). The history of psychiatric training will be described, the development of the organizations responsible for regulating

it will be reviewed, and the content and structure of residency training as it now exists will be described. Several recent changes in the conduct of GPE will be discussed and the above and other controversial topics reviewed.

HISTORY OF PSYCHIATRIC EDUCATION

Early History

Prior to Abraham Flexner's 1910 report for the Carnegie Foundation, medical education in the United States was in an abysmal state. There were no established standards for undergraduate medical education, no requirements for graduate medical education and little to no regulation of the practice of medicine. Different medical traditions including allopathy, osteopathy, and naturopathy provided highly varied training experiences. Physicians might then go directly into practice or seek employment, sometimes under the guidance of a more senior physician who had a particular interest. It was not unusual for physicians to practice in fields for which they had no particular training and for their interests and practice to shift during the course of their careers. Those engaged in what is now called psychiatric practice in the United States fell into two camps—on one hand, the alienists, and on the other, the physicians who conducted ambulatory practices in nervous conditions. These divisions were not original to the United States but were rooted in developments in the field in Europe. The "spa physicians" made great efforts to assert that their clients and practices were different from the mentally ill. The "alienists" explicitly dealt with severely ill patients and were involved, often as superintendents, with newly developed institutions, frequently state sponsored, which specialized in the care of severely mentally ill individuals. Originally innovative and providing access to moral treatment, these institutions became so overcrowded that they were at best able to provide custodial care.

Many physicians, of varying interests, practiced and trained in these settings. For example, Dr. James Hawthorne, who established such an institution in Portland, Oregon, was typical of the physicians of this era. A native of Pennsylvania, he began his study of medicine under the tutelage of a local physician Dr. Bascom, later obtaining a medical degree from the Medical University in Louisville, Kentucky. He opened a general practice in Louisville, which became very successful, and repeated this success in California, starting in 1850. He moved to Portland in 1857, opening a general practice, and subsequently established the Oregon Hospital for the Insane. The Hawthorne hospital eventually had 450 psychiatric beds and was supported on the basis of a contract with the state legislature. It was regarded as one of the finest such institutions in the United States, and Dr. Hawthorne, who had no formal training in psychiatry, was known as an expert in the illnesses of the mind. He was a member of the Association of Medical Superintendents of American Institutions for the Insane

(organized in 1844), which became the American Psychiatric Association in 1921. Many physicians practiced at the Hawthorne hospital. Most notably, Simeon Josephi came to the hospital and worked under Dr. Hawthorne's supervision. Dr. Josephi left his employment at the hospital to found the Oregon Medical School in 1863. This type of fluid arrangement for training and practice was typical of the times.

Influence of the Flexner Report

Unfortunately, but not surprisingly, this unregulated system led to the public being subjected to poorly trained physicians, naturopaths, and snake oil salesman all claiming to be legitimate medical practitioners. The American Medical Association (AMA) was organized in 1847 originally to deal with the lack of regulations and standards in medical education and medical practice. Despite the establishment of residency training programs at Johns Hopkins University in 1889, progress was quite limited until the Carnegie Foundation employed Abraham Flexner to study the condition of medical education in the early 1900s. The current system of undergraduate and graduate medical training was founded on Flexner's 1910 report.

Governmental and professional regulatory mechanisms soon followed and have proliferated into a complex group of organizations affecting GPE today. This resulted in the closure of inadequate schools and established allopathy and osteopathy as the only legitimate basis for medical training. Flexner strongly favored the residency program established by Johns Hopkins, and this became and has remained the framework for all residency training in the United States (Table 59.1–1).

Following the Flexner report several specialties (Ophthalmology, 1916; Otolaryngology, 1924; Obstetrics and Gynecology, 1930; Dermatology and Syphilology, 1932) established boards for the purpose of describing training in the specialty and examining candidates for certification. The American Board of Psychiatry and Neurology (ABPN) was established in 1934 as a collaborative effort of the APA, the American Neurological Association (ANA), and the AMA. Originally, like other Boards, the ABPN both accredited training programs and certified practitioners.

Table 59.1–1.
Major Organizations Affecting GPE

Organization	Abbreviation	Responsibility
American Association of Directors of Psychiatric Residency Training Programs	AADPRT	Promotion of excellence in psychiatric training; resources for program directors; organizes input to ACGME and ABPN from the field.
Association of American Medical Colleges	AAMC	Association of medical schools, teaching hospitals, and academic societies; improvement of health through enhancing effectiveness of academic medicine

American Board of Medical Specialties	ABMS	Coordination of activities for specialty boards
American Board of Psychiatry and Neurology	ABPN	Certification and maintenance of certification of psychiatrists and neurologists
American College of Psychiatry	ACP	Honorary society; develops Psychiatric Resident-in-Training Examination (PRITE); awards for outstanding residents and training programs.
Accreditation Council for Continuing Medical Education	ACCME	Approval of continuing medical education programs
Accreditation Council for Graduate Medical Education	ACGME	Development of residency training Program Requirement (PRs), milestones, accreditation of institutions and residency training programs
American Medical Association	AMA	Largest professional medical association; advocacy for patients and profession
American Osteopathic Association	AOA	Accreditation of osteopathic schools and residencies
American Association of Colleges of Osteopathic Medicine	AACOM	Coordinates and advocates for osteopathic medical schools; centralized services.
American Psychiatric Association and state psychiatric associations	APA	Professional association for psychiatrists; multiple educational efforts for students, residents, practitioners; advocacy for patients and the profession
Educational Commission for Foreign Medical Graduates	ECFMG	Credentialing of international medical graduates for training in the United States
Federation of State Medical Boards	FSMB	Coordinates activities of state licensing boards.
Liaison Committee on Medical Education	LCME	Accreditation of medical schools
National Board of Medical Examiners	NBME	US National Medical Licensure Exam (USMLE) for medical students and residents required for licensure
National Residency Matching Program	NRMP	Regulates recruitment of residents. Matches residents and programs.

Establishment of the Accreditation Council on Graduate Medical Education

The burden imposed on the Boards by the accreditation of training programs was substantial and in 1940 the AMA Council on Medical Education, the American Board of Internal Medicine, and the American College of Physicians established the Conference Committee on Graduate Training in Internal Medicine, a forerunner of the ACGME Residency Review Committees (RRCs). The American College of Surgeons and American Board of Surgery established their own accreditation bodies in 1949.

Academic educators soon realized that, with the establishment of Medicare and federal funding for residency training, the several accrediting organizations then in existence with widely varying standards for approval of training programs were not tenable and required reform. The case for

uniformity of standards with national scope was supported by the AMA, other medical groups, and the government. In 1972, the AMA sponsored the ABMS, the AHA, the AAMC and the Council of Medical Specialty societies to form a Liaison Committee for Graduate Medical Education (LCGME) to coordinate the activities of the independent RRCs then in existence. The failure of this effort indicated that an independent, self-sustaining organization was required to accomplish these tasks and the ACGME replaced the LCGME in 1981. The ACGME was charged with the responsibility for the accreditation and monitoring of residency programs throughout the United States. In the subsequent years, the current system of RRCs, program requirements, and periodic accreditation site visits was developed.

The evolution of the ACGME PRs in psychiatry has been a collaborative effort between the ACGME, the ACGME PRRC, psychiatric professional organizations, and the ABPN. This has resulted in more-uniform, higher-quality training throughout the United States and an alignment between completion of an accredited residency and eligibility to take the ABPN certification examination. Beginning in 2010, the ACGME undertook a major revision of the methods used to evaluate residents and training programs. Entitled the Next Accreditation System (NAS), this new system exchanges yearly reviews of data from all programs with the selection outliers for the old system of in-depth reviews of programs every 5 years following site visits. The details of this system are discussed below.

The American Board of Psychiatry and Neurology

The ABPN retained the task of certifying graduates of accredited training programs in psychiatry and neurology. The ABPN, like the other 24 specialty boards of the ABMS, is a nongovernmental, independent organization governed by a board of directors (Table 59.1–2).

The board is comprised of eight psychiatry directors and eight neurology directors, each of whom serve two 4-year terms (Table 59.1–3). Candidates for selection as psychiatry directors are solicited from the APA, the American College of Psychiatry (ACP), and the AMA. The ANA and the American Academy of Neurology (AAN) nominate candidates in neurology. Current directors of the board may also nominate candidates.

Table 59.1–2.
The 24 Member Boards of the American Board of Medical Specialties (Year Approved in Parentheses)

Allergy and Immunology (1971)[a]
Anesthesiology (1941)
Colon and Rectal Surgery (1949)
Dermatology (1932)

Emergency Medicine (1979)
Family Medicine (1969)
Internal Medicine (1936)
Medical Genetics (1991)
Neurological Surgery (1940)
Nuclear Medicine (1971)
Obstetrics and Gynecology (incorporated 1930)
Ophthalmology (incorporated 1916)
Orthopedic Surgery (1935)
Otolaryngology (incorporated 1924)
Pathology (1936)
Pediatrics (1935)
Physical Medicine and Rehabilitation (1947)
Plastic Surgery (1941)
Preventive Medicine (1949)
Psychiatry and Neurology (1934)
Radiology (1935)
Surgery (1937)
Thoracic Surgery (1971)
Urology (1935)

[a]Conjoint board sponsored by the American Board of Internal Medicine and the American Board of Pediatrics.

Certification methods have changed through the years and these changes are detailed elsewhere in this text. Two most recent developments are of great importance to psychiatric educators. As this text is in print, the last ABPN oral examination in general psychiatry will be given. The oral examination in child psychiatry will be discontinued not long afterwards. The new certification examination in General Psychiatry has proven to have very high reliability, with passage rates that are similar to those of the old Part I examination (Table 59.1–4).

Going forwards, all of the ABPN's examinations in the core specialties of psychiatry, child psychiatry, and neurology, as well as the subspecialties, will be single certification examinations conducted at testing centers throughout the United States. Psychiatric residency training program must certify the credentials of their graduates through the computerized ABPN PreCert system as a condition of eligibility to take the examination. Data from this system makes it feasible to accurately ascertain the quality of residency training programs as measured by certification examination passage rates for individual programs.

Performance of Candidates on the New ABPN Certification Examination

Year	Candidates	Passed (%)
2011	856	744 (87)
2012	1,288	1,091 (85)
2013	1,513	1,265 (84)
2014	1,867	1,675 (90)

Also of interest is the ABPN's return to a role in accreditation of residency training programs. The ABPN collaborates with other ABMS boards to develop a number of combined educational programs that are not ACGME accredited. The core programs contributing to the training are ACGME accredited programs but the training track for residents in the two programs is not. Residents complete training in these programs in less time than it would take to complete the specialty training programs separately. These programs include training that leads to certification in psychiatry and neurology, psychiatry and internal medicine, and psychiatry and family medicine. The Triple Board Program was established as a collaboration between the ABPN and the American Board of Pediatrics (ABP) in 1984. Graduates of these programs may take the certification examinations in psychiatry, child and adolescent psychiatry, and pediatrics.

A small but significant number of institutions offer these combined training programs. These programs cannot be accredited by the ACGME although the specialty programs which participate in them are reviewed and accredited by their respective RRCs. The ABPN has agreed to provide regular review and approval of the combined training programs in order to assure quality training for the residents in these programs and to assure

that graduates will be eligible to take the certification examinations in each specialty (Table 59.1–5).

The Subspecialties of Psychiatry. Child and Adolescent Psychiatry was the first subspecialty of psychiatry for which the ABPN developed a credentialing process and certification examination. Subsequently, nine other subspecialties were identified and the ABPN now certifies subspecialists in these areas (Table 59.1–6).

The ABMS has specific criteria for the establishment of new subspecialties, and approval for their inclusion must be obtained from that organization. All of the subspecialties in psychiatry, except Brain Injury Medicine, which is still in the grandfathering period, require completion of an ACGME accredited residency. The ACGME PRRC accredits Child and Adolescent, Geriatric, Forensic, Psychosomatics, and Addiction residencies. The other residencies are administered by other boards. All of the subspecialties are 1-year fellowships, except for Child and Adolescent Psychiatry, which is a 2-year program. Residents may enter Child and Adolescent Psychiatry during any part of a General Psychiatry program. One year of training may be counted for both programs, enabling completion of both programs in 5 years rather than 6. A current subject of discussion in the field is whether to allow completion or partial completion of the other subspecialty fellowships in the fourth year of the general residency. All of the subspecialty certifications require taking a single computerized certification examination except for Child and Adolescent Psychiatry. That specialty has traditionally had a Part II oral examination, which will be eliminated by the end of 2016.

Table 59.1–5.
ACGME Combined Specialty Track Programs in 2015

Name	Number of Programs	Number of On-Duty Residents
Internal medicine/Psychiatry	14	81
Psychiatry/Family Medicine	7	49
Peds/Psych/Child and Adolescent Psychiatry	10	87
Psychiatry/Neurology	7	20

Table 59.1–6.
American Board of Psychiatry and Neurology (ABPN) Subspecialties in Psychiatry and Year of First ABPN Examination

Subspecialty	Year of First Examination

Sleep Medicine[b]	2007
Hospice and Palliative Medicine[b]	2008
Brain Injury Medicine[b]	Pending as of 2015

[a]Interdisciplinary specialty involving psychiatrists and neurologists.

[b]Interdisciplinary subspecialties involving ABPN and other American Board of Medical Specialties member boards.

Many subspecialties are developed collaboratively between several ABMS boards. Sleep medicine is an example of such a subspecialty. One of the boards will take the lead in administering the subspecialty and developing the certification examination. Each member board is responsible for credentialing candidates from their own specialty. As new subspecialties are recognized by the ABPN and ABMS, a grandfathering period, usually 5 years, is allowed during which candidates who meet established criteria for experience in the subspecialty area may take the certification examination without completing a residency. After this period expires, candidates must complete appropriate residency training programs to be eligible to take the exam.

The number of core psychiatry subspecialty programs and subspecialty residents has not kept pace with the increase in the numbers of general programs and residents. Except for Child and Adolescent Psychiatry, these programs have fewer than 75 residents in training each year. This is problematic from the standpoint of providing an adequate workforce particularly in geriatric and addiction psychiatry. The failure to interest sufficient numbers of residents in subspecialty fellowship training is the subject of considerable discussion and distress for the profession (Table 59.1–7).

The American Board of Medical Specialties

In 1933, the American Hospital Association (AHA), the Association of American Medical Colleges (AAMC), the Federation of State Medical Boards (FSMB), the American Medical Association (AMA), the National Board of Medical Examiners (NBME), and representatives of the four specialty boards in existence at that time (Ophthalmic Examinations, Otolaryngology, Obstetrics and Gynecology, and Dermatology and Syphilology), established the Advisory Board for Medical Specialties. Originally the ABMS was to serve as an advisor to the Boards, a forum for discussion of common problems, and a coordinator of board work when feasible. When expressly delegated by the Boards, the ABMS was to assume control over common policies and procedures. The organization was restructured in 1970 into the American Board of Medical Specialties. The

AHA, AAMC, FSMB, AMA, and NBME, along with the Council of Medical Specialty Societies (CMSS), the Accreditation Council for Graduate Medical Education (ACGME), and the Educational Commission for Foreign Medical Graduates (ECFMG), continue to serve as associate members of the ABMS. The ABMS has in recent years assumed a more directive role with its 24 member Boards. In particular, the ABMS has established standards which the boards are required to follow, specifying what steps diplomats of the boards must take in order to maintain their certification. These Maintenance of Certification (MOC) programs currently consist of four elements: professional standing (medical licensure), continuing medical education (CME), self-assessment (SA), and performance in practice (PIP), which includes patient and peer feedback and systematic evaluation of the diplomat's clinical care. Additionally, all diplomats of the boards must document completion of a patient safety course.

Table 59.1–7.
Subspecialties of Psychiatry Showing the Number of Programs and the Number of Residents in Programs from 2008 to 2014

		2008	2009	2010	2011	2012	2013	2014
General	Programs	182	184	182	182	184	188	193
	Residents	4,800	4,848	4,952	4,997	5,014	5,200	5,286
Child	Programs	122	124	122	124	124	123	124

Psychosomatic	Programs	44	48	53	54	53	54	54
	Residents	52	58	60	79	53	89	87

In conjunction with the ACGME, the ABMS and some member boards have begun to offer US training standards and practitioner certification abroad. Singapore was the first country to request this program and now has a robust program of residency training and certification for several specialties that is similar to the US equivalents.

The Liaison Committee on Medical Education

Interestingly, accreditation processes for undergraduate medical education were unified later than the initial wave of certification for specialists. The Liaison Committee on Medical Education was not founded until 1942. Prior

to its founding, the AMA's Council on Medical Education and Hospitals inspected and approved medical schools and approved hospitals for internships. The AAMC approved medical schools for membership in the AAMC. Leaders of the AAMC and the AMA, in an effort to avoid duplication of effort, assure quality of training, protect medical students from the wartime draft, and counteract pressures to shorten medical training, established the LCME at a meeting in Chicago. The LCME established and has maintained the standard that made psychiatric education and rotations one of the required experiences for all medical students. This standard has been critical to maintaining an appropriate place for psychiatric education in the medical school curriculum when it has been challenged on intellectual, and more recently economic grounds.

PSYCHIATRIC EDUCATION TODAY

Resident Recruitment and the NRMP Match

Postgraduate psychiatric education today begins with what everyone calls "the Match." Prior to the establishment of The National Resident Matching Program (NRMP), enrollment in a residency training program depended on individual negotiations between graduating medical students and the training program's director. Students were often pressured to accept a position in a program immediately, frequently before they had had an opportunity to interview for and consider other programs. The NRMP was established in 1952 in an effort to prevent these abuses and provide a level playing field for all of the programs and applicants. The NRMP is governed by a board of directors, with nominees from the ABMS, the AMA, the AAMC, the AHA, the CMSS, the AAMC Organization of Student Representatives, the American Medical Student Association, the AMA Medical Student Section, and the Consortium of Medical Student Organizations.

Each year, the recruitment process, in anticipation of the NRMP match day in March, preoccupies most GPE program directors, senior medical students, and many current residents who are very interested in the younger colleagues who might join them in their residency program. Selecting and recruiting strong candidates for residency training is a critical task for departments. Successful recruitment benefits the department's training program, its future faculty, and the communities which depend on the department for the services of its graduates. Ideal candidates, like those described by Johann Christian Reil in 1803, are the subject of intense competition between training programs.

"Perspicacity, a talent for observation, intelligence, good will, persistence, patience, experience, an imposing physique, and a countenance that commands respect. All those qualities required for the cure of the insane are so rare as to make the staffing of institutions

difficult."

It is not much of an exaggeration to say that good residents make good teachers and good training programs. Bright, enthusiastic, conscientious residents are rewarding to teach and contribute to a stimulating scholarly environment. Unfortunately, residents who display the opposite characteristics can cast a pall over the entire training program.

The NRMP has specific guidelines that govern the interview and recruitment process for residency applicants, and all GPE programs and medical students must agree to comply with them in order to participate in the NRMP match. The NRMP has established a uniform date of appointment for graduate medical education positions and a system for matching medical students and residency training programs that depends on lists that rank program preference (by the applicants) and applicant preference (by the programs). These lists are computer matched to produce the best possible outcome for both parties. Each year, about 18,000 US medical students participating in the NRMP match and about 30,000 "independent" applicants apply for approximately 30,000 positions in over 4,000 graduate medical education programs across the United States. "Independent" applicants include former graduates of US medical schools, US osteopathic students, Canadian students, and graduates of international medical schools.

Table 59.1–8.
PGY-1 Match Rates

			Percent Matched		
Year	Positions	Total Applicants	US Seniors	IMGs	All
1990	20,101	19,004	93.3	59.7	83.7
1995	20,751	22,936	92.7	50.5	77.9
2000	20,598	25,056	93.9	38.5	73.4
2005	21,454	25,348	93.7	55.6	78.0
2010	22,809	30,543	93.3	39.8	71.2
2011	23,418	30,589	94.1	40.9	73.2
2012	24,006	31,355	95.1	40.6	73.1
2013	26,138	34,355	93.7	47.0	73.5
2014	26,678	34,270	94.4	49.6	75.0

Since 1995, the number of applicants for these positions has substantially exceeded the number of positions. This trend has accelerated over the last 10 years with the inclusion of many more US IMGs and Osteopathic medical students in the match. This has produced substantial anxiety on the part of today's applicants regarding their likelihood of obtaining a residency position. In fact, the probability of a graduate of a US institution succeeding in the Match has changed little over the last 25 years. About 94 percent of these graduates will match with a program they have

ranked. Other candidates have cause for considerable anxiety. They will succeed in obtaining a position less than 50 percent of the time. Most residency training programs in General Psychiatry fill their positions in the match. The proportion of residents from US medical schools is similar to what is found in Internal Medicine and Family Medicine residency training programs (Tables 59.1–8 and 59.1–9).

Funding of Residency Positions

The residency positions for which these candidates are competing are funded by a variety of means. The federal government is by far the biggest sponsor of training stipends through two means. First, teaching hospitals receive direct and indirect graduate medical education funding (DME and IME) directly from CMS. These payments are based on a complicated formula that takes into account the percentage of Medicare patients treated at the facility, the historical number of positions when the program was started, and regional cost variations. Many hospitals and universities have far more residents than are approved and funded under the "cap" allowed by this formula, and there are dramatic differences in reimbursement by region. The second mechanism is funds provided by the Veteran's Administration for residency positions, which in many programs provide a substantial number of stipends. State mental health divisions, community mental health centers, private hospitals, and other organizations also fund some residency positions. All of these organizations expect clinical services in return for the funds they provide. It is often very challenging for a program director to construct a program which satisfies the clinical service demands of the funders and provides the educational program required by the PRs of the ACGME PRRC.

Table 59.1–9.
Postgraduate Year 1 Psychiatry Positions Offered and Filled in the National Resident Matching Program (NRMP) Match (2010–2014)

Year	NRMP Positions Offered	Total Positions Filled (%)	Positions Filled by US Graduates (%)
2010	1,091	1,075 (98.5)	670 (61.4)
2011	1,097	1,068 (97.4)	640 (58.3)
2012	1,117	1,080 (96.7)	616 (55.1)
2013	1,297	1,282 (98.8)	681 (53.1)
2014	1,322	1,291 (97.6)	685 (51.8)

National Resident Matching Program, Results and Data: *2014 Main Residency Match®. National Resident Matching Program*, Washington, DC; 2014.

Program Requirements for Psychiatric Training

The ACGME's process for determining the requirements that programs

must meet involves obtaining extensive input from the field, revisions by the RRC followed by more feedback from the field, and subsequent revisions. The ACGME Committee on Requirements reviews the PRs and has the authority to withhold final approval. Increasingly the ACGME has sought to standardize the language and content of the PRs across specialties so that much of what is found in the psychiatric and psychiatric subspecialty PRs is the same as in other specialties. The PPRs cover the issues of institutional sponsorship and resources, qualifications of the program director and faculty, creation of an academic environment, necessary clinical experiences, mandatory educational curriculum, work conditions, evaluation of residents, evaluation of the program and faculty, and specific outcomes in the language of the ACGME competencies. Recently, the process of evaluation residents has become much more systematic with the development of the milestones (discussed later in this chapter).

Institutional Requirements. Institutions must make a substantial investment in their residency training programs in order to become ACGME-accredited. Institutional accreditation is required before any residency training program can be approved. The institution must appoint a Designated Institutional Official (DIO) who has authority and responsibility for the oversight and administration of the institution's ACGME accredited programs, and is ultimately responsible for compliance with the ACGME Institutional, Common, and Specialty Program Requirements. The institution must also establish a Graduate Medical Education Committee (GMEC) which conducts annual program reviews on all residency training programs and in general is responsible for the maintenance of a safe and effective learning environment. Many other aspects of institutional investment are mandated, including sections on resident contracts, work environment, learning environment, and responsiveness to ACGME oversight. The ACGME has recently started a new program of institutional review entitled Clinical Learning Environment Review (CLER). The purpose of this review is to assess the graduate medical education (GME) learning environment of each sponsoring institution and its participating sites. A site visit is conducted during which the site visitors assess the institution through direct observation and interviews of residents and other personnel. This program duplicates much of the work of the Joint Commission on Hospital Accreditation (JCAHO).

The PPRs further elaborate what is required to conduct a psychiatric residency training program. The subspecialty PPRs are similar and will not be separately covered. The requirements include special provisions addressing the physical facilities which are necessary for psychiatric training. Adequate office space for interviewing patients and equipment for

recording sessions with patients are examples of these types of requirements. The types, length, and supervision of clinical experience specific to psychiatry are detailed in the PPRs, as are certain aspects of the ACGME competencies.

The Program Director. The PPRs specify that the residency training program director (PD) must be an ABPN-certified psychiatrist with sufficient administrative and educational experience to take on the challenging task of leading the program. The PD is expected to have full authority over the program and to have sufficient tenure in the position to be effective. Core duties of the PD are mandated in the PRs. These include the selection of training sites and development of program letters of agreement (PLAs) between external sites and the sponsoring institution. The PD must appoint a site coordinator and faculty for each rotation. The PD is responsible for conducting regular evaluations of the rotations and of the faculty and for removing faculty from their teaching roles if necessary. The PD must select residents for the program, evaluate their performance, monitor their stress and provide for twice-yearly formal evaluations. Compliance with ACGME and institutional policies and procedures, particularly those concerning limitations of duty hours and grievance procedures, is required. A summative evaluation at the end of residency training is required and the resident's rotations and educational experiences must be conveyed to the ABPN at the end of residency to assure eligibility to take the certification examination. The PRRC has, not surprisingly, required that the institution fund and the PD devote at least one half of their efforts to the training program. Success in this highly technical and demanding position requires at least this much effort.

The Faculty. Psychiatric faculty in an RTP must also be certified by the ABPN, have a strong interest in education, and devote sufficient time to fulfill their supervisory and educational duties. Other teaching physicians should be certified by their specialty board. Nonphysician faculty must have completed training, certification, and licensure appropriate to their profession. Maintenance of an academic, scholarly environment is critical to the success of the educational program. All of the faculty should regularly participate in clinical teaching rounds, conferences, grand rounds, journal clubs, and other activities common to the academic setting. Some of the faculty must be engaged in research activities. Demonstration of the faculty's scholarship may be through acquisition of peer-reviewed funding, publication of peer-reviewed articles, other publications, presentations at regional and national meetings, and participation and leadership in regional and national professional organizations.

Clinical Experiences. The clinical experiences that psychiatric residents

must have during residency are listed in Table 59.1–10. Note that the first year of residency, the internship, must include 4 months of experience in a primary care setting. The purpose and format of the primary care experience are subjects of considerable debate in the field at this time. Currently, most residents complete these experiences on inpatient Internal Medicine wards caring for very ill patients for a brief period of time. These clinical situations are unlikely to be encountered regularly in practice by most psychiatrists. They do, however, have a formative effect on the resident's identity as a physician. Experience in ambulatory or integrated care settings may prove to be more valuable to the psychiatrists of the future.

Table 59.1–10.
Required Graduate Psychiatric Education Clinical Experiences

Experience	Months Required
Primary care	4
Neurology	2
Inpatient psychiatry	6–16
Outpatient psychiatry	12
Child and adolescent psychiatry	2
Geriatric psychiatry	1
Addiction psychiatry	1
Consultation/liaison psychiatry	2
Forensic psychiatry	—[a]
Emergency psychiatry	—[a]
Community psychiatry	—[a]

[a]Required experiences without specific time requirements.

Most programs include the required 2 months of experience in neurology in the first year, leaving 6 months which is usually comprised of required psychiatric rotations. Inpatient experiences must include at least 6 months with direct responsibility for the care of acutely ill general psychiatric patients. A wide variety of settings are acceptable for this experience including traditional inpatient wards, research wards, and day treatment programs. The outpatient requirement of a year must include longitudinal treatment of patients with multiple modalities. Some of the resident's patients must be seen weekly under supervision for psychotherapeutic treatment. Forensic, emergency, and community psychiatry experiences are not required to have a minimum duration but must include certain key experiences. For example, in their emergency psychiatry experience, residents must evaluate, manage, and triage acutely ill psychiatric patients. Elective opportunities that enhance and specialize residents training experiences must be available. These are usually provided in the more senior years of the residency (Table 59.1–10).

A unique aspect of the PPRs is the ability to double-count certain experiences for the completion of both the general and child and adolescent residencies. This enables residents to complete training in general and child psychiatry in only 5 years. One month of child neurology, pediatric consultation, addiction psychiatry, and 20 percent of the resident's ambulatory psychiatry experience may be double-credited and the experiences in community and forensic psychiatry can count for both programs. This feature, recognized by the ABPN as a legitimate path to eligibility for board certification, has been important to the successful recruitment of residents into child and adolescent training programs.

Didactic Curriculum. A formal didactic curriculum must be provided for the residents during training. The PD is expected to establish goals and objectives for the curricular components that are couched in terms of the ACGME competencies. These have now been considerably elaborated and are covered in the section below entitled Psychiatric Milestones. The curriculum must be designed in a progressive manner that enables resident progression in their knowledge of the field. It is not acceptable to provide the same seminar material to all of the residents. The time for the didactics must be protected from clinical duties so that resident attendance is not compromised. The program must document that resident attend at least 70 percent of these didactic sessions.

Evaluation of Residents. Due to recent radical changes in the process of program evaluation discussed below the process of resident evaluation in training programs has drastically changed. The ACGME now requires programs to report on each resident's progress twice yearly. A requirement for a Core Competencies Committee (CCC) has been established. The PD is expected to appoint the CCC which must consist of at least three faculty members. Residents may not be members of the CCC. The committee must utilize evaluations provided by clinical supervisors and other personnel on rotations, test scores from the PRITE examination, Clinical Skills Examinations (CSEs), and other evaluative methods. The CCC must rate each resident on the milestones semiannually and these ratings must be reported to the ACGME. These evaluations are developmental in approach and indicate areas of strength and weakness. The resident, PD, and faculty are expected to work collaboratively to improve resident performance in areas of relative weakness.

Summative evaluations at the end of residency must be recorded so that there is a record of the resident's completion of all required rotations, attainment of sufficient competency on the ACGME competencies to enable independent practice and ethical and professional behavior. Uniquely in psychiatric (and neurological) training, successful completion of clinical examinations, in which the resident interviews a patient while attaining

and maintain rapport, conducts a mental status examination, and presents the data collected in an organized fashion, is required by the ABPN for eligibility to take the board examination. Residents must successfully complete at least three such evaluations during residency. This in-residency oral examination was established by the ABPN as a requirement for eligibility to take the certification examination and is in the PPRs. It replaces Part II of the old board examination. The residency program must provide all of this data to the ABPN through the PreCert system to ensure the eligibility of the resident to take the board examination.

The Psychiatry Milestones

In 1999, the ACGME and ABMS, realizing that medical practice required more than medical knowledge and skill in patient care and procedures established additional competencies which physicians are expected to attain during the course of their training. These competencies should be regarded as desired outcomes that medical training produces. The six Core Competencies are Patient Care, Medical Knowledge, Practice-Based Learning and Improvement, Interpersonal and Communication Skills, Systems-Based Practice, and Professionalism. Requirements for inclusion of training in these areas are included in all of the ACGME PRs and describe behaviors, attributes, or outcomes that must be demonstrated by residents as they advance in training. For example, in the competency of Professionalism: "Residents must demonstrate a commitment to carrying out professional responsibilities and an adherence to ethical principles. Residents are expected to demonstrate: compassion, integrity, and respect for others; responsiveness to patient needs that supersedes self-interest; respect for patient privacy and autonomy; accountability to patients, society and the profession; sensitivity and responsiveness to a diverse patient population, including but not limited to diversity in gender, age, culture, race, religion, disabilities, and sexual orientation; and (specialty-specific outcomes)."

The milestones for residency training represent the next iteration in specifying the outcomes rather than the processes of residency training. Detailed accounts of the development of the ACGME milestones project have been published in the *Journal of Graduate Medical Education* and the *New England Journal of Medicine*. In brief, public and political concern about the outcomes of medical training resulted in call for reform from the Institute of Medicine (2000), Council on Graduate Medical Education (2007), Josiah Macy Jr. Foundation (2011), and Medicare Payment Advisory Commission (MedPAC) reports (2011). The ACGME response to this crisis in 2008 was to require the creation of milestones describing resident progress in the Core Competencies for all specialties. This project was conceived as a method for evaluation of individual resident progress that would be uniformly applied across the United States

and as a method to evaluate the efficacy of residency programs in producing the desired outcomes.

Internal Medicine, Pediatrics and Surgery were the first specialties to begin milestone development in 2009. In 2011, psychiatry and the other remaining specialties began development with the goal of completion of all specialty milestones by 2014. Representatives from the ABPN, APA, AADPRT, and ACGME selected individuals to participate in milestone development for psychiatry, and the Working Group and the Advisory Group were formed (Table 59.1–11).

The Working Group was charged with milestone development and began meeting in December of 2011. The Advisory Group reviewed this work and suggested potential improvements. The development of milestones required five meetings and numerous conference calls over the course of the next 2 years. Extensive feedback from the field was sought as part of this process and was incorporated into the final documents. Details of the Psychiatry Milestone development process have been published in Academic Psychiatry.

The milestones are intended to allow faculty to rate the development of a resident's skills, ability, knowledge, attitudes, and behavior in achieving the ACGME competencies during training. They are developmental in nature. Basic skills in an area are expected at the beginning of training. Residents are expected to enhance these skills and, by the end of residency, attain a level of accomplishment that will allow independent practice. The milestones are organized for the purpose of rating resident accomplishment into five levels. Level 1 corresponds to what is expected of

a beginning resident. As residents complete their rotations and educational experiences, they are expected to attain Levels 2 and 3 as intermediate stages of accomplishment. It is important to note that the levels in the milestones do not correspond to PGY levels. Residents will progress at different rates within a program and programs differ in what experiences they offer residents in each year of residency training. By completion of residency, residents will on average have progressed to Level 4 on most milestones. This accomplishment, however, is not sufficient for graduation. The milestones do not measure every quality that is important and the PD must make an independent judgment on the readiness of the graduating resident for independent practice (Table 59.1–12).

Table 59.1–12.
Description of the ACGME Milestone Levels

Has not Achieved Level 1: The resident does not demonstrate the milestones expected of an incoming resident.

Level 1: The resident demonstrates milestones expected of an incoming resident.

Level 2: The resident is advancing and demonstrates additional milestones, but is not yet performing at a mid-residency level.

Level 3: The resident continues to advance and demonstrate additional milestones; the resident demonstrates the majority of milestones targeted for residency in this sub-competency.

Level 4: The resident has advanced so that he or she now substantially demonstrates the milestones targeted for residency. This level is designed as the graduation *target* and does not represent a graduation *requirement.* Making decisions about readiness for graduation is the purview of the residency program director.

Level 5: The resident has advanced beyond performance targets set for residency and is demonstrating "aspirational" goals, which might describe the performance of someone who has been in practice for several years. It is expected that only a few exceptional residents will reach this level.

In the milestones, each of the six ACGME Competencies contains sub-competencies that describe specialty specific elements of the general Core Competency. In the Psychiatry milestones there are 22 sub-competencies. There are an additional 66 subheadings in the milestones which are called "threads" (Fig. 59.1–1).

Sub-competencies describe the progression of specific skills, knowledge, or attributes in a single area such as psychiatric interviewing. The underlying milestones are organized into threads which describe the component skills of the sub-competency and the progression of these skills across the levels (Fig. 59.1–2).

The psychiatry milestones, sub-competencies, and threads are presented in Table 59.1–13.

Milestones for each of the subspecialties of psychiatry were completed after work on the general psychiatry milestones was finished. This work utilized the experience of the original milestone committee members who participated and chaired the subspecialty development committees to rapidly complete this task. A schematic outline of the subspecialty

milestones was created to assist the committees in their task. Committee members met for a single face-to-face working session at the ACGME headquarters in Chicago. The Advisory Committee reviewed the work accomplished at the meeting and provided suggestions. The Working Group subsequently accomplished the revisions through conference calls and online participation (Table 59.1–14).

FIGURE 59.1–1. Format of the psychiatric milestones. (From The American Board of Psychiatry and Neurology. *The Accreditation Council for Graduate Medical Education and the Psychiatric Milestone Project*. July 2015.)

PC1. Psychiatric Evaluation A: General interview skills B: Collateral information gathering and use C: Safety assessment D: Use of clinician's emotional response					
Has not Achieved Level 1	Level 1	Level 2	Level 3	Level 4	Level 5
	1.1/A Obtains general medical and psychiatric history and completes a mental status examination	2.1/A Acquires efficient, accurate, and relevant history customized to the patient's complaints 2.2/A Performs a targeted examination, including neurological examination, relevant to the patient's complaints	3.1/A Consistently obtains complete, accurate, and relevant history 3.2/A Performs efficient interview and examination with flexibility appropriate to the clinical setting and workload demands	4.1/A Routinely identifies subtle and unusual findings	5.1/A Serves as a role model for gathering subtle and reliable information from the patient 5.2/A, B Teaches and supervises other learners in clinical evaluation
	1.2/B Obtains relevant collateral information from secondary sources	2.3/B Obtains information that is sensitive and not readily offered by the patient	3.3/B Selects laboratory and diagnostic tests appropriate to the clinical presentation 3.4/B Uses hypothesis-driven information gathering techniques[2]	4.2/B Follows clues to identify relevant historical findings in complex clinical situations and unfamiliar circumstances	
	1.3/C Screens for patient safety, including suicidal and homicidal ideation	2.4/C Assesses patient safety, including suicidal and homicidal ideation 2.5/D Recognizes that the clinician's emotional responses have diagnostic value[1]		4.3/D Begins to use the clinician's emotional responses to the patient as a diagnostic tool

The Milestones are a product of the Psychiatry Milestone Project, a joint initiative of the Accreditation Council for Graduate Medical Education and the American Board of Psychiatry and Neurology.

FIGURE 59.1–2. Example of an actual sub-competency and its threads from the ACGME psychiatry milestones. Note how the threads describe progression of skills across the levels. (From The American Board of Psychiatry and Neurology. *The Accreditation Council for Graduate Medical Education and the Psychiatric Milestone Project*. July 2015.)

The psychiatry milestones represent a major paradigm shift in the overall approach that programs take to resident training and assessment because of their focus on outcomes and their specificity. Because of the process of development they represent a true consensus of psychiatric educators regarding what residents need to accomplish and what programs need to teach. This shift in emphasis is not, however, without its critics. They have pointed out correctly that there is no evidence that utilization of the milestones will actually produce better psychiatrists. Detractors advocate resident assessment methods that are based on actual patient outcomes. The critics would prefer that there be no change in educational methods until prospective studies establish that there will be a positive outcome. Acceding to such objections would essentially guarantee that postgraduate education remain frozen in its current state. The ACGME has instead adopted a program based on modern quality improvement methods, essentially a PDSA cycle.

Assessment of Residency Training Programs

The milestones were not only conceptualized as a method for evaluation of resident progress but are also intended to be used eventually as a method of programs evaluation, and there have been many other changes to the

accreditation process.

Incorporation of Osteopathic Training Programs. The ACGME is now responsible for the accreditation of all residency training programs in the United States. In 2014, the American Osteopathic Association (AOA) entered into an agreement with the ACGME to consolidate the accreditation of osteopathic residency training programs under the ACGME. AOA accredited programs may elect to apply for ACGME accreditation until 2020. AOA specialty board certification for faculty in these programs will be acceptable to the ACGME during the transition period. The programs may have a co-director certified by AOA specialty boards as long as the other co-director is ABMS-certified. The AOA and AACOM will be integrated into the governance structure of the ACGME and will become a nominating organization for candidates for membership on the RRCs. All of the RRCs which will review AOA programs for accreditation will have osteopathic members. The AOA may withdraw from this agreement by 2020. It remains to be seen how successful the integration of the AOA programs will be (Table 59.1–15).

Table 59.1–13.
Psychiatry Milestones

Competency	Sub-competencies	Threads
Patient Care	PC1. Psychiatric Evaluation	A. General interview skills B. Collateral information gathering and use C. Safety assessment D. Use of clinician's emotional response
	PC2. Psychiatric Formulation and Differential Diagnosis	A. Organizes and summarizes findings and generates differential diagnosis. B. Identifies contributing factors and contextual features and creates a formulation.
	PC3. Treatment Planning and Management	A. Creates treatment plan. B. Manages patient crises, recognizing need for supervision when indicated. C. Monitors and revises treatment when indicated.
	PC4. Psychotherapy refers to: (1) the practice and delivery of psychotherapies, including	A. Empathy and process

	psychodynamic, cognitive–behavioral, and supportive therapies; (2) exposure to couples, family, and group therapies; and (3) integrating psychotherapy with psychopharmacology.	B. Boundaries C. The alliance and provision of psychotherapies D. Seeking and providing psychotherapy supervision
	PC5. Somatic Therapies. Includes psychopharmacology, electroconvulsive therapy (ECT), and emerging neuromodulation therapies.	A. Using psychopharmacological agents in treatment B. Education of patient about medications C. Monitoring of patient response to treatment and adjusting accordingly D. Other somatic treatments
Medical Knowledge	MK1. Development through the life cycle (including the impact of psychopathology on the trajectory of development and development on the expression of psychopathology)	A. Knowledge of human development B. Knowledge of pathological and environmental influences on development C. Incorporation of developmental concepts in understanding
	MK2. Psychopathology. Includes knowledge of diagnostic criteria, epidemiology, pathophysiology, course of illness, comorbidities, and differential diagnosis of psychiatric disorders, including substance use disorders and presentation of psychiatric disorders across the life cycle and in diverse patient populations.	A. Knowledge to identify and treat psychiatric conditions B. Knowledge to assess risk and determine level of care C. Knowledge at the interface of psychiatry and the rest of medicine
	MK3. Clinical Neuroscience. Includes knowledge of neurology, neuropsychiatry, neurodiagnostic testing, and relevant neuroscience, and their application in clinical settings	A. Neurodiagnostic testing B. Neuropsychological testing C. Neuropsychiatric co-morbidity D. Neurobiology E. Applied neuroscience
	MK4. Psychotherapy refers to knowledge regarding: (1) individual psychotherapies, including but not limited to psychodynamic, cognitive–behavioral, and supportive therapies; (2) couples, family, and	A. Knowledge of psychotherapy: theories B. Knowledge of

	group therapies; and (3) integrating psychotherapy and psychopharmacology	psychotherapy: practice C. Knowledge of psychotherapy: evidence base
	MK5. Somatic therapies refers to medical knowledge of somatic therapies including psychopharmacology, ECT, and emerging somatic therapies, such as transcranial magnetic stimulation (TMS) and vagus nerve stimulation (VNS)	A. Knowledge of indications, metabolism, and mechanism of action for medications B. Knowledge of ECT and other emerging somatic treatments C. Knowledge of lab studies and measures in monitoring treatment
	MK6. Practice of Psychiatry	A. Ethics B. Regulatory compliance C. Professional development and frameworks
Systems-Based Practice	SBP1. Patient Safety and the Health Care Team	A. Medical errors and improvement activities B. Communication and patient safety C. Regulatory and educational activities related to patient safety
	SBP2. Resource Management (may include diagnostics, medications, level of care, other treatment providers, access to community assistance)	A. Costs of care and resource management
	SBP3. Community-Based Care	A. Community-based programs B. Self-help groups C. Prevention D. Recovery and rehabilitation
	SBP4. Consultation to nonpsychiatric medical providers and nonmedical systems (e.g., military, schools, businesses, forensic)	A. Distinguishes care provider roles related to consultation B. Provides care as a consultant and collaborator C. Specific consultative activities
Problem-Based Learning and	PBLI1. Development and execution of lifelong learning through constant self-evaluation,	A. Self-assessment and self-improvement

Improvement	including critical evaluation of research and clinical evidence	B. Evidence in the clinical workflow
	PBLI2. Formal practice-based quality improvement based on established and accepted methodologies.	A. Specific quality improvement project B. Quality improvement didactic knowledge
	PBLI3. Teaching	A. Development as a teacher B. Observable teaching skills
Professionalism	PROF1. Compassion, integrity, respect for others, sensitivity to diverse patient populations, adherence to ethical principles	A. Compassion, reflection, sensitivity to diversity B. Ethics
	PROF2. Accountability to self, patients, colleagues, and the profession	A. Fatigue management and work balance B. Professional behavior and participation in professional community C. Ownership of patient care
Interpersonal Communication	ICS1. Relationship development and conflict management with patients, families, colleagues, and members of the health care team	A. Relationship with patients B. Conflict management C. Team-based care
	ICS2. Information sharing and record keeping	A. Accurate and effective communication with health care team B. Effective communications with patients C. Maintaining professional boundaries in communication D. Knowledge of factors which compromise communication

The Next Accreditation System (NAS). Previously, the ACGME fulfilled its accreditation responsibilities through a system of regular review of programs by the RRC. Data were collected every 5 years for programs in good standing. The PD wrote a Program Information File (PIF) which covered every aspect of program operation in relation to the ACGME PRs. A site visitor would travel to the program and confirm the PIF with interviews with the PD, residents, and faculty. The RRC would then review the data at its meetings, issue an accreditation decision, and issue citations for areas judged out of compliance with the PRs.

The accreditation process has been drastically altered under the NAS. Implemented for seven pilot specialties (emergency medicine, internal medicine, neurological surgery, pediatrics, diagnostic radiology, and urology) in July of 2013, this system is now being used for all 26 ACGME core specialties. The NAS changes what has been described as a "biopsy" model into a program of annual data collection and review for every training program in the United States. The data sources for this review include an annual resident survey, faculty survey, and data entered by the program into the Accreditation Data Systems (ADS). For many specialties, case logs, and board certification pass rates are reviewed annually. It is anticipated that aggregate data from the milestones will be incorporated into the accreditation system after enough experience has been gained.

The data from these sources is statistically analyzed by the ACGME and outliers are identified for review on the basis of decision rules which are formulated by the RRCs. The data, program history, and previous ACGME actions are then reviewed by ACGME staff for presentation to the RRC. An RRC member conducts a review of the program and presents recommendations at the RRC meeting. The RRC may elect to continue the program's accreditation, continue accreditation with warning, or to ask for a site visit. Programs may be placed on probation following a site visit if problems with the program a very severe. The usual outcome of these reviews is to communicate to the program and its sponsoring institution that there are Areas for Improvement (AFIs) or to cite programs for noncompliance with the PPRs. AFIs are issues that may be dealt with by the program and its associated GMEC. Citations require, in addition, communication with the ACGME concerning the program's plan to remedy the problem. Programs with citations are automatically subject to annual

review by the RRC.

This system has the potential to identify and correct problems in training programs much earlier than the previous accreditation system. Additionally, its developers believe that it will encourage a more rapid pace of program improvement. Criticism of the new system has focused on the increased workload and expense required to comply with the new requirements and on the validity of the data, particularly the resident survey. Program directors have expressed concern that residents are often confused by the questions on the resident survey and may answer the questions differently when properly oriented. Some studies do indicate that significant differences exist between the results from internal resident surveys and the ACGME resident survey.

RELATION TO CHANGES IN MEDICAL EDUCATION

These changes in residency training are not occurring in isolation. The traditional system of medical education has been resistant to the incorporation of scientific developments in educational theory and performance improvement that have long been implemented in other educational and corporate settings. Future physicians can expect to be educated quite differently. Medical schools are incorporating the concepts of competency-based education and selecting students who will adapt better to the modern practices of team-based medicine. The requirement that students demonstrate competence at each stage of education is becoming universal. This will require a more flexible approach to the

medical school curriculum than currently exists. For example, students matriculate to medical school at varying degrees of readiness. Flexible preparatory curricula are needed to meet varying student needs for additional education prior to their first day of medical school. Ideally, the goal is for every student and every resident to be uniformly excellent, to deserve an A grade. The purpose of competency-based undergraduate and graduate medical education is to raise the level of performance and to reduce the variability in educational outcomes.

Following residency education and board certification, it is becoming mandatory that physicians maintain and improve their competence, incorporate new knowledge, and develop new skills throughout their careers. The ABMS and specialty board maintenance of certification programs are oriented to this goal. These developments in undergraduate, graduate, and postgraduate medical education are a veritable revolution in the way doctors will be educated. Medical educations past has been one of discrete episodes of learning with little assurance that competence has been attained or will be maintained. Its future is as a lifelong learning process with feedback mechanisms ensuring that physicians practice at a uniformly excellent level.

▲ 59.2 Examining Psychiatrists and Other Mental Health Professionals

JAMES MORRISON, M.D., AND RODRIGO A. MUñOZ, M.D.

During the march from undergraduate training through postgraduate work and on to board certification, psychiatrists and other mental health clinicians will be examined hundreds of times on material in which they have invested thousands of hours of study and practice. That much has remained constant over the years. What's changed has been the nature of the examinations themselves. Generations ago, they were either oral or, when written, true–false tests and even essays. For many years, the ABPN was nearly alone among professional boards in retaining a live-patient component. Now, this remnant of the past has been relegated to the training programs, a move many see as stimulating improvement in the art of patient evaluation.

The oral examination excepted, the story of psychiatric testing has been increasingly one of national—actually, international—examinations. With a growing need to compare the abilities of clinicians who have trained at different institutions, not to mention the expense of producing new testing material, examinations standardized throughout the United States and Canada are now a central feature of nearly every psychiatry training program.

The uses and consequences of all of this testing are varied. For some students, examinations serve as an important spur to greater study effort. For others, they may signal an evaluation of subject matter mastery or a rite of passage or initiation. In some ways, examinations also serve the institution or fellow professionals by evaluating the effectiveness of teaching and training programs. Testing may serve society as a whole by ensuring quality of the licensees. Less altruistically, testing and its attendant certification may help restrict competition for patients among different groups of professionals.

MAJOR PSYCHIATRY EXAMINATIONS

The ABPN examination in psychiatry has been administered yearly since 1935. Almost since inception, it was given orally, even including basic science facts. By the mid-1960s, increasing numbers of candidates, an exploding volume of information, and the increasing demand for a procedure that was both comprehensive and impartial complicated the logistics of an oral examination. The logical solution was a written examination, which, during its first several decades of use, became a relatively inexpensive screening device for the vastly more complex and expensive oral examination. As of this writing, the oral examination is being phased out, even for graduates of years ago, who, going forward, will have to satisfactorily complete three live-patient clinical skills evaluations

at a training site approved by the Accreditation Council for Graduate Medical Education (ACGME). Only then will they be able to sit for the board examination, which has evolved into a computerized, entirely cognitive affair.

Cognitive Examinations

The first ABPN examinations depended, in part, on essays. Essay questions are easy and inexpensive to write, and they can plumb the depths of a candidate's knowledge. They also have significant disadvantages. Time constraints limit the number of knowledge areas that can be tapped. A candidate unfamiliar with just one of, say, five questions may start out perilously close to failure. Essay grading is time consuming and nearly impossible to do with complete impartiality. Poor handwriting or language skills (the latter a problem for some international trainees), which has nothing to do with knowledge of psychiatry, may figure too prominently in the grading process.

The demise of the essay examination and a brief flirtation with a true-false component in the early 1940s cleared the way for various types of multiple-choice questions. Several variations on these questions now form the bulk of standardized cognitive psychiatry examinations administered throughout the western world.

The ABPN cognitive examination is administered in the fall of each year at Pearson VUE centers throughout the United States. The current cognitive examination lasts eight hours and comprises 480 computer-scored questions covering both psychiatry and neurology (Table 59.2–1). Time and questions are divided equally between morning and afternoon sessions, both of which include vignette, basic psychiatry, and neurology material. The examination is scored as a whole; it is not norm-referenced; theoretically, every candidate could pass.

The move to computerized testing has introduced computer features and keyboard behaviors with which candidates must become familiar prior to any examination. These include:

- "Next" and "previous" buttons move the candidate through a sequence of questions.
- A "flag for review" button allows items to be seen again later; this function is not available for vignette items.
- A navigator displays a list of flagged questions.
- A clock shows time remaining in the session, always displayed in minutes and seconds.
- Videos may require a response before the next screen can be shown.
- Other features include the ability to highlight or strike through text, pull down a scratch pad, make a comment to use later in the examination or to alert ABPN to some aspect of a question, and a drug list (generics and

some brand names) that can be accessed at any time during the examination. (Staff members review all comments after the test has ended.)

- Using more than the allotted 50 minutes of break time will decrease the amount of examination time available.

Table 59.2–1.
Written Examination for ABPN Psychiatry Candidates

As of 2017, candidates for the initial psychiatry examination must answer 480 questions that cover the following areas. The "plus numbers" indicate relative number of questions in each subsection.

Basic concepts in psychiatry
Development through the life cycle (2+)
Behavioral and social sciences (1+)
Epidemiology and public policy (1+)
Diagnostic procedures (1+)
Clinical aspects of psychiatric disorders (3+)
Treatment of psychiatric disorders (3+)
Special topics—suicide, dangerousness, risk management, seclusion/restraints, abuse and violence, consultation, professionalism/ethics (1+)

Neurology and neurosciences
Neural development through the life cycle (1+)
Basic neurosciences (1+)
Diagnostic procedures (1+)
Clinical aspects of neuropsychiatric disorders (3+)
Treatment of neuropsychiatric disorders (3+)
Diagnostic and clinical evaluation of neurologic disorders/syndromes (3+)
Management and treatment of neurologic disorders (2+)

Clinical psychiatry
Specific psychiatric disorders (3+)
Treatment of psychiatric and neuropsychiatric disorders (3+)
Ethics (1+)
Epidemiology (1+)
Interpersonal communication skills (1+)
Systems-based practice issues (1+)
Factors affecting prognosis or complicating treatment (1+)
Special topics—suicidality, dangerousness, seclusion/restraints, risk management, psychiatric consultation, and child abuse, sexual abuse, and domestic violence (1+)

Note: More details are available at www.abpn.com.

In addition to more traditional questions of the sort discussed early in this chapter, cognitive testing now includes video vignettes: 1-to-4-minute clips from patient interviews with written historical material. A video vignette will typically engender 5 to 10 multiple-choice questions, some of which may require more than a single response—the computer software will not allow a candidate to proceed until the correct number of responses has been entered. The content of some USMLE questions may depend on the answer given to the one before; in other words, an individual investigative trail may depend to a degree on the candidate's own

responses.

At one time, the board spent inordinate amounts of time and money fighting the very few lawsuits brought by unsuccessful candidates who preferred litigation to the effort of further preparation as a means for achieving certification. Such behavior has decreased in recent years and, to date, no unsuccessful candidate's lawsuit has ever succeeded. But the drive to achieve the status of certification is powerful: forged board certificates have been discovered, and a 2002 paper claimed that up to 18 percent of physicians misrepresent their clinical credentials.

The Oral Examinations

Perhaps because it is the most verbal of all the medical sciences, for years psychiatry clung tenaciously to the oral examination format. Now, however, the responsibility for witnessing the examination of live patients has devolved upon the residency programs.

Part of the reasoning is that so-called long-form examinations (a single patient interviewed and discussed during the course of an hour) are now known to have poor psychometric properties. Their low reproducibility is partly due to the fact that they are case-specific (clinicians do not perform equally with all patients). Also, individual examiners will have differing opinions on the same clinical interaction, especially if there is no carefully constructed plan for the assessment of specific competencies (Table 59.2–2). In one study, the overall reproducibility coefficient of two long-case oral examinations was 0.39, as compared with 0.88 for single-best-answer multiple-choice questions.

Here is the bottom line: after years of trial, oral examinations have been found inconsistent and unreliable. As a result, the live-patient examination has evolved from a one-shot, do-or-die process to one that tries to assure the ability of every graduating psychiatrist to do a competent initial patient interview. This is, after all, a critical component of what mental health care professionals must do every day.

Table 59.2–2.
Accreditation Council for Graduate Medical Examination (ACGME) Competencies

1. Patient care
   a. Caring and respectful behaviors
   b. Interviewing
   c. Informed decision making
   d. Development and carrying out of patient management plans
   e. Counseling and education of patients and families
   f. Performance of procedures
      i. Routine physical examination
      ii. Medical procedures

   g. Preventive health services
   h. Working within a team
2. Medical knowledge
   a. Investigatory and analytical thinking
   b. Knowledge and application of basic sciences
3. Practice-based learning and improvemen
   a. Analyzing own practice for needed improvements
   b. Use of evidence from scientific studies
   c. Application of research and statistical methods
   d. Use of information technology
   e. Facilitating learning of others
4. Interpersonal and communication skills
   a. Creation of therapeutic relationship with patients
   b. Listening skills
5. Professionalism
   a. Respect and altruism
   b. Ethically sound practice
   c. Sensitive to cultural, age, gender, and disability issues
6. Systems-based practice
   a. Understanding interaction of individual practice with the larger system
   b. Knowledge of practice and delivery systems
   c. Practicing cost-effective care
   d. Advocating for patients within the health care system

Two Clinical Skills Evaluations

Two sets of live-patient examinations are now required of psychiatry trainees who would eventually become board certified: the ABPN's clinical skills examination (CSE) and the ACGME's clinical skills verification examination (CSV—training directors and others lament the confusion resulting from their similar names, sometimes interchanged; the authors will try to avoid these terms). These examinations are mandated as part of the training process and administered during each of the final 3 years of training to help assess a resident's progress. Because the two examinations have so much in common, this discussion will cover them both, as far as that commonality extends. Performance guidelines for the complete examination, with a plan for the discussion of diagnosis and treatment, are included in Table 59.2–3. Of course, the stakes for the CSE are relatively low—failure means only that the candidate must repeat the examination until they pass it three times.

Each of these examinations requires a 30-minute interview of a patient the examinee does not know (selected by the training director or a surrogate) and for whom only minimal information may be provided. The examination is ideally conducted by a psychiatrist examiner who doesn't know the examinee. After the interview is over and the patient departs, the examiner may offer the examinee a minute or 2 to review notes and prepare the presentation. During the remaining time (at least 15 minutes, but up to

half an hour), the examinee presents a précis of what has been learned about the patient's history and mental status evaluation, and answers questions about any aspect of the interview or presentation. The examiner evaluates the examinee's ability to interact with the patient, obtain material relevant to a full evaluation, and lay it out so that another person can understand it. Afterward, the examiner may give feedback to the trainee about overall performance during the examination process.

Nearly everyone regards the witnessed interview of an actual patient as a difficult step on the professional development road. This activity carries enough emotional baggage to make the process seem far different from the usual patient interview. It requires examinees to demonstrate how well they can establish rapport with the patient, gather information, elicit and interpret signs and symptoms, and present the information obtained to the examiner. Examinees' success depends, in part, on an effective plan for organizing these 45 to 60 minutes. Although the time allotment will vary with the individual patient, Table 59.2–4 suggests approximate times for the various portions of the interview.

The following sections will describe the complete interview and question-and-answer process, as it is used in the full ACGME examination. Each resident must perform one of these yearly; the ABPN does not specify the year of training for their administration, only that each applicant for the final board examination must have passed the examination three times with three different patients and at least two different examiners.

The Interview

A half-hour witnessed interview challenges any interviewer. In gathering data that adequately address diagnosis, the examinee must demonstrate compassion while tightly controlling the patient's verbal output. Careful control over the interview process is vital to obtain the necessary information within 30 minutes, yet establish and maintain rapport with the patient. After a few initial open-ended questions, to which the patient responds with uninterrupted speech about various areas of concern, the examinee should begin using closed-ended questions that rapidly review all pertinent portions of the standard psychiatric history and mental status examination. Loquacious patients and those who tend to wander from the point must be gently herded back onto the path. Although patients who are vague, circumstantial, hard to understand, hostile, or complicated prove more difficult to interview, examinees should try to regard them as an opportunity to demonstrate a capacity for empathy while eliciting information under difficult circumstances.

Table 59.2–3.
Performance Guidelines for a Live-Patient Examination

I. Physician–patient relationship

A. **Arrange the physical setting.** Sit face to face or across the corner of a desk, so you can vary the distance from the patient. Paranoid patients need more distance; depressed or anxious patients need more opportunity for comfort.

B. **Put the patient at ease.** Introduce yourself and the observers and briefly state the purpose of the interview. Your concern for the patient's comfort and well-being facilitates rapport.

C. **Demonstrate important personal qualities,** including compassion, empathy, responsiveness, sensitivity to variations in the patient's affect, and ability to cope with difficult situations. Consider your patient's refusal to talk or demand to leave the room not as a threat but as an opportunity to show your ability to cope. Examiners also value a candidate's awareness of personal biases, emotions, and performance, and the ability to respond to the patient without showing inappropriate surprise or making value judgments.

II. Conduct of the interview and eliciting data

A. **Establish eye contact** without staring or otherwise making the patient feel uncomfortable.

B. **Keep note taking to a bare minimum;** it can impair your ability to observe and listen empathetically.

C. **Begin with time for free expression** of the patient's problems; just 2 or 3 minutes shows your concern for the patient.

D. **Use nonverbal encouragements** to keep the patient talking; when appropriate, lean toward the patient (shows interest), or nod to indicate your desire for more information. "Yes," "I see," and "Ah!" can accomplish the same goals without interrupting the flow of information.

E. **Avoid jargon.** Long or scientific words or complex sentences can hamper communication.

F. **Redirect nonproductive speech.** If you mainly hear about baseball or the patient's relatives, gently restate what you need to learn.

G. **Request definitions** of vague terms such as "nervousness," "a long time," or "some."

H. **Follow the patient's flow,** rather than sticking with a rigid interview plan. You won't obtain all the information you'd like in 30 minutes, so demonstrate your ability to blend requests for specific information into the overall structure of the interview.

I. **Obtain as much detailed information** as you can, consistent with available time.

J. **Early on, use open-ended questions** to allow the patient scope to bring up the widest possible range of information.

K. **Later, use closed-ended questions** to obtain specific information.

L. **Touch on all the material** you will be expected to present (see Table 59.2–3).

M. **Work mental status questions into the flow** of your questions, to the greatest extent possible.

N. **Refer any specific diagnostic or treatment questions** the patient has to the treating therapist.

O. **Don't quit early.** Use every scrap of time available, until an examiner says it is time to quit. Then, with thanks for participating, immediately rise to excuse the patient.

III. Organization and presentation of data

A. **Concisely present your data,** organizing the information to support the most likely diagnosis.

B. **Draw your conclusions** from what you have seen and heard, as well as your knowledge of psychopathology and diagnosis.

IV. Phenomenology, diagnosis, and prognosis

A. Formulate a differential diagnosis based on your conclusions.

B. Evaluate these diagnostic possibilities to arrive at a working diagnosis and history.

V. Etiological, pathogenic, and therapeutic issues

A. **Discuss the possible causes,** including cultural, developmental, familial and genetic, psychological, and social factors; medical and neurological disorders; and substance use.

B. **Formulate a biopsychosocial treatment plan** for immediate and long-term management of your working diagnosis.

1. Discuss the indications, contraindications, and unwanted effects of drugs or other somatic interventions.
2. Discuss individual, group, supportive, insight-directed, behavioral, and other forms of

psychotherapy, as indicated.

3. Discuss which practical social interventions may help, such as community resources, day care, hospitalization, and residential care.

C. **Discuss possible complications,** including acting out, assaultive, suicidal, or violent behaviors; legal issues; noncompliance with treatment; or misuse of medications.

Note: Sections I–III apply to both the clinical skills examination required for board certification and the annual clinical skills verification mandated by the ACGME; Sections IV and V apply only to the latter examination.

Examinees should keep their own verbal output to a minimum; when they are talking, the patient cannot give them information. They should not discuss their own feelings, offer therapy, disagree with any aspect of the patient's treatment, or show irritation or other negative affect if the patient is slow to provide the information needed. Confrontation should be avoided at almost any cost, except when a patient's restlessness or other signs of discomfort indicate significant resistance to the entire interview process. Then, the examinee may have to confront the patient's lack of cooperation. Offering a chance to explain a sad or hostile affect might break through the resistance.

Table 59.2–4.
Time Allotment for Patient Interview

5 mins	Chief complaint and patient's free discussion of the issues
7 mins	Specific questions about diagnosis, pertinent negatives, and history of suicidal ideas, violence, alcohol, and drug use
5 mins	Medical history, review of systems, family history
5 mins	Personal and social history, evaluate character pathology
5 mins	Mental status examination
3 mins	Buffer time: pursue other issues, late-developing leads

From Morrison J, Munoz RA. *Boarding Time*. 4th ed. Washington, DC: American Psychiatric Press; 2008.

The emphasis of almost any interview will be altered by a presumptive diagnosis. A patient who is cognitively impaired may need a concrete style of interviewing that focuses on the mental status evaluation and activities during a typical day; an older patient needs more time to describe losses (of family, friends, mobility) and difficulties performing activities of daily living. Patients who have a psychosis or an anxiety or mood disorder will require special attention to the diagnostic criteria according to the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5). However, every patient requires a careful review of personal and social information, including current living situation, work, family, marital status, and leisure activities.

Table 59.2–5.
Outline for Case Presentation

Identifying data
Present illness
Past history
Psychiatric history

Predisposing factors (e.g., genetic)
Psychosocial stressors (e.g., abuse as child)
Stresses that precipitate present illness
Characteristic defenses—adaptive style
Proposed workup
Treatment plan
Prognosis

Presenting the Patient

In presenting just-gathered information to an examiner, organization is again the key. An examiner will expect a brief (5 minutes or so) recapitulation of pertinent facts in the case, not a verbatim retelling of the entire interview. A suggested outline is given in Table 59.2–5.

During the presentation, examinees sometimes discover, to their chagrin, that they have forgotten to obtain an important piece of information. Happily, they can recover, even from overlooking such vital data as suicidal ideation or substance use. If, during the presentation, they realize that they omitted something important, they can compensate by stating what they should have asked (with appropriate follow-up questions) and how they would use that information. Sometimes an examiner may even prompt an examinee for important information.

While presenting a patient whose principal symptoms seemed to be characterological, Dr. A had sailed right through to the formulation when an examiner coughed and asked, "Did you note any thoughts of self-destruction?" After a moment of horror-struck silence, the examinee blurted out, "You mean, like I'm having right now?"

Quickly recovering, Dr. A went on as follows: "I completely forgot to ask my patient whether she had ever tried to kill herself or ever had any thoughts to that effect. If I were seeing her in my practice, I'd immediately go out, bring her back into the office, and ask, 'Have you ever had any thoughts about harming yourself, made any suicidal attempts?' I'd want to know all the details of any attempts—methods, degree of suicidal intent, any physical harm. This is really important stuff: suicidal behavior figures in the diagnostic criteria for the mood disorders as well as borderline personality disorder. And it is quite common in a number of other conditions where it isn't a diagnostic criterion—schizophrenia, substance abuse, and somatization disorder, for example. I can't imagine forgetting to ask, except that I am pretty nervous."

At the end of the session, the examiners (this was before oral examinations were conducted at the residency level) agreed that Dr. A should pass.

Diagnosis and Treatment

For the yearly examination mandated by the ACGME, the examiner evaluates how well the examinee is able to think about diagnostic and therapeutic issues. (This portion of the examination completes the full former Part II oral examination of the ABPN. It is not part of what is currently required for board certification, but because the two examinations are often run concurrently, most residents will likely experience it with each yearly examination.)

During this portion of the presentation, examinees show how well they can manage clinical problems, set priorities, and recognize and cope with complications of therapy. They must be ready to offer a differential diagnosis, even if the patient's most likely diagnosis seems open-and-shut. They will also be expected to defend this evaluation with diagnostic criteria and critical thinking about treatment. Examiners hope to witness logical reasoning throughout the course of a clinical problem.

The formulation organizes in a brief paragraph the biological, psychological, and social factors that influence the evolution of the disease process and produce the current symptoms. This should be followed by suggestions for workup, which might include a physical examination, laboratory testing, imaging, and such simple devices as interviewing informants and obtaining records from other clinicians. Of course, all discussions of treatment should be based on a model that includes biological, psychological, and social elements.

Interactions with the examiner should be as candid as possible. Examinees should avoid using gamesmanship, trumpeting their own expertise, or ignoring examiner's interests and opinions. Respectful acceptance of other points of view suggests the ability to think flexibly. An examinee who does not understand a question should request clarification. Not only is this perfectly in order, it is the safest course to follow. Examinees who cannot answer a question are well advised to say so, then explain how they would go about finding the answer. No one can know everything, and many examiners feel that good physicians know their own limits. Examiners are advised to seek the examinee's areas of expertise and not linger in problematic areas, unless forced to do so by the exigencies of patient care.

TEST MAKING, TEST TAKING

Designed to test the extent of clinical knowledge acquired by the end of medical school, the United States Medical Licensure Examinations (USMLEs) for the National Board of Medical Examiners are administered by computer at various stages of training. Questions for the written portion of the American Board of Psychiatry and Neurology (ABPN) examination are developed using similar methods.

The USMLE psychiatry section development committee comprises eight or more members who serve staggered terms of up to 5 years. During item writing workshops, which now may take place online, each member shares with the group perhaps 50 questions. (Question writers are encouraged not to describe actual patients, who tend to be too complicated for testing of a single concept.) Criticisms are addressed in rewrite sessions that may be individual or in groups. Parallel committees and processes apply to each of the other major disciplines: internal medicine, obstetrics–gynecology, pediatrics, and surgery. USMLE will not divulge the percentage of Step II questions devoted to psychiatry.

No specific degree of difficulty is prescribed. Rather, there must be consensus that each item tests fairly the knowledge that students or graduating physicians (depending on step level) should possess before beginning the next stage of professional development. Many questions will pose problems that cross the boundaries of two disciplines—for example, the distractors might suggest that the answer could belong in the realm of either medicine or psychiatry.

Ultimately, the completed items are pretested in an actual examination. Because all examinations are now given by computer, new items can be tested at any time, along with the questions that contribute to a candidate's score. The latter are called "live" items, and they are the same for all examinations; the pretest items are distributed so that each will be answered by a representative sample of the 50,000 or more candidates who take the examination each year. Pretest items are evaluated against the live items, thereby influencing the composition of the next year's examination. The pretest also determines whether any of the distractors are left unchosen; if so, these may be discarded in favor of alternatives that will appeal to more candidates. As with other examinations, reliability is increased by more questions and by a longer completion time.

For each item is calculated a statistic called the point biserial discrimination index (PBDI), which quantifies the correlation between the item and the examinees' overall test performance. If it is positive, high-scoring candidates tend to do well on the item. A PBDI greater than 0.20 is desired. New test items may be discarded if they are answered correctly by fewer than 30 percent of examinees or have a negative PBDI. For all three steps, tutorial and sample test materials can be accessed at www.usmle.org.

Several old-style questions have been discarded because they are confusing or assess the examinee's ability to take tests rather than knowledge of the subject material. For example, the true-false question is written in terms of absolutes. Any item that involves a shade of gray requires the examinee to guess what the author had in mind. For example, "The prevalence of schizophrenia is 1 percent" might be answered differently by a clinician and an epidemiologist. The multiple true-false question is a complicated vehicle that requires a firm grip on logic as well

as knowledge of subject content. Its instructions are as follows: Mark "A" if choices 1, 2, and 3 are correct; "B" if 1 and 3 are correct; "C" if 2 and 4 are correct; "D" if only 4 is correct; or "E" if 1, 2, 3, and 4 are correct. (Example: Core symptoms of schizophrenia include [1] Delusions, [2] Disorganized thinking, [3] Hallucinations, [4] Homicidal ideas.)

For years now, two basic types of question formats have been favored on national tests: the single-best-answer multiple-choice question and the extended matching question (EMQ). Multiple-choice questions eschew simple regurgitation of isolated facts; they require that the examinee interpret and synthesize data so as to apply their knowledge to situations they may not have encountered previously. However, even when composed by professional test writers, multiple-choice questions can be interpreted ambiguously; candidates sometimes complain that subjects are confusing, controversial, or worse, trivial.

The EMQ derives from a theme—such as mood disorder—and includes a list of possible brief answers and a number of detailed lead-ins (stems). EMQs have several advantages. With a wide range of answer options, they can be readily adapted to new questions. They can be used repeatedly and scored flexibly, with greater weight given to those that are deemed more important. Overall, the EMQ is the best vehicle for discriminating knowledgeable from uninformed examinees; the five-item multiple-choice question is second best, with true-false finishing dead last.

An additional advantage of EMQs is that, when the answer is not precise, they can be written so that the candidate must select several answers, as for a differential diagnosis or unwanted medication effects. This sort of question, sometimes termed a "Pick N" item, might ask the examinee to select a subset of answers that should be considered in response to a given vignette.

Constructing a Test

1. Decide on the pass–fail criterion. A norm-referenced test (each candidate's score is reported as it relates to the entire group) is designed to produce variance and highlight differences in examinees. A criterion-referenced test (each score is given in terms of the absolute percentage correct) yields specific information about what the individual knows. Because both the USMLE and ABPN written examinations are criterion-referenced, all candidates taking either examination could theoretically pass. Ideally, multiple judges are involved in setting the standard for passing; several methods are described in a 2002 monograph.
2. Select the knowledge areas and question content to be tested. Obviously, testing should accurately reflect the material and must be nontrivial. Each area will require a certain number of items (approximately 30) to provide a reliable evaluation. Reliability is increased by greater test length and longer time allowed for the test.

3. Question content should cover problems that are common or potentially high-risk. Questions should assess knowledge likely to be needed by a clinician in the field, and avoid minutiae and disorders that are vanishingly rare. Additionally, focus on important areas of clinician knowledge and behavior, such as health and health maintenance, disease mechanisms, diagnosis, and treatment.
4. Choose the question format. Both the USMLE and the ABPN written examination rely mainly on multiple-choice questions of several types: (1) single best answer, a statement followed by several possible responses; (2) extended matching, as of a series of lettered answers to different numbered statements or vignettes; and (3) sequential multiple choice questions involving a vignette followed by several single-best-answer questions that may vary depending on the answer given to the previous question. This last has been favored in Part III of the USMLE.
5. In writing the questions, aim for clarity and brevity. Avoid vague terms such as *usually, frequently, often, commonly, rarely,* and *may* and absolutes such as *always* and *never*.
6. Questions should require the examinee to retrieve, select, organize, and apply knowledge, not just regurgitate facts. Question stems (the information that serves as background to the actual question) that contain detailed information will discriminate between examinees who score well and those who score poorly on the entire test.
7. Devise distractors. These should all be of the same type (homogeneous) and neither too hard nor too easy. A distractor so illogical that it is never selected should be discarded from future editions of the test.
8. Evaluate the new questions for ability to discriminate top from bottom candidates (i.e., have a positive PBDI). A pretest sample or previous edition of the test can help determine which candidates will answer an item correctly.
9. Discard pretest items that are often answered incorrectly by top examinees—these will have small or negative PBDIs.

ANATOMY OF A SINGLE-BEST-ANSWER TEST QUESTION

Complaining of voices in her head telling her to kill herself, a 31-year-old single woman was admitted to the hospital. Although she had had several prior admissions over the past 6 years, her clinical chart could not be found. She believed the voices she heard on and off for many years may have been the result of "interplanetary influence." An actress by training, she had not worked in her profession since the age of 24. She sustained herself with general relief and by cleaning offices. She thought she might have bumped her head several weeks ago. "But I was drinking," she said with a giggle, "and I don't remember much about it." She then denied habitual use of alcohol or other substances.

Fully oriented and coherent, the patient appeared distracted during the interview, several times gazing around the room and cocking her head to one side. She interpreted the proverb "A stitch in time saves nine" to mean that she should "sew up my ragged sleeve of carelock." Except for occasional laughter when she said something that did not seem especially funny, her affect was unvarying and she gazed straight at the examiner.

1. What diagnosis is most likely for this patient?

a. Alcohol dependence with hallucinosis
b. Bipolar mood disorder
c. Schizoaffective disorder
d. Schizophrenia
e. Subdural hematoma

2. Which medication will most likely provide rapid relief of symptoms?
   a. Amitriptyline
   b. Diazepam
   c. Divalproex
   d. Haloperidol
   e. Methylphenidate
3. Which further evaluation step is most likely to confirm the diagnosis?
   a. Blood chemistry panel and CBC
   b. Collateral history from a friend or relative
   c. Follow-up interview with the patient
   d. MRI of the patient's head
   e. Psychological testing
4. The patient's use of the term "carelock" is an example of:
   a. Inappropriate affect
   b. Neologism
   c. Paranoia
   d. Perseveration
   e. Tangentiality

Note the features of this set of questions and answers:

- ► The subject addresses a major area of concern to psychiatrists (psychosis is frequently encountered and fraught with risk).
- ► The stem is a relatively long, detailed clinical vignette.
- ► The questions pose several types of problem related to the information provided in the stem, but they are not linked (one answer does not depend on knowing prior answers). The first three questions require deduction from the facts given, not just recall of isolated facts.
- ► A knowledgeable examinee could answer correctly, even without reference to the stated choices.
- ► The fourth question is of an older and less satisfactory type: it draws on rote memory, rather than ability to assess a clinical situation and apply principles to it.
- ► The distractors are all logical and plausible (they are of the same length, format, and type of word or phrase as the correct answer). The answers (including distractors) are all relatively brief.
- ► Options are presented alphabetically so as not to favor a given letter or position in the list.
- ► The choices avoid vague terms such as *increase, decrease, stay the same,* and *none of the above*.

If desired, the same vignette could serve as the basis for additional questions about such topics as psychopathology, psychotherapy, and family history.

SAMPLE EXTENDED MATCHING QUESTION

For each patient in items 1 to 6, select from the common set of lettered choices (A through Q) the most likely diagnosis for the given chief complaint. Each choice may be selected once, more than once, or not at all.

A. Alcohol withdrawal
B. Antisocial personality disorder
C. Attention-deficit/hyperactivity disorder
D. Brief psychotic disorder
E. Female sexual interest/arousal disorder
F. Intellectual disability
G. Major depressive disorder
H. Major neurocognitive disorder due to Alzheimer's disease
I. Opioid intoxication delirium
J. Panic disorder
K. Persistent depressive disorder
L. Posttraumatic stress disorder
M. Pyromania
N. Schizoaffective disorder
O. Schizophrenia
P. Schizophreniform disorder
Q. Somatic symptom disorder

1. A mother notes that her 6-year-old son, whose developmental milestones have been delayed, has made slow progress in kindergarten.
2. A young married woman complains that she has never been able to achieve orgasm.
3. A college student smiles as she admits to a 2-month history of hearing voices.
4. A Gulf War veteran who has recently lost weight entertains suicidal ideas.
5. Increasingly, an elderly businessman forgets the appointments he has made.
6. A successful middle-aged lawyer complains that for years he has felt sad and lonely.

In the above question-and-answer set:

- Each vignette includes enough identifying data (gender, age) to present a visual picture of the patient.
- Although no vignette contains all the information needed for a definitive diagnosis, each allows the examinee to make a logical, informed choice.

The Use of Vignettes

Because they increase clinical relevance, vignettes have become a mainstay of written examinations, appearing in written or video format. As currently deployed on major examinations, they will be relatively brief (a few lines or a few minutes each), describe specific situations, and introduce several multiple-choice questions. Video vignettes may present a patient, a clinician, or both speaking together. Vignettes present common situations and diagnoses important in the practice of everyday psychiatry; esoteric disorders will not be on the menu. However, general medical conditions

and substance-related disorders are not esoteric; they may very well come up, over and over. Each vignette will include many features that help to decide diagnosis or treatment. These include gender and age, location of care, nature and duration of the chief complaint, brief recent history, and mental status findings. Thus:

A 23-year-old graduate student presents to student health, complaining that she has been depressed for "about 6 weeks." She denies any family history of mental disorder, but says that she and her boyfriend have had a "running dispute," in part about her loss of libido; last week, he moved out. Her appetite and sleep have since been diminished and she cannot focus on her studies. She has been neglecting work on her thesis, which is due next month.

Question 1. The patient's presentation in this vignette is most consistent with which of the following diagnoses? (Choose one.)

a. Acute stress disorder
b. Adjustment disorder with depressed mood
c. Chronic depressive disorder (dysthymia)
d. Major depressive disorder
e. Personality disorder

Question 2 Before the patient leaves the office, the clinician should (choose two):

a. Inquire about suicidality.
b. Telephone the boyfriend for his story.
c. Obtain a substance use history.
d. Arrange for psychological testing.
e. Discuss treatment options.

Each of these questions:

- ► Focuses on something important, rather than trivialities.
- ► Could be answered without reference to the choices.
- ► Does not add data to the stem or the options.
- ► Is relatively simple.
- ► Is phrased positively ("except" and "not" are avoided in the lead-in).

It is common practice to roll out the history piecemeal, with each brief vignette followed by one or two questions that may pertain to the cumulative history. Once a new item of information is presented, examinees are not allowed to go back to a previous question, for the obvious reason that new and important information may be revealed in later "episodes." Additional questions can be devised to cover somatic treatment, psychotherapy, issues of risk management, ethics, and quality of life. Often, different question sets allow reuse of vignettes from one examination to another.

Strategies for Surviving a Written Examination

1. Answer all questions.
2. Candidates who lack definitive knowledge should guess, unless the test subtracts points for wrong answers (rare today). A small chance of a right answer is better than no chance.
3. Watch the clock to help allot sufficient time to each section of the examination.

4. “Never” and “always” are red flags that can signal incorrect distractors.
5. “Possibly,” “sometimes,” and “maybe” may signal a correct answer.
6. Try to narrow the options by eliminating known incorrect answers.
7. Don’t look for patterns: test writers take pains not to give away correct answers by placing them at any constant point on a list.
8. Use the full time allotted. Candidates with time left at the end of the examination should check their work. Research has clearly established that examinees are far more likely to change an incorrect answer to a correct one than the reverse.

SUCCESS AND FAILURE ON EXAMINATIONS

Using the official ABPN grading card categories, examiners in the mid-1990s published a list of areas they regarded as crucial to a candidate’s success on live patient examinations in general. As a group, examinees who passed the examination overall handled each of these 18 items better than did those who failed the examination. These criteria sorted into two basic problem areas.

Content. Did the examinee…

1. Use appropriate opening and closing strategies?
2. Follow cues to new information?
3. Appropriately explore affective cues?
4. Demonstrate language and cultural sensitivity in communications?
5. Use a questioning technique that was open-ended but appropriately structured?
6. Control and direct the course of the interview into a cohesive whole?

Process. Did the examinee…

7. Obtain enough data about the chief complaint and history of the present illness?
8. Begin to sketch in relevant data concerning developmental, family, medical, and social histories?
9. Sensitively explore any history of alcohol and drug abuse?
10. Sensitively assess risk of suicide and homicide?
11. Present an organized, concise summary of important data?
12. Recount an organized, accurate mental status examination?
13. Consider emergency issues such as alcohol or drug use, suicide, and violence?
14. Present a rational, organized workup that included additional history, collateral information, and testing?
15. Choose an appropriate working diagnosis from a sufficiently broad differential for major mental disorders, personality disorders, and physical conditions?
16. Use all three dimensions of a biopsychosocial formulation?
17. Present a comprehensive treatment plan that included drugs,

psychotherapy, and criteria for hospitalization, and demonstrate knowledge of family systems and milieu principles?

3. Discuss negative and positive prognostic factors and transference and countertransference issues?

Stepwise logistic regression found four criteria that best predicted outcome. In descending order of importance, they were treatment plan (item 17), information cues (2), mental status examination (12), and interview control (6). Failing examinees scored lowest on information cues (2) and affective cues (3). Although decades of observations and anecdotes related by dozens of board examiners verify the essential truth of these findings, they have not been replicated.

Problems with Content

Issues of content can potentially involve virtually any clinical topic covered in this textbook, but examinees typically encounter difficulties with some of the following issues. Although some of the examples used in the following discussion are holdovers from the era of live-patient and videotaped Part II ABPN examinations, their lessons remain relevant today.

Inadequacies of Factual Information. Lack of facts concerning any modality of treatment or any psychiatric diagnosis should stimulate further review of relevant sections of a standard psychiatric textbook. Whereas no one expects examinees to memorize the DSM-5 criteria, a thorough understanding of their structure and basic content is vital. Indeed, if examinees can demonstrate their ability to provide safe psychiatric care, isolated knowledge deficits should not be devastating.

After interviewing a young woman with a first-break psychosis, Dr. B admitted to "complete naïveté" regarding the novel antipsychotic agent the patient was taking. "If I inherited the care of this patient, I'd look that drug up in AHFS Drug Information or PDR. And I'd also discuss it with the drug information pharmacist at our medical center." During the debriefing, the examiner specifically praised this cautious, information-seeking approach to uncharted territory.

Differential Diagnosis. For generations, the elementary clinical exercise known as the differential diagnosis has been a mainstay of medical decision making, but the stress of the witnessed interview sometimes causes examinees to narrow, rather than broaden, their focus. Some cling to a favorite diagnosis as if it were a life preserver; others appear to fear they are being tricked or trapped. However, examiners only want to find a pattern of sound diagnostic thinking that will serve future patients well.

After doing a fine interview, Dr. C made the flat statement, "The diagnosis is anxiety disorder, not otherwise specified," and then stopped. The combined efforts of two examiners could not persuade this examinee to admit that another diagnosis was possible. The senior examiner

noted, "Once many examinees get the patient to report a very well-defined psychiatric syndrome, they tend to forget that there is a differential diagnosis ... to consider. Even though the issue has been well addressed [in reading material concerning the boards], many people forget."

Most examinees are reasonably well versed in the latest diagnostic criteria, but sometimes one will mix up items from two or more criteria sets. Some overinterpret the data and make a diagnosis they cannot defend with the material at hand. An examiner will typically try to help the examinee work through such difficulties but most show little tolerance for the occasional candidate who invents criteria. Here, as everywhere else in an oral examination, it is far better to acknowledge a deficiency than to risk appearing intellectually dishonest.

Noting that a videotaped patient had several times glanced away, Dr. D hypothesized that the behavior could be caused by hallucinations. "Of course, there could have been activity off-camera that we couldn't see," the examinee volunteered. "I'd need to ask the usual sorts of questions about auditory and visual hallucinations, delusions, and so forth before I could say for sure. Would you like me to go through them?"

Dr. D was playing it safe by mentioning other reasonable interpretations. This is an excellent practice to follow in every examination—flexible thinking is the key to success.

Formulation. Even if they have done a reasonably competent job of gathering information, some examinees appear puzzled about what to do with it. They seem incapable of condensing what they have learned into the few sentences required.

After Dr. E presented the basic observations about a videotape interview, the examiner asked for a formulation of the patient. What came back was an unaltered recitation of the few minutes just witnessed. With prompting, Dr. E eventually mentioned diagnosis but seemed to recognize no opportunities for further investigation.

Later that afternoon, after viewing the same videotape, Dr. F responded, "This is a middle-aged man who was occasionally tearful and spoke slowly as he mentioned several symptoms that would support a diagnosis of depression. I didn't hear anything about previous episodes or manias, so my best [principal] diagnosis would be major depressive disorder, single episode. However, I'd want to quiz him more carefully about mania. I thought he glossed over the question about drinking, so I'd also have to know more before ruling out a substance-related mood disorder. I'd defer [a personality] diagnosis—not enough information. Contributing to his depression could be the fact that his mother died several months ago...as well as the fact that he has been worried about his job due to missing work. That would also be reflected in his global assessment of functioning score. I didn't think he looked hypothyroid so I wouldn't mention it...but with the routine labs I'd order a thyroid screen, just to be safe. My treatment plan would be biopsychosocial, and I'd consider . . ."

Further Evaluation. Examinees may appear uncertain about how to work up a patient. Some suggest laboratory tests that are inappropriate; others cannot explain how they would use the information once they'd obtained it. Many fail to mention that most useful (and inexpensive) of procedures, the collateral interview, which is especially vital when patients

are psychotic or have cognitive or personality disorders.

Treatment Recommendations. The importance of psychopharmacology to the treatment process and its emphasis in training curricula have ensured that most examinees are reasonably well prepared in this area. However, now and again the specter of treatment complications arises to haunt those who should have been better prepared to deal with potential complications of drugs they themselves have recommended. For example, unfamiliarity with the symptoms of neuroleptic malignant syndrome is surefire trouble for an examinee who has just recommended the use of haloperidol (Haldol).

Discussing treatment of a depressed, middle-aged man, Dr. G advocated trazodone (Desyrel) but failed to mention the possibility of priapism. "Try as we might to suggest that a discussion of sexual complications might be in order, we got nothing for our efforts," said Dr. G's examiner. "Now, not knowing the side effect of a particular drug isn't usually a calamity, but priapism is an infamous side effect, and it was the examinee who suggested Desyrel in the first place!"

Some examiners have reported feeling upset when examinees tell them that they "never do psychotherapy." "Despite all the good advice about addressing all forms of treatment, many examinees' formulations are completely unidimensional," one examiner reported. "They just kiss off psychotherapy by saying they refer all patients who need it to a social worker or psychologist. They seem to regard this as relieving them of all responsibility for knowing anything about interpersonal aspects of treatment. For some of us, this attitude is a nail in the coffin."

After an excellent presentation of a patient who had described many symptoms of borderline personality disorder, Dr. H would only consider behavior modification as a treatment option. The examiners repeatedly asked whether medication could be considered (the patient had even reported some depressive symptoms), but Dr. H wouldn't hear of it: "There is little solid evidence that medication has any long-range effect in borderline personality disorder." Even when one examiner postulated an extreme case in which such a patient developed severe depression, the response was the same—refusal to consider another course of action. Despite an outstanding interview, they could not justify a fully passing grade for this otherwise excellent examinee.

Rather than not knowing drugs, some examinees seem familiar with little else. The emphasis of all psychiatric training should be biopsychosocial, which means that, besides knowing dosages and side effects of the latest psychotropic medications, examinees must discuss social interventions (placement, self-help groups, family interventions, and the like) and the myriad forms of psychotherapy.

An unnecessarily uncomfortable half-hour was the fate of Dr. I, whose patient had a personality disorder with borderline features.

"For 10 minutes all this examinee would talk about was antidepressant medications," an examiner later complained. "Sure, we all saw the depressive symptoms. But we practically had to beat the examinee up to get a treatment approach that was anything but drugs."

Dr. I ultimately passed but, according to the examiner, it was "a near thing."

Despite numerous warnings that there are no pathognomonic signs in psychiatry and that no disorders have only one treatment, some examinees still pursue a single-minded approach to patients and their problems. They may quote the latest "truth" from a journal article and, when asked to explore alternative possibilities, respond with the journal title, page number, and publication year. In the words of one examiner, this is "tantamount to dying with their rights on."

Problems with the Process. As with content, issues of process can affect examinees in both the ABPN and ACGME required patient examinations.

Inadequate Rapport. From the opening moments of the patient interview, some examinees seem unable to forget their own needs and focus on those of the patient. They ignore the bits of social behavior that should put the patient at ease, such as making introductions, offering a choice of chairs, explaining the purpose of the examination, giving good eye contact, and showing empathy. As one examiner put it, "You rarely see a caring candidate who doesn't do well overall in the examination."

Rapport is especially an issue when an examinee's behavior indicates insufficient concern for the feelings or emotional state of the patient. Some examinees seem incapable of putting themselves in the patient's shoes; a rare candidate may show callous disregard for the feelings of a fellow human.

A board patient with an advanced case of acquired immune deficiency syndrome (AIDS) had lost his lover and been abandoned by his family. During the interview, he admitted that he felt depressed and often thought about death. When asked about the importance of the family's absence, Dr. J responded that it made "little difference, because the patient was dying anyway."

Whereas Dr. J's attitude was an extreme example, every examinee must demonstrate the ability to address the patient's comfort and feelings through the use of body language, eye contact, and sensitive responses to emotionally laden material.

Conduct of the Interview. Almost any interview is likely to yield some suggestions for improvement—better eye contact, fewer interruptions, a different focus or depth when following up on earlier questions. Other findings may require much more extensive remediation.

"I've got to say, I felt really uncomfortable during much of your interview," the examiner told Dr. K during a debriefing. "The patient had a story he was trying to tell, but you kept interrupting to ask questions about which medicines he had taken. And some of the important ideas he did manage to get across—his life didn't 'seem worth living,' for example—you didn't follow up."

Inadequate Control. Although examiners criticize the excessively controlled interview, in which a patient is given insufficient scope to discuss problems freely, they far more often criticize the inadequately controlled, directionless interview.

While the patient talked, Dr. L furiously scribbled notes. Actually, the interview started out well enough, with the patient discussing the anxiety symptoms that had brought him to treatment. However, soon he wandered off into a discussion of his wife's recent operation, then the problems the family had had with her surgeon's billing practices. The examinee went right along, transcribing his words with passive diligence. Although an examiner finally suggested a shift in focus, little changed, and Dr. L failed.

Examiners hope to witness an interview in which all of the important topics are covered and the examinee identifies and follows up on critical questions in a way that makes the patient feel party to a conversation rather than the subject of an interrogation.

Dr. M had to examine a woman who, for 18 months, had been a state mental hospital inpatient. Her problems included bulimia nervosa, obsessive-compulsive disorder, major depressive disorder, and multiple substance-related disorders. "And that was just the Axis I stuff," the examinee reported later.

Unable to fully evaluate any of these issues, Dr. M spent a few minutes addressing each problem before easing the patient into a discussion of the next. "My examiners seemed to recognize that I could get my arms around each of these issues sufficiently to formulate a plan for further evaluation and management. I didn't feel especially good about my interview, but I passed," he reported.

Anxiety. Nearly everyone performing a witnessed interview will feel some anxiety, but in the old Part II of the ABPN examination that could seem a one-time, do-or-die exercise in virtuosity, fear nearly incapacitated some examinees. It could reduce their ability to respond in a warm and sympathetic manner, or drive them to ignore important questions (such as hints of suicide or evidence of cognitive disorder) that needed follow up. Still others reported that their minds would "go blank" when they tried to recall even elementary didactic material.

All-consuming anxiety should not be such a problem with the new regime, where the examination is a normal part of the training process, with essentially unlimited opportunities to pass. Further, the current protocols require only one examiner; in the old Part II ABPN examination, it was two on one, with the added pressure that one might expect from facing a "panel of judges" rather than a single individual. In all likelihood, examinees who needed to use behavior therapy and drugs (such as beta blockers) for anxiety will become a distant memory.

Organization. Organizing and verbally presenting a complicated history is a skill medical students learn early in training. Unaccountably, it also lies at the core of the difficulties many psychiatrists encounter during

witnessed examinations.

> When asked to present the patient "as best you can," Dr. N encountered disaster. Instead of doing a focused presentation, this examinee attempted to recount the undigested interview, pretty much as it had just occurred. Jumping around from present illness to historical data to mental status examination, Dr. N became more and more anxious, compulsively—and futilely—shuffling through pages of scrawled notes.

It is remarkable how many examinees have mentioned that it took them a failure (or two) to learn the importance of presenting their patients "straight on through," not stopping to wait for questions, and only pausing when an examiner interrupted with a question. "In my training program, a presentation was more in the way of talking back and forth with the attendings. I learned that the boards require a presentation that is not only succinct but complete," noted one examinee.

Relationship with an Examiner. Some examinees have reported feeling that they have, in some way, run afoul of an examiner. In part, this impression may be fed by anxiety; it may also be a reaction to the neutral stance examiners must take toward examinees. Whatever the cause, some examinees find themselves arguing with examiners. Others pontificate, attempting to demonstrate special expertise or knowledge. Examiners sometimes regard such behavior as arrogant.

Lack of information is serious but, to an extent, expected. Interpersonal difficulties during the examination are quite another matter, for they suggest something inherent in the approach to people that could negatively affect the examinee's ability to care for patients. Although board examiners rarely express negative feelings about the candidates they examine, the reverse is not uncommon. Under stress, examinees are likely to react by becoming defensive and rigid. They may argue, clinging so tenaciously to a position that they cannot acknowledge, much less accept, the possibility that an examiner may be trying to suggest an alternative view of the patient. The fact that a given diagnostic or treatment option may be perfectly justifiable, even correct, does not excuse any examinee from the need to demonstrate flexible thinking.

Fatal Mistakes. Most examiners agree that a single error is unlikely to cause a CSE failure. Such an error would have to demonstrate an abysmal ignorance of facts or an overwhelming lack of concern for patient well-being—for example, suggesting that a suicidal patient could have a month's prescription of potentially lethal medication or, for some examiners, not asking a patient who uses drugs about suicide or failing to probe for a history of violence or substance abuse. For example, when interviewing a patient in a substance abuse treatment program, an examinee did not assess dangerousness.

Examiners must feel confident that the examinee can competently assess a patient for these behaviors crucial to diagnosis, to treatment, and, indeed, to life itself. Despite the logic of this principle (not to mention the publicity it has received in books, articles, and board preparation courses), some examinees still founder on a failure to follow up on clues the patient may present. These can include hints about suicide or death, tearfulness, abnormally reduced or excited activity level, and references to substance use.

> "I remember one examinee who didn't pick up on what the patient was saying," an experienced examiner commented. "The patient had mentioned drug abuse and the candidate just didn't get it. My partner and I hated to do it—this was a bright, young psychiatrist embarking on a promising career, who has since become an internationally known leader in psychiatry. But we were forced to issue a failure. The next year the candidate passed, but I still cringe when we run into one another at meetings."

PREPARING FOR THE BOARDS

How much time should examinees spend in preparation for the current ABPN certification examination? Unfortunately, data are entirely lacking. Of course, this time is highly individual: For weak examinees, long hours may not be nearly enough, whereas a strong examinee just completing training may require little additional preparation. Unhappily, it is all too often that the former learn who they are only as a result of taking the examination itself. That said, preparation for all candidates should probably include careful reading of a standard American textbook of psychiatry, preferably one that offers a study guide to provide familiarity with the sort of test question that may be asked.

Whether an examinee should also engage in a preparation course, either at home or on-site, is a matter for some conjecture. How helpful are these seemingly ubiquitous, definitely expensive review courses offered by universities and private organizations? Other than personal anecdotes and testimonials, essentially no data exist for psychiatry. One study in the field of surgery reported that formal review courses may assist the examinee at high risk of board failure, especially those who have already experienced one or more failures.

EXAMINERS

The requirement for conducting a witnessed, live-patient examination that will qualify the candidate for board certification is simple: the examiner must also be board-certified. A second requirement, which also holds for the yearly ACGME examination, is that at least two of the three required oral examinations be conducted by different examiners.

Beyond that, a couple of qualities are desired, though not mandated. One is that the two individuals involved should not have had a personal relationship with one another—it is hard, after all, to judge impartially

someone you know well. That could be a problem especially in smaller programs, where many potential examiners may already be involved in the teaching program. Of course, in cities large enough to support two or more training programs, a cross-town exchange can obviate even the appearance of partiality.

The other issue is uniformity. That is, without procedural instructions, how do examiners operationalize the task of promoting a standard of excellence in examinees? In the days of the oral boards, new examiners had to undergo a half-day training that imbued them with a uniform sense of purpose. (Even then, considerable variations in grading standards were noted.) Although there are written guidelines for evaluating performance, examiners may vary considerably in terms of what information they feed back and how they accomplish it. Now, with no formal training required, those who sit in judgment are left pretty much on their own to interpret their mission. To be sure, the numerous individual scoring points listed for both the ACGME and the ABPN examinations (Tables 59.2–6 and 59.2–7) can provide far more specific feedback than was ever available to candidates for the old-style Part II oral examination. However, examiners are also permitted informal comments that were formerly proscribed, potentially injecting a note of mentorship, even collegiality, into a relationship that was once strictly judgmental. It should come as no surprise that an ABPN task force has recommended formal training for examiners.

GRADING PROCESS

The criteria used for scoring the live-patient annual skills assessment required by the ACGME are given in Table 59.2–6. It is noteworthy that, even though the two examinations may be graded on the basis of the same patient interview, somewhat different criteria are used for the ABPN clinical skills evaluation; Table 59.2–7 presents the somewhat longer of two versions that are posted on their website. Note further the different wordings for the two sets of scoring criteria: the ABPN requires that the examinee perform at a level expected of a community psychiatrist, whereas the ACGME requires that residents demonstrate competence "for their level of education" before passing on to the next training year.

Table 59.2–6.
Grading of the Annual Clinical Skills Assessment of the ACGME

1. **Physician–Patient Relationship**

1–1. Develops rapport with patient

Excellent: Courteous, professional demeanor; Clear introduction to patient; Exhibits warmth and empathy

Good: Generally respectful; Adequate introduction; Adequate empathy

Fair: Arrogant, disrespectful, or awkward demeanor; Inadequate introduction; Lacks

empathy

Poor: Rude or inappropriate comments; No introduction or misrepresentation of the situation; Obvious anger or frustration

1–2. Responds appropriately to patient

Excellent: Responds empathically to verbal and nonverbal cues; Adjusts interview to patient's level of understanding and cultural background; Adjusts interview to new information

Good: Responds adequately to verbal and nonverbal cues; Occasional use of technical jargon; Adjusts interview to most new information

Fair: Shows minimal response to sensitive information; Minimal awareness of patient's capacity to understand or cultural background; Inflexible interviewing style; Misses important verbal and nonverbal cues

Poor: Responds with angry, abusive, or dismissive comments; Frequently loses composure; Criticizes, demeans, or condemns patient

1–3. Follows cues presented by patient

Excellent: Responds appropriately to verbal and nonverbal information; Follows up on all pertinent information; Seeks clarification of ambiguous information

Good: Misses no major verbal or nonverbal information; Generally follows up on major issues presented by the patient

Fair: Misses significant verbal and nonverbal information; Fails to ask for clarification of ambiguous information

Poor: Ignores or responds inappropriately to verbal or nonverbal cues; Grossly misinterprets verbal or nonverbal information

2. Conduct of the Interview

2–1. Listens to and facilitates the patient's narrative history

Excellent: Actively listens to the patient's story; Uses frequent, well-structured, open-ended questions to facilitate the story; Assists the patient to focus and clarify the story

Good: Passively listens to the patient's story; Occasionally uses open-ended questions to facilitate the story; Asks occasional clarifying questions

Fair: Interview consists primarily of directive, closed-ended questions; Inadequate or ineffective efforts to focus and clarify the story; Frequent interjection of assumptions or leading questions

Poor: Interview consists entirely of narrowly focused, closed-ended questions; Patient is repeatedly diverted from the narrative to check-list questions or irrelevant topics; Patient's narrative is disregarded, contradicted, or ignored

2–2. Obtains sufficient data for DSM differential diagnosis

Excellent: Assists the patient in describing the full range of symptoms and history; Explores all pertinent domains of information; Gathers adequate information for DSM checklists

Good: Allows patient to describe major symptoms and history; Explores the major domains of information; Focuses interview on DSM checklists

Fair: Limits interview to DSM checklists; Misses important domains of information; Shows little awareness or regard for DSM diagnoses; Fails to consider alternative diagnoses

Poor: Fails to gather sufficient information for major diagnosis; Misinterprets or misrepresents diagnostic information

2–3. Obtains psychiatric, medical, substance use, family, and social histories

Excellent: Assists the patient in presenting each aspect of the history; Gathers a wide range of biopsychosocial information; Maintains focus and logical progression of interview; Appears comfortable with difficult or sensitive topics

Good: Allows the patient to present an adequate range of material; Gathers adequate biopsychosocial information; Generally redirects the patient when necessary; Somewhat uncomfortable with difficult or sensitive topics

Fair: Interrupts or interferes with the patient's story; Misses important biopsychosocial information; Fails to redirect or focus a disorganized or hyperverbal patient; Avoids

difficult or sensitive topics

Poor: Ignores pertinent areas of the history; Asks cursory, disorganized, or irrelevant questions; Loses control of the interview; Responds inappropriately to difficult or sensitive topics

2–4. Screens for suicidality, homicidality, high-risk behavior, and trauma

Excellent: Approaches topic frankly, but with sensitivity and empathy; Asks questions appropriate to the context of the interview; Follows up with specific questions; Assesses specific suicide risk factors, if relevant

Good: Approaches topic somewhat awkwardly; Asks general screening questions; Follows up with 1–2 specific questions

Fair: Approaches topic with abrupt, accusatory, or incredulous manner; Asks only indirect or cursory questions; Obtains no detailed information

Poor: Fails to address suicidal or homicidal ideation; Disregards pertinent information in the history regarding patient's risk factors

2–5. Performs an adequate mental status examination

Excellent: All pertinent areas of the MSE were addressed; Appropriate areas of the MSE were integrated into other parts of the interview

Good: Most pertinent areas of the MSE were addressed; Occasional areas of the MSE were integrated into other parts of the interview

Fair: At least one essential element of the MSE was omitted; MSE elements were inadequately performed

Poor: Multiple elements of the MSE were omitted; MSE elements were ineptly performed

3. Case Presentation

3–1. Organized and accurate presentation of history

Excellent: HPI accurately reflects the patient's story; Presentation is logical, concise, and coherent; History integrates all important biopsychosocial factors; Presentation includes pertinent positive and negative findings; Presentation leads to a clear understanding of the patient

Good: HPI generally reflects the patient's story; Presentation can be followed; History includes adequate discussion of biopsychosocial factors; Presentation includes major pertinent negative findings; Presentation leads to an adequate understanding of the patient

Fair: HPI ignores or inaccurately represents the patient's story; Presentation is disorganized or chaotic; History misses important biopsychosocial factors; Presentation ignores some pertinent positive or negative findings; Presentation leads to a poor understanding of the patient

Poor: HPI distorts or misinterprets the patient's story; Presentation is incoherent or illogical; History shows no awareness of biopsychosocial issues; Presentation misinterprets or disregards pertinent positive or negative findings; Presentation is grossly inaccurate

3–2. Organized and accurate presentation of mental status findings

Excellent: All areas of the MSE are presented; Presentation is orderly, systematic, and easy to follow; Standard terminology and nomenclature are used; Findings are accurate and complete; Pertinent negative findings are included; An appropriate and accurate assessment of dangerousness is included

Good: Most areas of the MSE are presented; Presentation generally follows a standard outline; Clear and meaningful terms are used; All critical findings are included; Most important negative findings are included; An adequate assessment of dangerous is included

Fair: Several pertinent areas of the MSE are omitted; Presentation is disorganized and rambling; Ambiguous, inappropriate, or unclear terminology is used; Some critical findings are omitted or misrepresented; Important negative findings are omitted; Assessment of dangerousness is inadequate or only partially accurate

Poor: Major areas of the MSE are omitted; Presentation is incoherent and impossible to follow; Inaccurate, meaningless, or inappropriate terminology is used; Most critical findings are omitted

or misrepresented; Negative findings are not included; Assessment of dangerousness is omitted or is inaccurate

4. **Case Formulation and Differential Diagnosis**

Excellent: Comprehensive and well-integrated biopsychosocial formulation; Skillful integration of psychodynamic perspectives; Thorough conceptualization of patient's story; Well-structured and clinically appropriate differential diagnosis

Good: Good identification of biopsychosocial factors; Inclusion of appropriate psychodynamic issues; General awareness of patient's story; Adequate differential diagnosis

Fair: Omission of at least one significant biopsychosocial factor; Limited integration of psychodynamic issues; Minimal awareness of patient's story; Too narrow or too broad differential diagnosis

Poor: Inaccurate or incoherent formulation; Poor awareness of biopsychosocial factors; Minimal awareness of psychodynamic issues; Misdirected or inaccurate differential diagnosis

5. **Treatment Planning**

Excellent: Well-formulated, evidence-based, cost-effective treatment plan; Skillful coordination of somatic and psychosocial treatments; Full integration of patient, support system, and outpatient providers into treatment planning; Skillful development of a comprehensive safety plan

Good: General attention to evidence-based, cost-effective treatments; Awareness of available somatic and psychosocial treatments; Inclusion of patient and family preferences in treatment planning; Adequate attention to safety planning

Fair: Little awareness of efficacy or cost data in treatment planning; Limited attention to integration of somatic and psychosocial treatments; Cursory attention to patient and family treatment preferences; Minimal attention to safety planning

Poor: Grossly inadequate or inappropriate treatment; Narrow, rigid, or one-dimensional treatment plan; Lack of attention to or awareness of patient and family treatment preferences; Absence of appropriate safety planning

For each of 12 sections, score as follows: Excellent 7 or 8; Good 5 or 6; Fair 3 or 4; Poor 1 or 2. An acceptable overall score would be a mean of 5 or greater

Material adapted from American Board of Psychiatry and Neurology website.

Table 59.2–7. Scoring the ABPN Clinical Skills Evaluation

Physician–Patient Relationship (Overall)	Unacceptable	Acceptable
1. Opening and closing	Awkward strategies	Appropriate strategies
2. Informational cues	Ignored leads	Followed leads
3. Affective cues	Ignored	Explored appropriately
4. Communication style and rapport	Insensitivity interfered with data collection	Adequate language sensitivity
5. Questioning techniques	Abrupt and forced-choice questions	Open-ended but appropriately structured
6. Control and direction of interview	Scattered and fragmented questions	Developed, cohesive interview
Psychiatric Interview (Overall)	**Unacceptable**	**Acceptable**
7. Presenting problems and HPI	Inadequate obtained or too vague	Obtained adequate data
8a. Past psychiatric history	Ignored major issues	Gathered relevant data in at least brief form
8b. Family history	Ignored major issues	Gathered relevant data in at least brief form

8c. Medical history	Ignored major issues	Gathered relevant data in at least brief form
8d. Social/educational/occupational history	Ignored major issues	Gathered relevant data in at least brief form
8e. Developmental history	Ignored major issues	Gathered relevant data in at least brief form
9. History of drug and alcohol abuse	Ignored or too limited	Sensitively gathered
10. Assessment of suicide risk	Ignored or too limited	Sensitively gathered
11. Assessment of homicidal risk	Ignored or too limited	Sensitively gathered
12. Mental status examination	Omitted or too limited	Organized approach and performed appropriately
Case Presentation (Overall)	**Unacceptable**	**Acceptable**
13. Summary of important data	Disorganized	Presented cohesively and coherently
14. Mental status examination	Incomplete	Accurately summarized
15a. Emergency issues: suicide	Ignored	Considered
15b. Emergency issues: violence/abuse	Ignored	Considered
15c. Emergency issues: drugs/alcohol	Ignored	Considered
16. Recognition of need for additional history and collateral information	Absent or no rationale	Appropriate

In the numbered subsections, unacceptable behaviors are scored from 1 to 4; acceptable from 5 to 8.

The entire score sheet, formatted for computer entry of data, is available at http://www.abpn.com/access-residency-info/residency-training-information/psychiatry/

SUBSPECIALTY PSYCHIATRY BOARD EXAMINATIONS

In addition to the board examinations in general psychiatry, the ABPN offers certificates in 10 subspecialties. The oldest of these, dating from 1959, is the child and adolescent psychiatry examination. The most recent, brain injury medicine, was initiated in 2011.

Child and Adolescent Psychiatry

To sit for this examination, applicants must first be board-certified in adult psychiatry and have completed training in a child and adolescent psychiatry program approved by the ACGME. This computerized examination is administered once a year at Pearson VUE centers and lasts just over 5 hours. Its 280 multiple-choice questions assess core knowledge in the areas of child and adolescent development, consultation, developmental assessment/classification, psychopathology/classification, treatment, prevention, issues in practice, and biological and clinical science. Approximately one-quarter of the questions are based on clinical vignettes (written or video) of actual patients. The oral examination, long a staple of the child and adolescent psychiatry board process, has been eliminated. As with other psychiatry boards, certification is good for 10 years and subject to the usual maintenance of certification procedures (vide infra).

Other Subspecialty Certificates

By examination, physicians who are board diplomates in general psychiatry can earn certificates in other subspecialty fields added since 1991. Each requires one additional year of training (after the fourth postgraduate year) in an institution approved by the ACGME; training may usually be completed on a half-time basis. Each certificate requires a written, multiple-choice examination that in most subspecialties comprises 200 questions. Each is a 10-year certificate with the usual requirements for maintenance of certification through subsequent education and examination. Initial board certification in medical specialties other than psychiatry can qualify examinees for certification in those subspecialties marked with an asterisk (*).

Examinees for these certificates will be tested by computer in the following areas:

Addiction psychiatry—scientific foundations of addiction psychiatry, evaluation, treatment, systems-based practice.

*Brain injury medicine—patient evaluation and diagnosis, prognosis/risk factors, management, applied science; traumatic brain injury by severity and pattern, other neurologic disorders, systemic manifestations, rehabilitation problems and outcomes, basic science.

*Clinical neurophysiology—electroencephalography and electromyography, nerve conduction studies, other clinical neurophysiological studies, basic science.

Forensic psychiatry—civil and criminal law, legal regulation of psychiatry, corrections/correctional health care, legal systems/basic law, children/families, special diagnostic issues, death penalty.

Geriatric psychiatry—biological, developmental, social, and psychological aspects of aging; diagnostic methods; the interface between general medicine and psychiatry; neuropsychiatric and neurological aspects of aging; psychopathology and psychiatric diagnosis; treatment.

*Hospice and palliative medicine—approach to care, psychosocial and spiritual considerations, impending death, grief and bereavement, medical management, communication and team, ethical and legal decision, prognostication and natural history of serious illness.

*Pain—basic science, clinical research, animal models, ethics; assessment and psychology of pain; treatment (drugs and other modalities); clinical states (comprising taxonomy, tissue pain, visceral pain, headache and facial pain, nerve damage, and special cases: age-related, substance-using, and impaired individuals).

Psychosomatic medicine—issues of evaluation and management, symptoms and behaviors, treatment in these areas: dermatology, endocrine and metabolism, gastrointestinal disease, heart, HIV/AIDS, infectious disease and chronic fatigue syndrome, legal and ethical issues, lung,

neurology, obstetrics/gynecology, hematology/oncology, pain and palliative care, physical medicine and rehabilitation, kidney, rheumatology, transplant, surgery/critical care, pediatrics, organ transplantation; special topics such as drug interactions, systems-based practice issues, research/appraisal.

*Sleep medicine—normal sleep and variants, sleep–wake timing, insomnia, hypersomnolence, parasomnias, movement disorders, breathing disorders, sleep in other disorders.

MAINTENANCE OF CERTIFICATION

Since the mid-1990s, the ABPN certificates issued in general psychiatry and subspecialty examinations have been good for 10 years. Ideally, recertification for any profession as complicated and high-risk as the care of psychiatric patients requires the evaluation of many qualities, and hence the stimulus for the concept of an ongoing maintenance of certification in psychiatry—as well as in the other specialties of medicine.

Psychiatry recertification was originally planned to be an open-book, take-home examination. However, unless completed on-site, there can be no assurance that a given clinician actually took the examination, so in recent years, as mandated by the American Board of Medical Specialties, the ABPN has moved to a much more formal (and expensive) procedure. That is why certificate holders in psychiatry or any of its subspecialties must now pursue a multipart educational course structured to stimulate continuous improvement and learning. Although a little complicated to describe, the process is logical and well-designed to address its stated goals.

Of the ACGME competencies (Table 59.2–2), only medical knowledge can be fully assessed by written examination. So, to maintain certification past the initial 10 years, diplomates must: (1) assure their professional standing (have an unrestricted license to practice), (2) pursue continuing medical education (on average, 30 credits per year relevant to their specialty or subspecialty), (3) complete self-assessment modules, (4) complete performance in practice (PIP) modules, (5) demonstrate cognitive expertise, and (6) wait!—there's more promised yet to come. The first two of these require no further explanation; for the remaining parts, some details appear below.

Self-assessment—each 3-year period, an average of eight CME credits per year must come from completing ABPN-approved self-assessment activities. These must cover new information or best practices and provide feedback the individual can use for later improvement. The ABPN website lists dozens of self-assessment activities sponsored by various universities and other institutions. Some CME credits can be waived if a psychiatrist completes certain other activities, such as writing an (accepted) grant application, passing a cognitive examination, and writing an (accepted) article for publication.

Improvement in medical practice—also called performance in practice (and in any case abbreviated PIP), this group of programs assesses individual practice improvement in clinicians who are currently clinically active. Two modules are required: (1) assessment with best practices and practice guidelines of data from five of the clinician's own patient charts (perhaps they have, say, bipolar disorder or they receive a particular sort of treatment such as electroconvulsive therapy). Within 2 years, progress toward needed change would be judged by re-evaluating these (or other) five patients, similarly selected. (2) A second required PIP module uses feedback on the psychiatrist's effectiveness and/or efficiency from five peers or patients as a guide to self-improvement, which must be afterward reassessed. One each of the chart review and peer/patient feedback modules is required every 3-year period.

Patient safety—beginning in 2016, every individual applying for certification or recertification must complete 10 modules of an approved patient safety course. The more than five-dozen possible topics include the science of patient safety, measurement and outcomes, risk management, engaging patients and family, suicide risk, diagnostics and errors in psychiatry, and the epidemiology of errors and safety.

Cognitive expertise. Once in each 10-year cycle, psychiatrists must obtain a passing score on a multiple-choice, computer-administered examination. Currently, these are administered at Pearson VUE testing centers.

Of course, it approaches impossibility to evaluate the totality of a physician's competence, but the use of multiple methods would appear to enhance the likelihood of maintaining competence. And as currently structured, maintenance of certification should also reduce to a minimum both the financial and emotional burdens that physicians can experience during the initial certification process.

OTHER MENTAL HEALTH PROFESSION EXAMINATIONS

The ABPN only assesses graduate psychiatrists, not those in training (this is the purview of the ACGME). It forthrightly claims that it has no educational mandate and that it is not intended as a way of evaluating training strategies. Beyond such obvious methods as rating checklists and observation (direct or recorded), other examinations and formats have been brought forward to evaluate trainees and provide feedback to them.

Psychiatry Residency In-Training Examination

Nationally standardized examinations for residents still in training were adopted by many specialties during the last third of the 20th century. The Residency Review Committee for psychiatry requires that each program use a formal standardized test as a part of its evaluation of trainees; to

comply, all adult psychiatry training programs nationwide (as well as programs in Canada) have now adopted the 300-item Psychiatry Residency In-Training Examination (PRITE). In use since 1979, the PRITE is administered to more than 6,000 residents each year in fulfillment of the ACGME-required annual (in post-graduate years 2, 3, 4) evaluation of each resident's cognitive knowledge across biological, psychological, and social spheres.

This timed, closed-book, written, proctored examination offers trainees the opportunity to track their progress throughout training and to gauge their own performance against that of colleagues. It is developed by representatives of the American College of Psychiatrists in collaboration with the American Academy of Child and Adolescent Psychiatry, American Association of Directors of Psychiatric Residency Training, and Association for Academic Psychiatry; neurology consultants and current psychiatry residents collaborate.

To accommodate the schedules of individual training programs, the 5-hour PRITE can be administered on any 2 half-days within a 3-week window during the fall of each year; the window reduces the likelihood that questions will be circulated by the first examinees to take it. However the schedule is arranged, all residents in the program must participate; confidentiality of their results is guaranteed. PRITE examinations are administered following a written protocol by the training programs. Since 1996, there has also been a child PRITE, a 150-item test whose purpose and structure are similar to those of the general PRITE examination.

Resident input into test item development has been encouraged, causing some feeling that those who so participate reap a competitive advantage for their efforts. However, in the words of one participant, "I submitted my questions so long before they were scheduled for use that by the time of the examination, I couldn't remember what I had written!"

Training directors agree that scores will not be used to decide whether a resident will be dropped from a training program. However, many training directors use the results for individual counseling and for assessing the effectiveness of their programs. Roughly 15 to 20 percent of the PRITE emphasis is on neurology and the neurosciences; the remainder is on these principal psychiatric knowledge areas: adult psychopathology, alcoholism and substance abuse, behavioral science and social psychiatry, child psychiatry, consultation–liaison psychiatry, emergency psychiatry, forensic psychiatry, geriatric psychiatry, growth and development, patient evaluation and treatment selection, psychosocial therapies, and somatic treatment methods. Miscellaneous subjects include history of psychiatry, administrative psychiatry, and ethics.

The goal of the PRITE is truly to educate. Comparative percentile scores are reported for both the psychiatry and the neurology components of this examination. For the overall test and for each subsection, training directors

and each trainee receive the individual's exact numerical scores, ranking compared with peers in that program, and nationwide peer-group percentile rank. Training directors learn the grouped percentile ranks on each subtest for the residents in each training year, as well as how their residents compared nationally on each question. Residents also receive copies of the questions and answers, with references for further study examination.

Development and administration costs of the PRITE examination are borne by the training programs, which pay a flat fee per resident tested each year. Residents invest only their time. Copies of past PRITE examinations are available at a not-so-nominal fee (currently $150) from their website: http://www.acpsych.org/prite. Nonetheless, such openness mandates a yearly rewriting of the examination itself, which retains only enough questions from the prior year to allow comparison with examinations given in previous years.

Some training directors report that extreme scores on the PRITE strongly predict outcome of the ABPN board examination: "I've hardly ever seen a resident who scores above the 90th percentile on the PRITE who has any trouble at all with the boards," one training director reported. "But I counsel graduating residents who score below 50 percent to take at least one board review course."

Board Certification of Psychologists and Other Disciplines

For over 60 years the American Board of Professional Psychology (ABPP) has taken a quite different approach to credentialing: it relies principally on evaluating the actual work of certificate holders. For each of 16 current (as of 2017) specialty areas in clinical psychology, the multiple-step process begins with verification of credentials, followed by submission of extensive documentation to provide the basis for a later oral examination.

Although there is some variation depending on the subspecialty board the candidate is applying for, in general candidates submit a professional statement of their philosophy of practice, including awareness of cultural diversity, potential ethical dilemmas (perhaps one actually faced by the candidate), complex interpersonal interactions, and a description of current work coupled with the evidence base that underpins practice. In addition, there must be a practice sample. Whereas some subspecialties accept written descriptions of patient evaluation or treatment (perhaps with results of testing), others require at least one unedited, unrehearsed video of an actual patient evaluation or intervention. The video, typically running 50 minutes, must be accompanied by background material adequate to give members of the board an appreciation of the candidate's clinical competence. In some cases, the practice sample may be returned with a request for more detail. (Two specialty areas—forensic psychology and clinical neuropsychology—also require a written, multiple-choice

examination.)

The final step is a 3-hour oral examination conducted in person by three psychologists already certified in the relevant subspecialty area. A typical oral examination, which may be conducted by a panel or in three separate one-on-one sessions, will focus on the candidate's professional statement and work sample, though hypothetical examples are used to fill in any areas not covered in the practice materials submitted. The candidate must receive passing scores from at least two of the three examiners in each of several competency domains: science; knowledge and methods; assessment; intervention; consultation; relationships; interdisciplinary systems; individual and cultural diversity; ethical and legal standards; professionalism; and, when applicable, teaching, administration, research, and advocacy. Vignettes covering aspects of ethics may be introduced to spur further discussion. In essence, the oral examination process is similar to the writing and defending of a graduate school thesis.

Of the approximately 100,000 licensed psychologists in the United States, currently only about 4,000 are board-certified. Although most employers do not require certification as a prerequisite, some require it for continued employment; a few will pay for the employee's certification process; others may award a step-rise in pay for certification.

Beginning 2015, all certificates are issued for 10 years, with a maintenance-of-certification process much like that of other health care disciplines.

Social Work

Certification by the American Board of Examiners in Clinical Social Work relies on statements by the clinician and evaluations by two colleagues (chosen by the applicant). Annual recertification requires a statement of current direct clinical practice, continuing education, and state licensure. Credentials can be obtained in advanced generalist, child and family, and clinical supervision social work and in psychoanalysis. Through an independent organization, certification is also available in forensic social work.

Multiple-Station Examination Format

Similar to the practical examination used for decades in basic science courses, the objective structured clinical examination (OSCE) uses objective criteria to evaluate trainees' practical clinical skills. Typically, several stations are set up portraying clinical problems—a videotaped patient's interview to diagnose, results of laboratory values to interpret, an emergency scenario to evaluate. Test results are scored according to criteria the faculty determines in advance. Advantages are that a number of trainees can be evaluated within a short time, evaluations are objective, the

material tested is relevant to actual clinical situations, and the examinations can be quickly and cheaply administered.

Standardized Patients

Patients (often actors) trained in responses typical of a given disease have been used to present trainees with reproducible symptoms and histories, thereby addressing a leading source of examination error: individual patient variability. These "patients" can also be taught to rate their own reactions to those who examine them, yielding yet another evaluative dimension (though it may be subject to recall bias).

360-Degree Evaluations

Long used by businesses and some health care organizations such as the Department of Veterans Affairs are subjective assessments provided by supervisors, coworkers, students, and others (including patients) who work with the individual being evaluated. Questions can be tailored to fit any discipline—specific ACGME competencies as adapted to psychiatric practice, for example. The breadth of information obtained, often using standard Likert scales, can provide credibility that cuts through concern about possible bias. The resulting ratings and comments can help trainees become better aware of their individual strengths and needs for improvement. Gap analysis can help identify—and hence address—areas where one's overly sanguine (or critical) self-evaluation is discrepant with that of others.

The feedback module of ABPN's Improvement in Medical Practice (which, for historical reasons, it abbreviates PIP) is one such 360-degree evaluation. Every 3 years, clinicians are required to solicit feedback concerning their own clinical activities from five colleagues (including nonphysicians) or five patients. Each clinician must then identify opportunities for improvement and resurvey (the same or different respondents) within 2 years to determine what improvements have occurred. Areas for potential survey include patient care, medical knowledge, interpersonal and communication skills, professionalism, and medical knowledge, among others.

Psychiatrists In-Practice Examination (PIPE)

Practicing psychiatrists can assess their professional skills with the Psychiatrists In-Practice Examination. Its 200 online multiple-choice questions cover the content areas represented on the ABPN maintenance of certification examination. Feedback for each item as it is completed includes the correct response and two references for further exploration. Clinicians can earn up to 30 hours of CME if they answer at least 50 percent of the questions correctly; they have up to 1 year to complete the

exercise. A new PIPE is issued in July of odd-number years. Further information is available at https://www.acpsych.org/pipe.

EVALUATING THE SUCCESS OF EXAMINEES'AND EXAMINATIONS

Does interview control really equate to safe practice of psychiatry? How well do the boards and other examination formats test what mental health professionals need to know? An analogous question might be, does success in the 100-yard dash predict performance in the marathon?

Success of Examinees

For many years under the Part I/Part II examination system, the success rate for those seeking certification in general psychiatry fluctuated from the low 50s to the mid-70s percent. Indeed, until early in this century, the pass rate for those taking the oral examination was under 60 percent (with the Part I written examination running a few points higher). For the first 5 years (2011 to 2015) of the computerized cognitive examination, pass rates have averaged a much more robust 88 percent.

The reasons for this improvement are complicated and, probably, multifaceted. Of course, candidates just coming out of training may be better prepared now than they were in the past. (A large factor must be that only first-time candidates have taken the new-style written examinations.) But the examination itself may have changed in important ways. One of these is the fear factor: with less riding on a single throw of the dice that is worried over for months in advance, the relative absence of anxiety could play a role in raising the pass rate. Of course, the required cognitive examination is also potentially stressful, but it is arbitrated by a computer algorithm, not two strangers who for an hour sit in stone-faced judgment of the candidate's efforts.

One crucial factor may be ABPN efforts to improve the objectivity of its assessments. Here is some background: In a 1990 assessment of the reliability of evaluative judgment, 94 academic psychiatrists rated a videotape portraying the first 210 seconds of three interviews. The psychiatrists were asked to rate the interviews using a data checklist, a global rating scale, and an estimate of time allotted to various interviewing activities. Only a low level of agreement among raters was found for any of these methods; this performance did not improve when videotape segments twice as long were subsequently used. A 1991 study of agreement between examiners on the live-patient interview found that the examiners initially had a major disagreement (one said *pass,* the other *fail*) on 7 percent of candidates examined. A study from 1983 found that the results of the videotape and live-patient examinations disagreed (one showing "pass," the other "condition" or "failure" for 39 percent of candidates; 13.5 percent of all candidates were straight-up pass-fail discrepant. Data such as

these suggest that on-the-fly assessment by individual examiners may introduce much of the variation that was inherent in the oral examination process. In effect, computer-based testing and scoring has helped to pry the scores of modern candidates from the clutches of subjectivity.

Subspecialty Examinations

For years, the success rate for the child boards was about the same as for the adult oral exam—approximately 62 percent. Beginning in 2011, candidates who had entered into training since mid-2010 have been examined by a single computerized test, with the evaluation of the live patient relegated to the training programs, just as has been the case for adult psychiatry. For 2012 and 2015, the computerized examination yielded an average pass rate of 91 percent. Candidates who began training earlier have continued to be examined using the older, two-step (computer and oral) examinations, which have yielded pass rates averaging 87 and 76 percent, respectively. The reasons for the recent improvement are probably similar to those just given above for the general psychiatry examinations.

Other subspecialty examinations yield pass rates that tend to be stable for the specialty involved, though the subspecialties themselves vary considerably. Thus, the period 2011 to 2015 yielded pass rates of 95 percent for forensic psychiatry, 89 percent for geriatric psychiatry, 96 percent for addiction medicine, and 90 percent for psychosomatic medicine.

Recertification

As with initial certification, the maintenance of certification examinations for general psychiatry and for all of the subspecialties are not referenced tests; theoretically, all can pass. Furthermore, there is no limit on the number of times a candidate can take an examination in the effort to remain certified. In fact, over the past few years, a very high percentage of test takers have passed—which is only logical, inasmuch as this test is only a reaffirmation of competence already demonstrated. For example, from 2008 through 2015 the pass rates for general psychiatry and child and adolescent psychiatry have each averaged 99 percent. Through 2015, MOC pass rates for the subspecialties of addiction, forensic, and geriatric psychiatry have averaged 93, 95, and 95 percent, respectively.

Success of Examinations

With only one official ABPN examination to pass for certification, and no individual examiner judgments to consider, the issue of reliability of the examinations (consistency in a test–retest situation) has gone, so to speak, by the board. There remain, however, multiple opportunities to assess validity: the ability of an examination to yield an accurate measure of an examinee's capabilities. Several types of validity are relevant to these

examinations.

Content Validity. Does the examination evaluate material that experts consider vital to the assessment of psychiatric capability? That the content of the written psychiatry examination (Table 59.2–1) coupled with the oral examination (Table 59.2–3) covers the basic medical competencies (Table 59.2–2) would seem to defend a positive answer to this question. However, the concept of content validity carries with it the whiff of circular reasoning.

Construct Validity. Does the test actually measure what it claims to measure? In an examination that purports to assess competence in a medical specialty, test performance should correlate positively with amount of training. This was indeed the finding in a 1990 study that found PRITE scores rose with each year of psychiatry residency training.

Criterion Validity. In criterion validity, a new test is validated against an established measure of alleged accuracy. When both measures are administered simultaneously, concurrent validity is measured. When the established measure is made at a future time, as in a follow-up study, it is called predictive validity.

Following are some of the more recent studies that address aspects of examination validity.

Between-Examination Comparisons . Studies abound in psychiatry and other fields of medicine. Here are just a few of them.

- Two separate studies in surgery found that mock oral boards had substantial sensitivity and positive predictive value in relation to eventual performance on the certification examination.
- The senior in-residency examination for pathology correlated with pass rates for boards. Further, there was a strong correlation in the residency examination from year to year.
- In a 2013 study, the child in-residency psychiatry examination correlated positively with Part I of the ABPN subspecialty board examination, showing that "they assess the same achievement domain."
- A 1998 study of a psychiatry clerkship OSCE reported evidence of both construct and concurrent validity.
- A 1996 study of 701 psychiatrists found a "moderate" correlation (Pearson 0.67) between results of the PRITE and Part I (written) of the ABPN examination. Neurology score correlations were lower.

On the other hand, some studies have reported discouraging words. For example,

- OSCE performance was only weakly correlated with performance on the

national dental board examinations. The former may have measured qualities such as solving problems, thinking critically, and the ability to communicate, whereas the latter were designed to evaluate the examinee's ability to remember or recognize information.

- Performance on the OB/GYN in-training examination was in 2008 judged a weak tool to predict the probability of a resident failing the board's written examination.
- A 1996 study found no correlation between first-time success rates (Parts I *and* II) on the general psychiatry boards and passing the child and adolescent oral examinations on the first attempt.

The fact that programs lately tend to run both major psychiatry examinations concomitantly creates a perhaps now insurmountable challenge for predicting outcome of one from the other. On balance, however, the studies seem to suggest that there will be at least a modest correlation between the various examinations that psychiatrists must take over the course of training and beyond.

Processes

How the processes of medical care—laboratory tests, patient care instructions, and the like—are affected by certification or MOC is easy to evaluate, relative to the study of actual outcome. Various studies have evaluated how the medical processes operate and succeed.

- Internists performing in the top quartile of their MOC examination were more likely to perform mammograms and diabetes processes of care such as hemoglobin A(1c) screening and lipid testing.
- Diabetes quality measures improved for family medicine clinicians who pursued maintenance of certification activities. They also improved, though less so, for clinicians who did not. However, the writers expressed concern over evidence that clinicians preferentially attend CME activities in areas where they are already proficient.
- Another recent study suggests that family practitioners may choose MOC self-assessment modules based on what they already know, rather than what they need to learn.
- A 2017 study of quality measures for treatment of schizophrenia (such as use of atypical antipsychotic medication, polypharmacy prescription, and testing for glucose and lipid) revealed no statistical differences that could be explained on the basis of board certification of the treating psychiatrist. The same report found no process differences for neurologists treating ischemic stroke.

These and other published data seem to support the idea that certification and MOC can favorably affect the manner in which clinicians deliver care—at least, in non-mental health professions.

Outcomes

The strongest validation of the certification process comes from studies that demonstrate better outcomes among patients of clinicians who have earned a certificate. Currently, no such data exist for psychiatry, though there may be some in the pipeline. Other medical specialties have reported outcome data related to board certification or MOC, though some of these reports are less than fully supportive of the premise. And of course, studies may have been done and not published because they were negative.

- Surgeons certified in colorectal surgery had better survival rates among Medicare beneficiaries than did their non-certified colleagues. However, the authors were careful to point out that the board certification per se might not have yielded the result—"technique, training, experience, and focus of practice" could have been confounding factors.
- A "modest" association was reported in 2012 between physicians' cognitive skills on the general internal medicine MOC and a composite measure for the delivery of diabetes care.
- Patients were more likely to adhere to treatment for obstructive sleep apnea if it was prescribed by certified clinicians, who may have delivered a better educational experience.
- In 25 of 27 series reported in 2009, specialized surgeons had better cancer outcomes than did those who were not specialized. Two studies looked at the duration since passing boards; both found greater time (that is, more experience) equated to better outcomes.
- Ethics and morals are hard to define, let alone measure. However, separate studies found that physicians disciplined by medical boards in Oklahoma and California were less likely to be board-certified than control groups. A subsequent study found no such difference between disciplined and nondisciplined psychiatrists (board certification was reported for 43 percent vs. 46 percent, respectively). Yet another report revealed 5 times the likelihood of action against internal medicine practitioners who had not achieved board certification as those who had.

So as to avoid the appearance of cherry picking, here are some negative results.

- Surgeons with fundamentals of laparoscopic surgery (FLS) certification experienced 3 times as many bile duct injuries as did non-FLS surgeons did. The 2014 article deemphasized the negative effect of certification and instead highlighted the fact that the FLS+ surgeons were younger and less experienced.
- A 2013 summary article showed various modest advantages in provision of care for internists participating in MOC, but concluded that "the available medical literature does not provide strong support for the assumption that internists with certification or recertification have better

patient outcomes."

- No studies have supported superior performance of psychologists certified by the American Board of Professional Psychology. Actually, no studies have been reported at all.
- In a 2004 poster presentation, psychoanalysis patients of clinicians who were certified (by the Board on Professional Standards) did no better than patients of those who were not certified.

And *still* the only experimental study of ratings in mental health care delivery yet reported (in 1983) compared outcome of psychotherapy delivered by residents to nine patients using the following evaluations: didactic examination, global ratings by trainers, supervisors' ratings based on therapists' recollections of sessions, self-ratings, and independent evaluators' ratings of videotaped sessions. Patient outcome correlated only with the supervisors' ratings, which (as the authors acknowledged) could have been influenced by knowledge of that outcome. This halo effect was subsequently diminished when, after viewing videotapes of their trainees' actual therapy sessions, supervisors revised downward their overall evaluations. It appeared that trainees' personality characteristics and ability to discuss theoretical material boosted supervisors' opinions.

The ability of ABPN certification to signify quality mental health delivery is often held almost as a tenet of faith. With much to recommend it in terms of logic, it remains not only largely unproven, but even untested. At least the profession has begun to move beyond the observation of a single patient–provider encounter as predictor of how that trainee would perform in a different clinical situation. American psychiatry—indeed, every American medical specialty—should adopt as a task of utmost importance the search for correlations between board certification and patient outcome.

Summing Up

The relentless advance of scientific methods in the affirmation of a knowledge base has led to wholesale change in the methods whereby clinicians are evaluated and certified as fit guardians of the health of the public. The challenge now is to generate more and better studies to demonstrate that new examination methods lead to patient care that is improved in important ways.

Ethics and Forensic Psychiatry

▲ 60.1 Clinical-Legal Issues in Psychiatry

CLARENCE WATSON, J.D., M.D., SPENCER ETH, M.D., AND GREGORY B. LEONG, M.D.

INTRODUCTION

Among the medical specialties, psychiatry plays a particularly distinct role within the province of the law, given its potential application across a wide range of legal issues. Contained at the core of most legal principles is the general presumption that adults of sound mind possess the capacity to understand, appreciate, reason, and choose throughout a boundless range of life activities. When those mental capacities are called into question at the behest of a legal quandary, psychiatry may be summoned to assist with reaching an equitable resolution. The presence or absence of a mental health or cognitive disorder may significantly impact the manner that a legal issue, whether civil or criminal, is perceived and ultimately managed. For instance, the presence of major depressive or psychotic symptoms may impact an individual's legal right to refuse a recommended surgical procedure. Similarly, the presence of significant psychiatric symptoms at the time of a criminal act may negate an individual's culpability for that offense. The enduring relationship between the law and psychiatry has evolved over the centuries as a necessary element of humankind's aspiration toward just resolution of legal disputes. In no other place is this more evident than with the historical development of the legal concept of insanity in criminal law. Once reserved only for those individuals whose minds were equated with that of a wild beast, the legal concept of insanity has progressed to varied jurisdictional approaches in determining the degree of mental impairment necessary to absolve an individual of criminal responsibility. Equally as significant is the historical development of the doctor–patient relationship. Once considered a lopsided paternalistic arrangement, in which patients were expected to passively accept the medical care directed by their physicians, the doctor–patient relationship has matured into a dynamic interaction that centers on patients' autonomy,

including a patient's right to refuse treatment.

From an eagle's eye view, the interplay between psychiatry and the law can be broadly divided into situations involving clinical treatment interactions and situations involving specific legal matters that require the input of psychiatrists to settle a contested legal issue. The complexities within this broad division cannot be overstated, and accordingly, the subspecialty of forensic psychiatry was, in essence, produced from necessity and the ever-developing legal landscape. Clinical-legal issues such as patient confidentiality, informed consent, the right to refuse treatment, and medical standards of care are ubiquitous in the psychiatrist–patient therapeutic relationship. Potential involvement by psychiatrists as experts in contested legal matters, such as criminal cases, personal injury lawsuits, employment-related claims, testamentary disputes, or child custody cases requires familiarity with legal principles and jurisdictional laws, and the ability to apply psychiatric knowledge to the relevant legal inquiry at hand.

Over the course of centuries, the unique pirouette shared between psychiatry and the law has at times lacked grace, but nonetheless, has steadily moved toward a more elegant cooperative existence. Often marked by tensions inherent in speaking different native tongues of the respective realms of medicine and law, the cooperative existence has benefited from both medical and legal literature aimed at bridging the gap. This chapter is meant to contribute to those literary efforts and offer common ground for the understanding of clinical-legal issues involving psychiatry.

THE DOCTOR–PATIENT RELATIONSHIP

The concept of the doctor–patient relationship is naturally bound to the ancient roots of medicine itself. Evolving from a period when physicians were not distinguished from priests, magicians, or other ancient healers, the doctor–patient relationship initially resembled an archaic priest–supplicant relationship that hinged on a parental figure's power to manipulate nature on behalf of his ward. During the 4th century B.C., the Hippocratic Oath set forth a code of ethics outlining principles that remain essential features of modern-day medical ethics, including patient confidentiality, abstaining from sexual contact with patients, and preventing harm to patients. The familiar dictum, *Primum non nocere* or first, do no harm, further distilled the fundamental ethical principle at the core of the doctor–patient relationship.

Clearly, at the heart of these traditional ethical doctrines, physicians are charged with acting only in the service of patients' medical benefit. The ethical principle of beneficence, where ultimate medical benefit is paramount, was traditionally used to justify a paternalistic approach to medical care that was primarily physician-driven. However, during the late 19th and early 20th century, there was a growing sentiment that patients had the right to actively influence the course of their medical care. The

concept of patient autonomy gradually gained ground and ultimately displaced the long accepted institution of medical paternalism.

Patient autonomy was clearly endorsed in the 1914 case, *Schloendorff v. Society of New York Hospital,* which served as the figurative "canary in the coalmine" for medical paternalism in the dawn of an evolving informed consent doctrine. In that case, Justice Benjamin Cardoza ruled, "Every human being of adult years and sound mind has a right to determine what shall be done with his own body…" While not formally established in *Schloendorff,* the informed consent doctrine would become a more clearly defined legal requirement four decades later in the 1957 *Salgo v. Leland Stanford Jr. University Board of Trustees* case.

Certainly, at the inception of any doctor–patient relationship there attaches a body of legal and ethical obligations owed by the physician to his patient. The shift away from medical paternalism toward the incorporation of patient autonomy permitted a more appropriate balance within the therapeutic relationship. Such a balance between a physician and his patient naturally facilitates a treatment partnership; however, there are clinical situations that call for prioritizing medical benefit over patient autonomy. Justice Cardoza's words in *Schloendorff* indicated his awareness of two important caveats regarding the "right to determine what shall be done" with one's own body: adulthood and soundness of mind. It follows, of course, that the impact of existing psychiatric symptoms must be considered in the full clinical context when issues related to patient autonomy arise. Medical decision-making capacity, involuntary psychiatric treatment considerations, and patient confidentiality matters may all be influenced by the presence of significant psychiatric symptoms that temporarily deemphasize autonomy concerns.

MEDICAL DECISION-MAKING AND COMPETENCE

As initially framed in *Salgo v. Leland Stanford Jr. University Board of Trustees,* the law requires that physicians provide facts to their patients regarding treatment options that are "… necessary to form the basis of an intelligent consent." Through this case law, the informed consent doctrine was established and formed a basis for physician liability when patient harm occurs in the setting of inadequate communication of the risks associated with treatment. In order to sufficiently obtain a patient's informed consent, three elements must be present: the physician's disclosure, the patient's voluntariness, and the patient's mental competence. Exceptions to the informed consent requirement include medical emergency, patient's waiver of the physician's disclosure requirement, and invocation of therapeutic privilege in situations where the disclosed information would be detrimental to the patient.

Generally, the informed consent disclosure requirement dictates that patients receive information regarding their diagnosis, the proposed

treatment with the associated risks and benefits, treatment alternatives, and likely consequences of declining treatment. The 1972 case, *Canterbury v. Spence,* established that physician liability may be found if there is a causal connection between a physician's failure to disclose and a patient's injury, where the disclosure of the significant risks of treatment would have resulted in the patient's refusal of that treatment. According to the court in *Canterbury,* that causal connection is based on "... what a prudent person in the patient's position would have decided if suitably informed of all perils bearing significance."

Depending on the state jurisdiction, the legal standard for an adequate disclosure may vary between a physician-based standard and a patient-based standard. In states that utilize a physician-based approach, doctors are required to provide information to patients that a reasonable physician in his specialty would disclose. States that utilize a patient-based approach may require an objective standard that considers the information that a reasonable patient similarly situated would want to know to reach a decision. Some states may require a subjective analysis of the patient-based standard that considers the information that the specific patient would want to know given his or her circumstances.

The voluntariness requirement directs that a patient be permitted to weigh the disclosed information and reach a decision unencumbered by coercion. Accordingly, threats, manipulation, or intentionally misleading information during a patient's decision-making efforts would nullify informed consent. A patient must be given the opportunity to freely consider the physician's disclosure and freely reach a medical decision.

The competency element requires that a patient possesses the mental capacity to understand, appreciate, and utilize disclosed information to reach a rational decision. Legally, all adults enjoy a presumption of competence in medical decision-making and other routine life activities until adjudicated otherwise. Traditionally, the term "competence" is a judicial determination regarding decision-making capability. Conversely, the term "capacity" refers to a clinical determination regarding a patient's decision-making abilities. Accordingly, the psychiatrist's role in competency evaluations is to determine an individual's mental capacity, which may later be formally adjudicated in a legal competency proceeding. In contested matters, courts have upheld the rights of a competent adult to refuse treatment. Courts may, however, adjudicate a person as incompetent if psychiatric symptoms or cognitive deficits impair an individual's mental capacity to communicate a choice, to demonstrate factual understanding and appreciation of his situation, or to rationally manipulate factual information related to his situation. In cases of adjudicated incompetence, treatment decisions generally shift from the patient into the hands of a substitute decision-maker or designated guardian.

Significant symptoms of mental illness or cognitive disorders are the

typical culprits that undermine competence. However, the presence of those symptoms alone is not sufficient to establish lack of mental capacity or to prove incompetence. In the 1973 case, *In re Maida Yetter,* a patient who was committed to a state psychiatric hospital refused treatment for possible breast cancer. Although delusional, the patient offered a rationale that justified her treatment refusal and allowed the court to determine that she was competent to make that decision independently and did not require a substitute decision-maker.

INVOLUNTARY HOSPITALIZATION AND TREATMENT

Two traditional legal justifications, *parens patriae* and police power, provide state jurisdictions with the authority to involuntarily hospitalize, or civilly commit, mentally ill people for the purpose of treatment. *Parens patriae* refers to governmental power to care for individuals who are unable to care for themselves. The initial application of the *parens patriae* principle for the care of the mentally ill in the United States is found in the 1845 case, *In re Oakes,* which established the basis for courts to involuntarily hospitalize mentally ill persons for treatment and to prevent harm. The police power principle refers to the societal interest of permitting governmental authority to protect the general public from potential harm.

Jurisdictional statutes regarding involuntary psychiatric hospitalization vary from state to state, but generally require the presence of a mental illness and a degree of risk of harm to the patient or to others due to the patient's symptoms of mental illness. Typically, the clinical determination for the necessity of civil commitment weighs a patient's current symptoms, relevant historical information, and collateral information sources (e.g., family members, friends, etc.) in the setting of a patient's inability or unwillingness to cooperate with the examination. During these assessments, the critical issue that must be addressed is whether patients' current psychiatric symptoms place them at risk of harming themselves or others. Additionally, some jurisdictions specifically require that involuntary treatment be implemented via the least restrictive alternatives available, as outlined in the 1966 case, *Lake v. Cameron.* Accordingly, clinical consideration must be given to alternatives to involuntary inpatient hospitalization, such as day treatment programs, group home placement, or other outpatient settings, depending on the circumstances.

Usually, these civil commitment assessments involve emergency situations in which family members, ambulance personnel, or police bring the patient to the emergency department because of concerns that the patient will imminently engage in suicidal, self-injurious, or violent behaviors. In addition, a voluntary patient might demand an immediate hospital discharge against medical advice and compel the psychiatrist to consider whether civil commitment is necessary in lieu of discharge. Due to

the urgency of these clinical situations, civil commitment laws permit clinicians to initiate emergency involuntary hospitalization without an initial court determination. This allows for immediate and necessary treatment interventions without the delay that awaiting a court hearing would cause. Following a statutorily determined period, a judicial review hearing is typically required to weigh the patient's need for continued involuntary hospitalization versus a patient's right to be discharged from inpatient treatment.

The legal standard of proof in civil commitment proceedings is "clear and convincing," which is less than the "beyond a reasonable doubt" standard in criminal trials. It is important to note that involuntary hospitalization does not per se permit medical treatment over patients' objections. Some jurisdictions require additional legal proceedings to permit the involuntary administration of medication over patients' objections. Following adequate treatment targeting the symptoms that necessitated the civil commitment, the patient may be discharged to the community to continue outpatient treatment. In some states, patients with extensive histories of treatment nonadherence and frequent hospitalizations may be evaluated prior to discharge for the appropriateness of outpatient civil commitment in order to improve community functioning.

In addition to standard civil commitment laws for psychiatric treatment, some states have enacted specialized civil commitment laws for the involuntary treatment of violent sex offenders who continue to pose a risk of danger following incarceration. In 1997, the U.S. Supreme Court upheld the constitutionality of sex offender civil commitment laws. Under these specialized provisions, these convicted and incarcerated sex offenders are evaluated prior to their prison release to determine if commitment criteria are present, including the existence of a congenital or acquired mental abnormality, the number and severity of previous sexual offenses, and dangerousness.

Psychiatrists cannot lose sight of the inherently intrusive nature of involuntary treatment. Accordingly, clinicians are ethically obligated to exercise due diligence in obtaining all relevant clinical data prior to determining the need for civil commitment. The psychiatrist continues to bear the ethical obligation of avoiding unnecessary breaches of patient confidentiality. However, testimony and communications to mental health courts required by law for the purpose of civil commitment are permitted without patient consent. Nonetheless, clinical efforts to preserve patient dignity and foster a therapeutic alliance with the patient remain paramount.

CONFIDENTIALITY AND PRIVILEGE

Confidentiality and privilege are related concepts that center on privacy

rights belonging to patients regarding information shared with their physicians during the course of therapeutic relationships. Confidentiality represents physicians' obligation to their patients to not disclose information to third parties without a patient's consent. Privilege also deals with the protection of patient information; however, it refers to the more specific protection against physicians being compelled to provide protected patient information during court proceedings. Privilege is a right that specifically belongs to the patient, in that a physician cannot claim the privilege and refuse to disclose patient information once a patient has waived the privilege.

The doctrine of patient confidentiality is an ethical and legal duty that has been long recognized throughout the tradition of medicine as evidenced by the Hippocratic Oath's charge to preserve patient privacy. Certainly, it is not difficult to understand the basis for this duty. The very nature of the doctor–patient relationship prompts patients to trust physicians with intimate details of their lives, relationships, and bodies for the purpose of medical treatment. Patients' candid communication of these details facilitates effective medical treatment and would likely be discouraged if physicians were free to reveal those details publicly.

Physicians may be held liable for breaches of patient confidentiality through legal theories of medical malpractice, invasion of privacy, and breach of contract for implied warranty of confidentiality. State legislatures have also enacted statutes that prohibit unauthorized release of patient information. Accordingly, physicians may also be held liable for the breach of statutory duty of confidentiality. In addition, the U.S. Congress enacted the Health Insurance Portability and Accountability Act of 1996 (HIPAA), which provides a set of privacy regulations that governs electronic transmission of health information for insurance eligibility and billing purposes. Psychiatrists should note that the practice of telepsychiatry also falls under HIPAA regulations. Accordingly, psychiatrists must ensure that their videoconferencing systems are compliant with HIPAA and state privacy requirements. Violations of HIPAA privacy regulations call for the imposition of fines, however, these regulations do not provide for compensation to patients impacted by confidentiality breaches.

There are several exceptions to the confidentiality duty owed to patients by their psychiatrists. First, disclosures by psychiatrists without patient consent may be permitted in emergency situations in order to prevent imminent harm. Second, psychiatrists may breach confidentiality when acting to protect third parties from a potentially dangerous patient. In 1976, the California Supreme Court decided *Tarasoff v. Regents of the University of California,* which set into motion a nationwide trend establishing the duty of mental health professionals to protect or warn their patients' potential victims or to notify police of a risk of danger posed by a patient. Laws regarding the duty to warn or protect third parties vary by

state jurisdiction and are defined by state statutory and case law. These laws provide an avenue for clinician liability if harm befalls a third party as a result of a mental health professional's failure to disclose the danger posed by their patient. Generally, disclosures made in good faith for the purpose of protecting a third party will not result in liability for breach of confidentiality. Third, psychiatrists may disclose patient information when adhering to state reporting requirements involving concerns such as, child or elder abuse, unsafe drivers, or impaired health care professionals.

The physician–patient and psychotherapist–patient privilege doctrines evolved from the historical legal prohibition of compelled testimony from attorneys against their clients. The basis of that legal tradition was to protect the sanctity of the attorney–client relationship, which would be effectively eviscerated if lawyers could be forced to testify against the very clients that they represented. Much like the justification for requiring patient confidentiality, the physician–patient and psychotherapist–patient privilege facilitates a more open and effective therapeutic alliance. In all state jurisdictions, patients possess the legal privilege to prevent their psychiatrists and psychotherapists from testifying about them. Federal courts also recognized patients' privilege following the U.S. Supreme Court's 1996 ruling in *Jaffee v. Redmond*. As the privilege belongs solely to the patient, psychiatrists have no basis to refuse to testify, if their patients chose to waive that privilege.

However, the privilege is not absolute and may be pierced under a number of circumstances, thereby paving the road to compelled testimony by treating psychiatrists. Patients may lose the privilege in cases where they raise their mental status as an issue in a civil or criminal matter. Medical malpractice claims initiated by patients against their psychiatrists or therapists would also remove the privilege. The privilege does not apply in civil commitment proceedings. In child custody cases, the privilege may be set aside if the best interests of the child outweigh the negative impact of the psychiatrist's testimony. Finally, the privilege could be potentially nullified if the patient shared the information in question with their physician in the presence of a third party who is not involved in the patient's care.

PSYCHIATRIC MALPRACTICE

Psychiatrists tend to dread malpractice lawsuits in excess of the statistical likelihood of being sued and having a judgment entered against them. Across all medical specialties there has been a major reduction in the rate of paid malpractice liability claims during the last decade, which, unfortunately, has not been accompanied by commensurate decreases in the cost of malpractice insurance policies. There are approximately 10 paid claims for every 1,000 American allopathic physicians each year. By contrast, however, the Institute of Medicine estimates that more than

100,000 Americans die annually from medical mistakes, and about 6 percent of patients are injured by medical mismanagement.

About half of malpractice claims filed are litigated. Of these claims, courts dismiss more than half, and another 40 percent are resolved before a trial verdict. The remaining small minority of cases become jury trials, of which 80 percent result in a defense verdict favoring the physician. Nationally, the mean time for resolution of a litigated malpractice claim is 2 years. In one large state, about 2 percent of all malpractice settlement reports were for psychiatrists, compared with 9 percent for internists and 10 percent for general surgeons. The majority of malpractice actions filed against psychiatrists derive from accusations of negligent treatment, adverse effects of prescribed medications, and suicidal and assaultive behavior of patients. The remainder mostly concerns alleged mistakes in diagnosis, breaches of confidentiality, and boundary violations. A psychiatrist's participation in a malpractice settlement exceeding a threshold amount will result in a mandatory report to the federal National Practitioner Data Bank (NPDB), an entity that was first authorized in 1986 as a repository for information such as adverse licensure and hospital actions, and health care providers' malpractice payments. NPDB entries are routinely accessed by hospitals and licensing boards, and may trigger inquiries that cause discomfort for physicians who may have felt unfairly coerced to agree to a settlement.

The theory of medical malpractice refers to professional negligence that falls within the civil law domain, as defined by state statutes and case law. For example, in Florida, patients or their representatives may file lawsuits for personal injury or wrongful death against health care providers. In those malpractice actions, plaintiffs must prove by a preponderance of the evidence that the actions of the provider represented a breach of the prevailing professional standard of care. The standard of care in this context is a legal term that refers to skillful treatment, which in light of all relevant circumstances, is recognized as acceptable and appropriate by reasonably prudent providers in the same specialty, such as practicing psychiatrists.

The law recognizes that the mere existence of an injury does not automatically imply that provider negligence occurred without proof that the provider did in fact breach the standard of care. A bad outcome does not per se equate to bad care. An exception to this rule is the legal concept, *res ipso locquitor* or the thing speaks for itself, where the commission of an egregious error, such as failing to remove an abdominal clamp during surgery, shifts the burden of proof from the plaintiff to the defendant physician to show that negligence did not occur. For psychiatrists, such an egregious error would certainly include sexual misconduct during a therapy session under the guise of treatment.

The necessary elements for patients to successfully establish

malpractice claims have been neatly summarized as encompassing four D's: duty, dereliction, direct causation, and damages. The duty element requires that a doctor–patient relationship had been established, thereby creating a duty of care. Although seemingly straightforward for most treatment situations, there are some instances in which the nature of the professional relationship can be vague. Does a duty begin with the first contact between a potential patient and psychiatrist setting an appointment over the phone or only after the initial in-person meeting? When does the duty terminate? Does a covering physician assume responsibility for a patient seen briefly on rounds over the weekend?

The element of dereliction refers to a breach of the duty to provide reasonable and appropriate care. Psychiatrists are not legally expected to offer perfect, state of the art, or even excellent diagnostic and treatment services. All that is required is for the psychiatrist to perform as would other psychiatrists facing the same patient. Being board certificated in psychiatry is neither necessary nor sufficient to establish that no deviation from the standard of care has occurred. It may be useful to demonstrate compliance with authoritative treatises, such as the Comprehensive Textbook of Psychiatry, recent peer-reviewed publications, or professional association treatment guidelines. However, it is an accepted principle that every person is unique and, consequently, patient-centered care may call for modifications in the usual therapeutic approach. Accordingly, clinical judgment that adequately accounts for a patient's full clinical context, despite an eventual bad outcome, would likely assist in buffering against a claim of dereliction. When proposing an unusual treatment plan that may be later questioned, the psychiatrist would ordinarily be expected to obtain informed consent from the patient. The details of the consent discussion should be carefully inscribed in the medical record, and it may be helpful for patients to sign a note documenting their understanding and agreement.

The direct causation element requires a direct causal connection between a breach of the standard of care and a subsequent patient injury. The term "causation" is one that may have conceptually different meanings in medicine and law. For scientific-minded physicians, a cause–effect relationship identifies that a particular prior event is the physical cause if it resulted in the later effect. The law takes a very different approach. The salient issue is the proximate cause, by which the focus of legal inquiry is whether the act in question was necessary to produce the injury. A common test for direct causation is whether the harm would not have occurred "but for" the prior action.

Legal commentators have argued that direct causation is that necessary element of a set of conditions that are jointly sufficient for the result. For example, a psychiatrist's elderly patient endorsed symptoms of depression, weakness, postural instability, and osteoporosis. The patient fell to the floor

while rising from the office couch at the end of a session and immediately complained of severe pain. The patient was taken to a local hospital emergency room and diagnosed with a hip fracture. Surgery was performed, but the patient developed a postoperative infection that ultimately proved fatal. This tragic chain of events undoubtedly had multiple underlying medical causes. However, from a legal perspective the psychiatrist could be found to be negligent and the proximate cause for all of the patient's subsequent injuries and death. Depending on the facts, the crux of the matter may be that but for the mishap while rising from the psychiatrist's couch, the patient would not have had a broken hip, surgery, an infection, and death. In this regard the patient was surely an "egg shell" whose fall was the "straw that broke the camel's back." As lawyers are fond of saying, one takes plaintiffs just as you find them.

The damages element refers to the plaintiff's alleged injuries that resulted from the physician's dereliction of duty. The civil law recognizes several categories of damages that may accrue to victims of malpractice, all of which are exclusively financial. Monetary awards to successful plaintiffs are intended to compensate the plaintiff for the harm suffered. Compensatory damages address what the patient has suffered as a direct consequence of the substandard care, and include present and future medical costs, lost income, physical and mental impairment, pain and suffering, and decreased life expectancy. Punitive damages, also known as exemplary damages, may be awarded in addition to compensatory damages when a defendant's behavior was found to be particularly egregious or malicious. Punitive damages are not meant to compensate a plaintiff's loss; instead, they are meant to punish the defendant and to serve as a deterrent to the defendant and others regarding similarly wanton behavior. Punitive damages, which are not covered by insurance, rarely arise in malpractice actions against physicians.

Certain aspects of psychiatric practice involve a greater risk of liability. Electroconvulsive therapy (ECT) is a procedure that usually calls for additional training and special precautions, and may be associated with a greater likelihood of adverse events than conducting a psychotherapy session. Consequently, psychiatrists who wish to perform ECT may need to purchase insurance policies that specifically cover this procedure. Prescribing certain psychiatric medications also warrants a cautious approach. Conventional antipsychotic medications place patients at risk of developing tardive dyskinesia, which, when severe, can be disfiguring and disabling. Successful malpractice cases have been filed when psychiatrists failed to alert patients of this side effect risk and neglected to perform and document routine examinations for its detection. Similarly, the use of atypical antipsychotic medications may call for routine assessments for weight gain and abnormalities of blood lipid and glucose metabolism in addition to patient discussions regarding these associated treatment risks.

Increasingly, psychiatrists use formal education materials to supplement informed consent discussions when prescribing common psychotropic medications, such as benzodiazepines, stimulants, and lithium.

The specter of patient suicide affects all practicing psychiatrists; indeed, it is a truism in the field that there are two kinds of psychiatrists—those who have already had a patient commit suicide and those who will. Rather than encouraging fatalism, the ever-present danger of suicide for certain groups of patients should motivate psychiatrists to remain cognizant of the basic suicide reducing strategies. Knowledge of the evolving epidemiology of suicidal behavior is fundamental in assessing static and dynamic risk factors for each patient. There is no question that asking patients about the presence and severity of depressive symptoms and suicidal thoughts is essential for proper care. Such direct inquires do not suggest to or predispose a patient to become actively suicidal. Psychiatrists must respond to an escalating risk of suicidality with very careful monitoring and appropriate modifications in the treatment plan.

No discussion of psychiatric malpractice is complete without consideration of boundaries. Much has been written about the conscious and unconscious forces that are in play in both patient and psychiatrist during a session, especially in the context of psychotherapy. Maintaining the integrity of the therapeutic frame, however challenging, is the linchpin of treatment. Of particular concern are boundary violations that constitute frank lapses in care, such as psychiatrists becoming romantically involved with a current or former patient. This boundary violation is usually characterized by a progression from seemingly innocent conversation, to more frequent social contacts, to physical affection, to sexual activity. In these cases, psychiatrists can exhibit remarkable denial regarding the serious consequences of their own behavior. Not infrequently, a transgressing psychiatrist, such as one who may be lonely, depressed, and substance abusing, begins a destructive relationship with a vulnerable patient, whose judgment may be impaired by an idealizing transference and self-defeating tendencies. Such unethical behavior may result in malpractice and licensing board actions that jeopardize a professional career.

THE PSYCHIATRIST AS AN EXPERT

Expert Witness Testimony

Psychiatrists may be asked to participate in civil and criminal court matters by providing professional opinions based on their psychiatric knowledge and experience as applied to a particular legal question. Typically, the opinions are provided to a requesting party, generally the court or an attorney, either as a written or oral report. In some instances, the opining psychiatrist is required to testify in court, with a jury or judge considering

such testimony along with other evidence in order to reach a verdict. Psychiatric expert testimony takes place in the public purview and is often viewed by the public as a "battle of the experts" or more pejoratively, battle of "hired guns."

In some cases, expert witness testimony is legally required, such as in cases involving allegations of medical malpractice. For example, in order to support a medical malpractice claim that a defendant psychiatrist's treatment led to a patient's suicide, the plaintiff must present expert testimony to show what a psychiatrist of ordinary skill, care, and diligence would have done differently under similar circumstances. Of course, should this malpractice case go to trial, there may also be psychiatric expert witnesses testifying on behalf of the defendant psychiatrist. Two court cases have governed admissibility of scientific expert testimony in the United States, *Frye v. United States* and *Daubert v. Merrell Dow Pharmaceuticals, Inc.* As both cases indicate, it is ultimately the judge's decision as to the admissibility of the expert witness testimony.

Role Conflict as a Psychiatric Expert Witness

The fundamental professional role of psychiatrists involves a clinical or therapeutic perspective. In the clinical or therapeutic setting, the treating psychiatrist deals with the patient's narrative truth and makes no further attempts at confirming a patient's statements. In contrast, when a psychiatrist works outside of the health care setting in the legal arena, the clinical or therapeutic perspective loses its primacy and an individual's self-report should be viewed with objectivity and hence skepticism. Assuming both the therapeutic and expert witness roles for the same individual invites erosion of the psychiatrist–patient relationship, whether it involves completing a disability evaluation in which the treating psychiatrist does not find support for the requested disability, or especially in the case of testifying in court as a psychiatric expert witness.

Separating the therapeutic and forensic roles is the best solution, though at times the dual role cannot be avoided, as in the case of involuntary civil commitment or involuntary medication hearings in which the treating psychiatrist is usually the only professional to testify. There are times in which a treating psychiatrist could be called to testify as a fact witness regarding a patient, but this would entail testifying about symptoms, diagnosis, prognosis, and similar clinical matters versus providing the ultimate psychiatric-legal opinion such as those involving capacity or causation.

Testamentary Capacity

With the population bulge of the "baby boom" generation reaching older age, psychiatrists are being confronted with an increasing incidence of its

emblematic mental condition, dementia, and the related clinical-legal issues of capacity and competence. Although adults are assumed to have capacity for the various activities of daily living and life tasks, that presumption is rebuttable, especially in the presence of cognitive impairment. Each specific deliberative legal act, such as testifying in court as a witness, executing a financial transaction, and even getting married, has its own criteria for mental capacity that must be satisfied in order for that action to be valid. Among the elderly the process of writing a last will and testament is a common and highly valued event that has important implications that will arise after the death of the testator.

Legislatures and courts recognize that making a will is frequently in the province of persons whose mental acuity is significantly less than young individuals engaged in other tasks. Consequently, the cognitive standard for testamentary capacity is generally set particularly low. In most jurisdictions the necessary elements are that persons understand: (1) the fact that they are actually making a will, (2) the nature and extent of their property, (3) the disposition of that property, and (4) who are their natural heirs. From a mental status perspective, this domain of knowledge does not require that the person making the will is fully oriented and, indeed, having the diagnosis of Alzheimer disease per se would not disqualify a person from having sufficient cognitive ability to make or change a will if the criteria for testamentary capacity could be established.

Although simple to state, the prerequisite criteria for testamentary capacity may be, in practice, quite difficult to ascertain after a person's death when the will is finally read. For instance, person could have been suffering from severe dementia at the time of death. However, the document was actually prepared years earlier, and it is the state of mind at the time when the will was written that is dispositive if the document is later contested. A retrospective assessment conducted after death is challenging when there is inadequate evidence of the individual's prior knowledge and abilities. Medical records, deposition testimony from relatives and acquaintances, and information about activities of daily living can contribute to a determination of capacity.

Since wills may be the product of debilitated elderly persons who depend on the physical and medical care of others, there is another requirement that must be satisfied before the terms of the will are honored. Testamentary capacity demands that the testator not be subject to the undue influence of another person. For example, the philanthropist Brooke Astor died at the age of 105 in 2007. Her elderly son was convicted in criminal court of preying upon his mother's diminished mental state by defrauding her in life and coercing her to change her will in his favor rather than directing her assets to her favorite art institutions. An adult child who spends considerable time with a vulnerable parent may be expressing love and devotion. Alternatively, that situation may be exploited to benefit the

child at the parent's expense.

Psychiatrists may be asked to opine whether a certain party exerted control over the person making a will. Certainly whether there existed a confidential relationship and whether the will was rewritten to inappropriately benefit that person are critical factors. In this setting, a "confidential relationship" between two individuals occurs when one of the parties has an obligation to act in good faith for the benefit of the other party. The psychiatrist's expertise will be most relevant to the question of the extent to which the testator was vulnerable to being influenced due to medical or psychiatric illness and the power of the asymmetric relationship.

Criminal Competencies

The presence of competent decision-making is necessary for a criminal defendant navigating the criminal justice process starting from the initial arrest to the implementation of the death penalty. While competence is presumed for adults, the presence of a mental disorder may negate competence. The criminal competencies include: competency to waive Miranda rights, competency to confess, competency to stand trial, and competency to be executed.

The U.S. Constitution and its Amendments, along with subsequent federal and state case law and statutes, delineate the legal safeguards for individuals accused of committing crimes. At the entry point into the criminal justice system, law enforcement officials must inform a criminal suspect of their Miranda rights, such as the right to remain silent and the right to counsel. The presence of an active mental disorder or intellectual disability can negate an individual's capacity to voluntarily, knowingly, and intelligently waive their Miranda rights. Though very few adults lack the capacity to waive their Miranda rights, the majority of incompetence to waive Miranda rights involves juveniles where factors such as immaturity and emotional vulnerability are more likely to adversely impact voluntariness, knowledge, and/or intelligence. The competency to confess might be considered under the broader competence to waive Miranda rights. In 1986, the U.S. Supreme Court in *Connelly v. Colorado* ruled that absent physical coercion by police, an actively psychotic individual, who approached a police officer to confess about committing a homicide as a result of command auditory hallucinations to confess, had provided a valid confession.

The most common forensic psychiatric evaluation in the criminal justice system is that of competence to stand trial. The criteria for competence to stand trial is guided by several U.S. Supreme Court decisions with two having the most significance, *Dusky v. U.S.* (1960) and *Godinez v. Moran* (1993). The *Dusky* case established that competency to stand trial is composed of two prongs: (1) understanding of the criminal proceedings;

and (2) reasonable ability to consult with defense counsel. In the *Godinez* case, the court ruled that if criminal defendants are competent to stand trial, they are also competent for other activities in criminal proceedings, such as the competence to waive counsel, competence to enter a plea (waive trial), and competence to be sentenced.

For jurisdictions that permit capital punishment, the U.S. Supreme Court has mandated certain exclusions to the imposition of the death penalty, including mental retardation (now referred to as Intellectual Disability in the DSM-5) in *Atkins v. Virginia* in 2002 and for those under age 18 at the time of committing the capital offense in *Roper v. Simmons* in 2005. The U.S. Supreme Court in *Ford v. Wainwright* in 1986 and *Panetti v. Quarterman* in 2007 prohibited the execution of condemned inmates who are incompetent to be executed. Incompetence to be executed involves a condemned inmates' inability due to a mental disorder to understand the death penalty and the reason it is being imposed on them. Although cases of competence to be executed are quite rare, it has raised several ethical issues for society and the medical profession.

Criminal Responsibility and Psychiatric Illness

The determination of culpability and subsequent societal sanctions for those committing a criminal act finds its origins at least as far back as the dawn of recorded human history along with considerations given to those with abnormal mental conditions. The evolution of English law in the area of criminal responsibility of the mentally disordered over the past millennium has exerted great influence on how criminal responsibility has been determined in the United States. Although the number of psychiatric evaluations for defendants claiming that a mental condition negated their criminal responsibility for an offense accounts for a small proportion of evaluations performed for the criminal justice system, the issue of criminal responsibility of those with mental disorders is arguably the most visible to the general public due to extensive media coverage, both fictional and nonfictional.

To be proven guilty of committing a crime, the prosecution must prove beyond a reasonable doubt that the accused person not only committed a prohibited act (actus reus) but also had the requisite mental state or "guilty mind" (mens rea) for the forbidden act.

The insanity defense is used to prove that an individual did not possess the necessary mental state for criminal responsibility due to mental illness at the time of the act. From the preceding millennium, the concepts of the "wild beast test" and the ability to distinguish between good and evil (right and wrong) represented society's efforts to legally define "insanity." These efforts evolved and culminated in the formulation of the M'Naghten insanity standard in 1843 by the English House of Lords following an insanity acquittal in the English trial of Daniel M'Naghten. The M'Naghten

insanity test required the defendant to prove that he or she was "laboring under such a defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing; or, if he did know it, that he did not know he was doing what was wrong." The M'Naghten standard was quickly adopted for use by the U.S. judicial system. Among the 46 states that permit the insanity defense, approximately half use a M'Naghten type of insanity test. Four states (Montana, Idaho, Utah, and Kansas) disallow the insanity defense.

While the majority of state jurisdictions use the M'Naghten insanity standard, some states use other insanity tests. Currently, the most common other type of insanity test is that of the American Law Institute (ALI). To qualify for insanity under the ALI insanity test, a criminal defendant must demonstrate that as a result of a mental disorder, he or she "lacks substantial capacity to either appreciate the criminality of his conduct or to conform his conduct to the requirements of the law" (Model Penal Code §4.01, 1962). When comparing the two current major insanity tests used in the United States, the M'Naghten test has two "cognitive" prongs (knowledge of the "nature and quality" and "wrongfulness") versus ALI's one "cognitive" prong ("appreciate the criminality") and one "volitional" prong ("conform conduct"). Interestingly, some states that use an ALI-type of insanity test do not use the "volitional prong," thereby functionally making the insanity standard more like the M'Naghten test. Wording differences between the M'Naghten and ALI insanity tests would suggest that an insanity defense would be more likely successful in jurisdictions using the ALI insanity test.

In actuality, the overall use of the insanity defense is infrequent. The defense is raised in approximately 1 percent of felony cases with an estimated 25 percent success rate. The vast majority of insanity acquittals involve prosecutorial concurrence prior to trial. It is estimated that juries reject the insanity defense in 93 percent of cases going to trial. It has been argued that the legal system's requirement to not inform juries of the potential legal consequence of an insanity acquittal, that is, that a defendant acquitted by insanity would not be automatically released into the community, but would be subject to commitment in a state mental health facility, adversely impacts jurors' willingness to accept insanity defenses.

CHILDREN AND THE LAW

Children and adolescents can become entangled in the U.S. legal system in a multitude of ways, some of which are comparable to adults and some are fundamentally different. In fact, the number of youth involved in court actions has increased dramatically, driven by criminal activity in gangs and on their own, by the escalating rates of foster care, divorce and custody disputes, and by the proliferation of child abuse, neglect, and victimization.

Psychiatrists would benefit from a familiarity of the basic concepts of children and the law, if for no other reason than to better understand their adult patients whose early histories may be replete with such encounters and whose younger family members may become enmeshed in some aspect of the law.

Children, Juvenile Justice, and Violence

Juveniles can be both perpetrators and victims of crimes. States created parallel juvenile justice systems for youthful offenders that in many ways were responsive to the developmental immaturity that characterize children and younger adolescents. In 1899, Illinois established the first juvenile court separating the adjudication and confinement of youth as delinquents from the conviction and imprisonment of adults as criminals. The scope of juvenile courts expanded to encompass both criminal acts and behaviors that would not be considered illegal for adults, such as curfew violations, drinking alcohol, and truancy which have been called status (as a minor) offenses. The rationale for juvenile courts' broad jurisdiction is the promotion of social warfare by prioritizing education and rehabilitation rather than punishment.

Every state proceeded to adopt a system of juvenile courts, whose procedures were then significantly modified by the Supreme Court's landmark cases under Chief Justice Earl Warren. In 1967, the U.S. Supreme Court held that, although it was permissible to treat juveniles and adults differently in court, youthful offenders facing possible incarceration are entitled to the same constitutional rights of notice of charges, counsel, protection from self-incrimination, and the opportunity to confront and cross-examine witnesses, as afforded to adults. Three years later the Supreme Court also ruled that the "beyond a reasonable doubt" standard of proof also applied in juvenile court. Extending constitutionally based procedural rights to juveniles did not imply that juveniles could escape conviction and punishment, especially if they committed serious crimes. Prosecutors have the discretion to file for a judicial waiver that moves the youth from juvenile court to adult court in order to deny the protections that juvenile jurisdictions provide, including the preclusion of long prison sentences.

Most states exclude first-degree murder charges from the juvenile system, which for many years effectively allowed a convicted juvenile murderer to be sentenced to execution. The eligibility of a person, who committed their crime as an adolescent, for capital punishment proved to be controversial even among death penalty advocates. The Supreme Court reviewed the question of juvenile capital punishment and decided in *Roper v. Simmons* (2005) that defendants were not eligible for execution if their crimes were committed under the age of 18 years. The court's opinion in this decision drew heavily on scientific data concerning neuropsychological

development that contrasted adolescents with adults, which were presented in amicus briefs submitted by psychiatric and psychological professional organizations. In *Miller v. Alabama* (2012), the U.S. Supreme Court extended its reasoning to preclude as unconstitutional a sentence of life without the possibility of parole for convicted juveniles.

The Columbine High School tragedy in 1999 engendered an awareness of a looming threat of mass killings occurring in a school, possibly perpetrated by an adolescent or young adult. Despite heightened vigilance of the danger of a lethal attack on campus, a mentally ill college student at Virginia Tech University in 2007 murdered 33 persons, and in 2012 a mentally ill adolescent opened fire on and mortally wounded 20 children at the Sandy Hook Elementary School in Connecticut. There have been strident demands to develop strategies to profile potentially deadly students who may be targeting schools for deadly violence. Youths with the risk factors of a history of psychiatric illness, aggression, suicidal behavior, and/or family strife, and who have access to weapons may indeed be at higher likelihood for violence. However, less than 5 percent of crimes overall can be attributed to mental illness. Identifying those individuals at risk with any degree of certainty must overcome the daunting challenge of the high false-positive rate associated with predicting a rare event.

Most experts are skeptical of the wisdom of deploying armed security in elementary and high school buildings. Further, implementing zero-tolerance policies for aggressive behavior may disproportionally impact minority, disadvantaged, and special needs students who generally benefit the least from suspensions or expulsions. Alternatively, school-based interventions designed to decrease bullying and stigma, provide enhanced access to students for counseling and mental health care, expand communication among students, faculty, and parents, and eliminate or at least safeguard guns in the home, all hold promise of more effectively addressing the threat of interpersonal and self-inflicted violence.

Child Custody

Each year in the United States there are about half the number of divorces as there are marriages. Divorce proceedings sever the marriage contract between spouses, and although children may be a focus of the case, they are not considered formal parties to the legal action. The court has the responsibility to protect the well-being of dependent children affected by divorce, which may be straightforward when the parents are in generally agreement or hotly contentious when they are in battle. Child custody subsumes both legal custody, referring to the responsibility for making major decisions about health and education, and physical custody, referring to which parent is spending time with the child. Many jurisdictions favor awarding joint legal custody to both parents, unless there is evidence that this would be frankly detrimental to the child's best

interests. Under those circumstances the court may grant sole legal custody to one parent, with or without time-sharing with the other parent. A determination of the best interests of the child is made by evaluating all of the factors affecting the welfare and interests of the minor child and the circumstances of that family, including, but not limited to: the demonstrated capacity of each parent to facilitate and encourage a close and continuing parent–child relationship and to determine, consider, and act upon the needs of the child as opposed to the needs or desires of the parent; the moral fitness and mental and physical health of the parents; evidence of domestic violence, sexual violence, child abuse, abandonment, or neglect; and the developmental stages and needs of the child and the demonstrated capacity of each parent to meet the child's developmental needs.

Treating psychiatrists of a parent or child in custody or visitation litigation may have important information that could influence the court's ruling. The scope and limits of confidentiality in such matters may become a difficult and contentious question. Further, the availability of the psychiatrist to write reports, testify, or advocate in these adversarial legal proceedings is fraught with conflicting ethical, legal, and therapeutic duties. Many treating psychiatrists have sought to avoid becoming entrapped in these dilemmas by limiting their documentation and recollection, though it may not be possible to predict which patient will be the source of a subpoena. Consultation with an attorney and referral to a forensic psychiatrist may be advisable for the treating psychiatrist confronted with such circumstances.

Child Abuse

Reports of suspected maltreatment, which are mandated by law for health care and school personnel, will trigger investigations by the police or a child protective agency. If probable cause for maltreatment is found, such as bruises or malnutrition, the child can be removed from the home, and the agency might petition the court for alternative placement in foster care. Allegations of sexual abuse usually result in criminal charges against a parent, family member, or nonfamilial perpetrator. As the victim of interpersonal violence, children and adolescents suffer enduring psychological injuries, which may also lead to civil court actions seeking to recover compensation for the injured child. Younger children are more vulnerable since, as a rule, they are less able to protect themselves from being exploited by adult predators.

Society and the medical profession have traveled far in the last 100 years from a time when physical child abuse was unrecognized to the current era of far greater sensitivity to multiple forms of maltreatment, including neglect, emotional and physical abuse and sexual molestation. However, significant difficulties arise in the evaluation of allegations of

sexual abuse, especially in young children. The psychiatrist examining a child about whom there is an accusation of sexual abuse must face the challenge of infusing scientific objectivity into the practical task of providing judgments regarding the validity of symptoms, their putative etiology, the harms suffered by the child, the prognosis, and what present and future treatment interventions are indicated.

▲ 60.2 Ethics in Psychiatry

LAURA WEISS ROBERTS, M.D.

Ethics is a scholarly discipline that brings greater understanding of moral aspects of human experience and action. Psychiatry, more than any other field of medicine, concerns itself with studying and strengthening the capacities that make humans distinct and that allow people to attach, learn, love, reason, feel, live with one another, and make choices. Separately and together, the fields of ethics and psychiatry examine human meaning, intention, and consequences, and both are concerned with the expanse and limits of the self in the world. Thus by their natures, ethics and psychiatry are overlapping fields of inquiry.

With so much in common, it is perhaps surprising that psychiatry enjoys more than its share of ethical controversy. Psychiatry is viewed with some skepticism by society at large, and it is seen as ethically problematic. Psychiatrists themselves are often at odds on matters of ethical importance within the profession. Long-standing ethical issues related to power and intimacy in psychodynamic–psychotherapy relationships have now been joined by intriguing new ethical questions about privacy and boundaries in treatment conducted solely through asynchronous texting between patients and their therapists. Similarly, older dilemmas regarding the potential exploitation of vulnerable individuals in psychiatric research have now been joined by new debates regarding undue influence, unconscious bias, and conflicts of interest in human studies. Old controversies regarding patient confidentiality in publishing patient case reports are now joined by new uncertainties regarding privacy in analyzing social media postings to protect the health of the public by identifying suicidal adolescents, for example, or individuals at risk for engaging in violence. Novel issues pertaining to topics as widely varying as psychiatric genetics, interpersonal violence, sexuality, and global mental health disparities arise each day.

Indeed, ethical issues are to be expected in a field that is important for understanding the human condition and is also undergoing extraordinary advances, scientific to societal.

As for other specialist physicians who reside in the house of medicine, learning about ethics is helpful preparation for psychiatrists and psychiatrists-in-training who will encounter complex dilemmas in their everyday work. Familiarity with resources such as the ethical guidelines of the American Medical Association (AMA), the American Psychiatric Association (APA), and the American Academy of Child and Adolescent Psychiatry is a valuable first step. Knowledge of ethical codes of historical importance, such as the Hippocratic Oath of the 4th century BC and Percival's *Medical Ethics* from the late 1800s, provide perspective on the evolution of the standards of conduct for physicians. A clear working knowledge of resources from related areas, such as professionalism, legal concerns, gender-related issues, and cultural competencies, is also vital to sound ethical practice and training in psychiatry.

Are these general codes of ethics for physicians sufficient for an understanding of the ethical requirements of psychiatrists? Stated differently, should psychiatrists be held to a higher or different standard of ethics than other physicians? Psychiatrists are presently held to the same standard of ethics as other physicians. Many psychiatrists argue, however, that a more complete knowledge of ethics is particularly important for mental health practitioners because of the nature of mental disorders and the impact of stigma. Others argue that greater mastery of ethics is essential because of the influence psychiatrists may have over their patients' lives as a result of transference, that is, the set of emotions and thoughts brought to the therapeutic relationship from the patient's prior life experience. Yet others argue that this level of ethics knowledge is still not enough: true ethics expertise, robust decision-making skills, and disciplined ethics practices are of special importance for psychiatrists because of their professional responsibility to initiate treatment to protect a patient or others from harm when necessary—even if it is against the patient's wishes. For all of these reasons, psychiatrists and psychiatrists-in-training will ideally possess a thorough understanding of the field of ethics, with both its underpinnings and its applications.

Toward this aim, this chapter introduces the foundations of present-day ethics in psychiatry. Outlined are key bioethics principles and illustrations of approaches to identifying and resolving psychiatric ethics dilemmas.

ETHICAL SCHOOLS OF THOUGHT

Several ethical schools of thought have influenced how physicians understand ethical aspects of medical practice. Examples include the deontological school, utilitarianism, justice-based ethics, and virtue-based ethics.

These perspectives differ greatly on what constitutes the beliefs and actions of a good person and assess ethical behavior differently. The philosophers who developed these paradigms sought to explain as much as possible with a few simple rules. Such simplicity is elegant academically, though harder to apply in real life, as Table 60.2–1 notes. Each school of thought, taken alone or taken to an extreme, may lead to conclusions that most people in a pluralistic society would find unacceptable. Nevertheless, the models provide a framework for discerning and evaluating moral issues encountered in everyday experience.

The deontological school centered on the work of Immanuel Kant (1724 to 1804), who articulated the inherent sacredness of the individual person and the primary intention of a human being as a moral agent. He believed that certain ways of behaving are absolute from an ethical perspective, irrespective of consequences. Kant articulated a rule (the "categorical imperative") guiding all moral behavior. His first formulation of the categorical imperative was that a person should "act only on that maxim through which you can at the same time will that it should become a universal law." For example, in deciding whether to lie or steal or kill, individuals should think about whether they want others to engage universally in these behaviors. Kant's second formulation of the categorical imperative was to "act in such a way that you always treat humanity, whether in your own person or in the person of any other, never simply as a means, but always at the same time as an end." In other words, it is unethical to use another person solely as an object to obtain a goal without concern for the effect of one's actions on the person. Moral value, in Kant's system, relates to respect, rationality, and duty in relation to the moral agent.

Table 60.2–1.
Examples of Ethical Models of Thought

Model	Major Figure(s)	Key Features	Strengths	Limitations
Deontology, or the ethics of duty	Immanuel Kant	There is an absolute good and right. To be ethical, persons must fulfill these absolute duties unconditionally.	Some moral judgments apply in almost all circumstances to everyone (e.g., respect for persons).	Conflicting obligations. Too much emphasis on obligation, not enough on consequences or relationships. Very abstract.
Utilitarianism, or the ethics of consequences	John Stewart Mill Jeremy Bentham	Weigh the consequences of actions and rules. Those that bring about the	Useful in formulating public policy because it requires impartial assessment of all interests.	Difficult to translate into practice. Practices that harm individuals and groups may be ethically justifiable in this

		greatest good for the most people are most ethical.	Has beneficence as a goal.	model. May demand that the minority sacrifice too much for the majority.
Justice-based ethics	John Rawls	Decisions should be made with respect and fairness in relation to each individual.	Demonstrates respect for the individual person. Has equality as a goal.	Neglects principles beyond fairness in clinical decision making.
Virtue-based ethics	John Gregory Thomas Percival	Ethical decisions are rooted in qualities or character, such as honesty and faithfulness. Actions are right only if they are what a virtuous person would do in the same situation.	Internal values and habits rather than external rules and imperatives. Highlights importance of qualities of the individual, of personal character.	Virtue may be too unclear or pluralistic to serve as a basis for judgment. Persons may act wrongly out of virtue (e.g., withhold the truth from a dying patient to avoid emotional upset).

The utilitarian school of thought originated with Jeremy Bentham (1748 to 1832) and John Stuart Mill (1806 to 1873) in 19th-century England. They argued that the value of an act should be judged solely on its effect or consequences. Acts are ethically right, in this view, if their effect is to produce the greatest good for the greatest number of people. Acts are not right or wrong in and of themselves, according to act-utilitarians. Lying, stealing, and killing are not inherently wrong, for example. In this school, the ends justify the means. Rule-utilitarianism moves beyond act-utilitarianism to suggest that good individuals will undertake decisions guided by rules that—if followed by all people—would bring about the greatest good for the greatest number of individuals. In this formulation, there is more "forgiveness" for decisions with unpredictably negative outcomes. Rule-utilitarianism does not address the role of the intentions of individual moral agents, nor does it answer the question of what is "good."

More recently, in contrast with utilitarianism, John Rawls (1921 to 2002) developed a school of thought drawing from his concept of justice. It followed upon strengths of Kant's deontological approach in that it highly valued the individual as a moral agent. Rawls supported the rights of the individual as a matter of fairness. He gave primacy to the intrinsic worth of each person rather than to a metric that assessed greatest utility for the group as a whole. He stated, "Each person possesses an inviolability founded on justice that even the welfare of society as a whole cannot override." Rawls asserted that in deciding what to do and what rules and

systems to establish, people should place themselves behind a "veil of ignorance" and assume that they do not know who they are in the system. For example, in deciding what welfare benefits a society should offer and the amount of taxes to impose on the rich, people should assume that they do not know whether they will be rich or poor. In deciding what authority doctors have over patients, people should assume that they do not know whether they will be in the role of the doctor or in the role of the patient. Rawls' approach, as with that of Kant, does not rely on consequences of actions but, rather, their primary intent.

Virtue-based theory has contributed greatly to the ethical framework of medicine and the key concepts of professionalism. John Gregory (1724 to 1773) was a Scottish physician–ethicist, and Thomas Percival (1740 to 1804) was an English physician–ethicist. Their work, taken together, created the foundation for the modern ethical concept of medicine as a profession. Concerned about exploitative, self-interested, and entrepreneurial practices of physicians at the time, they articulated the virtues of scientific and clinical competence, dedication to the interests of the patient, and service to the public through ensuring the skills of peers and students or apprentices. Gregory described the moral qualities of an astute and compassionate physician:

> The chief of these is humanity; that sensibility of heart which makes us feel for the distresses of our fellow-creatures, and which, of consequence, incites us in the most powerful manner to relieve them. Sympathy produces an anxious attention to a thousand little circumstances that may tend to relieve the patient; an attention which money can never purchase... If the physician possesses gentleness of manners, and a compassionate heart, and what Shakespeare so emphatically calls "the milk of human kindness," the patient feels his approach like that of a guardian angel ministering to his relief: while every visit of a physician who is unfeeling, and rough in his manners, makes his heart sink within him.

Gregory and Percival individually emphasized the virtues of the honorable physician as demonstrating self-sacrifice and self-effacement and as seeking at all times to advance the field of medicine, not for financial gain but the benefit of others in society. The modern notion of integrity derives from this line of thought, and the work of Gregory and Percival continues to inform the discussion of conflicts of interest and how they may be avoided or resolved.

These four schools of thought have been highly influential in present-day principles of ethics that the AMA and APA advance. Other schools of thought exist in the United States and throughout the world, with rich and long-standing traditions and different implications for current practice. From legal and ethical points of view, the AMA and APA hold physicians engaging in professional activities in the United States to their codes of ethics and standards.

BASIC ETHICAL PRINCIPLES

The modern field of biomedical ethics takes primarily a principle-based approach. In their influential text *Principles of Biomedical Ethics,* Beauchamp and Childress defined the most critical among the principles to be autonomy, beneficence, nonmaleficence, and justice. The Belmont Report on human research ethics elevated the concept of respect for persons, and recent ethics scholarship has emphasized the principle of respect for the law. Other principles, such as compassion, confidentiality, fidelity, integrity, and veracity, are also central to the practice of psychiatry. See Table 60.2–2. Ethical analyses examine the interplay of these principles and seek to identify and resolve when ethical principles are in conflict.

APPROACHING ETHICAL DILEMMAS

Ethical dilemmas do not typically emerge in simple situations of doing good versus doing bad. In such situations, there is no dilemma. Indeed, ethical dilemmas come when two seemingly good things are at stake. Consider the example of a psychiatrist who receives a request from a worried and loving mother to provide information about issues arising in her son's therapy sessions. The son has a good relationship with his mother but has been bullied at school, feels embarrassed, and does not want his parents to know what is bothering him. For the psychiatrist, the good of responding empathically and with accurate information to the distressed mother competes with the good of protecting the fragile alliance with the patient. Dilemmas often come when two or more of the basic bioethics principles are in conflict or cannot be completely fulfilled given the circumstances of a particular situation.

Table 60.2–2.
Examples of Biomedical Ethics Principles

Autonomy	The notion of self-rule; the capacity to make authentic decisions related to one's body and mind.
Beneficence	Doing good; the commitment to seek to bring about benefit.
Compassion	Deep regard for the experiences and suffering of others.
Confidentiality	A legal privilege associated with the right of privacy; the obligation not to disclose information obtained from a patient or observed or gathered in caring for a patient.
Fidelity	"Faithfulness" or loyalty to ethical ideals.
Integrity	The notion of being whole or complete; the capacity to adhere wholly to the principles of the profession.
Justice	Equitable distribution of benefits and burdens in society.
Nonmaleficence	Avoiding harm or injury to others.
Respect for the law	The obligation to adhere to the law.
Respect for persons	Fundamental regard for the dignity, sacredness, and value of the individual.

Veracity	"Honesty," involving the positive duty to tell the truth and the negative duty to avoid deception.

Recognizing Ethical Issues and Tensions

The ability to identify ethical issues and tensions present in the patient care situation is thus the first and most basic of the ethics skills important to sound clinical practice of psychiatry. Recognizing the ethical features of a patient's case requires sensitivity, and this capacity is enhanced by knowledge of ethical principles and how they may come into conflict.

Seeing how ethical principles may compete or collide is informative and can help practitioners to discern a path forward. For instance, consider the case of a newly diagnosed cancer patient who, overwhelmed and fearful, attempts suicide by overdose. She requests aid in dying from her oncologist, who also feels overwhelmed and fearful because of the patient's reaction and refers the patient for a psychiatric evaluation. The psychiatrist learns that the patient's mother died from cancer and that she was her mother's only caregiver over the long and difficult course of her illness. The psychiatrist finds that the patient likely had a pre-existing depression before learning of her cancer diagnosis. The patient is decisionally capable, despite her distress, and the psychiatrist feels great empathy for the patient. In this example, many principles are in play and several are in tension: most clearly, honoring the patient's wish to die (autonomy) conflicts with the physician's responsibility to avoid harm (nonmaleficence). A superficial analysis would suggest that the patient's right, especially in an autonomy-oriented society, would trump all other considerations.

However, sound standards for clinical and ethical care are those that are informed by the full set of ethical principles that govern medicine. By recognizing the two principles that are in opposition—in this case, autonomy and nonmaleficence—and thinking through the other principles, the clinician begins to see additional options for intervention that align with standards of medicine. In this case, identifying ways of reducing the patient's physical and psychological suffering, treating her pre-existing condition, providing accurate information about the nature of her condition and potential treatments, and adhering to legal requirements all may contribute to an improved physical and mental health outcome for this patient. Ideally, clinical care and ethical reflection work together, as illustrated in this case. The disciplined exercise of identifying ethically salient concerns in a clinical situation and framing and exploring the relevant bioethics principles can help open up the thinking of the clinician. Reflecting on related areas that influence ethical facets of the case, such as legal, gender, and cultural considerations, is also valuable. These efforts, taken together, represent an important ethical skill and the initial step in clarifying ethically sound strategies for optimal patient care.

Gathering Additional Information and Expertise

Ethical questions sometimes arise in a clinical situation when there is simply too little information or when clinicians are working at the boundary of their experience or scope of practice. Additional information or broadened and deepened expertise may lead to a ready resolution of the problems at hand. Data or expert guidance could come from the patient's prior medical records or clinical practice and ethics guidelines. In addition, speaking with an experienced supervisor, seeking advice from a colleague with specialized expertise, requesting an ethics or a legal consultation, and/or reviewing supplemental clinical data from outside sources may help.

Consultation-liaison psychiatrists see the value of additional data-gathering and consultation as resolving apparent ethical issues all of the time. Psychiatric consultation services have long fulfilled an important ethical function in most hospitals. An example is a patient who is declining potentially life-saving care for what appears to be an irrational reason and is demanding to return home against medical advice. A psychiatric evaluation may reveal an underlying condition, such as an addiction, delirium, early dementia, or poor pain control, interfering with the patient's decision making. Once this underlying condition is treated and the symptom burden lessened, the patient's decisional capacities may improve, leading to what appears to be a more rational decision to the care-giving team. If the patient is not experiencing a threat to his or her decisional capacity, it is important to explore the patient's values, background, and reasons for making a decision that contrasts with the medical recommendation. Cultural and religious preferences, fears based on past experiences, or issues related to family stresses may be influencing the decision. This additional background information may be very helpful in developing health-preserving strategies for this patient, such as consulting a religious leader, inviting emotional support from a family member or counselor, or identifying appropriate social service resources. In all of this, the caregiving team is wise also to obtain consultation from the legal service of the hospital. Information on the role of state or federal law in the case will help the physicians to determine whether temporary or long-term guardianship may be appropriate to pursue.

Thus, in approaching an ethically complex clinical situation, recognizing the ethical dimensions of a patient's care and then seeking additional information or expertise are the two initial steps to take in resolving dilemmas and developing ethically astute treatment plans.

Identifying Risky Situations and Arranging for Appropriate Safeguards

Many situations in patient care present predictable ethical challenges, and with experience, astute clinicians begin to anticipate when these ethically

risky situations are likely to occur. A clear illustration is when a patient is impulsive and the caregiving team must ensure the safety of the patient and others, for example, family members or the clinic staff. The clinician may be tempted to make choices that differ from usual clinical practices because of the situational threat. When the patient is a celebrity or an influential person, for example, other ethical risks can enter into the clinical picture. Staff members may be tempted to review the patient's electronic medical record, and care-giving physicians may begin to change their usual clinical practice, consciously or not, in order to garner favor with the special patient. A very different example is when there is a need to report child abuse or neglect. In this case, the psychiatrist may feel emotionally conflicted, wanting to abide by the law but feeling worried about the impact of the intervention on the therapeutic alliance with the family or about the impact of the investigation on the child. When entrusted with the care of vulnerable individuals, such as trauma survivors, children, or extremely ill patients, psychiatrists will recognize numerous ethical risks that may arise.

Such situations arouse concern, as they should, and signal the need for additional safeguards to ensure that an appropriate standard of care is upheld. Psychiatrists working in emergency departments, addiction centers, correctional settings, and employee health programs frequently encounter very difficult ethical dilemmas. Additional safeguards may include scheduling more frequent appointments for a suicidal patient, including a broader health care team, introducing alternative decision makers for a vulnerable patient, or obtaining permission from the patient to engage the family more fully. When a psychiatrist routinely works with high-risk patients, the clinical setting itself must have more safeguards. For example, a psychiatrist who manages a very difficult population and performs random drug screens as part of usual patient care may increase security for patient records and provide physical safety training for clinical staff. A geriatric psychiatrist who works with many individuals with advanced dementia may need to have a close working relationship with other clinicians, legal advocates, and the court in order to facilitate optimal patient care. In sum, heightened safeguards help address the ethical risk that is associated with psychiatric practice in all settings. When such risk is predictable because of the context or the patient population, ethically astute psychiatrists will build these safeguards into their routine practices, for the good of the patients and the caregiving team.

Working within One's Scope of Practice and Engaging in Continuous Learning

Psychiatrists acquire expertise beyond general medicine to include specialized knowledge in the care of individuals with mental disorders. Working within this scope of clinical competence is considered ethically important because of the risk of doing harm when a psychiatrist has insufficient expertise to care properly for a patient. If physicians are

confronted with patient care situations that are outside their scope of competence, then referral or, at the very least, consultation and supervision are appropriate. Sometimes physicians are in settings where no other provider is nearby; these situations warrant every effort to obtain additional expertise and services. In rural settings, telehealth services may bring additional expertise to the care of the patient. In training settings, close supervision of early-career physicians helps ensure an appropriate standard of care. In emergencies, even if clinicians are outside the scope of their usual practice, they are expected to do their best effort and certainly not to abandon the patient in extreme need.

Related to the ethical obligation to work within one's areas of competence is the responsibility to continue to learn. Remaining aware of advances in one's field is critical to optimal patient care and ensures that the clinician's scope of practice and domains of competence remain within community standards and, ideally, attain the state of the art. This imperative relates to the fundamental concepts of serving the best interest of the patient and avoiding harm in clinical care.

Reflecting on One's Values and Perspectives

Psychiatrists are taught to pay close attention to their responses to a patient, for example, how the patient looks, the story the patient tells, the emotions the patient demonstrates. Awareness of countertransference (the set of emotions and thoughts the psychiatrist brings to the therapeutic relationship from prior experiences) is valuable in clinical care, and it also provides insights into the ethical dimensions of a patient's care. Indeed, to conduct ethically sound patient care, it is very important for psychiatrists to be able to see how their experiences, attitudes, and feelings may influence their perceptions of the ethical aspects of a clinical situation. Awareness of one's reactions may help prevent ethical blind spots and even breaches of ethical conduct. When a psychiatrist finds a patient very attractive or when the patient makes the psychiatrist very uncomfortable or angry, these emotional cues should be seen as clinical and ethical signs that require acknowledgment, clinical interpretation, and a therapeutic response.

Ideally, team-based care and teaching settings will create opportunities to consider how different team members or supervisors and trainees view the ethical issues present in a patient care situation. Astute team leaders will facilitate explicit discussion of these issues and guide their colleagues in defining the conflicting ethical principles. Clarifying differences in the points of view of team members may prevent later misunderstandings. Demonstrating the importance of speaking further with the patient, gathering additional data, working within one's scope, introducing specialized expertise, and building in appropriate safeguards are also important for the patients cared for by the team or the trainee.

DECISION-MAKING STRATEGIES

Several proposed strategies for making decisions in patient care have value. Jonsen, Siegler, and Winslade created a four-part model that many health care settings have adopted: (1) clinical indications, (2) patient preferences, (3) quality of life, and (4) socioeconomic or external factors. In this model, the first of the four parts, clinical indications, has the greatest weight. It refers to the physician's obligations to diagnose a patient's condition carefully, inform and educate the patient about the illness process, consider the available treatment options in light of appropriate standards of care, make therapeutic recommendations that adhere to these standards, and ensure that treatments are provided competently and fulfilled properly in partnership with the patient. In psychiatry, this step is the same as in other areas of medicine.

The second element of this decision-making model, patient preferences, is grounded in the principles of respect for persons and autonomy. Once the physician presents the patient with recommendations based on what is clinically indicated, the physician elicits the preferences of the patient. In the practice of psychiatry, the nature of mental disorders may interfere with the ability of patients to identify or express their preferences or affect decisional capacity or authentic voluntarism. The ethically astute psychiatrist will do all that is possible to ensure that patients truly have voice in decisions affecting their care and will not coerce or exploit patients' potential vulnerability by imposing care that is refused. When a patient is unable to provide informed consent, appropriate decision-making safeguards, such as an alternative decision maker, should be put in place (in accordance with state law).

Quality of life is the third element in the Jonsen, Siegler, and Winslade model. It refers to the sense of personal satisfaction individuals express and/or experience with regard to their physical, mental, and social situations. Perhaps the most important consideration in assessing quality of life is direct engagement with patients regarding their values and points of view. The physician must not make assumptions about what represents a good life for the patient. Clinical indications and patient preferences are weighted more heavily than quality of life in the decision-making model. When overweighted or incorrectly assessed, quality of life could be used to justify decisions that do not meet current ethical standards in society.

The fourth element in this clinical decision-making model entails socioeconomic or external factors. These factors are diverse and include the interests of society, the role of family members, cultural factors, and costs and limitations in access to care. This element is last primarily because of the obligations of beneficence. The United States defines denying a patient life-saving treatment in an emergency on the basis of ability to pay as unethical and illegal, for example. In less acute situations, however, a discussion with patients about the costs of care and how these costs may

affect their choices of treatment is important and ethically acceptable.

EXAMPLES OF ETHICAL PRACTICE STANDARDS IN PSYCHIATRY

Several texts and resource documents provide comprehensive overviews of ethical practice standards in psychiatric practice. Key concepts related to several ethical practice standards for psychiatry are briefly outlined below and draw upon the schools of thought, biomedical ethics principles, and the four-part ethical decision-making model described in this chapter.

The Therapeutic Relationship and Professional Boundaries

The therapeutic relationship presupposes that the physician is worthy of the trust of the patient. The physician's expertise and the physician's intention to do good, avoid harm, and place the patient's best interest above all other interests are the basis of that trust. Professional boundaries are behaviors that align with these fundamental commitments to serve the well-being of the patient.

Interactions with patients that do not serve their interests but, instead, fulfill or gratify the interests of the physician can fracture or destabilize this foundation. One example is the ethical problem of intimate relationships arising between physicians and patients. The APA is explicit in its direction that psychiatrists must not engage in sexual relations with patients (including former patients). Such intimacies are inherently exploitative; they interfere with therapy, risk harm to the patient, and undermine confidence in the profession, thereby damaging the ability of others to benefit from psychiatric care. The profession of psychiatry sees sexual contact during therapy for whatever purpose, or ending therapy in order to start a romance, as indefensible.

Some have argued that the power differential between a former therapist and patient is the primary reason to forbid relationships between them. Many relationships, however, have power differentials because of the different earning capabilities of the partners, different levels of educational achievement, or a society that gives more power to one gender, one class, or one ethnicity. The reason to bar sexual relationships between psychiatrists and present and former patients is much more complex. One simple example is that this prohibition protects patients from being lured into a relationship that the patient would not otherwise desire because of genuine need for treatment. The prohibition also helps the psychiatrist to stay focused on the patient's well-being at all times, avoiding thoughts of a possible future relationship from affecting the conduct of the therapy. Epstein developed the Exploitation Index to help therapists identify potentially exploitative practices in the care of their patients.

Therapeutic boundary violations are behaviors that subordinate the interests of the patient to the interests of the physician. These violations

need not be sexual, although they are equally forbidden. Psychiatrists should not try to influence the political views of the patient, for example, and similarly, psychiatrists should not accept expensive gifts directly from patients. Engaging in business activities with a patient or former patient also risks misuse of influence and may represent exploitation of confidential knowledge obtained in therapy.

Therapeutic boundary crossings are behaviors that are intended to serve the interests of the patient but differ from usual ethical practices. Therapeutic boundary crossings should be viewed as exceptions but are often ethically acceptable. A psychiatrist disclosing personal information to build rapport with a distant and troubled patient or accepting a small gift at the holidays to demonstrate respect for a patient's culture and origin are two examples of boundary crossings.

Traditional views of the boundaries in the therapeutic relationship derive from reflection on long-term, dynamically oriented psychotherapy relationships, typically occurring in urban contexts. Novel questions arise when considering other roles, interventions, and settings. For example, is a child psychiatrist caring for impoverished and traumatized youth in a culturally unique community held to the same expectations as a therapist caring for an older, successful businessperson in a major metropolitan location? Are psychiatrists who see patients once in an emergency department held to the same standard of personal–professional role separation as their ambulatory clinic counterparts? Does a psychiatrist who is consulted about the suitability of a patient with Parkinson disease for neurosurgical intervention establish a therapeutic relationship with the patient in the same manner as with a patient needing treatment for depression? Intuitively, these situations require more nuanced responses than strict rules or inflexible codes of ethics. For this reason medical ethics is understood to evolve, by its very nature. This fact does not permit psychiatrists to deviate from expected standards but, rather, permits psychiatrists to apply standards (and, more important, their underlying intent) to novel situations.

Confidentiality

The importance of confidentiality in tending to illness dates back to Hippocrates, who said, "What I may see or hear in the course of the treatment or even outside of the treatment in regard to the life of men, which on no account one must spread abroad, I will keep to myself, holding such things." Confidentiality refers to the physician's duty to not release information learned in the course of treatment. Salient information may relate to disclosures by the patient, observations of the physician, or laboratory findings or notes from prior treatment in the medical record. Protection of patient confidentiality fosters the therapeutic alliance and is a prerequisite for patients to be willing to speak more freely and openly with

their doctors. If confidentiality were not ensured, individuals would be less likely to seek help and would tend to withhold crucial information, diminishing the effectiveness of the treatment. Table 60.2–3 notes illustrations of optimal practices for protecting confidentiality in psychiatric practice.

Psychiatric records, including even the identification of a person as a patient, must be protected with particular diligence. A psychiatrist may release confidential information only with the authorization of the patient or when compelled by law. Even when patients have given permission for their personal information to be used, safeguards are still needed. It is important to disclose only that information which is truly necessary for the situation at hand. In teaching and research one should not unnecessarily release patients' names or information that might allow others to identify them. Presenters of patient material in ward rounds and case conferences should remind attendees not to repeat what they hear. Confidentiality and the ethical obligation to withhold information endure even after a patient's death.

Table 60.2–3.
Examples of Optimal Approaches to Confidentiality in Clinical Practice

- Provide accurate information to patients about the realities of confidentiality in the clinical setting.
- When appropriate, remind patients that the purpose of the medical record is to be shared as a way of providing optimal care by a team of health professionals.
- Openly discuss with patients the legal limitations of confidentiality and avoid assuring patients that their disclosures will be "completely" confidential.
- Do not speak to others or, if working in a team-based care setting, avoid talking with others beyond the health care team, about patients' care without explicit, written permission to do so.
- Actively work within organizations and professional societies to develop state-of-the-art confidentiality safeguards as science, clinical care, health policy, the law, and health care systems evolve.
- Seek consultation and expert guidance when confidentiality safeguard questions arise.
- Model best practices in confidentiality to colleagues, team members, and trainees.

New ethical questions arise every day regarding confidentiality in novel forms of treatment, whether medical or psychosocial. For instance, what are appropriate privacy protections for psychotherapy occurring by telephone, video, the Internet, electronic mail, or real-time texting? Are current practices sufficient for new models of care involving teams, networks, and health care systems, which might disseminate information electronically across integrated national and perhaps international sites? How will innovators in clinical research and genetics protect the personal information of specific individuals whose biomarkers, taken together, represent a unique biological signature?

Informed Consent

Informed consent is an ethical and legal standard that exemplifies the principle of respect for persons and seeks to bring the principle of autonomy to life in clinical medicine. Informed consent is the idea that capable and knowledgeable individuals may freely choose a course of action pertaining to their health. Informed consent can involve accepting a recommended treatment or choosing an alternative, including no treatment (i.e., informed refusal).

Informed consent involves three components: information-sharing, decisional capacity, and voluntarism. With respect to information-sharing, physicians should provide patients accurate and balanced information regarding (1) the nature of their illness or condition; (2) the need for intervention; (3) the anticipated risks or benefits and their relative likelihood, including rare but very serious risks; (4) appropriate alternatives and their attendant risks and benefits; and (5) future consequences of the different choices, to the extent possible. Physicians should offer this information at the level and in a language that the patient understands and in a nonpressured environment. Physicians should build opportunities to clarify points of information and to correct misimpressions into the conversation. Individuals who cannot provide consent must receive information at the level at which they can understand it, and physicians should seek the individuals' acceptance, when possible. See Table 60.2–4.

Grisso and Appelbaum characterized decisional capacity as having four subcapacities. The first is the physical and mental ability to communicate. This subcapacity does not refer to the ability to speak a particular language but, rather, the ability to express—if only through eye blinks or hand signals—a choice. The second subcapacity is the ability to understand relevant factual information. The third subcapacity is the ability to reason, that is, to weigh the different factors and risks and to think through the choice at hand in an objective and flexible manner. The fourth subcapacity is to appreciate the meaning of the decision and to evaluate the choices in the context of one's life. This capacity is close to the concept of insight, which usually refers to patients' ability to understand the nature and impact of their illness. The capacities should be viewed as a continuum, not simply as present or absent. Many psychiatric conditions erode the cognitive strengths that underpin these capacities.

Voluntarism is the capacity that relates to one's ability to act freely, in the absence of coercion, in expressing one's authentic wishes. "Deliberateness, purposefulness of intent, clarity, genuineness, and coherence with prior life decisions" are key elements of the capacity for voluntarism.

Informed consent standards are more rigorous for high-risk decisions. This concept is referred to as the "sliding scale" for informed consent. When patients make a choice that may endanger them (e.g., choosing one

form of chemotherapy over another), the standard for decisional capacity is higher than when they make a choice that poses minimal or virtually no risk (e.g., having their blood pressure taken). Because declining recommended treatment usually entails heightened risk, the standard for informed refusal also is higher. Physicians must give extra care in providing information and counseling patients regarding alternatives and in verifying decisional and voluntarism capacity if a decision under consideration, whether accepting or refusing an intervention, is high risk.

Table 60.2–4.
Examples of Optimal Approaches to Informed Consent in Clinical Practice

- Provide accurate information regarding the nature of the illness and the need for clinical intervention; anticipated risks and benefits of the proposed intervention, including rare but serious risks; alternatives to the proposed treatment and their likely outcomes, including no intervention.
- Avoid using overly complicated language and overwhelming patients with too much technical information.
- Be attentive to patients' comfort, communication style, and interpersonal cues.
- Invite patients to ask questions and double-check their understanding of what was explained.
- Provide additional information if requested by patients.
- Use translators when appropriate and, if desired by patients, include family members in the information-sharing session(s).
- Supplement the information-sharing dialogue with written materials as appropriate.
- Evaluate each of the four components of decisional capacity: capacity to communicate, capacity to understand, capacity to reason, and capacity to appreciate.
- If symptoms or stressors interfere with optimal decision making, seek to ameliorate patients' discomfort to help support their ability to approach the decision process.
- Invite patients to express their preferences.
- Explore the reasons and hopes behind these preferences.
- Provide emotional reassurance and eliminate, to the extent possible, coercive pressures that patients may be feeling.
- Clarify patients' values and patterns of past personal decisions.
- Create a context of nonjudgmental support and open and ongoing communication with patients.

When an individual is not capable of informed consent or refusal, others who are legally authorized may make decisions for the patient. In some cases, the patient may designate the alternative decision maker. For young children, a parent or guardian may make the decision. At times, a formal legal process must identify a suitable decision maker. State laws differ in how to identify decision makers and what direction decision makers receive, such as whether to make the decision that appears to be in the best interests of the patient or the decision that most closely resembles what the patient would choose, if it were possible (i.e., "best interests" vs. "substituted judgment" approaches).

Overlapping Roles and Conflicts of Interest

Differing and overlapping roles are common for professionals who serve society as clinicians and also as teachers, consultants, administrators, and

public policy experts. Having more than one role generates ethical questions and often ethical tensions because the duties of each role, by definition, do not align perfectly. (Having more than one role creates dual role, or dual agency, problems.) When roles receive compensation from different sources, issues also arise in relation to competing interests and divided loyalties. Many controversies related to conflicts of interest have become a focus of governmental policy and media reports. Ethically, conflicts of interest matter greatly in that patient needs may be subordinated to the interests of physicians who are motivated by greed rather than serving patient well-being. Conflicts of interest occurring at multiple levels—among individual physicians, institutions, and systems of care and research—have eroded public trust in the medical profession.

To illustrate, dual agency conflicts may arise for psychiatrists who work in the military, occupational health programs, or correctional settings. For example, psychiatrists may be called on to use their expertise to make a recommendation on a patient's fitness for duty, competency to stand trial, or disability. As a result of the evaluation, the patient ultimately may be returned to front-line military or police work or to prison or may receive (or not) financial compensation. The ethical question of what decision serves the best interests of the patient becomes moot in these situations in which the other duties of the psychiatrist, such as protecting the public, become predominant. Particularly vexing dilemmas arise in the correctional setting, where psychiatrists may be called on to treat patients against their will when treatment would improve their disorder at the expense of their interests. Psychiatrists may not ethically force treatment on patients to make them competent to be executed. The issue is less clear concerning making patients better able to stand trial when doing so might lead them to spend more time in jail. Honesty, transparency, objectivity, and rigor—always important—are especially salient in the context of dual agency. The key issue to ethical behavior in such situations is to provide accurate information about the nature of the evaluation process, including information about the physician's responsibilities beyond those to the patient and about how usual expectations regarding patient confidentiality are not in force. Before the examination begins, physicians must notify the individuals explicitly about how they will disclose or report the information and conclusions from the evaluation.

Physicians can manage many conflicting roles and conflicts of interest in professional roles through the conscientious use of safeguards such as role separation, recusal, financial limits, responsibility limits, and additional supervision or oversight. Because the public trust is at stake in issues of conflict of interest, broad dialogue and scrupulous attention to emerging guidelines and principles are very important for all fields of medicine, including psychiatry. Integrity—namely, intending good, being transparent, adhering to professional standards, and simply behaving in a

manner that is worthy of trust—is key. Psychiatrists, moreover, should play an active role in educating the public on the value of professionals participating in broad activities in society, such as research, education, administration, and policy making, in order to bring the greatest positive value of medical expertise to broader society.

Psychiatric Opinions

In 1964, Barry Goldwater was the Republican candidate for president of the United States. *Fact* magazine sent a questionnaire to US psychiatrists asking whether Goldwater was psychologically fit to serve as president. Despite any direct knowledge of Goldwater derived from an in-person interview, approximately half of the psychiatrists who responded to the survey said he was not fit to serve in the role. The magazine then published an article proclaiming, "1189 Psychiatrists Say Goldwater is Psychologically Unfit to be President." In response, the APA asserted that it is unethical to render psychiatric judgments about a person in the media.

It is clearly unethical for psychiatrists to render a definitive psychiatric opinion about someone for whom they have only very limited information or only a biased source of information, such as the media. The practice appears nevertheless to be quite common. Invoking one's expertise as a psychiatrist without full knowledge of a patient is misleading and inappropriate. It is, however, ethical to render an opinion about someone one has not evaluated if one has an adequate source of unbiased information and is prudent in stating the limits of one's knowledge. In fact, psychiatrists commonly render opinions about people they have never met. When senior psychiatrists supervise residents or other mental health practitioners, they render opinions and make suggestions on treatment although they may not have met the person in question. Psychiatrists are sometimes asked to render an opinion on testamentary capacity—whether someone who is now deceased had the capacity to make an informed decision and whether the person was subject to undue influence. Moreover, esteemed psychiatrists have studied political leaders and historical figures and thereby advanced the understanding of history and human behavior. Similarly, it is ethical for psychiatrists to reanalyze the data of a neutral forensic evaluator and make conclusions about parties they have not interviewed if there is adequate information in the neutral forensic evaluator's report to do so.

Thus, the ethics of rendering an opinion about a person whom one has not examined depends on several factors. Key issues include the purpose of rendering the opinion, the quality of information, and the reason for not interviewing the person.

Responsibilities to Third Parties

Several court rulings have stated that psychiatrists have a responsibility to third parties. These concerns are more properly forensic in nature but are relevant to good ethical practices because of the ethical notion of respect for the law. Court rulings create case law, not ethics. Nevertheless, case law leads to new expectations and indicate society's view of professional responsibilities. Legal rulings also have value because they point attention to issues that need deeper consideration by ethicists. In the original and subsequent *Tarasoff* decisions, for example, the courts upheld the position that psychiatrists must act overtly to protect the community. Courts have held psychiatrists liable when their patients, or former patients, have injured or killed people with guns or by reckless driving (e.g., 1983 *Jablonski v. U.S.;* 1988 *Naidu v. Laird;* 1980 *Lipari v. Sears, Roebuck and Co.;* 1983 *Petersen v. Washington*). Subsequent legislative rulings have limited psychiatrists' liability in such matters. Psychiatrists who provide incorrect information place themselves at risk if such action harms the interests of a third party (e.g., *Molien v. Kaiser Foundation Hospitals* and *Ramona v. Isabella*). When clinicians give direct suggestions that affect third parties, such as advice to get a divorce (rather than limit interventions to helping patients evaluate their choices in the context of their lives), clinicians leave themselves liable for the consequences. The liability is increased if they become directly involved by participating in a confrontation with the third party.

ETHICS AS FUNDAMENTAL TO MEDICAL PROFESSIONALISM

Service to society is the *raison d'être* of the professions. In medicine, physicians provide expertise to advance human health and to lessen the burden of suffering associated with illness. Medical professionals, including those in the field of psychiatry, have the opportunity to develop distinct expertise to help others. These professionals have responsibility for creating and applying new knowledge, training others, and participating in leadership throughout the profession and broader society. These professionals also have the duty to ensure that colleagues uphold the clinical and ethical standards of their disciplines. Self-care and vigilance to avoid emotional exhaustion and impairment are thus important responsibilities of professionals. In return, physicians, like other professionals, are entitled to fair compensation for the work they perform in their special societal role. Part of the social contract of each profession is that professionals will, at a minimum, live up to the ethical commitments of the field. More deeply, members of the profession will seek progress ethically as well as in the scientific basis and clinical practices of each field and discipline in the profession.

ACKNOWLEDGMENT

The author wishes to acknowledge the work of Dr. Roy H. Lubit, who wrote

this chapter in the 9th edition of the *Comprehensive Textbook of Psychiatry,* part of whose work was adapted for this chapter.

▲ 60.3 Correctional Psychiatry

HENRY C. WEINSTEIN, M.D., AND JOSEPH V. PENN, M.D.

INTRODUCTION

Correctional psychiatry occupies a unique place in medical practice. As in all matters "forensic" it functions at the boundaries of law and medicine. As a subset of forensic psychiatry, it is fraught with potential bias and conflicts of interest. The shadows of issues of ethics and morality are ever-present.

Multiple factors, including legal, social, fiscal/health care reimbursement, and political, over the past 50 years have led to the current substantial presence of inmates with psychiatric and substance use disorders in the correctional systems of the United States.

Some examples of these factors include the downsizing of public mental health inpatient facilities, "zero tolerance" arrest and sentencing policies as part of the "war on drugs," and the deinstitutionalization of many individuals with chronic and persistent mental illness.

One of the unintended consequences is what is now referred to as the "criminalization of mental illness." Mental and substance-related disorders, chronic medical conditions, and infectious diseases such as human immunodeficiency virus (HIV) and hepatitis B and C are significant public health problems affecting individuals in US correctional facilities.

It is often said that American jails, prisons, and other correctional settings have become the default mental health system for this high-risk population. In particular, the sheer number of inmates with severe psychiatric disorders in the US prison system and the "revolving door phenomena" in which many mentally ill people move continuously between homelessness and the criminal justice system represent a national public health crisis. There is a similar risk of reincarceration among prisoners with co-occurring severe mental illness and substance use disorders.

This chapter will present an overview of American correctional systems and make recommendations for the psychiatric assessment, treatment, and consultative, administrative, and other roles and possible ethical challenges that a psychiatrist may face practicing in correctional settings.

An estimated 6,899,000 persons were under the supervision of adult correctional systems at year-end 2013. Of these, there are more than 2.2 million inmates in US jails and prisons. It is estimated that of these, 350,000 have severe and persistent mental illness, that is, carry a diagnosis of a serious mental disorder such as schizophrenia, bipolar disorder, or severe depression.

There are many different types of correctional facilities. These include lockups, jails, state and federal prisons, US Immigration and Customs Enforcement (ICE) detention centers, Bureau of Indian Affairs detention centers, US military prisons, jails, and detention centers. There have been recent concerns regarding access to care and other medicolegal issues for persons with severe mental illness in the US ICE system.

The most common correctional settings for adults are jails and prisons. Jails are city- or county-operated correctional facilities that confine individuals involved in the criminal justice system who are awaiting trial or serving short sentences for misdemeanors. There are approximately 3,500 jails in the United States. Detention refers to the period following arrest in which an individual is held in secure custody prior to or after court proceedings. There is a great deal of variety regarding the duration of time that individuals remain in jail (e.g., hours, days, weeks, typically 1 year or less). Some individuals may remain in jail for years for more serious charges while awaiting legal disposition of their case, or they may serve their sentence in a jail setting. There is significant variability in size with some small rural jails holding 10 to 50 detainees and some major metropolitan jails holding 7,500 to 10,000 detainees.

A prison is a facility operated under the auspices of a state or federal government for the confinement of adults convicted of a felony whose sentences generally exceed 1 year. There are approximately 1,300 state and federal prisons in the United States. Individuals in prisons may be serving one or more life sentences, and some states have the death penalty.

Similar to adults, mental and co-occurring substance-related disorders are significant public health problems affecting youth in juvenile justice

settings. There has been a significant increase in the need for psychiatric and mental health services for youth in the juvenile justice system. While involved with the juvenile justice system and family courts, juveniles may be housed within juvenile detention centers, reception or diagnostic centers, community-based or other residential treatment programs, or juvenile correctional facilities. Some juveniles may be held in county jails, and some youth may be transferred/sentenced to adult prison settings. In many states, certain felony offenses committed by adolescents are moved to adult criminal court. This practice has led to an increase in the detention and incarceration of younger offenders in adult jails and prisons. Data reflect rates of SMI among incarcerated adolescents that are substantially above those found in the community.

HISTORY OF CORRECTIONAL PSYCHIATRY IN THE UNITED STATES

The psychiatric care of the mentally ill in jails and prisons has a long history in the United States. Benjamin Rush (1745–1813), who wrote the first general book on psychiatry in America in 1812, *Medical Inquiries and Observations Upon the Diseases of the Mind*, and is regarded as the father of American psychiatry, wrote extensively on the treatment of deviant behavior. Rush deemed public punishment, which was common at the time, to be counterproductive and proposed private confinement, labor, solitude, and religious instruction for criminals. His outspoken opposition to capital punishment contributed to the Pennsylvania legislature's decision to abolish the death penalty for all crimes other than first-degree murder. He founded the Philadelphia Society for Alleviating the Miseries of Public Prisons, the first prison reform group in the world. This group survives today, more than two centuries later, and is now called the Pennsylvania Prison Society. It promotes correctional reform and social justice.

However, until recently, in regard to conditions in jails and prisons, courts maintained a "hands-off" policy, a doctrine that regarded the inner workings of correctional facilities as beyond the responsibility and authority of the judicial system and best left to correctional professionals.

The attitude of the courts toward prisoners was epitomized by a statement in a 19th-century case in the state of Virginia: "A convicted felon is one whom the law in its humanity punishes by confinement in the penitentiary instead of death… for the time being, during his term of service in the penitentiary, he is a slave of penal servitude to the State… for the time being, the slave of the State" (*Ruffin v. Commonwealth*).

It was during the 1970s, during the tidal wave of the civil rights movement, that various studies and court cases exposed the abominable conditions of health and mental health care in the jails and prisons of the United States. These disgraceful findings lead to the reform of the correctional system and an accelerating sea change in correctional

psychiatry and health care.

The confluence of a number of interrelated forces spearheaded this reform, including professional organizational advocacy by the American Medical Association (AMA) and the American Psychiatric Association (APA), "conditions of confinement" lawsuits, which were now entertained by the courts, and the development of standards and guidelines for health and mental health care in jails and prisons.

In 1974, the AMA carried out a survey of sheriffs administering local jails. It revealed that nearly two thirds of the jails' correctional health care consisted of no more than first aid (16.7 percent reported that not even first aid was available). This survey also found that fewer than 20 percent had facilities for caring for alcoholics, only 10 percent had any facilities for inmates with drug addiction, and only 14 percent had facilities for inmates with mental illness. Studies of prison correctional health care revealed that prison correctional health care was no better than that in jails. It was also clear that almost all jails and prisons lacked mental health–screening mechanisms and testing services, and, therefore, inmates' mental health problems went undetected and untreated.

In the same year, 1974, the APA published a Position Statement prepared by the APA Committee on Psychiatry and the Law (Table 60.3–1). In 1975, the Federal Law Enforcement Assistance Administration (LEAA) provided a grant to the AMA to upgrade correctional health care. The purpose of the grant was to develop a model correctional health care system and to establish a clearinghouse to develop and to distribute information on correctional health care issues. Another important goal was the development of a national accreditation program with correctional health care standards. In 1977, the AMA published its first jail correctional health standards; 16 jails were accredited for compliance that year. In 1979, the prison and juvenile correctional health care standards were published.

At the same time, the judicial system was establishing the unique legal context of psychiatric services in jails and prisons—that such services are constitutionally guaranteed. In 1976, the US Supreme Court, in the case of *Estelle v. Gamble*, held it unconstitutional for prison officials to be deliberately indifferent to the serious medical needs of those in their custody, and in 1977, a federal court, in the case of *Bowring v. Godwin*, extended this requirement to psychiatric care.

Table 60.3–1.
American Psychiatric Association Position Statement on Medical and Psychiatric Care in Correctional Institutions (1974)

The American Psychiatric Association recognizes that so-called correctional institutions are established by various levels of government. Their ability to provide a full range of medical (including psychiatric) services varies according to a multitude of factors: e.g., public opinion, funding, and administrative structure in relation to the goals set for a particular institution, such as punishment, containment,

deterrence, rehabilitation, and/or treatment.

An essential part of a minimum medical care delivery system consists of the early detection, diagnosis, treatment, and prevention of psychiatric illness. Many "correctional" facilities are not so structured as to supply this care delivery system even minimally.

It is never part of the penalty imposed to deprive a prisoner of adequate medical (including psychiatric) care. Furthermore, it is never proper to use medical (including psychiatric) care for punitive and coercive purposes or as an instrument of social repression. The fact of incarceration imposes upon public authority the special duty to provide adequate medical services, including psychiatric services. Availability of such services is and should be a right of each incarcerated individual.

In 1983, as an outgrowth of the LEAA-funded AMA program, the National Commission on Correctional Health Care (NCCHC) was established. The NCCHC consists of 37 professional organizations, including the AMA and the APA. It assists correctional institutions in upgrading their correctional health care services and, most important, has established correctional health care standards and correctional health care accreditation processes. These standards, which are revised regularly, represent the state of the art in correctional health care, and with the 2007 publication of the NCCHC's Standards for Mental Health Services in Correctional Facilities, the state of the art, as well as evidence-based practice, for mental health services in jails and prisons.

In 1989, the APA published Psychiatric Services in Jails and Prisons. This document, referred to as the APA Guidelines, was developed by correctional psychiatrists for correctional psychiatrists and describes in detail the principles governing the delivery of psychiatric services in jails and prisons; the specific requirements for an adequate process of screening, evaluation, and treatment; the specific roles of the correctional psychiatrists; and the application of the principles and guidelines to specific populations. The second edition of the APA Guidelines was published in 2000, the third edition, now titled *Psychiatric Services in Correctional Facilities*, was published in 2016.

There have been some recent efforts to pursue alternatives to incarceration of persons with severe mental illness and substance abuse disorders. One of the most promising alternatives is the diversion model, designed to prevent or minimize detention of the nonviolent mentally ill and to divert persons with severe mental illness to appropriate community-based mental health services in lieu of incarceration. Postbooking programs such as drug courts and mental health courts that are similarly designed to divert nonviolent mentally ill individuals from jails and prisons into closed supervised treatment programs have also been particularly promising.

Correctional Psychiatry as Community Psychiatry

Each year correctional facilities release approximately 12 million inmates. Because society inevitably shoulders the cost of their treatment, the period

of incarceration is an opportunity to create an infrastructure to identify and to treat these patients. In a biosphere in which life is interdependent, the mental health status of the least members of society strongly influences the mental health status of the greatest members of society. Effective correctional psychiatric systems will have a positive influence on the public's mental health. So, in recent years, it has become increasingly evident that correctional psychiatry must be considered an integral part of community psychiatry and that correctional health must be conceptualized as an important aspect of public health.

The title, "The Health Status of Soon-to-Be-Released Inmates," indicates how the NCCHC's project and publication focused on this insight. It stated:

> Prisons and Jails offer a unique opportunity to establish better disease control in the community by providing improved health care and disease prevention to inmates before they are released. Implementing the recommendations in this carefully researched report will go a long way toward taking advantage of this opportunity and contribute significantly to improving the health of both inmates and the larger community.

Many systems are implementing innovative community reentry initiatives and/or expanding discharge planning or continuity of care programs for mentally ill inmates who are about to be released. These programs attempt to link inmates shortly prior to or at the time of release into long-term community-based outpatient services to help them manage their mental health problems and reduce their risk of recidivism.

A Career in Correctional Psychiatry

The practice of correctional psychiatry can provide a wide variety of rewarding opportunities—to work within a unique system that has multiple challenging patients, access to care issues, the balance between safety, custody, and control, other correctional barriers and challenges, and other intersecting system pathologies usually not met in other contexts, to open up a new world of interest and interesting colleagues and correctional professionals, to learn about this critical social phenomenon, and to participate in this special aspect of public psychiatry and public service.

The correctional psychiatrist's expertise and role as a diagnostician, consultant, and team leader, and the ability to evaluate and diagnose individuals with serious mental illness, differentiate medical illnesses or comorbidities from psychiatric disorders, and consult to medical and administrative and correctional staff and leadership are all essential roles and functions. Although in some correctional systems, a psychiatrist's role may be limited to diagnostic evaluation and medication treatment and management, correctional psychiatrists have the opportunity for other roles in the provision of correctional mental health care—such as screening, evaluation, suicide prevention, other health care and correctional staff

education and training, quality reviews, working on improving clinical outcomes, and systems and process improvement.

The psychiatrist's knowledge and familiarity with the ever-growing and increasingly complicated use of psychotropic medication(s) and diagnostic abilities make him or her an indispensable member of the facility team and an important component of the correctional facility's security apparatus. Psychiatrists who practice in a correctional setting need to have an awareness and understanding of the operations of the facility and the issues affecting it, including access to care, continuity of care, and the interface with multiple systems (e.g., police, probation, courts, social services, community and state systems for offenders with serious mental illnesses). Effective psychiatric treatment and consultation in correctional settings requires knowledge of the organizational structures, policies, procedures, and other systems issues relevant to mental health issues and the daily schedule and "culture" and ongoing issues in the institution.

Psychiatrists working in correctional settings must be vigilant in regard to their personal safety and security issues and aware of actions that may compromise their safety and/or the safety and confinement of incarcerated individuals. Before entering a correctional facility, the psychiatrist should become aware of the type and function of the correctional facility and custody issues, what different issues may arise when attempting to evaluate or provide care to individuals with differing custody levels, and also in the event of fire alarm, altercation, riot, and hostage negotiation. The correctional psychiatrist's variety of roles in the provision of essential services can go beyond the direct care of patients. This may might involve consultation on processes, protocols, the decision of which instruments to use, and other policy review and improvement. The goal of these initiatives is to improve the processes and functioning of the staff and the facility. There may be opportunities for teaching of other mental health professionals and especially the cross-training of security staff and the opportunities to learn about the subtleties of security and respect for the professionalism of the correctional profession. As more academic departments recognize the value of clinical rotations and electives in jails and prisons, further opportunities for leadership in supervision and teaching of medical students, psychiatric residents, forensic psychiatry fellows, and other mental health professionals arise.

A career in correctional psychiatry can represent the development of an area of expertise that can lead to opportunities to help lead and guide this new field. One can become an "authority" in correctional psychiatry, help guide and grow the field, and serve as a presenter at state, national, and international conferences. There are opportunities to serve as a physician surveyor for the NCCHC and other correctional accreditation organizations. There appears to be a growing amount of litigation in state and federal courts. Thus, there is an opportunity for psychiatrists to

participate in litigation and testify as an expert witness. Some courts rely on psychiatrists to serve as court monitors within correctional systems.

Finally, there is the opportunity for the correctional psychiatrist to help educate the public, media, judges, lawyers, probation, courts, state leaders, and other individuals on the growing mental health and medical needs within correctional settings. There are many opportunities to work collaboratively and proactively with local, state, and national lawmakers, and governmental leaders and policy makers, assist with new legislation, serve as resource witnesses during legislative sessions, and help identify and secure sources of funding of additional staff and adequate psychiatric and mental health services for persons with mental illness and other vulnerable populations within jails and prisons. Participation in this laudable effort can give special meaning to working with this often-neglected and high-risk patient population. This proactive work is akin to risk management in health care and is particularly important due to an increasing trend toward litigation against jails, prisons, and other correctional systems and their leadership and at times individual correctional health care providers or organizations in state and federal courts.

THE LEGAL AND ETHICAL PRINCIPLES UNDERLYING THE PRACTICE OF CORRECTIONAL PSYCHIATRY

The Legal Context of Correctional Psychiatry

In 1970s, the crucial years of the reform of the correctional system, a series of court decisions established the principle that psychiatric services in the jails and prisons of the United States are constitutionally guaranteed. This legal doctrine holds that under the Eighth Amendment of the US Constitution, which prohibits "cruel and unusual punishment" whenever a state or the federal governmental entity takes custody of a person, it must provide for the necessities of life that the person otherwise is unable to obtain. These include food, clothing, shelter, and medical care, which include psychiatric care.

In 1976, the Supreme Court, in the case of *Estelle v. Gamble*, held it unconstitutional for prison officials to be deliberately indifferent to the serious medical needs of those in their custody, and in 1977, the federal court case of *Bowring v. Godwin* extended this requirement to psychiatric care. In 1980, another federal court case, *Ruiz v. Estelle*, listed a number of specific components that are required:

1. Participation by trained mental health professionals
2. Systematic screening and evaluation
3. Safeguards against psychotropic medications that are prescribed in dangerous amounts, without adequate supervision, or otherwise inappropriately administered

4. Treatment that is more than mere seclusion or close supervision
5. Accurate, complete, and confidential records
6. A suicide prevention program

In 1989, the case of *Langley v. Coughlin* listed a number of other specific criteria that, if not met, could provide a basis for successful inmate legal claims. Many of these criteria explicitly required providing for so-called secondary or supportive rights, such as taking psychiatric histories and maintaining medical records, in recognition of the fact that such rights are required to facilitate the primary right to diagnosis and actual care. *Langley v. Coughlin* also explicitly requires that care not be limited to psychotropic medication.

Madrid v. Gomez, in 1995, a State of California Department of Corrections legal case, added several factors that may determine the constitutionality of a correctional mental health system:

1. An inmate must have a means of making his or her needs known to the medical staff.
2. Sufficient staffing must allow individualized treatment of each inmate with serious mental illness.
3. An inmate must have speedy access to services.
4. There must be a system of quality assurance.
5. Staff must be competent and well trained.
6. There must be a system of responding to emergencies and to prevent suicides.
7. Inmates also have a right to a hearing and procedural protections before involuntary psychiatric hospitalization or forced administration of antipsychotic medication.

It should also be noted that in addition to these constitutional mandates, jail and prison mental health services may be required to meet other legal requirements. These include federal laws, such as the Americans with Disabilities Act, and various federal regulations, as well as state requirements established on the basis of state law through constitutions, statutes, and regulations. In addition, of course, correctional psychiatric services are always subject to other legal liabilities, such as for medical malpractice. Thus, individuals and systems may be sued in state or federal court, depending upon a variety of factors, either for malpractice, deviation from the standard of care, or alternatively under Federal constitutional 1983 actions, for example, “deliberate indifference,” and failure to afford access to care and/or continuity of care. However, it must be noted that the constitutional guarantee of mental health care in correctional facilities does not extend to treatment for substance use disorders. The position of the courts has been that the provision of care and treatment in cases of substance use disorder (e.g., for drug abuse) in jails and prisons is not considered an aspect of psychiatric care and, therefore, is not considered as

constitutionally required. However, there is such an obvious need for treatment of substance use disorders in jails and prisons that it is usually included in correctional programs.

The Ethical Context of Correctional Psychiatry

Although psychiatrists practicing in correctional settings face complex and often unique ethical problems, they are bound by the same body of ethical principles as psychiatrists practicing in any setting to follow the standards of professional ethics as set out in the APA's Annotations Especially Applicable to Psychiatry to the AMA's Principles of Medical Ethics. Although the Preamble to the AMA's Principles states, "A physician must recognize responsibility to patients first and foremost," it then adds the words "as well as to society."

In the correctional setting, profound conflicts in orientation, mission, purposes, aims, objectives, and even value systems arise from the psychiatrist's duties to the patient clashing with his or her duties to the department of correction and staff and other inmates, which can be regarded as an aspect of the correctional psychiatrist's duties to "society."

The Problem of Dual Loyalty in Correctional Psychiatry. In the correctional setting, there is a conflict between the two distinct roles of the correctional psychiatrist: As the inmate's treating physician and as an employee and agent of a local, state, or private correctional agency. This problem of "dual loyalty" (which has also been called the "the double-agent problem") is pervasive, and, therefore, it is imperative that correctional psychiatrists be aware of these complex conflicts, which may subtly (or not so subtly) influence their medical decisions.

Although a new section of the Principles adopted by the AMA states "a physician shall, while caring for a patient, regard responsibility to the patient as paramount," the reality is that correctional psychiatrists practice in a setting of power and control in which the correctional staff might view psychiatric intervention as an impediment to control and in which, on the contrary, inmates might seek mental health care genuine reasons (e.g., for mental distress and impairment) or alternatively for a variety of reasons. Some of these nonclinical reasons may include a variety of medication-seeking or location-seeking behaviors (e.g., to be transferred off a unit after some type of conflict with staff or a peer, fear of harm/injury, life endangerment claims, to receive certain psychotropic medications for abuse trading as contraband and diversion, to achieve a certain preferred housing environment/location, escape certain work demands/designations, other classification and housing assignments [e.g., low bunk, first row, avoidance of stairs, air conditioning housing] that are preferred to their current housing assignment, to receive disability benefits upon release, or other perceived favorable legal, parole, and probation outcomes).

Medical Autonomy in Correctional Psychiatry. Navigating between institutional and inmate demands requires a focus on medical autonomy, in that nonmedical personnel cannot overrule the professional judgment of correctional psychiatrists regarding their patients' needs. On the contrary, medical autonomy means that only legitimate clinical decisions direct patient care, not the patient's wishes. One simple way of understanding this concept is that inmates/offenders get what they "need" (what is determined to be medically necessary by correctional staff) rather than what they "want" (plastic, cosmetic, or elective surgery procedures, other treatments that are not clinically indicated or are not within accepted community standards of care).

For example, the APA's Annotations emphatically state, "The physician should not delegate… to any nonmedical person any matter requiring the exercise of professional medical judgment."

The NCCHC's Standards, relating as they do to a variety of mental health professionals, refer to this principle as "clinical autonomy" or "mental health autonomy" and state "Clinical decisions and actions regarding mental health care provided to inmates with mental health needs are the sole responsibility of qualified mental health professionals," explaining that "the standard intends to ensure that clinical decisions are made for clinical purposes and without interference from other personnel." An example is given that "if custody staff requests that an inmate be medicated for behavioral or any other reason, the clinical decision to medicate should be based on the health professional's independent determination of clinical need."

The Doctor–Patient Relationship in Correctional Psychiatry. The importance of the doctor–patient relationship is emphasized in the APA's Annotations with the statement, "Physicians generally agree that the doctor–patient relationship is such a vital factor in effective treatment of the patient that preservation of optimal conditions for development of a sound working relationship between a doctor and his or her patient should take precedence over all other considerations."

Do no harm is a basic tenet of medicine, and psychiatrists are accustomed to acting in patients' best interests. Another basic tenet in medicine is that of patient autonomy. By this it is meant that the patient's right to control his or her treatment and, indeed, his or her body is a priority. Both of these values may be at odds with correctional perspectives and policies, and the correctional environment might threaten to coerce professional judgment and actions into meeting security needs rather than the mental health needs of individual inmates.

For example, correctional institutions and health care organizations may for a variety of reasons sometimes place demands on correctional psychiatrists, nursing staff, and other health care staff to withhold, limit,

reduce, delay, or to find a shortcut to appropriate psychiatric treatment services for a variety of reasons (e.g., cost, security risks, lack of sufficient correctional staff to escort an offender for an appointment, lab test, or procedure on-site or off-site, lack of transport equipment, and perceived "deservedness"). Simultaneously, inmates can be insistent and manipulative, sometimes seeking psychiatric care for inappropriate reasons, described previously as med-seeking, location-seeking, and other behaviors. Therefore, the correctional psychiatrist must constantly monitor unintended identification with correctional authorities and countertransference with inmates.

It is paramount for correctional psychiatrists to be aware of relevant financial, fiscal, reimbursement, agency, and role issues that might affect their ability to provide optimal and clinically indicated care to their incarcerated patients or those who require these services. Psychiatrists should be aware that the same professional standards, oversight by state medical boards, and state regulations that pertain to clinical practice in the community "free world" also apply to the services they provide within correctional settings.

Confidentiality in Correctional Psychiatry. Although the usual principles of psychiatric confidentiality apply to the delivery of psychiatric services in jails and prisons, the special needs presented by these settings, especially in relation to security, legal status of the offender (if still a jail detainee with pending legal charges, or if in a state or federal prison system with new charges), require certain modifications based on the responsibilities of the custody staff, as well as the safety and security of the patients, other inmates, and the staff. The APA Guidelines state, "The rights of the patient to… confidentiality must be weighed against the needs of other inmates as well as the institutional needs of safety and security." Table 60.3–2 lists the treatment situations in which the usual rules of confidentiality may not be applicable. Table 60.3–3 lists other situations in a jail or a prison that are part of the mental health treatment process that might require changes from the usual rules of confidentiality.

It is critical for psychiatrists and other mental health staff working in correctional settings to define and maintain their role as a clinician, working in the best interests of the patient, as opposed to a forensic evaluator, or as an agent of the court, law enforcement, or of the state or local jurisdiction. Without a release of information, treating psychiatrists should avoid verbal or written communication with attorneys and other court personnel, and they should avoid inappropriate communication with the media. This is a particular challenge with certain high-profile offenders (e.g., particular heinous offenses, high-profile crimes, politicians, community leaders, and media, sports, and other celebrities), where there may be significant local or national media interest. Responses to media

requests and for interviews regarding individual offenders should be declined and instead directed to appropriate facility and/or health care administrative staff such as a media relations department or individual. Within a correctional setting or system, there is a natural tendency toward curiosity and discussion of high-profile offenders. Psychiatry and other health care leaders should encourage all staff to avoid reviewing the chart/electronic medical record (EMR) of any high-profile offender or seeking out interaction/discussion with that individual or others treating that individual if the health care professional is not directly involved in the evaluation and treatment of this individual and, therefore, is not on a "need-to-know" basis (e.g., not part of that individual's treatment team).

Table 60.3–2.
Treatment Situations in Jails or Prisons under Which the Usual Rules of Confidentiality Might Not Be Applicable

The patient is self-injurious or suicidal
The patient is assaultive or homicidal
The patient presents a clear and present risk of escape or the creation of disorder within the facility

Table 60.3–3.
Situations in a Jail or Prison That Might Require Changes from the Usual Rules of Confidentiality

The patient is receiving psychotropic medication
The patient requires movement to a special unit for observation, evaluation, or treatment of an acute episode
The patient requires transfer to a treatment facility outside the jail or prison

It is also recommended that the correctional psychiatrists specify clearly any limits on the usual precepts of confidentiality before initiating treatment, except in emergencies. However, this notice may be presented to the inmate in general terms, such as applying to situations in which the patient or the institution may be at risk.

Public Areas. In a situation familiar to psychiatrist practicing in various facilities, the NCCHC Standards advise, "Mental health staff should be reminded not to discuss patients' mental health information in front of custody staff or other inmates, including those working in or near the mental health services area." In addition:

> Non-mental health staff who observe or overhear a clinical encounter are instructed that they also are required to maintain confidentiality. Evidence that staff who have access to the mental health records have been instructed in the need for confidentiality may take several forms including policies and procedures, memoranda to staff, meeting minutes, and reviews during roll call or in-services. Where correctional staff are assigned full time to mental health or substance abuse clinics, programs, or residential care units in correctional settings and, therefore, are members of the treatment team with specific duties and responsibilities, they are bound by the

same confidentiality rules as the other clinical staff.

On the contrary, correctional psychiatrist must be able to share relevant confidential information with facility administrators (on a "need-to-know" basis) when it relates to the medical management of a patient, security issues, or a patient's ability to participate in programs. Similarly, it is appropriate that there be communication with nonclinical staff regarding an inmate's significant mental health needs that must be considered in classification decisions to preserve the health and safety of that inmate, other inmates, or staff (Table 60.3–4).

The NCCHC standards point out:

Table 60.3–4.
Inmate Mental Health Needs That Must Be Considered in Classification Decisions

Nonclinical staff are advised of inmates' mental health needs that might affect the following:
Housing
Work and program assignments
Disciplinary measures
Admissions to and transfers from institutions
Mental health and custody staff members communicate about special accommodations needed for the following:
Inmates who are chronically mentally ill
Inmates who are suicidal
Inmates who are developmentally disabled
Inmates who have significant addiction or other serious mental health problems

Since mental health problems affect housing decisions, work or program assignments, and disciplinary management... communication between security, health services, and mental health staff assures that the mentally ill inmate's activities of daily living are restored or maintained to the greatest extent possible. A consistent and reliable method of communication among staff regarding the special mental health needs of inmates is the lynchpin to successful compliance to this standard.

The correctional psychiatrist should be sensitive to the fact that confidentiality is especially important to those for whom the lack of confidentiality might have serious legal and other consequences, such as those detainees with pending legal charges. Some practical suggestions for psychiatrists and other mental health staff might include the avoidance of exploration into the details or circumstances of the alleged criminal act(s) and the individual's state of mind, criminal intent, mitigating factors, or other defense strategies. Similarly at risk are those who have experienced sexual violence, sex offenders, or persons with HIV/acquired immunodeficiency syndrome (AIDS).

The issues surrounding confidentiality in jails and prisons are so complex that it is especially important that clear and specific written policies be developed and maintained. However, in facilities in which there

are no written policies, the correctional psychiatrist should clarify these issues with the institutional authorities and develop working policies as to the degree to which confidentiality of information can be ensured.

Collecting Forensic Psychiatry Information in a Jail or Prison

A paradigm of the problem of dual loyalty is the collection and use of forensic psychiatric information by the correctional psychiatrist. The APA Guidelines set out the

> distinction [that] must be drawn between information obtained by a correctional psychiatrist in the course of treatment, and information obtained from the inmate in the course of an evaluation for non-treatment purposes. Some examples of the latter types of examinations are evaluations, at the request of an attorney or the court for an evaluation of competency to stand trial, mitigating factors, or criminal responsibility (such as in an insanity evaluation), or for a report for probation or the parole board.

It is in these circumstances that the principle of "do no harm" comes to the fore. Thus, the APA Guidelines note, "More complex ethical issues are raised when a treating correctional psychiatrist is asked to determine whether a patient can be sanctioned for an infraction or rules violation." Clearly, the correctional psychiatrist would want to help the inmate if the information could mitigate a sanction but would be reluctant to participate if the information aggravated the sanction: "In these cases, the usual rules in regard to confidentiality typically may not apply and it is the responsibility of the evaluating psychiatrist to set forth clearly to the inmate any such limitations on confidentiality as part of the informed consent process."

Similarly, when the correctional authorities ask correctional psychiatrists to collect information for forensic purposes, the NCCHC standards support the refusal of the correctional psychiatrist to do evaluations of inmates for use in adversarial proceedings or to order blood tests to determine drug or alcohol use (unless it is for clinical reasons). However, in cases of sexual assault, the NCCHC Standards permit health professionals to gather forensic evidence of the alleged victim if requested but not that of the alleged perpetrator.

These matters are of such concern to the NCCHC that it has promulgated an explicit standard prohibiting health care workers from collecting "forensic information." The standard on Forensic Information in the Standards for Mental Health Services in Correctional Facilities states, "Mental health staff are prohibited from participating in the collection of forensic information," which is defined as "physical or psychological data collected from an inmate that may be used against him or her in disciplinary or legal proceedings."

In a clear reference to the problem of dual loyalty, this Standard states:

> The intent of this standard is to ensure that the role of the mental health

staff is to serve the mental health needs of their patients. The perception of a neutral mental health services staff is compromised when they are asked to collect forensic information that may be used against inmates.

It then provides some examples of ethical conflicts for mental health services staff:

- Performing psychological evaluations of inmates for use in adversarial proceedings (e.g., court, probation, or parole hearings)
- Conducting body cavity searches for contraband
- Collecting blood or urine specimens for drug analysis

According to the NCCHC, "Such acts undermine the credibility of these professionals with their patients and compromise clinical staff by asking them to participate in acts that are usually done without inmates' consent." However, "where state laws and regulations require that such acts be performed by health/mental health staff, the services of outside providers or someone on the institution's staff who is not in a therapeutic relationship with the inmate is obtained."

Relevant also are the Ethics Guidelines for the Practice of Forensic Psychiatry of the American Academy of Psychiatry and the Law (AAPL), which deal with this issue explicitly, noting, "When a patient is involved in parole, probation, conditional release, or in other custodial or mandatory settings, psychiatrists should be clear about limitations on confidentiality in the treatment relationship and ensure that these limitations are communicated to the patient."

Informed Consent in Correctional Psychiatry

The issue of informed consent is the subject of great attention throughout medicine and surgery. It is, as the APA Guidelines note, particularly of concern in psychiatry, in which involuntary treatment might be invoked because the competency of an individual might be in question and/or because some emergency exists, but the Guidelines add that the inherently coercive settings of jails and prisons might create additional difficulties for the correctional psychiatrist in regard to consent. It is interesting to note that one legal case stated that it is impossible to obtain true informed consent in this setting.

In general, as the Guidelines note, the principles of informed consent as embodied in the ethical guidelines of the APA's Annotations remain applicable to patients in jails and prisons and, therefore, to the extent possible, the patient should participate in decisions about evaluation and treatment, and correctional psychiatrists should offer to discuss with their patients the nature, purpose, risks, and benefits of the potential types of treatment.

Because involuntary treatment is controversial and complex, the APA Guidelines say only "the actual institutional policies and the decisions of

the correctional psychiatrist in regard to the right to refuse treatment should conform with the rules and procedures of the jurisdiction in which the facility is located."

On the contrary, the importance of this subject is highlighted by the fact that there are two separate NCCHC standards that apply. The first, Informed Consent and Refusal of Mental Health Care, states, "All examinations, treatments, and procedures are governed by informed consent practices applicable in the jurisdiction" and notes that "the intent of this standard is to support the ethical principle that patients have the right to accept or refuse mental health interventions." Moreover:

> Competency may be an issue when mentally ill inmates refuse treatment. Management of such refusals, particularly if they seriously jeopardize the patient's health, requires a collaborative approach of psychiatric, psychological, criminal justice, and legal authorities. If there are no dire consequences to the refusal, the mental health professional may simply note in the record that the person was a "no show" for an appointment or refused medication.

The second NCCHC standard, Emergency Psychotropic Medication, states, "Mental health staff follow policies developed for the emergency use of forced psychotropic medications as governed by the laws applicable in the jurisdiction" (the definition of "forced medications" is "those given without the patient's consent").

It should be noted that the terminology used in the NCCHC Standards is dramatically different from that generally used in psychiatry. As a rule, psychiatric facilities use terms such as "treatment over objection" or "refusal of medication." The Standards focus on the word "forced" and its implications. Thus, the discussion of the latter standard states:

> This standard's intent is to have a clinically approved protocol for emergency situations when an inmate is dangerous to self or others due to a medical or mental illness and when forced psychotropic medication may be used to prevent harm, based on a prescriber's order. The standard supports the principle that psychotropic medication may not be used simply to control behavior or as a disciplinary measure.

It goes on to say, "This standard applies to emergency situations only. For guidance in forcing psychotropic medications on a more frequent basis or as part of an ongoing treatment plan, staff are referred to current case law (e.g., *Washington v. Harper*)."

Privacy in Correctional Psychiatry

The APA Guidelines state, "To the extent possible, treatment should be provided in a setting that is conducive to the achievement of its goals. This includes not only the particular physical setting, but also an atmosphere of empathy and respect for the dignity of the patient." However, the Guidelines note that although "the usual principles of privacy… apply to the delivery of psychiatric services in jails and prisons, correctional psychiatrist must recognize the inevitable and, indeed, necessary loss of privacy in

correctional psychiatric practice."

The NCCHC Standard is more specific and more detailed. Under the heading of "Privacy of Care," it requires that "mental health services are conducted in private and carried out in a manner designed to encourage the patient's subsequent use of services... in private, without being observed or overheard by staff or inmates."

The discussion of this Standard states, "The intent of this standard is to have mental health care encounters conducted in private and to protect the patient's dignity. The patient–clinician relationship may be eroded if privacy is not provided during clinical encounters." On the contrary, "when the patient poses a probable risk to the safety of staff or others, security personnel are present." Similarly, the Standard takes account of one of the unique conditions of correctional psychiatry by pointing out that "in corrections mental health triage commonly occurs at cell-side. As the triage discussion becomes more involved than a simple triage, the clinician should be aware of the need to maintain privacy and move the patient to a clinical setting."

A number of specific situations are dealt with. Thus, the standard addresses the issues of privacy and confidentiality in regard to interpreters, stating:

> The use of interpreters may be frequently employed during the mental health assessment process since a psychiatric evaluation is more likely to be valid when language and culture are appropriately addressed. Interpreters need to be advised on how to protect the patient's privacy. The use of inmates as interpreters should be discouraged and used only in urgent or emergency situations.

When safety is a concern and security presence cannot be minimized, it is recommended that alternative strategies for partial auditory privacy be considered—for example, white noise devices that can mask normal conversation.

Mental health crises are often accompanied by behavior requiring security intervention. In such an emotional environment, there are additional challenges to maintaining privacy and confidentiality. Clinicians new to the correctional environment should be trained to deal with these challenges during their orientation.

It is appropriate to end this section with another quote from the NCCHC Standards: "Maintaining ethical boundaries and professional attitudes is difficult in correctional institutions. However, orientation for new hires and continuing education on potential ethical conflicts can help mental health services staff maintain their ethical perspectives."

PSYCHIATRIC TREATMENT IN JAILS AND PRISONS

Providing competent and quality psychiatric treatment in jails and prisons is an unusually complex undertaking. The psychiatrist is a guest in the house, in the domain of corrections, practicing psychiatry on the turf of

corrections, where custody, control, containment, and maintaining order and security are the primary goal. This task is immediately apparent at the time of entering a facility, walking through a series of electric gates and past razor wire fences, and then going through an inspection for proof of identification, clarification/confirmation that the individual has security clearance and can enter the facility, security review of any/all belongings (medical books, reference materials, food items, and in many facilities personal cell phones and other electronic devices are not allowed), and a pat-down search with metal detectors. The correctional psychiatrist must adjust to the culture of corrections, and, although psychiatric treatment might be legally mandated, the correctional psychiatrist is obviously not in charge of the rules, policies, procedures, processes, and the institution in which care is provided.

The Policy Goal of Psychiatric Treatment in Jails and Prisons

According to the APA Psychiatric Services in Correctional Facilities (Second Edition):

> The fundamental policy goal for correctional mental health care is to provide the same quality of mental health services to each patient in the criminal justice system that should be available in the community. This policy goal is deliberately higher than the "community standard" that is called for in various legal contexts, because resource restrictions on community care can sometimes limit the adequacy of available services. Correctional systems provide additional challenges not present in the community, given that incarcerated persons have no options for care other than what is provided in the correctional facility.

The Purposes of Psychiatric Treatment in Jails and Prisons

Psychiatric disorders and psychiatric comorbidities are overrepresented in correctional populations compared with the general population. Correctional facilities and systems are, therefore, legally obligated to address the medical and mental health care needs of individuals in their placement. The purposes of psychiatric treatment in jails and prisons as set out by the APA Guidelines are listed in Table 60.3–5. These principles are echoed in the NCCHC Standards, which add that the goal is the "best level of functioning" and "In the correctional setting, as in most other environments, the immediate objective of mental health treatment is to alleviate symptoms of serious mental disorders and prevent relapses to sustain patients' ability to function safely in their environment."

Psychiatric Treatment Programs

Table 60.3–6 lists some examples of the APA and NCCHC psychiatric treatment programs for jails and prisons.

The Program Priorities of Psychiatric Treatment in Jails and Prisons. The psychiatric treatment program priorities in jails and prisons as set out by

the APA Guidelines are listed in Table 60.3–7.

Models of Health Care in Jails and Prisons

Different correctional settings have different organizational models for health care delivery, and it is important that the correctional psychiatrist become familiar with the model that his or her institutions follow in order to effectively deal with such issues as the chain of command and the allocation of resources, along with others. In many facilities, medical services and mental health services may be under the same or under separate authorities with different administrators and lines of reporting and supervision. Variations include situations in which the correctional psychiatrist is a full-time or part-time state, federal, or county employee, employed by a university health or a private health care system, or is a locums tenens, part-time or temporary individual contractor providing mental health services to any of the above or alternatively an employee or individual contractor for a national for-profit organization that is responsible for medical and/or mental health care services.

Table 60.3–5.
The American Psychiatric Association Guidelines on Purposes of Psychiatric Treatment in Jails and Prisons

To relieve the unnecessary extremes of human suffering
To make the correctional facility safer for everyone who lives, works, or visits there
To enable patients to avail themselves of the rights of due process
To permit inmates the opportunity to make use of programs offered

Table 60.3–6.
American Psychiatric Association (APA) and National Commission on Correctional Health Care (NCCHC) Psychiatric Treatment Programs

APA Psychiatric Treatment Programs
Depending on the particular correctional facility, psychiatric treatment can occur in any one of a variety of programs, including the following:
An acute care program
A longer-term program
A transitional care program
An outpatient treatment program
An inpatient hospital treatment program
NCCHC Psychiatric Treatment Programs
The National Commission Standards list the following types of programs:
Mental health programs without a residential component
Acute mental health residential units
Nonacute mental health residential units

Jails and prisons differ in the scope of mental health services provided.

Jails process most detainees who have a short length of stay, and, accordingly, jails are primarily concerned with the stabilization and management of acute conditions such as acute psychosis, substance intoxication, withdrawal, and suicide prevention.

While a person is in a jail, the purpose of mental health treatment is to prioritize the detainee's health and safety, but, when appropriate, this might also include the goal and outcome of restored competency to be arraigned or restored competency to stand trial so that their pending legal proceedings may resume. Because this is a forensic and nonclinical role, typically jail psychiatry staff are not involved in the assessment of whether an individual is competent or is not competent to stand trial. Similarly, they are typically not involved in the treatment of restoration of competency to stand trial, but this may vary by location (and whether the jail has a competency restoration program on-site or if this is a separate on or off-site program). Of course, once an individual returns to the jail, ensuring continuity of care and the psychotropic medications (typically initiated in the state hospital or competency restoration program) and other treatments is essential and can be very challenging.

In a prison setting, the outcome might be to return the inmate to the general population with the ability to participate in prison programs, including clinically indicated mental health programs, psychotropic medication administration, monitoring, further psychiatric evaluation and treatment, and preparation for release. Prisons should be considered communities in which individuals spend many years of their lives. As such, prisons need a greater range of services that emphasize long-term supports for particular vulnerable individuals, including sheltered and/or residential units (for individuals with stable conditions who cannot be placed into the general population), case management, individual and/or group therapies, and other in cell programming materials (self-study materials and the like). Programs should be available to prison inmates who repeatedly self-injure, mutilate, those with the need for frequent/repeated psychiatric hospitalizations who might require step-down programming, followed by sheltered or residential unit placement with other similar offender patients, and more intensive treatment to insure medication compliance, monitoring of their activities of daily living (ADLs), and medication and illness teaching and education, than that is typically available within general population settings. Sheltered housing and tailored assessment and treatment programs for individuals with developmental disabilities are also necessary.

Table 60.3–7.
American Psychiatric Association Guidelines on Priorities for Psychiatric Treatment Programs in Jails and Prisons

Recognizing and providing access to treatment for each inmate with serious mental illness or in psychiatric crisis

Consulting with other health care providers and correctional administrators and staff

As resources permit, treating patients who are in need of mental health care but who are not seriously and persistently mentally ill or in acute psychiatric crisis

The Therapeutic Milieu for Mental Health Treatment

According to the APA Psychiatric Services in Correctional Settings (Second Edition): "Adequate and appropriate access to mental health treatment means that patients have no unreasonable barriers to receiving services. Examples of unreasonable barriers include disincentives, including fees that deter a patient from seeking care for legitimate mental health needs; interference with the prompt transmittal of a patient's oral or written request for care; unreasonable delays before patients are seen by mental health staff or outside consultants; insufficient custody staff to transport inmates to clinic; inadequate waiting room space; and punishment for seeking or refusing care."

Also, according to the APA Psychiatric Services in Correctional Settings (Second Edition):

> The importance of private space for confidential doctor–patient interactions cannot be overstated. Inmates with mental illness may be vulnerable or targeted by other inmates. Without the assurance of privacy, some patients may not seek mental health services or adhere to treatment. However, efforts to speak privately should not be pursued at the risk of reducing patient access to care. For example, a patient may refuse to come out of the cell to attend the clinic for an appointment but may wish to speak with the psychiatrist at cell-side. Psychiatrists need to ensure that such refusals to come out do not arise from external disincentives, such as cell shakedowns occurring during psychiatric appointments. Patients should be encouraged to speak in private settings, but clinicians must use their judgment regarding safety considerations, unit rules, access to treatment, patient wishes, and the therapeutic alliance.

Table 60.3–8 lists the APA Guidelines conditions that would contribute to a therapeutic milieu for treatment.

Access to Mental Health Care and Treatment

Constitutional provision and statutory law require that an inmate in a correctional setting have access to mental health treatment, and this principle is emphasized in the APA Guidelines on Psychiatric Services in Jails and Prisons, which state, "Timely and effective access to mental health treatment is the hallmark of adequate mental health care." In addition, it is striking to note that the very first standard of the NCCHC's new Standards for Mental Health Services in Jails and Prison is on access and requires that "inmates have access to care to meet their serious mental health needs," defining access to care as meaning that "in a timely manner, a patient can be seen by a clinician, receive a professional clinical judgment, and receive care that is ordered" and adds that this principle is "the foundation upon which National Commission on Correctional Health Care

standards are based."

Table 60.3–8.
American Psychiatric Association Guidelines on Conditions That Contribute to a Therapeutic Milieu for Treatment

A therapeutic milieu implies the following conditions:
A sanitary and humane environment
Written procedures and adequate staffing to permit adequate observation
Adequate allocation of resources for the prevention of suicide and assault
Medical and mental health staff available to provide adequate treatment and supervision
Social interactions that foster recovery
The ability to transfer an inmate to an appropriate mental health facility when the foregoing conditions cannot be met

Furthermore, this section notes that access to care procedures should be flexible enough to accommodate inmates with mental illness and functional deficits, and that such deficits can manifest as the following:

- Inability to recognize an emerging health or mental health need
- Inability to follow usual procedures in requesting health or mental health care
- Severe anxiety or suspicion preventing follow-up care
- Behavior that makes care especially challenging

Barriers to Inmates Receiving Services. To determine whether there is adequate and appropriate access to psychiatric treatment, it is critical that the treatment delivery system be analyzed to ensure that there are no unreasonable barriers to patients' receiving services. Some examples of unreasonable barriers listed in the APA Guidelines are listed in Table 60.3–9.

Modalities of Treatment

The APA Guidelines state, "Whatever the setting or the program… treatment in a jail or a prison should employ a variety of therapies, including biological, psychological, and social," and, most important, they add that psychiatric treatment "must be more than merely prescribing of psychotropic medication, and correctional psychiatrists should resist being limited to this role."

Again, to emphasize, treatment modalities must be provided in a manner consistent with generally accepted psychiatric practices, with a focus on evidence-based practices. At the same time, treatment must also be in accord with institutional requirements. A written, individualized treatment plan must guide psychiatric care.

Table 60.3–9.

American Psychiatric Association Guidelines on Examples of Unreasonable Barriers to Patients' Receiving Psychiatric Services

Instituting or allowing disincentives that would deter a patient from seeking care for his or her legitimate mental health needs
Interfering with the prompt transmittal of a patient's oral or written request for care
Allowing unreasonable delays before patients are seen by mental health staff or outside consultants
Charging fees or costs that prevent or deter patients from seeking care
Punishing an inmate for seeking or refusing care

Similarly, the NCCHC Standards define mental health services to "include the use of a variety of psychosocial, psychoeducational, and pharmacological therapies, either individual or group, including biological, psychological, and social."

Evidence-Based Treatment. Correctional psychiatrists must strive to provide evidence-based treatment as the standard of care in jails and prisons. Evidence-based treatments can be defined as treatments that, in appropriate studies, (1) have been rigorously tested, (2) have yielded consistent, replicable results, and (3) have proven safe, beneficial, and effective for most people diagnosed with the particular mental illness.

Because correctional psychiatry is a critical part of public psychiatry, it is appropriate to quote from the Report of the Criminal Justice/Mental Health Consensus Project, which describes the development of the concept as it promotes the utilization of evidence-based practices in public psychiatry:

> In recent years, enormous advances have been made in treatments available for persons with mental illness. New medications have emerged; new services, supports, and interventions have proven effective. Researchers have conducted studies and collected data—they have developed an "evidence-base"—which demonstrate the effectiveness and applicability of some of these treatments and approaches.
>
> Gradually, a body of research literature is growing to support the choice of particular interventions in certain situations. While some researchers might argue over the standards by which an intervention or treatment approach is judged to be evidence-based, there is general agreement that the term and designation imply that a given practice has withstood rigorous scientific examination.
>
> The public mental health system must take steps to ensure that practice keeps pace with research.

Psychopharmacology in Jails and Prisons. As a paradigmatic managed care context, costs in correctional facilities are closely monitored and medications are particularly vulnerable to substantial cost control. The correctional facility or system formulary is the means by which this is done. Consistent with the principle of evidence-based treatment, the correctional psychiatrist must seek to ensure that the facility formulary permits the inmate with mental illness to be treated with the most suitable and clinically appropriate/medically necessary medication. Facilities need to avoid formulary restrictions that lead to negative clinical outcomes for

patients. Formulary decisions should be based upon safety, evidence base to support, comparison and efficacy data to other comparable agents in the population under consideration, convenience of administration, abuse and diversion and other safety issues, and not solely on cost issues alone. There should be an administrative review process to seek nonformulary approval of certain agents.

- Medication given without documentation of a suitable examination including an adequate history.
- Medication prescribed without the necessary laboratory workup or monitoring.
- Medication given when records document contraindications or a previous adverse effect or it is known to be ineffective.

However, in the practice of correctional psychiatry, there is the additional risk if

- Medication is prescribed, which appears to be given for punitive rather than therapeutic reasons.

Prescribing psychotropic medications within correctional settings is a particular challenge. Both medical and psychiatric professionals who provide health care services in correctional settings may be naïve to the potential for abuse, "cheeking" and other types of medication diversion, trading, and the like with commonly prescribed medications. Many of these medications are not typically targets of such misuse in the free world. In correctional settings due to a ready supply of traditional substances of abuse, creative means of seeking substances or abuse are employed. These methods include creating fermented beverages (e.g., "pruno") and diverting medications with CNS effects that are maximized by nasal insufflation, injection, and other means of administration. Examples of medications that are highly abused within correctional settings include Quetiapine and bupropion (Wellbutrin).

There is no current peer-reviewed resource document or national practice guideline on the evidence-based prescription of psychiatric medications in correctional facilities. Practicing psychiatry and prescribing psychotropic agents within jails and prisons is substantially different than it is in the community. Some of these differences include strict formulary controls, high rates of comorbidities such as substance use disorders and personality disorders, high rates of malingering, the abuse and diversion of prescription medications, and various operational challenges unique to these environments. Therefore, each decision to start, continue, hold, discontinue, or change the mechanism of administration of certain psychotropic medications (e.g., crush and float) for offender patients requires careful consideration by the psychiatrist and has a myriad of implications for the individual patient offender and staff.

It is generally recommended that psychiatrists should use psychotropic medications in a safe and clinically appropriate manner and after review of the potential risks, benefits, side effects, and alternatives. As with any mental disorder, barring maintenance treatment, it is unwarranted to prescribe psychotropic medications in the absence of distinct target symptoms or when placement and mental health follow-up services are unclear.

To avoid risk management problems, it is generally recommended that medication be used according to U.S. Food and Drug Administration (FDA) —approved indications and doses, and if this is not preferred, then it is suggested that the correctional psychiatrist obtain and document a second opinion.

Among the various special clinical issues that are especially of concern in correctional settings is the very high prevalence or comorbidity of substance abuse disorders among offenders with mental illness. Correctional psychiatrists will inevitably be prescribing psychotropic medications for inmates with substance abuse problems and should, therefore, have education and training in substance use disorders and the treatment of co-occurring (mental illness and substance abuse) disorders.

Another important clinical issue in correctional facilities is that sleep complaints are very common. There is, obviously, a difficult confluence of the real stresses of the environment on one hand and manipulation by malingering inmates on the other. The correctional psychiatrist must ask whether the sleeplessness is episodic or has been a lifelong problem. Has the patient previously sought medical attention? Has he or she previously abused street drugs as a way to get to sleep? Is the sleep disorder a symptom of depression? Is the sleep difficulty the result of an accurate perception of risk in the cell area or the result of a paranoid perception of risk in the cell area? Is the patient having nightmares, or is the patient going into mania? It is obvious that initially consideration must be given to a nonpharmacological approach to sleep disorders. Some examples of useful recommendations include the implementation of behavioral interventions and strategies such as regular exercise, avoidance of caffeine products, avoiding daytime naps, and other sleep hygiene approaches.

Precautions against abuse are necessary, and so, for example, it is recommended that directly observed therapy (DOT) or crush and float or other strategies be implemented for medications with particular overdose or bartering risks. The administration of medication is usually delegated to staff—both clinical and correctional. The training required by this situation is set out in two NCCHC standards. One, titled, Medication Services, states that: “This standard intends that mental health prescriptive practices are commensurate with current community practice. The responsible physician and the responsible mental health clinician develop facility-specific guidelines regarding prescriptive practices for psychotropic medications....

Medications are prescribed only when clinically indicated (e.g., psychotropic medications are not used for disciplinary purposes, nor are sleep-inducing medications used for behavior modification purposes)."

Of interest, considering the legal issue of substance abuse treatment noted earlier, the NCCHC Standards state, "Inmates entering the facility on verifiable prescription medication, including methadone, continue to receive the medication in a timely fashion as prescribed, or acceptable alternate medications are provided as clinically indicated."

The second NCCHC Standard, "Medication Administration Training," sets out the requirements in regard to this topic and states, "Training topics should include psychotropic medication security and accountability, documentation of medication administration, side effects, phototoxicity, drug diversion (e.g., hoarding, selling), changes to the formulary, risks of medications, and therapeutic regimens adherence."

Ensuring Access

Access to mental health treatment in a jail or a prison is ensured by appropriate screening, referring, evaluating, providing intervention, and providing consultation within the facility.

Screening

In jails and prisons, screening is critical, and, not surprisingly, both the APA Guidelines and the NCCHC Standards emphasize the importance of appropriate screening. The APA Guidelines describe in detail the sequence of screenings and assessments that lead up to treatment (Table 60.3–10).

For example, the APA Guidelines describe the progression in regard to an individual with a substance abuse disorder who might present during receiving mental health screening with any of a variety of medical, neurological, or psychiatric problems. The receiving mental health screening instrument should include questions relating to the individual's use of alcohol and other drugs, the patterns of use, and observations related to whether the offender is under the influence of alcohol or drugs or experiencing withdrawal symptoms. The Guidelines note that the correctional psychiatrist should have an important role in the development of the screening instruments, in the training of staff in its use, and in educating correctional security, medical, and mental health staff about the signs and symptoms of intoxication and withdrawal.

Table 60.3–10.
American Psychiatric Association Guidelines on Sequence of Screening and Assessments Leading up to Treatment

Screening
- Receiving mental health screening

Intake mental health screening
Referral for mental health evaluation, followed, as necessary by
Brief mental health assessment
Comprehensive mental health evaluation
Mental health intervention, if necessary

A positive receiving mental health screening for substance intoxication should trigger an immediate mental health screen for the presence of depressed mood and/or suicidal ideas. Similarly, the intake mental health screening should include questions on an inmate's history of alcohol and other drug use, as well as observations for the presence of signs of intoxication or withdrawal symptoms. Again, the role of the correctional psychiatrist is in the development of the instrument and staff training. The brief mental health assessment and the comprehensive mental health evaluation are particularly important in ensuring a proper diagnosis as the basis for the appropriate clinical management of an inmate with a substance use problem.

The NCCHC notes that "receiving screening" is the means by which "newly admitted inmates' emergent or urgent mental health needs are identified and met through an immediate referral to mental health staff."

Both the APA and the NCCHC require a subsequent "intake" screening that must take place within 14 days.

The importance of screening is further demonstrated by the development of specific instruments to ensure successful screening.

The step-by-step sequence ensures that an inmate who is identified through reception screening, intake screening, or by various processes at any time thereafter (including self-referral) as possibly in need of mental health treatment is provided with a suitable mental health evaluation.

Referral. Emphasizing that within a correctional facility the referral process is critical, and noting that this can be simple or complex, depending on the facility, the urgency of the situation, and the mental health coverage provided, the APA Guidelines state that the referral process, as set out in the facility's operating standards, should be time constrained and specifically define the roles of the various participants, that the maximum time for response to each referral should be stated, and that timely referral and response should be designated as indicators of quality care.

Evaluation. The nature and quality of the particular mental health evaluation are related to its context. For example, in a lockup, in which the major focus might be the removal of an inmate with severe mental illness to a psychiatric facility, evaluations tend to be brief and focused. In a jail or a prison, in which various levels of mental health housing and treatment might be available, such evaluations and interventions could be more

detailed and extensive.

Consultation. An important role of the correctional psychiatrist is to take the initiative in providing consultation to staff with regard to certain situations. Some of these are listed in the NCCHC Standards, such as consulting with regard to inmates who have chronic illness (i.e., asthma, heart disease, diabetes, and hypertension) or communicable disease (e.g., HIV, hepatitis, syphilis, gonorrhea, or chlamydia); counseling patients coping with the psychological effects of their disease; and consulting with regard to inmates who are physically or developmentally disabled and either assisting staff in managing such inmates or providing behavioral consultation so that the inmate can deal with the emotional and attitudinal consequences of his or her disability during incarceration. Mental health staff can help develop appropriate social skills or work with other facility staff to arrange for special housing to ensure personal safety.

Consultations might also be called for with regard to inmates who are chemically dependent; pregnant or have recently given birth, for example, to minimize the postpartum phase and separation anxiety from the newborn; and of course, elderly or terminally ill inmates.

Rape and Victims of Sexual Assault. A full description of the psychiatric assessment and prevention of sexual abuse and exploitation within correctional setting is beyond the scope of this chapter. The following provides a summary overview.

The Federal Bureau of Prisons estimates that 9 to 20 percent of male inmates are raped in prisons. Rape is also a reality in women's prisons. In 2003, the Prison Rape Elimination Act (PREA) became federal law; however, this phenomenon continues to be a challenge to manage with regard to prevention and aftercare.

Under the PREA, Congress created the National Prison Rape Elimination Commission. Its duties include writing standards aimed at reducing the incidence of prison rape and reporting on the incidence of rape and ranking facilities on that measure.

The Bureau of Justice Statistics report for the year 2007 indicated the following:

An estimated 60,500 inmates (or 4.5 percent of all state and federal inmates) experienced one or more incidents of sexual victimization involving other inmates or staff.

Nationwide, about 2.1 percent of inmates reported an incident involving another inmate and 2.9 percent reported an incident involving staff.

Among the 146 prison facilities in the 2007 National Inmate Survey (NIS), which was conducted in 146 state and federal prisons between April and August 2007 with a sample of 23,398 inmates, six had no reports of sexual victimization from the sampled inmates, and 10 had an overall

victimization rate of at least 9.3 percent.

Among the 10 facilities with the highest overall prevalence rates, three had prevalence rates of staff sexual misconduct that exceeded 10 percent.

The NCCHC has a standard entitled Federal Sexual Assault Reporting Regulations, which requires that each facility have "written policy and procedures regarding the detection, prevention, reduction, and punishment of rape consistent with Federal law" and notes that "the intent of the standard is for correctional facilities to comply with applicable federal law and that the Prison Rape Elimination Act of 2003 addresses the many aspects of rape in correctional institutions, including the actions to be taken by correctional administrators, and is the foundation of this standard."

The national PREA standards were released in 2012 (http://www.prearesourcecenter.org/library/488/standards/department-of-justice-national-prea-standards). There is now a need for compliance with this federal mandate for facilities in the fields of adult, juvenile, and community corrections. Both correctional staff and health care staff might need education, training, and psychological support in managing either victims or perpetrators of sexual assault. Both the NCCHC and the American Correctional Association (ACA) are playing a vital role in supporting correctional institutions in the implementation of and the compliance with the health care aspects of the PREA with education, curriculum developments, and technical assistance. Specialty training on complicated PREA issues is available for psychiatrist and medical and mental health care practitioners. The curriculum includes information on detecting and assessing signs of sexual abuse and harassment, the medical forensic examination and forensic evidence preservation, and effective and professional responses and reporting. In August 2013, the U.S. Department of Justice began auditing facilities to ensure compliance with the Act. For technical assistance, health care practitioners should contact the PRC at: www.prearesourcecenter.org.

Primary Health Care Professionals with Regard to Inmates with Medical Problems. These consultations with medical staff should be documented in the clinical record. Any facility staff member who works with inmates (e.g., inmate work supervisors, custody staff, case managers, teachers, or chaplains) might benefit from instruction on how to deal with inmate behavioral problems.

Sick Call and Nonemergency Mental Health Care Requests and Services . Although the correctional psychiatrist works with inmates by appointments in an office situation if possible, in most correctional facilities, access to general health care is by means of "sick call."

The importance of this access is emphasized by the NCCHC Standards,

which, as noted earlier, state that the means by which "inmates' routine mental health care needs are met" is that "all inmates have the opportunity daily to request mental health care. Their requests are documented and reviewed for immediacy of need and the intervention required. Mental health appointments and providers' clinics are conducted on a timely basis and in a clinical setting by qualified mental health professionals." The NCCHC Standards are quite specific and require that "all inmates have the opportunity daily to request mental health care" and that "verbal or written requests for mental health care are received daily by mental health staff and triaged within 24 hours."

There is a separate NCCHC standard for emergency services, and emergency mental health care is defined as "care for an acute mental illness that cannot be deferred until the next scheduled mental health clinic or routine appointment," which must be available 24 hours a day, 7 days a week. Details of responding to a mental health crisis are set out in a discussion.

Treatment Planning

The correctional psychiatrist has been trained as early as medical school to understand the importance of a detailed, in-depth, professional treatment plan. In any context or location, this requirement is a crucial reflection of the necessary standard of medical and psychiatric care. This is reflected in the APA Guidelines, which, with regard to discharge planning, note that "it is recommended that discharge planning be a part of the initial treatment plan." So too, the NCCHC Standards require that "mental health services are provided according to individual treatment plans" and discuss this subject in considerable detail, requiring that "patients receive care that is tailored to their individual needs… [including] consideration of cultural and language differences."

Disaster Planning. It is imperative that every correctional facility have a detailed disaster plan specifically for inmates with mental illness and/or medical diseases and treatments (e.g., dialysis dependent, supplemental oxygen) and/or limited mobility. The lessons learned from the horrific problems for the inmates in the New Orleans Jail arising out of the Hurricane Katrina disaster were many, especially that the extensive planning required for such a complex operation must include in-depth coordination with community resources and regularly scheduled and monitored practice drills. It must be clear, however, that the security service, usually the Department of Correction, has the ultimate responsibility for the "care and custody" of the inmates in a jail or a prison. The responsibilities of the psychiatric service or larger mental health services are ancillary to this.

The NCCHC Standards require that correctional facilities have an

emergency response plan that includes provisions for a mass disaster drill —a simulated correctional emergency [that] frequently involves a natural disaster (e.g., tornado, flood, earthquake), an internal disaster (e.g., riot, hostage incident, arson, kitchen explosion), or external disaster (e.g., mass arrests, bomb threat, power outage). Simulated correctional emergencies frequently involve multiple casualties that require triage by health and mental health staff. It is recommended that the emergency plan be "practiced and critiqued at least annually so that mental health staff is familiar with emergency preparations."

Discharge Planning. Studies of recidivism among persons in the justice system with mental illness indicate that effective discharge planning is essential to the continuity of care and a critical part of adequate psychiatric treatment in jails and prisons.

Despite court interventions developed for detainees with mental illness, there is still a lack of coordination and continuity of care for such persons on release. After incarceration, former inmates with mental illness have residential, financial, health, and mental health needs. Face-to-face linkage with community services has the greatest likelihood of success. Because most jails cannot control the court's release decisions, they usually do not know when an inmate is to be released, and so most jails do not provide case management or discharge planning services. To provide such services, discharge planning must start at admission. Providing uninterrupted medications after release is an important challenge. Without psychiatric medications, recidivism is almost inevitable. As the APA Guidelines state, "Timely and effective discharge planning are essential to continuity of care and an integral part of adequate mental health treatment."

This is true whether the patient is being released into the community or transferred to another correctional facility. Because discharges (e.g., from jails) or transfers (e.g., between prisons) can occur on short notice, it is recommended that discharge planning be a part of the initial treatment plan. Essential services that should be included in adequate discharge planning are psychiatric assessments, appointments to be arranged, notifications, staff responsibilities, linkages to community-based services, help with the obtaining of necessary financial benefits (e.g., Medicaid) and housing (due to the high incidence of homelessness in the jail and prison populations), placements, and appropriate linkages.

The NCCHC Standards suggest a number of components for a discharge-planning program:

- Formal linkages between the facility and community-based mental health organizations
- A list of community-based mental health providers that is used for referral

- An inmate education session that emphasizes the importance of follow-up aftercare
- Arrangement for follow-up mental health services before an inmate's release
- Preparation of mental health summaries
- Assistance to inmates with their application to entitlement programs
- If appropriate, a supply of medications provided at the time of the inmate's release

Reentry Programs. Whereas discharge planning is an aspect of services in jails and prisons, the last decade has seen the proliferation of reentry programs, which can provide court-based diversion, discharge planning, and transition services to people with mental illnesses being released from city jails or state or federal prisons. These programs (usually government funded—generally state or county) evaluate, select, and then actively link (and follow up) the inmate with mental illness reentering the community to a wide variety of services, including intensive case management, mobile services, outpatient treatment, psychiatric rehabilitation, housing, vocational and educational services, access to entitlements, family supports, and substance abuse treatment.

A Recent Landmark Case with Regard to Discharge Planning and Reentry; the New York City v. Brad H. Case

Fortunately, jails can emulate several model programs that provide aftercare discharge planning. For example, in August 1999, five prison inmates who suffered from psychiatric disabilities filed a class action lawsuit in New York State Supreme Court on behalf of themselves and all other similarly situated persons, challenging, among other things, New York City's practice of discharging inmates with psychiatric disabilities from the Rikers Island jail in the middle of the night, with only a $3 Metrocard and $1.50 in cash and without any psychiatric medications or referrals to services. The settlement in 2003 in this, the Brad H. case, requires that New York City provide discharge-planning services for inmates with psychiatric disabilities subsequent to their release from jail. The settlement requires the City to meet the following obligations:

- Release inmates during the day, when service agencies are open
- Make medication and transportation to community residences or shelters available on discharge
- Help eligible inmates to obtain Medicaid, Social Security, disability, and public assistance benefits before release
- Enable family and community members with clinical information about an inmate to relay such information to discharge-planning or jail mental health staff

- Establish a monitoring system overseen by the court that will set performance goals for City agencies and assess their compliance for at least 5 years

Of course, these requirements should also apply to prisons. However, prisons are usually distant from the inmate's home community. This reality makes it difficult for state prison and local mental health providers to have service agreements. When parole of an inmate includes the recommendation for psychiatric treatment, the need for prerelease planning is increased.

This important area of reform of the correctional system gained added impetus from the Second Chance Act of 2007, federal legislation designed to ensure the safe and successful return of prisoners to the community by providing the following: Grants to states and local governments to promote the safe and successful reintegration into the community of individuals who have been incarcerated, including employment services, substance abuse treatment, housing, family programming, mentoring, victims services, and methods to improve release and revocation decisions using risk-assessment tools; grants to nonprofit organizations that can be used for mentoring adult offenders or offering transitional services for reintegration into the community; grants to improve the availability of drug treatment to offenders in prisons, jails, and juvenile facilities; and grants to states, local governments, and Indian tribes to develop and implement family-based treatment programs for incarcerated parents who have minor children. The Second Chance Act provides guidance to the Bureau of Prisons for enhanced reentry planning procedures. Specific information on health, employment, personal finance, release requirements, and community resources is to be provided to each inmate released.

It also authorizes the U.S. Justice Department's National Institute of Justice and the Bureau of Justice Statistics to conduct reentry-related research and establishes a national resource center to collect and disseminate best practices and to provide training on and support for reentry efforts.

The Facility Information Technology System: Needs Assessment and Allocation of Resources

With regard to a correctional facility's information technology system, the APA Guidelines point to a capacity for "needs assessment" and state:

> It is critical that the administration of the correctional facility have the capacity to gather and assess information relevant to the prevalence of mental illness in the facility because this data forms the basis of the needs assessment that assures an adequate level of care.

The allocation of resources within a jail or a prison (which should be set out in written documents) is obviously determined by many factors, including the extent of resources available, the size of the facility, the

overall organization of the services provided, the mission of the facility, and the lengths of stay of the inmates confined there.

The Facility Quality Assurance Plan. One important aspect of the reform of the correctional mental health system calls for each jail or prison to have a quality assurance plan that systematically reviews the quality of mental health services and the efficiency and effectiveness of the utilization of staff and resources in the delivery of services.

Other quality assurance activities in the jail or the prison include the following:

- Credentialing
- Reviewing service access and utilization
- Managing records and resources
- Reviewing morbidity and mortality
- Identifying and preventing risk
- Monitoring and reviewing of high-risk critical procedures such as overriding treatment refusals and responding in emergency situations

Accreditation and Standards. The first national health care standards drafted specifically for correctional institutions came from the American Public Health Association (APHA). Unfortunately, there was no consideration regarding how to enforce the standards.

In 1977, the AMA published its first jail correctional health standards; 16 jails were accredited for compliance that year. In 1979, the prison and juvenile correctional health care standards were published. Then, as mentioned earlier, in 1983, the NCCHC was established and developed correctional health care standards and a correctional health care accreditation processes.

The NCCHC has become the major organization establishing correctional health care standards and providing correctional health care accreditation. In 2007, the NCCHC published separate standards for the accrediting of mental health programs in jails and prisons, Standards for Mental Health Services in Correctional Facilities. The most current NCCHC standards include the Jail (2014), Prison (2014), Mental Health (2015), and the Juvenile Standards (in press, the last version was 2011).

The NCCHC also has developed standards for opioid treatment programs within correctional settings. These Opioid Treatment Programs (OTP) standards represent the requirements for corrections-based opioid treatment programs seeking accreditation from the National Commission. The NCCHC used federal regulations and community standards as a guide and modified them to take into account the issues unique to providing services in a correctional facility. The NCCHC OTP Standards (similar to other NCCHC standards) are divided into nine general areas: health care

services and support, inmate care and treatment, special needs and services, governance and administration, personnel and training, safety, health records, health promotion, and medical legal issues. With regard to the OTP standards, all of the standards are linked to specific federal regulations.

Many types of "noncorrectional" health care organizations—such as hospitals, nursing homes, and psychiatric facilities—are accredited by The Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations). Similarly, jails, prisons, juvenile detention, and other correctional facilities may be accredited by the NCCHC (an offshoot of the AMA as described previously), the ACA, The Joint Commission, or a combination of the above. Although national accreditation is typically voluntary, it is often a contractual requirement for universities, other health care systems, and private vendors who provide health care services to correctional systems. In addition, when facilities undergo investigation or litigation, or are placed in receivership or federal oversight, they are often mandated to establish and maintain national accreditations.

Staffing. The effectiveness of any correctional psychiatric system is largely dependent on staffing considerations. Owing to the complexity of how different correctional facilities are situated—for example, some are in rural settings, whereas others are in the heart of downtown—no national staffing model fits all facilities. Staffing must be sufficient to ensure that every inmate with serious mental illness or in psychiatric crisis has timely access to evaluation by a competent mental health professional. More important than the number of staff is access to adequate care. Accordingly, none of the national correctional health care standards mandates staffing patterns other than that there be an adequate number and type to meet the needs of the population.

Several variables must be considered when trying to decide the best staffing pattern for specific institutions. Institutional size and inmate length of stay are important considerations in determining the best mental health staffing patterns. For example, considering their volume of admissions and shorter length of stay, jails might require more intake screening staff than a similarly sized prison with fewer scheduled intakes and longer lengths of stay. The number of inmates at each custody level within a facility also determines staffing needs. For example, a maximum security facility needs more health staff to check on a confined inmate's mental health than an equally sized minimum security facility in which inmates can report to sick call if distressed.

A satellite work camp facility that houses younger, healthier inmates might need less psychiatric health care staff than a similarly sized facility that houses inmates with chronic psychiatric disorders in a day care program. Considering that epidemiological studies reveal that female

inmates have higher incidence and prevalence rates of mental illness than male inmates, and given the high rates of exposure to traumatic stress that female inmates experience, it can be seen that women require more access to psychiatric services.

Whether correctional facilities obtain psychiatric services off-site or on-site affects the number of correctional psychiatrists needed. Furthermore, some prisons have special functions within their state systems that alter their staffing patterns. For example, some prisons act as mental illness repositories for their department of corrections and accordingly need more psychiatric staff for inmate psychiatric care.

Requirements that are external to the facility, such as state licensing regulations or court orders, can also shape health staffing patterns. The number of psychiatrists needed to staff correctional facilities is affected by some states allowing liberal use of "physician extenders"—for example, nurse practitioners or physicians' assistants—to do mental health functions. However, it is important to note that because of the unique importance of psychotropic medications and the unique role of correctional psychiatrists in providing such medications, every system must have enough psychiatrists to provide these services.

According to the APA guidelines, Psychiatric Services in Correctional Facilities: "There are no prevailing national standards for psychiatric staffing in correctional or other settings. Nevertheless, courts and regulatory agencies, court monitors, and health consultants frequently seek to establish staffing ratios in correctional settings in order to comply with constitutionally mandated minimally acceptable medical care. Governmental agencies with oversight of correctional settings often seek such ratios to assess their budgetary needs. Correctional facilities have historically not had enough psychiatrists to adequately provide the services described here. In practice, a facility-specific staffing needs analysis is a fundamental step in determining the actual psychiatric staffing required to meet the standards of care in any given facility. Correctional administrators and other leaders need guidance about adequate psychiatric staffing. Needs and type vary on the basis of patient acuity and treatment need, patient volume and turnover, facility location (whether services will be provided on site, via telepsychiatry, or a combination of both modalities), the role and function of the facility, the targeted inmate population, any unique or specialized unit or facility treatment/rehabilitative mission, and changes to any of the above. Although it is very difficult to establish exact psychiatrist-to-patient ratios, the amount of psychiatric time must be sufficient to ensure that there is no unreasonable delay in patients receiving necessary care, and all relevant and necessary psychiatric functions must be met."

The Use of Inmate Workers in Treating Patients. An issue perhaps unique to correctional facilities is the use of inmate workers. The

psychological aspects of using inmate workers have costs and benefits. For the inmate worker, there may be specific benefits, including perhaps learning a valuable occupation/work skill, remuneration and other token benefits (e.g., earning good time, extra privileges, decreased level of security/supervision), out of cell time, social interaction with staff and other inmates, sensory stimulation, and the benefits of self-esteem. As is noted in the NCCHC Standard on Inmate Workers, "understaffed correctional institutions may be tempted to use inmates in the delivery of mental health care by performing services when personnel are not available. However, this should be avoided since it gives inmates unwarranted power over their peers and creates additional risk for the institution."

On the contrary:

> There are circumstances, however, in which inmates may be appropriately used to help mental health staff with routine tasks. Inmate participation in appropriate peer mental health or substance abuse programs is permitted provided that such individuals are appropriately trained and supervised. Inmates are always supplemental in these peer mental health-related programs and are not substitutes for regular programming or mental health staff. Inmates may assist other inmates in activities of daily living (ADL) (i.e., assisting in ambulation, bathing, dressing, feeding, and toileting) in regular housing or mental health residential units may participate in support groups that assist inmates with mental health problems, e.g., a buddy system for potentially suicidal inmates. In a correctional setting, usual community practices, such as using peer counselors in group therapies, may need to be modified to prevent inmates from being placed in a position of power over their peers.

Peer-to-Peer Programs. Peer-to-peer programs have proven their worth in prison ministries, chaplain volunteer, and other spiritual ministries. Other peer activities may include volunteer work, providing care and training to service dogs for Veterans, and other individuals with disabilities, for example, the Patriot Paws programs. There are other self-help peer-to-peer organizations as Alcoholics Anonymous (AA) and Narcotics Anonymous (NA). This concept is being extended into areas of reentry and continuing postincarceration support.

The APA Guidelines state, "As safety and security allow, self-help and peer support programs or activities contribute to the overall goals of the psychiatric services and where and when available should be promoted and encouraged."

However, within the correctional community, this is not an uncontroversial area. Concerns about the power of inmate workers were cited earlier. There are valid security concerns about prior inmates working within a correctional facility.

Issues in Administration and Management

Integration of Services. Within clinical services, mental health, psychiatric, and psychological services should be integrated with medical and substance abuse services. These, in turn, should be integrated into the

overall management of the facility.

NCCHC Standards address administrative issues in detail and require administrative meetings and reports: "Mental health services are discussed at administrative meetings. In addition, mental health care staff meetings are held to review administrative issues." Moreover, "This standard is intended to facilitate mental health care delivery through coordinated monitoring, planning, and problem resolution by mental health, health, correctional, and administrative personnel. It is also intended that mental health staff be informed of relevant correctional, administrative, and health care issues."

Furthermore, the NCCHC Standards encourage mental health staff to attend medical and correctional staff meetings to promote positive working relationships within the institution and to facilitate and coordinate their respective areas of responsibility.

Written Policies and Procedures

Mental health administrative personnel in a jail or a prison should establish written policies on such critical issues as (1) staffing patterns, (2) admission, (3) referral, (4) discharge criteria, (5) health care information management, and (6) interagency and intra-agency communications, especially with regard to confidential medical and mental health information.

Leadership. The APA Guidelines note, "Psychiatrists can provide administrative leadership and clinical care. Even when control may be in the hands of nonpsychiatrists, attention to quality care serves the best interests of the patient." The APA guidelines also urge that "attention always must be focused on the priorities of quality care and the best interests of the patient." It is especially important to have clinical input when decisions are made about an inmate who is receiving mental health care regarding such issues as (1) disciplinary issues, (2) work and housing assignments, and (3) transfers in and out of the institution.

Perhaps idealistically, the APA Guidelines comment that "an environment which promotes therapeutic interactions may be created in a jail or a prison setting if there is clinical leadership with authority, staffing, and resources to work towards such an environment."

Scope of Practice. To promote "a good working relationship between all disciplines, including nurses, psychologists, psychiatrists, social workers, correctional officers, correctional counselors," the APA Guidelines state:

> Each mental health professional working in a correctional setting should work within his or her own profession's scope of practice, as defined in that jurisdiction's licensure process (usually by the state), and within his or her own training, expertise, and skills. As such, mental health

professionals provide services within a standard of care. However, it must be noted that chronic shortages of professional resources may be a problem in correctional settings and although this may engender a "siege mentality," the correctional psychiatrist should not compromise his or her professional responsibility. At the very least, a psychiatrist's responsibility includes the need to communicate shortcomings and resource needs to the appropriate authority.

Professional Development. It would be ideal if correctional psychiatrists had received specialty education and training at various levels before undertaking employment in a correctional setting. However, education and training in correctional psychiatry are relatively rare in medical schools and psychiatric residencies, although forensic psychiatry fellowships now require it.

Jails and prisons should seek expertise in correctional psychiatry through various means, such as recruitment of staff with subspecialty training, the offer of continuing professional education, and consultation. For the practicing correctional psychiatrist, professional development is essential and should be available in the educational and training program of the facility or in other continuing medical education activities such as relevant courses or, at a minimum, in textbooks and journals.

The educational and training program of the facility should include substantial cross-training of security staff by clinical staff and vice versa. Psychiatrists and other mental health professionals will benefit from training and orientation by security staff to the jail or prison "culture," including such matters as (1) social order, (2) security threat groups and gang affiliations, (3) inmate hierarchy issues and attitudes toward sexual offenders, and (4) utilization and/or misuse of the mental health practitioner and system.

Another aspect of professional development for the correctional psychiatrist is communication with colleagues who are working in other correctional facilities to share experiences and provide mutual support. In addition, correctional psychiatrists should become familiar with and consider joining subspecialty organizations, such as the AAPL, and the Society of Correctional Physicians (SCP), which provide for continuing education and subgroups that share this interest. There are several other organizations of interest, including the Academy of Correctional Health Professionals and the American Correctional Health Services Association (ACHSA). There are several national correctional conferences including the NCCHC, the SCP, and the ACA.

The APA Guidelines advise that correctional psychiatrists be informed about and sensitive to security needs and issues and the concerns of security staff, and they recommend that an organized program be developed to teach and train correctional personnel about mental health issues, noting that among the programs that will especially benefit from carefully administered integration are those relating to (1) developmental disabilities, (2) neurological impairments, (3) alcohol and drug abuse, and

(4) sex offenses.

The NCCHC Standards are very detailed in this regard and have a specific standard, titled Mental Health Training for Correctional Officers, that requires that "a training program [guide] the mental health-related training of all correctional officers who work with inmates," specifying that:

1. All correctional officers who work with inmates receive mental health-related training that:
   a. is established or approved by the responsible mental health authority in cooperation with the facility administrator; and
   b. includes at a minimum:
      i. recognizing signs and symptoms of mental illness;
      ii. communicating with inmates who have positive signs of mental illness;
      iii. procedures for suicide prevention and intervention; and
      iv. procedures for appropriate referral of inmates with mental health complaints or suicidal behaviors to mental health staff.
2. Correctional officers assigned to mental health areas, including mental health programs, residential units, or segregated housing areas receive additional training from mental health staff in order to fulfill their specific roles.

It states, in addition, "In a correctional setting, custodial professionals and mental health (and other medical) professionals benefit from cross-professional training by participating in the others' in-service training."

Finally, whenever possible, the correctional psychiatrist (and, indeed, the facility) should develop an active liaison and/or affiliation with an academic–medical or other educational institution(s). This relationship can be quite advantageous in recruitment and retention, in staff continuing education, as well as career satisfaction, the opportunity for case consultation, and the maintenance of high-quality services.

Preventing Burnout

Clinical and administrative work within correctional settings is varied and challenging. Correctional systems face challenges in funding for health care and in recruitment and retention of a qualified health care workforce. This work can also be frustrating, and "burnout" is an inherent risk. Psychiatrists are encouraged to participate in professional activities, pursue continuing medical education opportunities, and communicate with other colleagues who work in correctional settings to share experiences, identify examples of strategies and approaches to challenging issues, and to provide mutual collegial support. Work in a correctional setting can be quite intense, stressful, and frustrating, and, therefore, the correctional psychiatrist must be alert to the risk of burnout, as evidenced by a long-

term sense of exhaustion and a loss of interest.

There are a number of means by which this can be avoided. Most important is the recognition of the signs and symptoms of burnout. As an example, the clinical workload, supervision duties (medical students and psychiatric resident physicians, physician assistants, and nurse practitioners), explicit clarification of duties, responsibilities both on-site and via phone after-hours and on weekends, and on-call expectations should be clarified at the start and periodically. Similarly, specific times for teaching and supervision and other prioritization of work tasks, the correctional psychiatrist might be able to minimize burnout and at the same time fulfill a basic responsibility. (Ideally, the employment agreement with the facility or system should provide specifically for such activities.) The correctional psychiatrist might also try to diversify his or her work in the facility or vary the practice settings. Thus, many correctional psychiatrists might choose to work only part-time in a correctional setting while maintaining practices in other settings (e.g., private practice, hospital based, community mental health).

The continuing education programs in correctional psychiatry will give a fresh perspective and perhaps an opportunity to network, as should support of the informal type—relationships and consultation with colleagues can be augmented by membership or participation in professional organizations such as the National Commission's Academy of Correctional Health Professionals, the APA's Caucus of Psychiatrists Practicing in Criminal Justice Settings, the AAPL, the ACHSA, or the SCP.

Cultural Sensitivity

The APA Work Group to Revise the APA Guidelines on Psychiatric Services in Correctional Facilities identified that correctional facilities differ from most community settings in gender and racial, ethnic, cultural, and sociodemographic factors. They have high percentages of male inmates, minority ethnic groups, and homeless or impoverished individuals.

This contributes to cultural differences among differences between the security staff, the psychiatrist and other medical and mental health staff, and the inmates. The subject of cultural sensitivity (or, as it is sometimes referred to, cultural awareness or cultural competence) is becoming increasingly the focus of attention in all areas of psychiatry. As in any treatment setting, incarcerated individuals deserve equal care regardless of gender, gender preference, racial/ethnic background, socioeconomic status, education, or other cultural factors.

For present purposes, note that the APA Guidelines strongly state, "In order to properly either evaluate or treat inmates the correctional psychiatrist must overcome the consequences of these often substantial cultural differences in background, socioeconomic class, education, and other types of diversities."

The APA Guidelines recommend that:

Correctional facilities should provide training to ensure sensitivity to cultural differences and support efforts to overcome impediments to the delivery of mental health services. Such training can foster positive attitudes and acceptance of other cultures by means of didactic and experiential components. The goals and objectives of such training should relate to attitude, knowledge, and skills. Positive attitudes and acceptance of other cultures increase with exposure to and awareness of other belief systems. Desired outcomes include improved acceptance of diverse populations, empathy for the minority experience (including the internalization of experiences of prejudice), and an understanding of concepts of ethnocentric bias and its potential effects.

Standards and Practice Guidelines

Practice Guidelines. The APA publishes Practice Guidelines that provide evidence-based recommendations for the assessment and treatment of a wide range of psychiatric disorders of considerable importance to correctional psychiatrists, including acute stress disorder and posttraumatic stress disorder (PTSD), bipolar disorder, borderline personality disorder, psychiatric disorders related to HIV/AIDS, major depressive disorder, obsessive-compulsive disorder (OCD), panic disorder, schizophrenia, substance use disorders, suicidal behaviors, and others.

PSYCHIATRIC PATIENTS IN CORRECTIONAL FACILITIES

Demographics

The importance of demographic studies of psychiatric disorders in correctional facilities cannot be overemphasized. For advocacy purposes and for public health considerations, the results of this research dramatically portray the critical need for psychiatric services in jails and prisons.

However, the true incidence and prevalence of psychiatric disorders in correctional facilities are quite difficult to obtain. Well-designed, carefully done epidemiological studies are costly and complex to carry out and because of the high inmate turnover rates, doing a point prevalence study of mental illness in jails is quite problematic. The best way to detect incidence and prevalence of psychiatric problems in jails is to find cases on admission. Prison inmates stay for longer terms, and conducting a point-prevalence epidemiological study of mental illness in this setting is more feasible. Despite these difficulties and limitations, the epidemiology of mental illness in correctional facilities is gradually becoming known. In general, most authorities now estimate that about 16 percent of the correctional population has serious and persistent mental illnesses. Thus, in 2006, an estimated 350,000 seriously mentally ill offenders were incarcerated in the nation's jails and prisons. (This is contrasted to the fewer than 55,000 patients in state psychiatric hospitals.)

Jails. With regard to jails, the few available epidemiological jail studies highlight that, after controlling for demographic differences between jail samples and the epidemiological catchment area (ECA) samples, jail prevalence rates of mental illness are two to three times higher than those in the general population (Fig. 60.3–1).

Prisons. Because prison inmates stay for longer terms, there are more prison population–based epidemiological studies of mental illness than there are in jails. The ECA study found that 6.7 percent of inmates in prisons had experienced schizophrenia at some point, compared to 1.4 percent of the US household population. A number of studies reveal that, at any given time, a little more than 2 percent of the inmate prison population is in inpatient or residential psychiatric care.

More than 30 percent of male inmates and 78 percent of female inmates with mental illness reported prior physical or sexual abuse, and inmates with mental illness in correctional facilities are more likely than other offenders to have a higher prevalence of homelessness, unemployment, alcohol and drug abuse, and physical and sexual abuse before their current incarceration.

Special Populations in Correctional Facilities

WOMEN IN CORRECTIONAL FACILITIES. As noted in the APA Psychiatric Services in Correctional Facilities, 3rd Edition: Female inmates frequently encounter different stressors before, during, and after incarceration than their male counterparts. Most women in correctional settings are mothers and have at least one child for whom they have been the primary caregiver prior to incarceration. Women who are pregnant during their incarceration are especially vulnerable. More than 75 percent of women entering correctional settings report a history of emotional, physical, or sexual abuse as a child or adult. They have higher rates of domestic violence victimization than men. Incarcerated women have greater risk than men for sexually transmitted diseases and HIV because of prostitution, higher rates of substance use disorders, and drug offense arrests and are more likely to be victims of sexual assault while incarcerated. Demographic studies have shown that compared to men, a greater percentage of women entering a jail or prison have a serious and persistent mental illness. Although the rates of bipolar disorder and schizophrenia are similar for incarcerated men and women, a much larger percentage of women are diagnosed with major depression and severe anxiety disorders, especially PTSD. In addition, a higher percentage of women than men in jails and prisons enter these settings with a history of substance abuse.

FIGURE 60.3–1. Serious mental disorders among the general population and among jail admissions.

Although the number of women in jails and prisons is relatively small

compared to the number of men, their percentage of the total correctional population is rising. Thus, at year-end 2006, women made up 7.2 percent of the population under state or federal jurisdiction, up from 6.7 percent in 2000. Until recently, most psychiatric treatment programs for women have been based on treatment models designed for men. It is now recognized that female inmates require very different screening, evaluation, and treatment, and with the reform of the correctional system, treatment programming provided to women in jails and prisons is changing dramatically.

ABUSE AND PTSD. One aspect of this change is the recognition that that female inmates have had high rates of victimization (sexual and physical) causing PTSD. The trauma of being raped before 16 years of age was the most frequently reported antecedent to PTSD among female prisoners.

In national surveys of prison inmates, the prevalence of HIV infection among incarcerated women ranged from 2.5 to 20.0 percent, which greatly exceeds the rates of HIV infection among women in the general population. The rates of HIV infection among female prisoners are often three times those of male prisoners.

A large percentage of women (up to 70 percent) entering correctional settings report a history of abuse either as a child or as an adult. Therefore, it is extremely important that in the screening process female inmates be asked questions related to abuse histories. (It should be noted that a substantial number of male inmates have also suffered childhood sexual abuse, and, therefore, many of these principles might also apply to them.)

PREGNANCY, CHILDREN, AND FAMILIES. Programming for women in correctional facilities must consider that most women in correctional settings have dependent children and at least one child for whom they have been the primary caregiver. Their concerns about their children require special counseling on parenting and perhaps child custody.

Clearly, it is especially important to attend to the health and mental health care of women who are pregnant or who have given birth recently. Furthermore, the correctional psychiatrist should be alert for and should minimize the risks associated with peripartum depression and psychosis, other adjustment disorders, and distress, and ensure that the facility establish a policy that a comprehensive mental health evaluation be conducted or has any mental health problems during the pregnancy, delivery, or postpartum period.

TRAINING WITH REGARD TO GENDER-SPECIFIC ISSUES. The unique issues presented by the presence of female inmates in a jail or prison call for staff training (both clinical and corrections) in gender-specific issues such as differences in symptom presentation, especially among women with abuse histories. In particular, the use of seclusion and restraints with women raises special

concerns because these interventions might mirror the pattern of historical abuse. As a result, these methods, which are used for reasons of safety, might inadvertently retraumatize inmates. In response to this, a number of hospitals and community mental health systems have developed special protocols for seclusion and restraint of women that involve the treatment team and the patient working together, early in the treatment process, to develop interventions that can help an agitated female patient to calm down. This has general applicability, in that much of the behavior that might seem to require restraints might be de-escalated by "talking the person down" and understanding what is really going on. The behavior might be the result of dissociative phenomena or flashbacks of abuse rather than psychotic symptoms or poorly controlled impulsivity.

Similarly, it is important that staff (and inmates) be taught (and trained) as to what constitutes sexual harassment and abuse of inmates. In addition, because of the higher prevalence of mental illness among women and their generally higher degree of willingness to participate in services, it is generally agreed that the per capita mental health staffing for female inmates should be significantly higher than that for men.

Inmates with Substance Use Disorders in Correctional Facilities. The correctional psychiatrist must have knowledge and familiarity in the assessment and treatment of incarcerated individuals with substance use disorders because it is estimated that up to 70 to 90 percent of offenders have a substance use disorder at the time of their entry into the criminal justice system, and criminal behavior often occurs when an individual is under the influence of alcohol or other drugs. Furthermore, and very important to note, some serious suicide attempts and completed suicides in jails may occur within the first 24 to 48 hours of admission and are often carried out by inmates who are either intoxicated or experiencing withdrawal symptoms.

Table 60.3–11.
American Psychiatric Association Position Statement on Treatment of Substance Use Disorders in the Criminal Justice System (2007)

It is the position of the American Psychiatric Association that:

All arrestees should be evaluated for the presence of substance use disorders and of withdrawal syndromes. Jails should be prepared either to provide quality treatment for alcohol and/or drug withdrawal and associated comorbidities or to arrange timely transfer to an appropriate medical facility if detoxification services are not available on site. As with any other illness, when a person who is arrested is receiving prescribed medication for an addictive disorder, that medication should be continued until a comprehensive mental health evaluation has been performed and a new treatment plan provided.

Prisons should make available quality treatment for substance use disorders to all inmates who qualify for such treatment. This should include psychiatric evaluation, treatment with appropriate medication and nonpharmacological interventions, prerelease planning, and adequate follow-up treatment on a residential or outpatient basis after release.

For any parolee who has received prerelease substance abuse treatment, the continued cooperation in follow-up treatment should be a condition for continuation of parole.

Courts established for diversion purposes, such as mental health courts, drug courts, and driving while intoxicated courts, should ensure that treatment recommended for participants in these programs follows the principles outlined in this position statement.

In 2007, the APA Assembly and the APA Board of Trustees approved a position statement prepared by the APA Council on Addiction Psychiatry on the treatment of substance use disorders in the criminal justice system, as shown in Table 60.3–11.

DETOXIFICATION. When psychotropic medications are required during detoxification to manage medical or prevent impairment and sequelae, agitation and symptoms, or agitation, a physician must be responsible for managing the detoxification process.

Prescription of benzodiazepines might be useful to prevent or attenuate withdrawal symptoms and detoxify the inmate. However, their use should be short term and on a tapering dose schedule to ensure that the prescribed medication does not serve as a substitute for the substance of abuse.

When circumstances warrant, an inmate should be detoxified or free from substance use for a reasonable period of time before psychotropic medications are prescribed unless psychotic or suicidal symptoms are present. The opiate- or other substance-dependent pregnant female presents special challenges to correctional systems, and review of NCCHC standards and other accepted practice guidelines is recommended.

COMMUNITY SUPPORT. Wherever feasible, and only with custody approval and clearance, outside community, volunteers, spiritual leaders and chaplains, and self-help meetings should be allowed in the correctional facility to permit integration and identification with the community on release.

Of course, from the public health perspective, rehabilitation with regard to substance abuse must be considered as a long-term commitment and must extend past the period of incarceration to have a positive effect on criminal recidivism and alcohol and other drug abstinence. For these reasons, discharge planning must include referral to community-based substance abuse treatment.

Inmates with Co-occurring Disorders in Correctional Facilities. In 2006, the Bureau of Justice Statistics stated that about 74 percent of inmates in state prisoners and 76 percent of jail inmates who had a mental health problem also met criteria for substance use disorder. Nearly 63 percent of state prisoners who had a mental health problem had used drugs in the month before their arrest, compared to 49 percent of those without a mental health problem.

For the correctional psychiatrist, the nondetection of one or more co-occurring disorders in jails and prisons risks the exacerbation of any behavior problems and elevates the risks of suicide and poor outcomes in treatment.

For these reasons, the APA Guidelines recommend that the detection of one type of disorder (i.e., substance use or mental illness) immediately triggers an investigation into the other type of disorder. The importance of a coordinated system of screening, referral, assessment, and diagnosis for co-occurring mental health and substance use disorders is that one type of disorder can mimic the other, interfere with detection of the other, or overshadow the other type, and one type might affect the presentation of the other type of disorder. Table 60.3–12 lists the recommended APA Guidelines strategies for inmates with co-occurring disorders.

THE INTEGRATION OF MENTAL HEALTH AND SUBSTANCE ABUSE SERVICES. The APA Guidelines emphasize that substance abuse services should be integrated with mental health services and that psychosocial problems and skill deficiencies should be addressed with individualized programming created through comprehensive assessment and consultation with the inmate's clinician, family (or significant others), and correctional medical and mental health clinicians.

In contrast to the APA position recommending the integration of services, the NCCHC in its standard on Substance Abuse Services relegates the roles of the medical and mental health staff to referral:

> Increasingly, in larger correctional systems, inmates with [substance use]... disorders are receiving treatment for these problems from specialized treatment providers. Substance abuse counselors who treat [substance use]... problems should be properly qualified to do so by a recognized accrediting body. Medical and mental health care providers can facilitate the treatment process by referring inmates for treatment, providing counseling to motivate inmates to receive treatment, legitimizing self-help groups, tailoring controlled substances prescribing practices, and otherwise being a partner in the process of treatment.

Table 60.3–12.
American Psychiatric Association Guidelines on Recommended Strategies for Inmates with Co-occurring Disorders

Services must be focused on the integration of treatment programming by addressing the person's mental health and substance use disorders simultaneously.
Each type of disorder must be treated as primary, with a focus on understanding how they interact with each other.
Medication must be prescribed with caution. Where circumstances warrant, an inmate not previously prescribed psychotropic medication generally should be detoxified for a reasonable period of time before psychotropic medications are prescribed unless psychotic or suicidal symptoms are present.
Psychosocial problems and skill deficiencies should be addressed with individualized programming.
Treatment should be integrated with self-help groups and support networks, which may be invaluable tools in assisting treatment participants in maintaining their commitment to daily alcohol and drug abstinence.

Interventions must be designed for the particular setting, each setting requiring differing intensity, length, and types of services.

The presence of co-occurring disorders requires special attention to discharge planning, which must address housing and job needs, family reconnection, and continued treatment.

There is agreement, however, that inmates with co-occurring mental illness must not be barred from participation in substance abuse treatment programs and that self-help, 12-step, and peer support groups and networks play an important role in the rehabilitation of abusers of alcohol and other drugs in the correctional system.

Inmates with HIV/AIDS in Correctional Facilities. Inmates with HIV/AIDS present complicated clinical challenges for the correctional psychiatrist because the most common psychiatric manifestations of HIV/AIDS include (1) early signs of dementia, (2) paranoia, and (3) other psychotic and affective symptoms. Impressive strides have been made in the treatment of HIV/AIDS resulting in decreased morbidity and mortality. HIV/AIDS is now viewed more as a chronic disease rather than a terminal illness.

As the APA Guidelines note, the risks of social stigma and issues of personal safety complicate confidentiality for the infected inmate, other inmates, and correctional and clinical staff. The usual cultural differences among inmates and security and health care staff may be exacerbated in cases of inmates with these infections, especially HIV/AIDS. "Issues of confidentiality are complicated by the risks of social stigma and issues of personal safety." Therefore, education of both staff and inmates is very important with regard to HIV/AIDS.

One important aspect of the HIV/AIDS situation is that housing requirements in some jurisdictions might create barriers to access to mental health treatment, and housing isolation might exacerbate the inmates' feelings of abandonment and lead to a worsening of symptoms of mental illness.

The APA Guidelines further suggest that the correctional facility undertake an outreach program and/or periodic rescreening to foster early detection and utilization of mental health services by inmates with HIV/AIDS. The APA guidelines also recommend the following: Education of staff and inmates about infectious diseases and the means of transmission is especially important for both personal and population health risk reduction. Inmates need access to health educational materials and resources on prevention of transmission and consequences of continued high-risk behaviors for HIV and viral hepatitis such as promiscuity, unprotected intercourse, and intravenous drug abuse, and disease transmission.

Inmates with Hepatitis C Infection/Coinfection in Correctional Settings. As

noted in the APA Psychiatric Services in Correctional Facilities, 3rd edition, in recent years, hepatitis C infection or coinfection has surpassed concerns regarding HIV and AIDS. Current challenges of hepatitis C virus (HCV) in corrections include the large number of infected offenders, the increased use of medications, and more sophisticated and expensive treatment standards. The prevalence of HCV infection is higher among correctional populations than among the general US population. Although most HCV-positive offenders are asymptomatic, those who develop a chronic infection risk serious complications and death. HCV-infected inmates who receive interferon treatment may develop depressive symptoms, mood fluctuation, and suicidal ideation. Chronic HCV infection is the leading cause of end-stage liver disease in correctional settings. More cases of liver failure are expected as the proportion of older offenders continues to increase. HCV-infected offenders who progress to end-stage liver disease require frequent and costly medical hospitalizations and emergency department services for the treatment of bleeding, abdominal fluid retention, and other serious complications. Ultimately, the only viable option for some of these offenders will be liver transplantation, a procedure with ethical questions, and fiscal/budgetary impacts due to the substantial initial and subsequent costs.

From a clinical perspective, increased ammonia level is commonly associated with behavioral disturbance and presents as a delirium with waxing and waning symptoms that requires timely medical intervention. These behavioral changes may be attributed as being “psych (psychiatric)” in etiology and, therefore, staff education and training is paramount. Chronic HCV infection is a risk factor for liver cancer and a contributing factor in many liver cancer deaths. Many correctional health care system providers are facing unprecedented challenges in addressing the growing HCV epidemic. These challenges revolve around financial and logistical impediments to evaluating and treating such a large number of HCV-infected offenders along with a constantly evolving consensus about how to best manage the disease in the correctional setting. Meeting these challenges has enormous public health implications because most HCV-infected offenders eventually return to their home communities with the potential to infect others. Accepted standards of care for the management of HCV infection recommended by the National Institutes of Health and other key groups are rapidly evolving.

The use of interferon required mental health screening and evaluation when clinically indicated for the development of depressive symptoms and suicidal ideation. This increased the mental health and psychiatric service need demands for correctional facilities. Some systems have limited antiviral treatment options, and some limit treatment to those patients at highest risk for developing cirrhosis and subsequent liver failure. Offenders with end-stage liver disease and associated conditions are particularly

difficult to treat. They may not need medical hospitalization but require specialized housing (often with supplemental oxygen, vital sign and cardiac monitoring, and on-site nursing and medical staff), specialists who can manage end-stage liver disease and associated complications, access to laboratory studies, and coordinated treatment by nursing, medical, psychiatry, and mental health staff.

Inmates with Intellectual and Developmental Disabilities in Correctional Facilities. Offenders with co-occurring mental illness and intellectual or developmental disability encounter unique difficulties in the criminal justice system and have special treatment needs. From 4 to 10 percent of inmates have intellectual developmental disorder (formerly referred to as mental retardation or borderline intellectual functioning), that is, significantly subaverage intellectual functioning and impairments in adaptive functioning and "it is estimated that 40 to 70 percent of individuals with mental retardation in jails and prisons have diagnosable psychiatric disorders."

This is a substantial number of inmates in the correctional population who have intellectual disabilities that present special problems for the correctional psychiatrist. Some of the difficulties to which the correctional psychiatrist must be alert are listed in the APA Guidelines (Table 60.3–13).

According to the APA Psychiatric Services in Correctional Facilities, inmates with intellectual or developmental disability and co-occurring mental disorders are unfortunately the most likely to be preyed on and ridiculed by other inmates. Their inability to process information rapidly or to comprehend instructions, their low frustration tolerance, and their impulsivity may have severe disciplinary consequences. Custody and treatment staff need additional training and education on intellectual and developmental disabilities to lessen the likelihood that they misperceive behaviors as intentional rule infractions or attribute them solely to intellectual disability while an SMI goes untreated.

Table 60.3–13.
American Psychiatric Association Guidelines on Difficulties in the Correctional Population

Deficits in communication skills contribute to the problem for correctional psychiatrists, who depend primarily on interview and spoken language for making assessments of the problems and recommending the appropriate intervention.
Self-injurious behavior may be viewed as a manifestation of a depressive disorder, a manifestation of a diminished ability to tolerate stress, a symptom of anxiety, a problem of impulsivity, or a learned behavior leading to being the center of increased attention from others.
Inmates with this combination of difficulties are the most likely to be preyed upon and ridiculed by other inmates.
Their inability to process information rapidly or to comprehend instructions and their low frustration tolerance and impulsivity may have severe disciplinary consequences.

Each inmate's needs must be assessed individually in regard to housing, support, protection, and observation by mental health and security staff. It is important, however, to ensure that inmates with mental retardation/developmental disability and mental illness are not precluded from receiving or participating in services or programs available to all other inmates.
Therefore, security and treatment staff alike should have additional training and education on mental retardation/developmental disability in order to minimize the likelihood that behaviors are misperceived as intentional rule infractions or attributed solely to mental retardation while failing to treat a serious mental illness.

Geriatric Inmates in Correctional Facilities. The Federal Bureau of Justice Statistics notes that US prison population is aging, and that "expressed in terms of percent change, the oldest age group, inmates age 55 or older, recorded the largest change—an increase of 85 percent since 1995." Effective access to mental health services for older inmates requires recognition of the special challenges facing inmates and mental health professionals, especially as the number of offenders older than 65 years in state and federal prisons increased at 94 times the rate of the overall sentenced population between 2007 and 2010. The aging of the correctional population will be a major problem in the 21st century.

As noted by the APA Guidelines, for the correctional psychiatrist, older inmates have medical needs that sometimes might present with psychiatric symptoms and might complicate psychiatric intervention in terms of medication, relevance of counseling, structure of time (programming) of the inmate, and housing. These problems are more likely to be chronic, permanent, and progressive, might be related to the possibility of dying in custody, and might be expensive (Table 60.3–14).

For the older inmate, the isolation can be expressed in a variety of ways, and, when extreme, can exacerbate or create mental illness or psychiatric crisis. Special issues are related to (1) acceptance after release from incarceration, (2) provision of food, shelter, and clothing after release, (3) assault and potential greater sequelae of injury, and (4) isolation from older, "free" relatives and friends who might be unable to travel to visit.

Table 60.3–14.
The APA Guidelines on Psychosocial Concerns of Older Inmates

Estrangement from or lack of connection to other inmates in the general population, given the relatively small (though increasing) percentage of older inmates
Physical vulnerability to more serious consequences of assault
More difficulty and greater length of time to adjust to a new environment
Higher rate of completed suicide
Greater possibility of dying during incarceration
Higher incidence of loss of external supports, e.g., spouse, parents, friends, and other external supports

Some of these issues might benefit from mental health intervention, including group or peer counseling. Psychiatric and clinical staff need training in the special needs and care required by older inmates, and they

can help educate custody staff to recognize and deal with cognitively impaired inmates who might not respond appropriately to a direct order, mobility issues, and those who might demonstrate early confusion and cognitive impairments and associated sight and hearing impairments.

The Dying Inmate. Facilities should have written policies and training to address the in-custody dying inmate–patient. When feasible, the care of an inmate with terminal illnesses should involve use of a hospice approach —a facility that emphasizes providing support and humane care to a dying patient rather than trying to cure the underlying disease. This might be inside the prison (less likely to be needed in jail) or a contract facility outside of the prison. Another consideration is the use of compassionate release (also called "medical parole"), which is available in a majority of states. Compassionate release can have a number of advantages, including cost savings for the prison health care system, which can be substantial.

The use of inmate volunteers (peer trainers) who are oriented in basic health issues, universal precautions, and mobility management can reduce the dying inmate–patient's (or his or her family's) perception that "the prison isn't doing enough." Group therapy, realistic planning, and suicide prevention are specific interventions that the psychiatrist should either provide directly or ensure provision by other mental health professionals.

CRITICAL CLINICAL ISSUES IN CORRECTIONAL PSYCHIATRY

Suicide Prevention

Suicide is a sentinel event in prison, and preventive efforts reflect the adequacy and comprehensiveness of mental health, psychiatric, custodial, and administrative services in a correctional system. The risk of suicide is dramatically higher among incarcerated jail and prison inmates than among the population at large. Suicide rates for men in jails are approximately 9 to 15 times higher than for the general population, and prison suicide rates are approximately 1.5 times higher than in the general population. An increased risk of suicide associated with mental illness also has been found. Researchers examined psychiatric disorders and completed suicide in the nation's largest state prison system and their findings highlight the importance of maintaining suicide prevention programs in correctional settings, with particular emphasis on screening and monitoring of patients with severe psychiatric disorders.

Therefore, suicide prevention—identifying and responding to suicidal inmates—ultimately, a suicide prevention program, is the collective responsibility of administrative, custodial, and clinical staff.

Legal cases that were decided during the period of reform of the correctional system held that it is a legal requirement that every jail and prison must have a suicide prevention program that identifies and

responds to each suicidal inmate and takes an active approach to his or her management.

The APA Guidelines recommend, and to meet the suicide prevention standard, an essential standard from the Jail, Prisons, Juvenile and Mental Health Standards of the National Commission that mental health staff and the correctional psychiatrist must ensure that the suicide prevention in a particular jail or prison includes the following components:

An adequate suicide prevention program must include the following components, which should be available in a written policy and procedure manual that all staff can easily access:

- Training for all staff who interact directly with inmates to recognize warning signs and intervene appropriately with individuals at risk for suicide
- A formal and detailed suicide risk assessment process
- Identification of inmates at increased risk of suicide through screening at or near the time of admission to the facility and through referral at any time during an individual's incarceration
- An effective and well-understood referral system that allows staff and inmates to bring a suicidal inmate to the prompt attention of a mental health clinician
- Timely evaluation by a mental health clinician to determine the level of risk posed by a referred inmate
- Timely implementation of monitoring interventions such as close observation (at least every 15 minutes), continuous monitoring, alternative housing, or referral to a higher level of care (e.g., infirmary or hospital). When indicated, a psychiatrist either on call or in person assists in the decision about interventions. Any mental health clinician may order an increase in monitoring level, but a decrease in level may be ordered only by a psychiatrist or doctoral-level mental health clinician after an in-person evaluation.
- Housing options that allow for adequate monitoring of suicidal inmates by staff. Suicidal inmates should not be placed in isolation settings without continuous monitoring. Continuous monitoring for active suicidality should occur regardless of housing location. Supervision aids such as video monitoring may be used as a supplement to, but not as a replacement for, active staff monitoring.
- Communication among mental health, correctional, medical, and other staff of the specific needs and risks presented by a suicidal inmate
- Timely provision of mental health services, including medication, individual and group therapies, and crisis intervention, for chronically or acutely suicidal inmates
- Accurate, behaviorally specific, and highlighted documentation in the medical record of behaviors or statements that indicate suicide risk

- Quality improvement reviews with psychiatric staff participation of suicide attempts and completed suicides to help prevent future occurrences
- Critical incident support, opportunities for peer-to-peer discussion, and availability of Employee Assistance Program support for completed suicides to assist staff and inmates to deal with feelings of guilt, fear, grief, and anger

High-Risk Periods. It is obvious that an inmate might become suicidal at any point during incarceration. The high-risk periods that both the APA Guidelines and the NCCHC Standards emphasize are listed in Table 60.3–15.

An inmate who is placed in and is unable to cope with administrative segregation or other specialized single-cell housing assignment might also be at increased risk of suicide. In addition, an inmate who is in the early stages of recovery from severe depression is very much at risk.

Table 60.3–15.
Periods of High Risk for Suicide in a Jail or Prison

At the time of admission to a lockup, jail, or prison
After new legal problems (e.g., new charges, additional sentences, institutional proceedings, denial of parole)
After the receipt of bad news regarding one's self or one's family (e.g., a serious illness in the family or the loss of a loved one)
After suffering some type of humiliation or rejection (e.g., sexual assault)
On being placed in and unable to cope with administrative segregation or other specialized single-cell housing assignment
In the early stages of recovery from severe depression

Correctional facilities must have written policies and clearly defined procedures instituting a program for identifying and responding to suicidal inmates. In addition, the quality assurance activities in the facility should confirm its suicide prevention practices.

Self-harm is a general term for a variety of activities, including self-mutilation without the wish to die. It takes many other forms, such as swallowing dangerous objects and suicide "gestures." The following are some examples of self-harm: cutting, carving, scratching, burning, biting, banging head or hitting other body parts, ripping or pulling skin or hair, interfering with wound healing, ingestion of sharps (ingestion of glass, razor blade or parts, or other items) and toxic or inedible substances or objects, and object insertion (e.g., into urethra, anus, vagina, extremities, wounds). Self-harm in this sense invokes questions of malingering and manipulation.

Although there are many more suicide attempts and incidents of nonlethal self-harm than completed suicides, any threats of self-harm or

self-injurious behavior must be taken seriously. Self-harm behaviors, regardless of motivation, can result in significant morbidity and mortality. For this reason, even behaviors that do not lead to injury should be taken seriously and not dismissed as merely "suicidal gestures."

Because self-harm is hard to control, it is a serious challenge for correctional officials and a complex clinical situation for the correctional psychiatrist who must determine whether the self-harm is the result of a mental disorder. This requires a variety of means to assess the problem, including risk assessment methods and protocols, and might require temporary housing on a mental health unit.

When self-mutilation is determined not to be the product of a mental disorder, the inmate may be denied admission to a mental health unit. This may confuse family members, attorneys, courts, patient advocates, and correctional authorities, who view such behavior as a sign of mental instability. It is, therefore, essential that the correctional psychiatrist follows clear protocols for self-harm to determine whether it is a psychiatric symptom, a manipulative gesture to escape a dangerous situation, or an effort to manipulate the system for personal gain. Careful and thorough documentation and communication with custody personnel are the key factors. Treatment, however, must be individually tailored and calls for a team approach.

Seclusion and Restrain in Correctional Psychiatry

The use of seclusion and restraint in the correctional context is complicated by the fact that corrections facilities have procedures with regard to nonmedical seclusion and restraints. As a consequence, the correctional psychiatrist must be very familiar with the principles and practices related to this subject and be prepared to act on them.

Because of this importance, both the APA and the National Commission have addressed the complex issue of seclusion and restraint in correctional facilities. In 2006, the APA published the Resource Document on the Use of Restraint and Seclusion in Correctional Mental Health Care, which provides a detailed and nuanced discussion of this complex topic. It is strongly recommended that every practicing correctional psychiatrist carefully study and review this document. It "discusses the use of seclusion or restraint for purposes of mental health intervention in jails and prisons, in contrast to its use for correctional purposes (i.e., specifically custody reasons)," and states:

> The use of seclusion or restraint for correctional purposes is generally driven by classification and disciplinary issues unique to the correctional setting. For example, an inmate's security classification may require the use of handcuffs and leg irons (i.e., restraints) during movement outside of the inmate's cell or housing unit. Restraints may also be used by custody staff to control an inmate's assaultive behavior that is not related to mental illness. With few exceptions, cell extractions (both calculated use of force and on an emergency basis) by custody staff are governed by custody policies and procedures even when they involve mentally ill inmates.

However, there are generally special provisions in such policies and procedures when such a use of force involves the mentally ill inmate that usually includes attempted assessment/intervention by mental health staff prior to the use of force. Disciplinary segregation has many characteristics similar to seclusion such as confinement to a cell and restricted access to personal belongings. Custody guidelines for using these security measures are generally very different than those relevant to the use of seclusion or restraint for mental health purposes and will not be addressed in this document.

With regard to the correctional setting specifically, this APA Resource Document details such matters as the location where the restraints or seclusion are being employed, the time frames that are required, and the devices that are permissible under various circumstances. It includes an appendix quoting the authoritative 1999 Health Care Financing Administration (HCFA) rules for the use of seclusion and restraint.

The same principles are contained in NCCHC Standard entitled Use of Restraint and/or Seclusion for Mental Health Reasons, which states, "Clinically ordered restraint or clinically ordered seclusion are available for patients exhibiting behavior dangerous to self or others as a result of mental illness." The following definitions are illuminating:

Clinically ordered restraint is a therapeutic intervention initiated by medical or mental health staff to use devices designed to safely limit a patient's mobility. Custody restraint is not the same as clinically ordered restraint. When custody staff order the use of restraints, medical staff monitor the health status of inmates while in custody restraint and mental health staff respond to security or medical staff requests for consultation regarding the use of, or response to, custody-ordered restraint.

Clinically ordered seclusion or "time-out" is a therapeutic intervention initiated by medical or mental health staff to use rooms designed to safely limit a patient's mobility. It is not the same as segregation or isolation as generally applied in corrections (i.e., referring to housing separate from general population and used primarily for punitive purposes). The term also does not refer to the temporary imposition of "lockdown" as directed by correctional authority in order to regain control in a tier, building, or facility.

Malingering

Common sense points to the fact that malingering is a pervasive problem in correctional facilities and of special concern for the correctional psychiatrist. Throughout the period of incarceration and the various correctional procedures and processes and at every level, secondary gain can be substantial. Moreover, given the character and temperament of certain correctional offender patients, it calls for constant vigilance.

The ability to detect malingering in the correctional context is especially important not only because of its ubiquity but also because although the mere presence of malingering does not preclude a finding of mental illness. As a rule, malingerers can be wasteful of resources and, therefore, detract

from the quality of services that correctional psychiatrists can provide to inmates who are truly in need of treatment. Under suitable conditions, such as when a corrections officer is part of a treatment team, the long-term observations of the security staff can provide valuable information with regard to an inmate's malingering.

Inmates in Segregation Housing

There remains a great amount of controversy regarding the empirically validated psychological effects of segregation and what effects, specifically this has on individuals with or without serious mental illness. In sum, it appears that prolonged segregation exposes individuals to potential psychological, physiological, and medical risks. Those with SMI have special vulnerability to the adverse effects of social isolation. Psychiatrists should assist correctional systems with the development of evidence-based behavioral interventions that avoid the potential harm of social isolation.

One example where psychiatrists and mental health professionals can help provide guidance to custody is the following. Consultation and training for disciplinary hearing officers before conducting the due process hearing (that would result in placement into a restrictive housing setting such as administrative segregation, disciplinary housing, or the like) helps them to recognize when mental illness is a contributor to inmate misconduct. Mental health professionals should be contacted and consulted by disciplinary hearing officers when mental illness is suspected. The NCCHC Standard broadly defines segregated inmates as "those isolated from the general population and who receive services and activities apart from other inmates." These housing units can be labeled as "administrative segregation, protective custody, disciplinary segregation, or a supermax tier." It notes that "for the purposes of this standard, the living and confinement conditions define the segregated status, not the reason an inmate was placed in segregation." The NCCHC Standard has an additional category—"extreme isolation"—which "refers to situations in which inmates are seen by staff or other inmates fewer than three times a day."

The APA Guidelines assert that "the challenge of providing correctional psychiatric services to inmates in segregation housing is a critical reflection of the correctional facility's quality of care and the inmate's access care."

It is not surprising that especially in jails and prisons that lack adequate mental health services, inmates with severe mental illness often find their way into segregation housing, often quite unnecessarily, as when their mental illness prevents them from understanding or adhering to correctional rules.

The APA Guidelines state that when an inmate is segregated for any reason from the general population, the responsibility to address serious mental health needs remains in effect (Table 60.3–16). Indeed, because of the stressful nature of segregation housing, facilities should make special

efforts to assess and address mental health treatment needs in these settings. Although correctional psychiatrists should not be involved in the decision to place an inmate in disciplinary segregation, once an inmate is there, the psychiatric staff should monitor his or her mental health status because an inmate who is placed in and is unable to cope with administrative segregation or other specialized single-cell housing assignment might also be at increased risk of suicide.

Table 60.3–16.
The American Psychiatric Association Guidelines on Principles for Mental Health Services in Segregation Housing

The APA Guidelines recommend that in providing essential mental health service in segregation housing, the following principles should be observed:

No inmate should ever be placed in segregation housing solely because he or she exhibits the symptoms of mental illness, unless there is an immediate and serious danger for which there is no other reasonable alternative. (This principle does not refer to medical or psychiatric seclusion, which should follow state mental health law and professional practice.)

When an inmate is placed in segregated housing for appropriate correctional reasons, the facility remains responsible for meeting all of the serious medical and psychiatric needs of that inmate. Thus, such inmates must receive any mental health services that are deemed essential, their segregation status notwithstanding.

Inmates who are in current, severe psychiatric crisis, including but not limited to acute psychosis and suicidal depression, should be removed from segregation until such time as they are psychologically able to tolerate that setting.

Inmates who are known to have serious mental health needs, especially those with a known history of serious and persistent mental illness, when housed in segregation, must be assessed on a regular basis by qualified mental health practitioners to identify and respond to emerging crises at the earliest possible moment.

Institutions should provide for regular rounds by a qualified mental health clinician in all segregation housing areas. During these rounds, each inmate should be visited briefly to assess any emerging problem. The clinician should also communicate with segregation security staff in order to identify any inmate who appears to be showing signs of mental deterioration or psychological problems.

Similarly, the NCCHC recommends, “inmates who are seriously mentally ill should not be confined under conditions of extreme isolation.”

The Commission adds, “policies should also address how vulnerable populations like adolescent, elderly, pregnant or mentally ill inmates are managed in segregation. Since segregation can exacerbate pre-existing conditions staff should be extra cautious when placing vulnerable inmates in segregation.”

The APA developed a position statement (APA, 2012) that includes the following:

Prolonged segregation of adult inmates with serious mental illness, with rare exceptions, should be avoided due to the potential for harm to such inmates. If an inmate with serious mental illness is placed in segregation, out-of-cell structured therapeutic activities (i.e., mental health/psychiatric treatment) in appropriate programming space and adequate unstructured out-of-cell time should be permitted. Correctional mental health authorities should work closely with administrative custody staff to maximize access to clinically indicated programming and

recreation for these individuals.

The SCP (2013) also published a similar position statement.

ISSUES THAT ARE UNIQUE TO CORRECTIONAL PSYCHIATRY

The "Lifer": Inmates Serving Life Sentences

Psychiatrists may encounter inmates with one or more life sentences, life without parole, referred to as "lifers." These individuals pose a unique challenge to the correctional psychiatrist. Because these individuals will not be released from prison, many usual incentives such as parole, token incentives, and the like have less effect.

The APA Psychiatric Services in Correctional Facilities notes that "inmates draw on many resources to assist their adaptation to incarceration, such as family contact, peer support, work, education, and spiritual pursuits, including the practice of faith-based traditions." Some individuals may lack these psychosocial resources such as no regular family contact, no visitors, no one on their visitation lists, no one to help fund their commissary purchases, family estrangement, and the like.

Inmates on Death Row

"Death row" individuals, inmates housed on death row, who are awaiting exhaustion of legal appeals, or whose legal appeals are exhausted and remain housed within death row psychiatry pose a myriad of complicated clinical, ethical, and legal questions. Some examples of issues include the death row psychiatric assessment, considering "justifiable" depression, suicide risk management, individuals on death row who require psychiatric hospitalization, psychiatric treatment thereby restoring one's competency to be executed, and how to balance ethical/role boundaries between clinical and forensic work. Because of the lengthy appeals process and high stakes involved, mental illness and intellectual disabilities are commonly raised in postconviction proceedings typically on eighth amendment claims (arguing that the execution of the mentally ill and/or mentally retarded constitutes cruel and unusual punishment).

Inmates with mental illness on death row present the correctional psychiatrist with unique and complex ethical issues. Because the participation of a correctional psychiatrist in an execution would violate the principle of do no harm, Annotation 4 of Section 1 of the APA's Annotations states that "a psychiatrist should not be a participant in a legally authorized execution." Much has been written about the interpretation of the word "participate," and it is clear that the medical community is unanimous that any action that would further the implementation of an execution is prohibited. Furthermore, there is no doubt that this applies to evaluations of competency to be executed. However, what about treatment of an incompetent inmate to achieve competency? This is a controversial area,

and whereas in general the correctional psychiatrist is obliged to provide treatment to patients in need to relieve suffering regardless of the subsequent nonclinical consequences, it has been suggested that physicians who are opposed to the death penalty not practice on death row. Similarly, it was held in the case of State v. Perry that the patient retains the right to refuse treatment and the state cannot treat over objection so as to impose the death penalty.

The NCCHC Standard "Inmate Executions" states that "Mental health staff does not participate in inmate executions," and sets out the following compliance indicators:

An inmate's treating clinician does not provide a competency evaluation for execution.

Mental health services staff members do not assist, supervise, or contribute to the ability of another individual to directly cause the death of an inmate.

Mental health staff members provide ongoing mental health services to inmates in death row as clinically indicated according to individual treatment plans.

It is noted that the intention of this standard is that mental health staff not be involved in any action that would directly cause the death of an inmate because such involvement in inmate executions poses an ethical dilemma: "In order to be effective mental health care providers, correctional mental health care staff must maintain an appropriate professional relationship with their patients. This relationship is lost when mental health care staff assumes a role in inmate executions." The NCCHC Position Statement entitled Competency for Execution recommends that "the determination of whether an inmate is 'competent for execution' should be made by an independent expert" and not by correctional psychiatric staff.

On Being Asked to Witness the Use of Force. In what is a unique situation, correctional officials or inmates might request a correctional psychiatrist to witness incidents in which use of force is necessary (e.g., moving a recalcitrant inmate to a new cell or a different site). Although correctional authorities might hope that the psychiatrist will attest to the appropriateness of the action, and inmates might hope that the presence of such witnesses will limit unnecessary force, correctional psychiatrists would do well to avoid such purely custodial functions because it might place them in a complex no-win position.

Witnessing Inmate Abuse. A thorny problem for the correctional psychiatrist is what to do in the case of clear inmate abuse by security. Inmate abuse has been a topic that is under the radar for correctional psychiatrists, but although it has been the subject of "conditions of

confinement" litigation, it had not been dealt with directly as a professional issue.

This state of affairs was recently addressed by the publication of an NCCHC Position Statement entitled Correctional Health Care Professionals' Response to Inmate Abuse (Table 60.3–17).

Hunger Strikes in Jails and Prisons. Hunger strikes (the refusal of nutrition as a means of passive resistance) are a daunting problem in jails and prisons. Although the history of hunger strikes goes back at least to the Roman Empire and in the Western world, there is generally a right to go on a hunger strike that is protected as a matter of "privacy" or a "liberty interest" or can be regarded as an expression of free speech, clearly, in a correctional facility other factors come into play. Correctional authorities are charged with the "care and custody" of the inmates. Therefore, the following principles should apply:

- The correctional facility must provide for the evaluation of the situation for treatment if necessary and perhaps for legally allowable intervention.
- The medical services must provide for the evaluation of the medical stability of the inmate.
- The correctional psychiatrist must be available to evaluate such an inmate's psychiatric condition and whether there is a need for treatment.
- The correctional psychiatrist must also evaluate the motivation for the hunger strike and the inmate's capacity to understand the consequences of his or her actions and the medical decisions being made.

Although it might be understood that most inmates participate in hunger strikes for political or manipulative reasons and usually are not mentally ill, if an inmate with mental illness participates in a hunger strike to the point of an emergency, community standards allow for caregivers to decide what is in the best interests of a patient who is not competent to decide.

The majority of US courts that have considered the question hold that an order to force-feed does not violate a hunger-striking prisoner's constitutional rights because the institution in which the inmate is housed is responsible for his care while incarcerated and there are other compelling governmental interests, such as the preservation of life, prevention of suicide, and enforcement of prison security, order, and discipline, that outweigh any constitutional rights asserted. It is interesting to note, however, that international authorities argue to the contrary. International courts have tended to allow hunger strikes to proceed even to death or disability. Thus, forced feeding of prisoners is prohibited by the Tokyo Declaration of 1975, by the World Medical Association, and, affirmed in 1992, by the Declaration of Malta.

Table 60.3–17.
The National Commission on Correctional Health Care Position Statement on Correctional Health Care Professionals' Response to Inmate Abuse

Should correctional health staff witness or become aware of an inmate being subjected to harm in any of the forms described previously, it is their duty to report this activity to the appropriate authorities in order to protect patients and other inmates. The following principles are to guide correctional health care professionals in averting and reporting the mistreatment of inmates.

Correctional health care professionals' duty is to the clinical care, physical safety, and psychological wellness of their patients.

Correctional health care professionals should not condone or participate in cruel, inhumane, or degrading treatment of inmates. When such abusive treatment is either witnessed or suspected, they should identify and report such incidents to the appropriate authority.

Correctional health care professionals should refrain from participating, directly or indirectly, in efforts to certify inmates as medically or psychologically fit to be subjected to abusive treatment.

Correctional health care professionals should refrain from being present in the interrogation room, asking or suggesting questions, or advising authorities on the use of specific techniques of interrogation.

Correctional health care professionals should refrain from gathering health information for forensic purposes or sharing confidential health information or its interpretation to authorities for use in cruel, inhumane, or degrading treatment of inmates.

Correctional health care professionals should abstain from authorizing or approving any physical punishment of their patients and should refrain from being used as an instrument of their employer to weaken the physical or mental resistance of inmates are to be managed and what staff should do when abusive actions are suspected or witnessed.

Correctional health care professionals should review their employer's policies and procedures and work to ensure that they appropriately address how inmates are to be managed and what staff should do when abusive actions are suspected or witnessed.

Correctional administrators should ensure that policies and procedures address protections for employees who report the abusive actions of others.

Professional custody and health administrators should support efforts to eliminate abusive behavior toward inmates by ensuring that all staff receive regular training on appropriate and professional behavior in dealing with inmates. Use of experts outside of the correctional system can be helpful in providing objective training on this issue.

In 1994, the ACHSA adopted a Position Statement that allows forced feeding when the legal procedure for medication over objection has been followed:

The management of a hunger striking prisoner presents an ethical conflict between the obligation to preserve life and relieve suffering on the one hand, and the obligation to respect patient autonomy on the other. Correctional health care providers should make every reasonable effort to honor patient self-determination. However, the deprivation of freedom which incarceration imposes will affect decision making by the inmate patient. Therefore, special efforts in patient education and counseling are indicated.

A prisoner may begin a hunger strike for various reasons. If pursued, it may have a fatal outcome, unless there is medical intervention. Correctional health care providers have a special duty to protect inmates from self-destructive behavior. When a prisoner initiates a hunger strike, and efforts to counsel and dissuade are not successful in terminating the strike, the responsible physician is obligated to obtain thorough medical and psychiatric evaluations and to monitor weight loss and other parameters of deteriorating health in an appropriate medical setting. Treatment of intercurrent medical problems must be offered. The hunger-striking inmate should be informed that authorization will be requested to intervene with forced feeding when life is in danger.

Since forced feeding is a form of involuntary treatment, the responsible medical authority must seek the consent of the court or a legally appointed guardian, following the local requirements for involuntary treatment. The physician should make it clear to the court and to all others concerned, however, that ethical medical conduct in this setting demands medical intervention to preserve life from actions that are self-destructive.

ACHSA members should give careful consideration to the development of policies and procedures that provide a responsible and compassionate approach to the hunger-striking prisoner and which make it clear that efforts will be made to intervene with forced feeding in order to save life.

The APA Psychiatric Services in Correctional Facilities recommends the following: "Hunger strikes are considered a medical emergency, and psychiatrists are often asked to evaluate inmates to determine if they have the mental capacity to make an informed decision regarding continuation of the hunger strike, Psychiatrists can perform evaluations to rule out underlying mental illness as a cause of the hunger strike (e.g., suicidal depression or delusions regarding prison food)."

There is currently no consensus to guide psychiatrists in the United States on the ethical standards of force-feeding to end hunger strikes in correctional facilities. Although the World Medical Association and the AMA, with limited exceptions, have taken stands against the practice, the Supreme Court of Connecticut, in *Commissioner of Correction v. Coleman* (303 Conn. 800 SC 18721 [2012]), found that the state's interest in the inmate's health and legitimate penological interests in the safety of the facility outweighed the inmate's right to autonomy. Furthermore, the court ruled that "force-feeding did not violate constitutional rights to free speech and privacy."

Biomedical Research in Correctional Psychiatry

In many ways, biomedical research in correctional facilities presents the correctional psychiatrist with paradigmatic conflicts of dual loyalty. Therefore, the correctional psychiatrist must be aware of the many complex issues regarding research in jails and prisons.

Research with prisoners as subjects requires special legal safeguards and ethical, as well as clinical considerations. In addition to precautions accorded to each patient in studies, researchers must provide extra safeguards pertaining to the subjects' incarceration, in that the incarceration itself can be viewed as an inherently coercive setting that undermines an inmate's ability to provide freely given informed consent for participation in research.

Because research in correctional facilities has a long history of human subject abuse, there are special federal regulations governing research in these facilities. However, these federal regulations do not apply to certain other governmental agencies, such as the Department of Justice, which regulates its own extensive research in correctional facilities.

In addition, as the APA Guidelines also note, "there are other types of research design, including systems research, epidemiological and non-invasive studies that can yield useful information about the precursors of mental illness in offenders, incidence and prevalence of mental illness, program design, physical plant design, and planning for services."

The Correctional Psychiatrist's Role in Specific Custody and Security Issues

Classification Committees

To be fully effective, the corrections system's classification processes must have some basic information about inmates' psychiatric needs. For example, an inmate might need to be assigned to a prison with programs and resources for the chronically mentally ill. In addition, suicide prevention protocols generally recommend that inmates who are exhibiting signs of withdrawal or depression should not be single-celled. Accordingly, unit classification committees should be aware of psychiatric conditions that might affect where inmates are housed or assigned to work. This presents a problem of how to provide important information to classification groups about inmates' mental health without violating confidentiality. It has been suggested that a form be devised that summarizes any medical restrictions regarding unit housing or job placement without revealing the inmates' precise condition or diagnosis.

Institutional Transfers. Classification committees continuously juggle custody and medical classifications of inmates with their workforce requirements and available space. Most institutions provide a list of the next day's transferees to correctional psychiatric staff so that they can assemble the inmate's mental health records. Correctional psychiatric staff should ensure that the receiving unit has the requisite psychiatric resources to continue to meet the patient's needs. Each facility should have a policy that allows psychiatric staff to put a psychiatric hold on any interunit transfer of an inmate. Decisions regarding admission to and discharge from inpatient facilities are the sole provinces of clinicians.

Disciplinary Hearings. As a rule, correctional psychiatric staff should not participate in disciplinary hearings and should never be part of the punishment decisions. However, there are occasions when information from psychiatric staff might be helpful in protecting the inmate from inappropriate discipline. For example, a schizophrenic patient might refuse to comply with a correctional officer's directions because of negativism rather than defiance.

PERSISTING CHALLENGES IN CORRECTIONAL PSYCHIATRY: AN AGENDA FOR ADVOCACY

Although recent years have brought considerable progress in the reform of

the correctional system, there remain significant challenges to improving correctional psychiatric care and treatment. To put these challenges into perspective, it must first be first acknowledged that many problems have been solved and many barriers have been overcome or resolved. Historically, the public was reluctant to provide better conditions for those who broke its laws or offended its sense of morality. However, in recent years, the pendulum has been swinging away from a policy that prioritized retribution, and it is now being increasingly understood that incarceration represents opportunities for rehabilitation and the prevention of recidivism. Indeed, as correctional facilities have become increasingly overcrowded and costly to the taxpayer, such policies as harsh sentences for minor drug offences and "three strikes" laws are being questioned. Most important, whereas in the past correctional leadership had concerns that psychiatric services might interfere with and jeopardize security, in recent years, this has evolved into an understanding of the value of psychiatric services to security.

One persisting problem is that many correctional facilities are still located in rural areas and, as a consequence, are out of the medical mainstream, with limited access to psychiatric specialists and, in this regard, are underserved. Special efforts are being initiated at both the governmental and the professional levels to offer incentives to attract psychiatrists, especially early career psychiatrists, to serve, at least for some period of time, in such areas.

FIGURE 60.3–2. Adult correctional populations from 1980 to 2004.

In the past, there was no doubt that most correctional facilities were not satisfying places to work. Now, as the result of efforts of advocacy organizations, professional organizations, and the development of guidelines, standards, and accreditation to improve the delivery of psychiatric services in jails and prisons, this is also changing. Most

important, there was concern that the correctional atmosphere subverted the atmosphere of trust that is necessary for the doctor–patient relationship, which made many psychiatrists uncomfortable in a correctional environment. This, too, is changing, and the correctional institutional barriers that sometimes prevented the practice of good psychiatry or made professional psychiatric practice challenging are, in most cases, a thing of the past.

Nonetheless, there are a number of major persisting problems that can be regarded as social policy issues: overcrowding, the criminalization of the mentally ill, and racism in the criminal justice system.

Overcrowding

The overcrowding that has resulted from the increase in the correctional population over the last three decades has made many large jails, such as the Cook County Jail in Chicago, the Los Angeles County Jail, and Harris County Jail in Houston, Texas, the country's largest mental institutions (Fig. 60.3–2).

In 2006, more than 7.2 million people were on probation, in jail or prison, or on parole. At year-end 2006, this represented 3.2 percent of all US adult residents, or one in every 31 adults. State and federal prison authorities had jurisdiction over 1,570,861 inmates at year-end 2006: 1,377,815 in State jurisdiction and 193,046 in Federal jurisdiction. Local jails held 766,010 persons awaiting trial or serving a sentence at year-end 2006. An additional 60,222 persons under jail supervision were serving their sentence in the community.

The Criminalization of the Mentally Ill

Some of the factors contributing to the high rates of people with serious mental illness in the criminal justice system include, as reasons for the increased entry, that is, at the "front door" of correctional facilities, the process of deinstitutionalization and its accompanying phenomenon of "transinstitutionalization," the inadequate access of the seriously and persistently mentally ill to community treatment, the fact that these patients are arrested at disproportionately higher rates and often have co-occurring substance-related disorders, the prejudice that the mental ill are more violent, and the use of jails and prisons as housing of last resort (Fig. 60.3–3).

At the "back door," there are problems of discharge planning and reentry into the community, including the facts that these patients spend longer periods of time incarcerated, the pathogenic nature of incarcerated environments, the lower rates of parole, and the higher rates of recidivism due to inadequate community mental health services.

Finally, there are obvious overarching public policy issues that

permeate the criminal justice/mental health realm. The United States has the largest percentage of its population incarcerated than any other country in the world. Since 1989, the National Drug Control Strategy, which called for a mandatory minimum sentence for drug crimes, caused the jail and prison populations to grow at a rapid rate. In 1985, the percentage of sentenced drug offenders was approximately 13 percent. Currently, it is more than 30 percent. The importance of the relationship between the increase in the number of inmates incarcerated for drug offenses and the disproportionate increases in the numbers of female, nonwhite, and foreign-born inmates cannot be overstated (Fig. 60.3–4).

RECENT DEVELOPMENTS IN CORRECTIONS

Lesbian, Gay, Bisexual, and Transgender Persons and Gender Dysphoria

According to the APA Psychiatric Services in Correctional Facilities, trauma and stigma experienced by lesbian, gay, bisexual, or transgender (LGBT) individuals can increase their psychological distress and decrease their willingness to seek mental health services. When incarcerated, they risk additional discrimination and abuse. Compared with heterosexual inmates, studies have reported that they have 10 times the rate of sexual victimization by other inmates and up to three times the rate of sexual victimization by staff. This risk needs consideration on arrival at any correctional facility. LGBT individuals differ in degree of comfort with their sexual orientation or gender identity and whether they are “out” or “closeted.” Their choice about disclosure can change when moving from the community to jail or prison and between institutions. A respectful and nonjudgmental approach by the correctional psychiatrist can help LGBT inmates explore their choices and cope with their concerns. Transgender inmates, for example, may feel distress when housed in settings that do not allow them to express their gender identity or when they elect to stay closeted because of safety concerns. A therapeutic relationship in which they feel known by someone safe can improve emotional well-being.

FIGURE 60.3–3. Transinstitutionalization from 1950 to 2000.

FIGURE 60.3–4. Jail incarceration rates by race and ethnicity, 1990 to 2006.

The evaluation and treatment of gender dysphoria, formerly known as gender identity disorder, is a particularly challenging area. The evaluation and treatment and decision-making processes of whether to continue, discontinue, or initiate hormonal treatment for offender patients are complicated. This is further complicated within correctional settings and even more so due to correctional systems being subject to PREA audits and enforcement. Custody leadership makes decisions regarding classification, housing, transportation issues, and whether they allow access to gender-preferred clothing and toiletries and housing assignments. Beyond hormonal treatment, many correctional systems do not have uniform policies about permissible treatment for transgender inmates. To date, no correctional systems have provided sex reassignment surgery, but this may change in response to ongoing litigation by transgender inmates (e.g., two current high-profile cases are in Massachusetts and California). Consistent with the prevailing position of professional medical organizations, including the APA, courts and society in general are increasingly

recognizing gender dysphoria as a medical condition appropriate for treatment.

USING TECHNOLOGY IN CORRECTIONS: THE ELECTRONIC MEDICAL RECORD AND TELEPSYCHIATRY

Many county, state, and federal correctional systems have moved toward the implementation of correctional EMR systems. This is particularly helpful in multisite systems, or high-volume intake facilities with rapid turnover, or alternatively in large systems where there is common movement, transfers, and turnover of inmates both intra- and intersystem. Thorough medical documentation is a useful protection against litigation and to help clarify an individual's assessment and treatment plan and to ensure continuity of care.

Telepsychiatry is becoming a more accepted and standard practice in correctional settings and in the community as the national shortage of psychiatrists increases. Greater comfort by correctional psychiatrists and other mental health professionals with this technology increases accessibility of expeditious services for patients, and due to less need for off-site transport for psychiatric evaluation, this technology reduces the cost and burden on staff to travel with an offender (typically at a minimum at least two correctional officers per transport). This use of technology reduces the risk of escape and other community safety risks. It also eliminates the risk of assault to psychiatrists as that which can and does occur on the unit, albeit rarely, during face-to-face encounters.

THE FUTURE OF CORRECTIONAL PSYCHIATRY

A confluence of forces is accelerating the reform of the correctional system to the benefit of correctional psychiatrists and their patients. Intense advocacy efforts, especially by families members of persons with serious and persistent mental illness in the criminal justice system, through patient advocacy groups such as the National Alliance on Mental Illness and Mental Health America, are becoming increasingly effective in lobbying legislatures to increase mental health funding, staffing, and psychiatric services in jails and prisons.

The APA is joining with other professional groups to develop programs and priorities for legislative action, including such groups as the Campaign for Mental Health Reform and the Mental Health Liaison Group. This has, in turn, drawn the attention of county and state governments not only in terms of the requirements of the humane aspects of care and treatment and concerns about litigation but also the fiscal aspects. More and more evidence is accumulating that it is of benefit to the taxpayer to prevent recidivism by means of diversion programs, drug courts and mental health courts, jail-based and other competency restoration programs and well-developed reentry programs, as well as psychiatric services in juvenile

justice settings, and in adult jails and prisons.

In his 2004 State of the Union Address, President George W. Bush said, "America is the land of second chance, and when the gates of the prison open, the path ahead should lead to a better life." The Second Chance Act of 2007 mentioned earlier assists states and local government entities, in partnership with nonprofit organizations, to establish prisoner reentry demonstration projects.

It is becoming increasingly clear that part of the overcrowding problem, as well as the escalating costs, can be addressed by providing correctional psychiatrists with the means to keep persons with serious and persistent mental illness from being warehoused in the jails and the prisons.

The mental health field is becoming increasingly sophisticated in targeting inadequate services in areas such as discharge planning and reentry policy in an effort to bring about major reforms, as in cases such as the Brad H. case mentioned earlier that ensures efficient and effective discharge planning and reentry programs. The legal community through the American Bar Association has produced its own Criminal Justice Mental Health Standards. The concept of "therapeutic jurisprudence" has found adherents in the judiciary.

The media is becoming increasingly aware of the importance of the numbers of persons with mental illness in the criminal justice system, and innumerable editorials have dealt with various aspects of reform. There are now journalists, websites/blogs (in Texas, there is Grits for Breakfast), who specialize in various aspects of corrections and correctional psychiatry.

The academic community is no longer ignoring the shame of the incarcerated mentally ill and recognizes the public health implications of this situation. This is evidenced by the flood of recent textbooks and the many articles in the literature and the ever-growing numbers of conferences on correctional psychiatry. In 1996, the Accreditation Council on Graduate Medical Education (ACGME) recognized the subspecialty of forensic psychiatry, which includes substantial correctional components. The didactic curriculum for the forensic fellowship training requires that the "psychiatric curriculum includes the… evaluation and treatment of incarcerated individuals," and the "clinical experience must include experiences in the… treatment of persons involved in the criminal justice system." In addition, "Clinical placement must provide [forensic fellows]… with experience in the evaluation and management of acutely and chronically ill patients in correctional systems such as prisons, jails, community programs, and secure forensic facilities."

Sophisticated demographic studies demonstrate that a significant percentage of the population of the mentally ill in jails and prisons are inappropriately incarcerated in correctional contexts and should be transferred to the civil mental health system.

Professional organizations are providing a voice for correctional

psychiatrists. The APA has since 2002 supported a Caucus of Correctional Psychiatrists. The importance of this subject of addressing both health and mental health in jails and prisons has led the ACA to adopt standards and an accreditation process and the NCCHC to develop separate mental health standards.

The advent of private companies (including some specializing in mental health care) competing to win contracts for the management and administration of correctional facilities has added the potential for greater accountability, by contract, to state and local governmental agencies.

Correctional psychiatrists in particular are aware that medical science is advancing on issues such as the biological bases of the characteristics that lead to criminality and deviance and the prospects of targeted change and evidence-based treatment. For example, there have been seminal studies of the developmental capacities of youth and their responsibility for various criminal acts.

Finally, in recent years, comparative studies have been carried on from the international perspective to compare correctional psychiatric systems in the United States with those in other countries with regard to the costs and benefits of different systems of providing services.

These are days of great ferment, with an increasing effort to improve psychiatric services in jails and prisons, which points to an encouragingly bright future for correctional psychiatry and for jails and prisons as a place for excellence in practice, teaching, and ethical and IRB-approved research.

▲ 60.4 Neuroimaging, Psychiatry, and the Law

JOSEPH R. SIMPSON, M.D., PH.D., AND JONATHAN D. BRODIE, M.D., PH.D.

INTRODUCTION

Methods for visualizing the structure and function of the living human brain have become increasingly informative over the past four decades. Dramatic scientific and technological advances have made neuroimaging ubiquitous in 21st century psychiatric research. Yet in spite of the great strides made in the development of the techniques, neuroimaging is not standard practice for diagnosing the conditions most commonly encountered by psychiatrists, such as mood disorders, anxiety disorders, and psychosis. Currently, clinical psychiatrists use neuroimaging on a routine basis only to rule out neurological causes of their patients' symptoms.

However, research is not the only segment of the mental health field where applications of neuroimaging have been rapidly expanding. Neuroimaging is being introduced as evidence in court with growing frequency. The ongoing refinement of the techniques has allowed this use of neuroimaging to move far beyond its original applications, such as identifying structural lesions caused by traumatic injury, cerebrovascular accident or hypoxia. In an ever-increasing number of civil and criminal cases, neuroimaging is being offered as evidence to support a wide range of neuropsychiatric diagnoses and conditions. Some attorneys have argued that neuroimaging can establish the presence of specific current or past mental states or mental capacities, or the lack thereof. The past decade has also seen attempts to use modern neuroimaging techniques to peer into a person's thoughts and classify him or her as being truthful or deceptive.

The appeal of neuroimaging for attorneys is obvious: A brightly colored image, produced by expensive, sophisticated technology, is infused with an aura of irrefutable scientific truth. The seemingly authoritative "brain scan" can be pointed to as proving the assertions the attorney is making. A judge or a jury may find it difficult to disregard the evidence of their visual sense, which seems to demonstrate abnormal brain activity in, for example, the plaintiff in a civil trial who is arguing that he has been injured, or the defendant in a criminal trial, arguing that she is not responsible for the alleged crime due to a mental disorder.

In an adversarial legal system such as the one used in the United States, attorneys act as advocates for one side. Much of their work in court, therefore, is focused on persuading the judge or jury by presenting their arguments in the most favorable light. They are under no obligation to point out the limitations of their evidence, or the merits of any evidence

which would tend to undermine their case. Of course, the advocate does not have free rein. The use of neuroimaging is, like all scientific evidence in the legal arena, constrained by two mechanisms: the so-called "gatekeeper" function of the judge, who must rule on the admissibility of proposed scientific testimony, and rebuttal by the opposing attorney, through cross-examination and/or the calling of an expert who will contradict some or all of the initial expert's testimony.

The use of neuroimaging in a legal context raises a number of fundamental questions. What imaging methodologies are potentially helpful in court, and for what purposes? Are there some questions that neuroimaging cannot address? In terms of social policy, do some current or potential future applications of neuroimaging risk infringing on the rights of those who are subjected to them, or of interfering with the fact-finding role of the judge or jury?

It is an oft-repeated truism that the human brain is the most complex system known. Psychiatrists know well the difficulties inherent in attempting to identify and analyze thoughts, emotions, and motivations, and their causes, effects, and interactions. Neuroimaging is not now, and will not soon become, similar to fingerprinting or DNA evidence, where the result of the test essentially settles the question being asked Either the DNA matches or it does not. Such stark dichotomies are generally not the case where neuroimaging is concerned. This is especially true for psychiatric applications. Psychiatric neuroimaging is not used in a courtroom situation the way a plain x-ray film might be used to demonstrate a broken bone. Rather, neuroimaging findings are most often used in court to support the diagnostic findings of other forms of assessment, such as neuropsychological testing or a comprehensive psychiatric diagnostic evaluation.

The challenge faced by attorneys and the experts they retain is determining whether the neuroimaging results they seek will be based on a valid, appropriate use of the technology, and if so, whether the findings are relevant and add value to the legal argument being made. These are complex questions which must be addressed in each case where neuroimaging may be utilized. Expert witnesses who seek to incorporate neuroimaging into their testimony must have a thorough understanding of the capabilities and limitations of the technology, including an understanding of which questions neuroimaging is unlikely to shed light on. It is incumbent on the psychiatrist who proposes to make use of neuroimaging in a legal setting to ensure that the science is appropriate for the task, and that the attorneys do not draw unsupportable conclusions.

Furthermore, whether neuroimaging is appropriate in a given case is dependent not only on the science of the imaging technique, but also on the legal question to be addressed. The same data may be valid and relevant in one legal context but not another. For the past 2 decades, judges have

struggled with questions of the admissibility and relevance of neuroimaging findings. As neuroimaging techniques continue to be developed, refined, and applied in a wide range of legal situations, these debates will continue. The well-informed psychiatrist, with his or her knowledge of the brain and behavior, neuroimaging techniques, and forensic mental health concepts, is in a position to provide indispensable information to the court system throughout the legal process.

OVERVIEW OF IMAGING TECHNIQUES

Regardless of the technique, the objective of neuroimaging is to detect some property of the brain (as measured by attenuation of x-rays, magnetic moments or dipoles, electrical signals, radioactive events) without invading the brain. It is important to realize that each imaging technique has a characteristic sensitivity, precision, accuracy, and fidelity with respect to a physical and/or physiological process or processes, and is generally performed in an artificial environment divorced from the very circumstances and behaviors that prompted the test.

It is not obvious when looking at a functional or structural brain image that the image represents a series of complex manipulations of the raw data that the technology acquires. It is always necessary to construct and apply a model. A model, by definition, is a set of simplifying assumptions that are made to reconstruct the mass of acquired imaging data so it is interpretable in physiological terms in an experimental context or design. It is also necessary to perform statistical analysis and comparisons that are generally different in the forensic context than they are in a research environment. Nevertheless, the imaging expert is normally expected to draw experimental conclusions and clinical inferences from the imaging data, regardless of whether or not the appropriate statistical comparisons can be made.

What is being imaged are in fact electrical signals generated by the technology (e.g., photons from a radioactive event or annihilation, changes in a magnetic field, absorption of x-rays) that are detected, amplified, corrected for spatial localization and tissue attenuation, filtered and reconstructed, smoothed, fitted to an anatomical reference brain, and compared to either a similarly obtained reference state or to a reference group. Ideally, the reference group would be comprised of subjects who are matched for gender, handedness, age, education, general medical history, etc. In practice, these conditions are rarely met, and the reference groups tend to be smaller than is desirable or statistically appropriate.

What the technology is measuring, what is imaged, and what the user employing the technology is attempting to infer and interpret are specific to each modality. In the case of computed tomography (CT) scans, what is measured is the attenuation of x-rays as they pass through tissues of different density, while magnetic resonance imaging (MRI) scans measure

the magnetic properties of the protons in water molecules in their microenvironment as they “relax” after being polarized by an extremely strong homogeneous magnetic field. Different properties of the tissue environments can be highlighted by manipulation of the pulse sequences, which are the specific conditions of the magnetic perturbation of the baseline. DTI or diffusion tensor imaging is a subset of MRI in which the orientation of water molecules in neural fiber tracts are highlighted from the MRI data.

In contrast, the functional imaging techniques of positron emission tomography (PET) and single-photon emission computed tomography (SPECT) attempt to measure metabolic properties of the tissue by means of the introduction of an external radioactive tracer that “labels” a specific biochemical entity that is intrinsic to a brain process, such as blood flow or metabolism, or syndrome-specific markers such as abnormal proteins or receptor distribution and properties. Functional MRI (fMRI), which takes advantage of the association between regional blood flow and neural activity, has become the most widely used technique for functional brain mapping and visualization of stimulus-specific regional brain activations.

Over a relatively wide range of metabolic demand, increased demand is coupled with increased blood flow, which leads to an increase in oxygen extraction from the blood and a consequent reduction in the oxyhemoglobin/deoxyhemoglobin ratio. Since these two molecules have different magnetic properties, the BOLD (blood oxygen level dependent) signal that emerges can be detected, and is related in a direct but complex manner to neuronal activity. It is unfortunate that technical aspects of fMRI, such as the influence of magnetic field strength, field heterogeneity, subject movement, signal strength, tissue artifacts, etc., that can distort or even invalidate the imaging data, are often lost in the color-coded, highly processed, and distilled images that are generally far more clear than the data warrant.

A less widely used, yet experimentally similar functional imaging technique is quantitative electroencephalography (qEEG), which uses computerized techniques to more accurately localize the familiar electrical signals from the brain that are detected by scalp electrodes. The electrical changes can be distinguished either from baseline or from a comparison reference group after data analysis that includes the mathematical solution to the Inverse Problem, that is, the problem of identifying the intracerebral loci from which the signals arise.

At the time of this writing, the imaging techniques of general applicability in the courtroom have been broadly grouped into two large categories: structural imaging (CT and MRI, including DTI) and functional imaging (PET, SPECT, fMRI, and qEEG). All of these techniques in fact reflect physiological properties of the brain, and the distinction is largely predicated upon whether they are relatively static (state-independent) or

relatively dynamic (state-dependent), thus defining the context in which the data to be acquired will be interpreted. If the image is largely invariant over time and is not perturbed by transient stimuli, it is termed structural.

It is important to realize that there are two streams of data that must be joined to produce the eventual image of the physical or physiological data. The first stream is the instrument stream: this includes all of the considerations that must be accounted for in data acquisition and processing, such as specific signals versus random signals (noise), the homogeneity of the detection elements, the sensitivity and specificity of the method, and the stability of the measure during the time the image is being acquired.

The second stream is the physiological stream: this includes deconvoluting the total of specific and random neural activity that is observed in the field of view, correcting for variations in stimulus threshold and response, heterogeneity of response over the time course of the experiment, degradation of the data due to factors such as movement, location of the signal source in the brain, and session effects such as fatigue, loss of attention, change in mental state, etc. This is relatively easy with the structural imaging techniques such as MRI in which much of the information can be discerned by means of varying the signal acquisition parameters. It is more complex for the functional techniques.

Finally, one has to evaluate the fidelity and relevance of the data and its reproducibility over time (e.g., the next day, months, or years before or after the image was obtained). Yet the complexity of the human brain requires a set of simplifying assumptions to increase the signal-to-noise ratio. Are the particular assumptions reasonable? Can they be validated? Is the technology appropriate to address the question of interest? The answers to these questions are not necessarily simple or obvious. For example, can one reasonably expect that a scan of any type will reveal or predict a particular behavior or thought that took place months or years before? The task is not so different from that faced by a psychiatry resident attempting to make diagnoses on individual patients who are all peacefully asleep in their beds.

It must be kept in mind that for many techniques a simple challenge that can elicit a behavioral response does not give a signal adequate for either identification or comparison. In the research context, the challenge is often repeated multiple times, and the signals are then summed and compared to data acquired from a large group of subjects or to multiple acquisitions of the same subject in a reference state.

An aspect of brain imaging that is generally underemphasized but is of enormous importance to psychiatry and to forensic psychiatry in particular is the notion of resolution. Since an image is a pictorial representation of a dataset, it is generally appreciated that spatial resolution is of great significance, and hence that greater resolution is always a benefit. The

spatial limitation of any imaging technique is generally governed by the physical principles that are intrinsic to each methodology. Nevertheless, one can use statistical analysis techniques that enhance the apparent resolution, albeit at the expense of including further assumptions. Thus, a more detailed picture is not necessarily a better picture or a picture with greater fidelity to the actual physical/physiological system being imaged.

Temporal resolution can be divided into two parts and is related to the process to be evaluated. If one is interested in the structural image, the time to acquire that image can be relatively long without impairing the data (e.g., seconds to minutes or even longer) while for functional data, it is important to have a time of data acquisition that is consistent with the process to be measured. For example, it takes but milliseconds to form a thought, but only electrical techniques acquire data fast enough to be consistent with that process, while the more common functional techniques such as fMRI and PET take seconds or minutes to acquire sufficient data for analysis.

Paradoxically, one of the great difficulties of image analysis is the necessity to truncate much of the data. There is a tendency to emphasize the gross features that are relatively easy to distinguish because they are common to much of the population. This is done at the peril of ignoring much of the idiosyncratic data because it is difficult to isolate it from the noise. This is a long-standing problem for which there is no obvious solution. It should not be too surprising that the brain, like the heart and other organs, can develop collateral pathways in response to damage, and that individuals will develop unique pathways to use their brains to interact with their environment. Even with genetically engineered laboratory rats, reared together, the response to the same visual stimulus leads to heterogeneous brain activation. Unfortunately, the imaging techniques currently available lack the sensitivity to identify likely compensatory pathways, and these generally go undetected.

As a simple example of data truncation and elision, consider a reunion with an old friend with whom you have had no contact in years. Within a paragraph or two, a conversation ensues as if time has hardly passed. The clear implication is of the enduring stability of character structure and personality organization and the relative insensitivity of these to enormous amounts of intervening stimuli and contexts. In the courtroom, there is the implicit, but erroneous, expectation that brain imaging is capable of filling in the gaps between fact and fantasy, between wishful thoughts and actual deeds, an expectation more consistent with the appeal of phrenology than with the limitations of present science.

COMMON USES OF NEUROIMAGING IN COURT

In recent years there have been attempts to introduce neuroimaging as evidence in a wide range of legal contexts. However, there are a few legal

scenarios for which the presentation of neuroimaging evidence is becoming especially common. These can be divided into two broad categories. The first group consists of cases in which the diagnosis in question clearly stands to be supported by neuroimaging findings, and, conversely, weakened if no neuroimaging abnormalities are found. In these cases there is an easily understandable and relatively direct connection between the neuroimaging and the clinical condition at issue. In some cases, neuroimaging may have been a part of the diagnostic workup even before any litigation began. The primary examples are traumatic brain injury and dementia. Brain injuries not caused by mechanical traumas (e.g., automobile accidents, falls, assaults, gunshots), but resulting from medical compromise (e.g., cardiac arrest, obstetrical complications, toxic exposures) also fall into this category.

For the second category, neuroimaging is used not because a diagnosis or suspected diagnosis suggests a high likelihood of identifying abnormalities, but because the standard of admissibility for the imaging evidence has been significantly lowered. This occurs specifically in the penalty phase of a capital case. With the question posed to the jury literally a matter of life and death, the defense will seek to introduce any and all evidence that may possibly sway the jury toward sparing the defendant's life. In this phase of a capital trial, the judge allows a wide range of evidence to be admitted for purposes of mitigation, and relaxes the standards which apply in other proceedings.

Examples of Legal Situations Where Neuroimaging May Be Introduced

There are many legal questions where one side seeks to establish either a specific clinical diagnosis, or that functional impairment is present. In civil proceedings such as personal injury and malpractice cases, the plaintiff can introduce neuroimaging to support a claim for damages. Questions of capacity arise in the context of contract disputes, wills, and guardianship. In these types of cases neuroimaging may be used to buttress the argument that the person examined currently lacks the relevant capacity. Disability, that is, determining whether someone is capable of working, is another area of law where neuroimaging could theoretically be applied, although this is currently less common than other uses.

In criminal cases, neuroimaging is most likely to be used for the purpose of diminishing culpability. Typically used by the defense, it can be used to argue diminished capacity (which, if successful, results in a conviction for a less severe charge, for example, second-degree murder instead of first-degree murder or manslaughter instead of second-degree murder). Neuroimaging might also be used when the defendant has pled not guilty by reason of insanity, or conceivably in an unconsciousness defense, which could result in a full acquittal. But perhaps the most common situation where neuroimaging is used in a criminal context is

death penalty mitigation, discussed in more detail below.

Traumatic Brain Injury

Head injuries are extremely common, and many result in some degree of disruption of brain functioning. This disruption is indicative of injury to the brain, that is, traumatic brain injury (TBI). Such injuries are typically classified as being mild, moderate, or severe. For moderate and severe traumatic brain injury, structural neuroimaging with CT or MRI will typically identify pathology acutely, such as hematomas and areas of acute intraparenchymal hemorrhage; later, in the subacute and chronic stages, areas of gray matter necrosis (encephalomalacia), gliosis, and enlarged ventricles (due to tissue loss) can be detected.

In some situations the organic damage resulting from a moderate or severe traumatic brain injury may be difficult to visualize. For example, in injuries caused by rapid acceleration or rotation of the head, axonal shearing, termed diffuse axonal injury (DAI), can occur at the microscopic level, potentially leading to significant functional impairments. Unless the area affected by the DAI is of significant size, it may be undetectable by standard CT and structural MRI modalities. If DAI is suspected, specific MRI sequences such as gradient-echo offer superior possibilities of detection.

Modern neuroimaging techniques, especially structural MRI, find one of their most robust and least controversial uses as courtroom evidence in cases of moderate and severe TBI. Most commonly, findings of structural damage are used to augment evidence of neuropsychiatric impairment obtained through neuropsychological test batteries and/or psychiatric interview and review of records. Similarly, evidence suggesting embellishment, exaggeration, or outright malingering of behavioral or cognitive problems is strengthened if no lesions are found with neuroimaging.

Functional neuroimaging with SPECT or PET is often performed in forensic cases of suspected TBI. For optimal utility, such studies should be correlated with structural imaging with MRI when possible, or else with CT. Typical findings are hypometabolism in, and in some cases extending beyond, the cortical areas of damage seen on the structural scan. Correlating a functional scan obtained months or even years after the TBI with a CT or MRI scan obtained in the acute period after the initial incident provides additional evidence that the functional changes are the result of the TBI and not some other cause.

Abnormalities in SPECT and PET are relatively nonspecific, and can be seen in a variety of psychiatric and medical conditions in addition to TBI. These imaging techniques do not produce a consistent pattern in TBI patients that allows for the exclusion of other causes. In cases of mild TBI (mTBI), some authors have warned against the use of SPECT or PET due to

the high rate of false positives.

There is controversy surrounding the use of both structural and functional neuroimaging for legal purposes in mTBI. Even the definition of what constitutes mTBI is not free from debate. Beyond dispute is the fact that functional recovery after mTBI is highly variable across patients, both in terms of time course and in terms of whether there is ultimately complete recovery or residual impairment. While most people who experience mTBI recover fully with no sequelae, a small subset are left with deficits and some are significantly impaired.

When an alleged mTBI and its aftereffects are central to a legal case, both sides can put forth strong arguments in favor of their point of view and dispute key elements of the case. Was there in fact an mTBI in the first place? If there was, is there ongoing functional impairment, or is the patient deliberately exaggerating or manufacturing deficits for secondary gain? Or is there another, unrelated cause explaining the patient's current difficulties?

Under these circumstances it is not surprising that the legal system will look to neuroimaging in the hopes of providing some clarity to the proceedings. Unfortunately, it is not clear that the current state of the science is up to the task when it comes to mTBI. Structural MRI as well as functional techniques such as SPECT and PET often show no abnormalities in mTBI, and there is no specific pattern of findings with these modalities that confirms the existence of an mTBI. Some expert witnesses do employ SPECT and PET in mTBI, but this approach is not universally accepted, and their testimony is not always admitted into evidence by the judge.

The relatively new MRI technique of diffusion tensor imaging (DTI), which generates maps of white matter tracts, allows for quantification of the integrity of those tracts. In theory, this method could identify disruption of white matter connectivity even in cases where other structural or functional techniques do not show any abnormalities. However, the application of DTI in a legal setting to establish the presence of an mTBI is currently controversial and is by no means accepted by all neuroimaging experts. DTI is not a standardized procedure like a CT scan or even a standard structural MRI scan. Currently it is primarily a research tool, with different laboratories using different parameters, statistical methods, and mathematical transformations of the raw data. Furthermore, DTI shares weaknesses common to most neuroimaging techniques: in general, it cannot identify the cause of any abnormalities that are seen. It also cannot establish that such identified abnormalities are the cause of the patient's functional impairments.

To summarize, structural neuroimaging, primarily with MRI, is routinely used in legal cases involving moderate and severe TBI with little to no controversy. In some cases functional neuroimaging with PET or SPECT is also helpful. The state of the science when it comes to mild TBI is

unsettled, with experts arguing vehemently both for and against the use of functional neuroimaging as a method for illuminating the legal question.

Dementia

Dementia, also known as major neurocognitive disorder, is another diagnostic category for which it is relatively common to see neuroimaging data introduced in legal proceedings. Except for cases of dementia directly resulting from a TBI and a few other rare circumstances, dementia does not result from someone's harmful acts or omissions, so legal cases involving dementia are more likely to center on issues of capacity or of criminal responsibility, rather than personal injury or malpractice. Many of the same caveats that apply in cases of TBI also apply here. Neuroimaging is not diagnostic of dementia, and it is possible to have dementia without definitive neuroimaging abnormalities, as well as to have abnormal imaging findings suggestive of a dementing illness without actually meeting criteria for dementia.

In recent years there has been significant progress in identifying and differentiating various forms of dementia, including, for example, the isolation of genetic markers for different subtypes subsumed under the rubric of frontotemporal dementia. Neuroimaging protocols for dementia have also become more sophisticated. Specific ligands for PET imaging of amyloid plaques and neurofibrillary tangles have seen widespread use in research and may soon enter clinical use. It can be anticipated that these types of scans will eventually be used in court, in addition to the more traditional structural MRI and PET or SPECT scans visualizing metabolism which are often submitted as evidence today. Combining information from neuroimaging (whether structural, metabolic, or specific for pathological features such as amyloid) with genetic data has the potential to provide even more persuasive evidence for the presence of a dementia.

It must always be kept in mind that in nearly all legal contexts the mere fact of a diagnosis, even something as potentially devastating to functional abilities as dementia, is not sufficient to settle the legal question. As will be pointed out throughout this chapter, in most cases in which a psychiatrist is invited to participate, the legal system is primarily concerned with mental states and/or capabilities. While neuroimaging can be useful in supporting a diagnosis of dementia, the impact of that diagnosis on the subject, as plaintiff, defendant, testator, etc., must be established through behavioral data obtained by examining the subject (if living), obtaining collateral information from family members or other witnesses, and reviewing available medical records. Formal neuropsychological testing is also crucial in many cases of dementia involving a living subject. Ultimately, even after a diagnosis of dementia is made, the nexus between that diagnosis and the mental state or capacity at issue must still be shown, and neuroimaging is not a stand-alone tool for achieving this.

Death Penalty Mitigation

In those US jurisdictions which provide for capital punishment for murder, the proceedings are bifurcated into two phases. In the guilt phase of a capital trial, the jury reaches a verdict of Guilty or Not Guilty, just as in any other criminal case. If the verdict is Guilty, a second phase, the penalty phase, occurs. In this proceeding, the prosecution presents aggravating evidence for the purpose of persuading the jury that the defendant should be sentenced to death. The defense in turn presents mitigating evidence with the goal of convincing the jury to vote for a sentence of life imprisonment.

The rules of evidence in the penalty phase of a capital trial are significantly different from the rules governing evidence in other criminal proceedings. The defense is allowed to present evidence such as the defendant's history of being abused as a child, for example, or bring up his positive character traits, or point out his exemplary behavior since being incarcerated.

With increasing frequency, neuroimaging is being performed on capital defendants, and the results introduced at the penalty phase of the trial. Efforts by the prosecution to bar neuroimaging evidence, which are often successful in other criminal settings, are likely to fail when the defense seeks to introduce neuroimaging as mitigation evidence. Capital sentences have been overturned on appeal because the trial judge denied the defense's request to perform neuroimaging, as well as in cases where defense counsel failed to request neuroimaging.

When neuroimaging is offered as mitigation evidence in the penalty phase of a capital trial, it is likely to be allowed due to the wide latitude granted for most types of evidence to be admitted in that phase. Perhaps even more importantly, the jury is able to use such neuroimaging evidence for the general purpose of reducing the punishment from death to life in prison on the basis of any brain abnormalities. It is not necessary that a specific diagnosis be demonstrated. Similarly, no specific link between any abnormal brain structure or function and the crime for which the defendant has been convicted need be established. Neuroimaging evidence that the defendant's brain has some type of abnormality may simply add to the jury's list of mitigating factors. Under these circumstances, the likelihood of neuroimaging being useful to the defendant is higher than in most other criminal cases.

Given the lowered barrier to admission, and the relatively high potential for tilting the balance in favor of sparing the defendant's life, it is not surprising that neuroimaging has become very common in capital cases. In fact, failure to at least consider obtaining neuroimaging in a capital case on the part of the defense attorney could be considered grounds for an appeal based on a claim of ineffective assistance of counsel.

Recently a new approach to the use of neuroimaging in death penalty mitigation has emerged. Antisocial personality disorder (ASPD) and psychopathy have generally been considered aggravating factors. However, an argument can also be made that such conditions are mitigating in the context of a death penalty deliberation, in that the abnormal condition of the defendant's brain reduces his ability to recognize moral imperatives and therefore to exercise control over his behavior and to appreciate his culpability.

Functional MRI results suggesting a diagnosis of psychopathy have been introduced in the penalty phase as a mitigating factor. However, there is also a concern that in such cases, scientific evidence supporting the presence of ASPD or psychopathy could in fact be used by the prosecution as an aggravating factor, who would argue that the defendant represents a future danger and is not amenable to rehabilitation. These issues are discussed further in a subsequent section.

OBSTACLES TO THE USE OF NEUROIMAGING IN LEGAL PROCEEDINGS

Capturing Thoughts

Perhaps the single greatest obstacle that confronts the meaningful introduction of imaging data into legal proceedings is that the imaging for forensic purposes is almost invariably done after the fact and under essentially laboratory conditions. That is, a major limitation in the attempt to understand the relationship of brain activity to behavior is that there is generally no image of the brain that is antecedent to the behavior or activity that is at issue in the legal proceeding. Another obstacle is posed by the inability of any present technique to image a thought, to establish intent, or to establish the relationship between brain organization and function and any specific behavior or set of behaviors. While it might seem superficially attractive to ascribe a particular behavior to a particular brain organization (e.g., psychopathy), not all psychopaths commit crimes, nor has it been established that a particular brain organization facilitates the commission of a crime, any more than the fact that most murders in the United States are committed by people with dark hair establishes that hair color either predisposes to or is causal of criminal activity.

For ease of discussion, consider the introduction of imaging data in the legal context from two different perspectives: the introduction of structural imaging data and the use of functional imaging data. First and foremost, one must define the question that is to be answered by the introduction of imaging data. In the case of injury, there are at least two major questions: First, is there evidence of injury, and evidence of the consequences of injury? Second, does the imaging modality reflect the question at hand?

For example, if there is a history of trauma, is there evidence of trauma on the brain image? Was the timing of the imaging relevant to the event

itself? One may have had trauma with loss of consciousness, but an MRI scan taken several years later might show no evidence of a persistent structural alteration. Alternatively, an image taken several years later might show evidence of damage, but this in no way establishes the state of the individual's brain at the time of the alleged trauma. In other words, there could have been a pre-existing condition; without a scan before the trauma of record, one can never be certain that a pre-existing condition was not present. On the other hand, a CT scan performed shortly after alleged trauma could provide incontrovertible evidence of a recent bleed. While the scan may be helpful inferentially or interpretively, it is neither necessary nor sufficient to impute *behavioral* causality in the absence of other information.

By the same token, a DTI scan of a person's brain after trauma might show a disturbance in the connectivity of long fiber tracts, but in and of itself without correlative data one cannot establish that the disturbance in connectivity was due to the event in question. Furthermore, a disturbance in connectivity does not *prima facie* determine clinically significant behavioral compromise, which must be measured by other methods. It must always be remembered that structural imaging techniques image structure, not function, and functional relationships to structural abnormalities must be established by other means.

Large-scale, multi-year research efforts, such as the Human Brain Project in Europe and the National Institutes of Health's BRAIN (Brain Research through Advancing Innovative Neurotechnologies) Initiative, are now underway with the goal of bridging structure and function. The "connectome" and functional connectivity maps identify synchronous neural responses to stimuli. These are useful landmarks of neural pathways that are clearly associated with responses to specific stimuli, but in and of themselves are neither necessary nor sufficient to account for concomitant behaviors. Not all people take the superhighway; some use back roads and some use other modes of transportation, but when they arrive at their destination there is no way of distinguishing among them, unless the signal-to-noise ratio is markedly greater than the threshold of the methodology employed.

If the legal question is one of intent and relates to the state of a person's mind at the moment of a specific behavior that has occurred in the past, it is fairly obvious that there is no imaging technique that can elicit the historical state of mind. If the question is the likelihood of diminished capacity or responsibility, imaging can and has been used, but is subject to many caveats. There is ample evidence from many different functional imaging techniques that there are identifiable characteristics obtained by imaging groups of subjects that appear to be highly correlated with certain neurological and psychiatric conditions when the sample size is large and compared to groups that are well matched demographically. This is

particularly true in the dementias and even in “functional” disorders such as schizophrenia and major depression and perhaps even the world of behavioral types and disorders such as psychopathy.

The issues that arise in the courtroom have to do with the relevance of group data with high interindividual variance when the values are applied to the individual who shows a difference from the group norm. In general, imaging data is of greatest utility when it is used to show consistency with or support for another form of evaluation rather than being thought of as pathognomonic in and of itself.

In the landmark New York City case of People v. Weinstein, the question before the court was the admissibility and relevance of a fluorodeoxyglucose (FDG) PET scan to the behavior of the defendant, who had pushed his wife out of their apartment window to her death in the course of a domestic quarrel. He was arrested and charged with murder. A routine pretrial CT scan revealed the presence of a subarachnoid cyst that was pressing and distorting Mr. Weinstein’s frontal cortex. A subsequently performed FDG PET scan unsurprisingly revealed that this functional image was indeed grossly abnormal by any standard, since this very large cyst occupied a significant amount of the calvarium. By history, the cyst was likely about 40 years old and yet Mr. Weinstein lived an unremarkable professional and social adult life, maintaining a white-collar position and never exhibiting any symptoms that warranted an imaging procedure and with a total lack of awareness that his brain was, structurally speaking, highly abnormal.

The defense contended that this brain abnormality led to diminished ability to inhibit an aggressive impulse, yet there had been no evidence of diminished ability to inhibit impulses that was apparent over many years that his brain was structurally deformed. After the evidentiary hearing, the Court allowed the introduction of the PET scan into evidence. Prior to trial, Mr. Weinstein accepted a plea agreement and pled guilty to a reduced charge of manslaughter.

Not having a reference scan of the subject before an accident or illness or before a specific behavior is manifest limits the value of the imaging modality as proof in and of itself of a change in state. Nevertheless, there is increasing introduction of imaging data in the courtroom. While experts can argue about the technical relevance, most would agree that an image is so compelling and can be so persuasive despite its technical limitations, that it is rarely excluded from at least the mitigation phase of a trial (see prior section). When the issue is one of possible diminished capacity, either due to diminished response to a behavioral or cognitive challenge as shown by either fMRI or PET scanning, functional imaging has had its impact in the courts, and this will likely continue. When the issue is one of altered behavior or diminished cognitive functioning subsequent to traumatic brain injury, then techniques such as DTI or altered tissue properties such

as shown in structural MRI have been compelling ancillary information, even if they do not directly measure the properties at issue.

Whether this type of functional imaging *per se* should be used as primary evidence of diminished capacity in such matters is the subject of considerable debate and dispute, since it is obvious that there are people with aberrant brain images that are discovered incidentally since their behavior is otherwise unremarkable. On the other hand, there are people with aberrant behavior who have normal scans and people with aberrant behavior who have abnormal scans dependent upon the technique that is used. Structural imaging is often the least contributory when the issue before the court is of a specific behavior, although it can be useful and relevant in support of alterations of brain parenchyma that correlate temporally with a documented brain injury and persistent change of mental state.

The explanation for this lies in the enormous plasticity of the human brain and its ability to function normally despite innumerable interindividual variations. A most extreme example of this was noted years ago when a PET scan of a normal British volunteer, a university graduate and mother, whose PET scan was remarkable for a thin cortical rim of gray matter, with little discernible subcortical metabolism and whose visual cortex was in the front of her brain rather than the occiput. She had been a volunteer "normal" subject and had no antecedent psychiatric, neurological, or behavioral concerns.

A more common occurrence is illustrated by the case of *U.S. v. Gigante*. Mr. Gigante had two separate SPECT scans that were read as abnormal and consistent with schizophrenia or dementia, a CT scan read as abnormal and consistent with dementia, a PET scan read as abnormal and consistent with Alzheimer dementia, yet he later admitted to feigning in the service of evading justice. Whether or not any of his scans were in fact abnormal should be considered in the light of whether a significant deviation from a group mean is a sufficient indicator of abnormality. Five years later, Mr. Gigante was clearly no longer demented and remains perhaps the only documented case of an Alzheimer dementia diagnosed with a medical certainty who was cured by incarceration.

The case of *Illinois v. Dugan* is an example of the medicalization of a psychiatric disorder in the service of death sentence mitigation for a convicted child murderer. The defense argued that the fMRI images of the defendant, obtained 2 decades after the crime, showed a pattern that was clearly consistent with that of a large group of incarcerated psychopaths. The defense argued that on the basis of the similarity of the defendant's scan to that of the scans of other psychopaths, Mr. Dugan must have had "diminished capacity," since psychopathic personality meets a set of diagnostic criteria. Thus, the defense contended, he is (perhaps was) biologically not normal, and should not be subject to the death penalty

under Illinois state law.

The relevance of imaging findings to the legal questions is of course highly dependent upon the central question in any individual case. This generally ranges from the determination of direct brain damage that is generally established by structural imaging techniques, to the relationship of a pattern of brain organization or activity to a particular behavior such as a crime, to the attribution of the persistent change in posttraumatic behavior that can be attributable to an "abnormal" brain image. In particular, imaging data obtained by the functional imaging techniques are generally highly dependent upon medication status, hormonal influences, and mental state at the time of the scan, which are likely to be far different from the conditions relevant to the central legal questions.

Defining Normality

Images obtained months or years after the behavior at issue, and their analysis and interpretation that are presented to the court, are related by inference to a hypothetical "normal" prior scan that the subject presumably would have had, in order that any change in mental status, mood regulation, impulse control, activities of daily living, etc. can be attributed to those brain functions or structures that could be related to the behavioral presentation. For example, how does one establish for a given individual whether or not his ability to play sports has been compromised on the basis of an image? How does one establish on the basis of an image whether or not a claim of a persistent mood change was due to a specific antecedent injury? In addition to the issues of comparison of the subject to a reference group, the expert is faced with the fact that rarely does one have access to an image of that individual patient taken under the same conditions prior to the legal matter at hand.

The scientific obligation would be to establish that the change in the image in fact is causally related to the changed behavior. The legal standard sets a much lower bar. In general, these concerns are often obviated in the face of indisputable structural damage in large regions of the brain known to subserve a particular behavior or set of behaviors or by the inference that something unusual in an image should be equated with a functional medical or psychological limitation. Much of this reasoning comes from lesion studies that by their very nature often failed to generate or identify compensatory mechanisms and pathways, both functional and physical.

The examples above give an indication of the complexity of the concept of normality. Normality is not merely a statistical term associated with a defined mathematical distribution, but is complicated by the realization that any such definition must be context dependent. It may be normal to be of diminutive stature in a population of pygmies; it may be normal to be very aggressive in an athletic competition; it may be normal to be unusually quiet while sitting in an auditorium listening to a lecture; it may be normal

to restrict entry to one's own home yet highly abnormal to act in a similar fashion when the property is not one's own. Clearly, the concept of normality has to be considered in a much more complex set of domains than is typically associated with the interpretation of a brain image in a forensic situation, where reductionist tendencies would lead one to consider only that the events before the court determine or are determined by the imaging data.

"Unusual" is often equated with "abnormal," and abnormal, particularly in the context of regional decreases in metabolic activity as shown either with PET or fMRI, is generally equated with dysfunctional. This equation is incorrect but also widely used. It has never been shown that there is an energy consumption requirement that differs between an efficient thought process and an inefficient one. There is no evidence in the literature, for example, that it takes more energy to think a bad thought than a good thought.

Perhaps the most common characteristic of functional brain imaging is intersubject variability. When 20 medical students were asked to perform the same simple verbal fluency task, the individual BOLD responses varied from virtually no response to very large regional changes. There is no generally acceptable interpretation for this variation. Is it a function of differing amounts of background noise, or is it related to the efficiency of a given brain, or to a whole host of ever more complex neurochemical relationships that are as yet poorly understood? In studies with genetically bred rats reared together and even scanned together, there is abundant evidence from many laboratories that there is significant metabolic variation both in the resting state and in terms of stimulus response that belies the simple assumption that identical twins have identical brains, even at the level of a rodent. When studying an individual human being, with or without stimuli, there is an unusually large variability of metabolic activity over the course of a single 24-hour period.

This makes the concept of normality surprisingly complex. Indeed, scientists might study a population defined by other terms, such as psychopathic behavior that has led to incarceration, and find that their brains have an organization that may be strikingly similar. However, there is, as yet, no evidence that the brains of psychopaths who have not been incarcerated or who have not behaved in a criminal fashion are organized differently. There is an almost irresistible tendency for people to be reductionist and attempt to use brain imaging as the modern equivalent of 19th-century phrenology in which a particular organization or observation leads to or explains or facilitates a complex set of behaviors. At the present time, while there indeed is a difference of opinion, there is little evidence to support the notion that any of the current imaging technology has as yet produced a pathognomonic signature of a particular thought, feeling, or behavior.

What is normal in one context is abnormal in another. It is often forgotten that even in the mathematically defined normal (Gaussian) distribution, a measured value two standard deviations from the mean does not mean that the value is necessarily abnormal. To equate abnormality with dysfunction is a distortion of the definition of the terms, yet is widely used without clarification or qualification in the psychiatric literature. For example, it is well known that some antipsychotic medications will cause an increase in regional brain metabolism, while others will cause a decrease in regional brain metabolism in the very same brain regions. In both clinical situations, the patient's psychotic symptoms improved. It has also been known for the past 2 decades that a particular brain stimulus will cause regional changes in the BOLD effect measured by fMRI that are increased in some regions and decreased in others. While the decrements are often ignored when images are displayed to illustrate activation associated with a particular pathology, it is clear that these decrements have physiological meaning; indeed, they have been interpreted and placed into the context of the "default mode" of the brain.

The images of a given subject used in the courtroom are generally evaluated in comparison with group normalized images. It is hardly surprising, therefore, that the images from any individual will differ from a group normalized image. If, for example, one were to take 12 jurors in the jury box, one could indeed normalize (i.e., average together) their faces to produce a single composite image from this group of (presumably) normal people. Yet no single individual's image will conform to that normalized image. If one were to use a different dimension and measure height, the individual heights of the jurors might vary from 60 to 80 in. Not a single individual might have a height equal to the mean, and for none of them would either measure reflect their ability to function as a juror, their marital status or their economic standing.

The expert, judge or jury can ask whether or not the image is normal, with normality being defined as being without obvious pathology. The unusual case of the college graduate whose visual cortex was where the frontal cortex is usually located noted above illustrates but one difficulty with defining normality. To be normal, must the brain be normal in all dimensions, that is, be functionally isotropic? If not, is there some dimension that is more relevant to the case at hand than another? Was she anatomically normal? Was she behaviorally normal? Was she functionally normal, both physiologically and psychologically, etc.? Most important is whether the imaging methodology and scan conditions allow the accurate measure of the property that is most relevant to the legal issue. Hence the distinction between what is measured, the information gleaned from the analysis of the imaging data, the inferences that are drawn from that analysis, and the comparison with either a "normal" reference or a comparison state are crucial to presenting a bona fide scientific picture to

the court. It is easy to present pseudoscience. Without knowing how they were acquired, analyzed, simplified, and interpreted, it is well known that images convey such an enormous amount of data in such a concise fashion, that even of poor quality, they will be at least as apparently meritorious to the unsophisticated as the most elegantly and rigorously acquired and presented data.

In a forensic context, the concept of normality can be very complex. Should normality be predicated on properties of a group of people chosen at random? Should it be a group chosen for the absence of psychopathology, or ethnic similarity, or education, or political beliefs, age, etc.? How many demographic variables should be included to assure an adequate comparison with the index subject? Should subjects be tranquilized, should they be exposed to ambient stimuli? Should their brains be constrained by a task, or left unconstrained in the so-called resting state? Should the eyes be open or closed? Is the brain function to be imaged so sensitive that a minor change in state will alter the image, or so stable and insensitive that the signature remains invariant over time? Clearly brains come in different shapes, sizes, and ages, and have had different life experiences and reflect genetic and epigenetic diversity. These and similar considerations make the task of establishing an appropriate reference group a formidable undertaking. Nevertheless, images are generally proffered in the courtroom in support of one contention or another and of course will show that virtually any subject will differ physiologically from the group norms. In large measure this is accomplished by means of scaling the images to either magnify differences in a graphical display; by using arrows to delineate regions of difference between the index subject and the reference image(s) even if the data have low statistical significance or provide little physiological evidence for the forensic contention; and most impressively the use of visual contrast that can make small differences seem huge.

A common example of this is scaling the data of a set of images in such a manner that the regional differences are artificially embellished. For example, if the putatively important region of interest had an arbitrary average rating of 83 units and every region above 80 units was colored red and everything below 80 units black, then an area might appear to be physiologically dead that is only a few percent lower than the area that is physiologically active. While there is nothing illegal about presenting data in this manner, it certainly can be misleading. The differential sensitivity of the eye to colors of different wavelengths is well known, and is often exploited in the presentation of marginal data in the court room.

The problem remains that any individual image is analyzed with reference either to the same brain under different conditions, or to a group of reference brains whose signals have been summed, smoothed, and normalized. In the forensic situation, it is virtually impossible to acquire

the scan that is an appropriate reference to the behavior at issue both because what is measured are electrical signals, not behaviors, and because it is impossible to know the antecedent state of the brain before the matter at hand has transpired. This results in imaging data that has to be evaluated in probabilistic terms, that is, it must be addressed on a statistical basis and virtually never leads to a unique solution.

Although the solution is not necessarily unique, it does not mean that imaging data is of no utility in the forensic context. Advances in technology, and advances in the analysis of brain images in conjunction with powerful new statistical techniques have indeed brought spectacular insights into brain functioning under a variety of conditions that were heretofore never available. From early region-of-interest analyses to the leap afforded by statistical parametric mapping based on the theory of Gaussian fields, to pathway analysis in time-locked connectivity measures and many other analysis strategies that are constantly being developed, explored, and validated, there is every reason to believe that brain imaging is here to stay in the forensic setting and will become increasingly introduced as evidence. Whether this will be as compelling to the cognoscenti as it is for the layman has yet to be settled.

Nevertheless, whether warranted or not, the pressure to reduce the relationships among mind, brain loci and pathways and complex behaviors to a unique interpretable pattern is both in vogue and clearly attractive. At the present time, it is critical not to turn science into phrenology. Brain imaging should not be granted the status of an unalterable truth nor consigned to the garbage heap of useless pseudoscience, for it is neither. It must be remembered at all times that these techniques are measuring various physical properties of the brain with detectors outside of the brain, using, of necessity, many simplifying assumptions, both mathematical and physiological. The various modalities employed have different sensitivities, specificities, temporal and spatial resolutions and greater or lesser proximity to the behavioral question that is generally before the court. Each measurement has its own set of errors and uncertainties. To this must be added the fact that every calculation in the chain of processing leading from the behavior and its underlying physiology to the final image that is displayed is predicated upon multiple, diverse simplifying assumptions and inferential conclusions. At the time of this writing, brain imaging is still in a state of rapid development after less than half a century of development. A high degree of caution should accompany any claims that brain imaging alone will explain behaviors or that for any behavior there must exist a characteristic brain image.

The "Christmas Tree Effect"

The preceding discussion highlighted some of the key challenges to the reliable and relevant application of neuroimaging data to legal questions.

Many of these obstacles can only be appreciated after detailed discussion and explanation, and involve highly technical concepts. A number of observers have expressed concern that judges and juries may be unable to keep these caveats in mind, and will be swayed by the seemingly infallible brain scan, even when the claimed results of that scan are unwarranted, or are accurate but irrelevant to the legal question at hand. This leads in turn to the argument that the presentation of images obtained with expensive, high-technology scanners is in many cases likely to be more prejudicial than probative. In other words, the apparent scientific proof of abnormalities in the brain obtained with neuroimaging will be given excessive, unfair weight by the judge or jury.

The concern that judges and especially juries would have difficulty identifying the proper boundaries of interpretation of neuroimaging data has led some authors to argue for a restrictive approach to admitting brain images. The idea that the sophisticated science used to create such images would cause juries to ascribe undue weight to those images is sometimes referred to as the "Christmas Tree Effect." Related to this issue is the concern that in the 21st century, juries harbor the expectation that parties to a legal action should be able to present precise results obtained using advanced scientific techniques—and if no such data is forthcoming, they will automatically consider the case to be weak. This concern has been referred to as the "CSI Effect," after several popular television series which follow the exploits of fictional crime scene investigators who solve crimes by processing the evidence criminals leave behind, including, of course DNA, but also evidence such as soil or plant material which can be tied to a specific location, flecks of paint from an automobile that can be linked to a specific model and year, and so on.

If the fear of the Christmas Tree Effect and/or the CSI Effect is justified, one would expect, for example, that a jury presented with an image of a defendant's brain lighting up with abnormalities would conclude—on that basis—that the defendant must have had diminished responsibility at the time of the crime. In another scenario, the jury would view images of a plaintiff's brain in a personal injury lawsuit and conclude that the presence of abnormalities indicated with bright colors on a scan means that the action or negligence of the defendant is the cause of those abnormalities, and that the plaintiff is deserving of compensation, when in fact the plaintiff may not have any functional deficits, and/or any impairments (as well as the imaging changes themselves) could be entirely unrelated to any actions or omissions by the defendant in the suit.

Although often cited as an objection to the use of neuroimaging data in court, just how much prejudicial influence can be ascribed to the Christmas Tree Effect is still a matter of debate. Studies of mock jurors have had mixed results, and it appears that earlier studies suggesting that brain imaging was prejudicial may have been overstated. Later studies have

reported that their subjects were able to evaluate the relevance of brain imaging data to the legal question at hand, and did not simply vote in favor of the side that presented that data. Actual systematic polling data from real jurors who have had to confront neuroimaging evidence could shed more light on the question, but so far it does not seem that such a study has been reported in the literature.

In any event, the risk that the prejudicial effect of neuroimaging will outweigh its probative value cannot be dismissed. It necessarily falls to judges to act as gatekeepers to minimize this risk. Given the preceding discussion, it is possible to identify some factors that judges should consider when assessing whether to admit neuroimaging evidence. Neuroimaging results that are offered in isolation, without any correlated behavioral or clinical observations, should obviously be met with extreme skepticism. Scans that are performed without some basis for suspecting neuropsychiatric abnormalities risk earning the pejorative label of a "fishing expedition." On the other hand, scans that were performed and interpreted in the ordinary course of a diagnostic workup, prior to the beginning of litigation, are likely to be viewed favorably, given that they were ordered with a medical and not a legal purpose in mind and are thus less likely to be subject to biased interpretation.

More generally, neuroimaging studies for which there is a solid scientific foundation supporting their usefulness for the condition in question (e.g., moderate to severe TBI, dementia), and where the relevance of the results to the legal issue is clear, should not be barred out of concern that the mere presentation of colorful images will somehow interfere with the jury's ability to weigh the arguments in the case. On the other hand, when imaging evidence is offered to support controversial or dubious claims, allowing that evidence to be presented may create a risk of improperly swaying the jury, given the aura of hard science associated with brain imaging. One such controversial area, the use of fMRI as a means of identifying deception, will be discussed later. Other assertions that should be approached with great caution include, for example, the use of PET or SPECT as evidence of posttraumatic stress disorder (PTSD), the use of DTI to diagnose mild TBI, speculating about intent, planning, etc., on the basis of brain imaging, and the claim that imaging results, in and of themselves, can identify the cause of a particular brain abnormality, and not just its existence.

The Person versus the Brain

The rapid advances in neuroimaging over the past quarter-century have been integral to a profound debate taking place at the intersection of philosophy, law, and neuroscience. At one extreme of this debate are those who argue from a reductionist point of view, asserting that advances in the neuroscientific understanding of the brain demonstrate that free will is an

illusion. Given such a conclusion, some reductionists such as Joshua Greene and Jonathan Cohen have called for a complete overhaul of the criminal justice system, including purging from it the concept of punishment and focusing instead only on public safety and deterrence.

Even stopping well short of the extreme reductionist position, it is possible to envision neuroimaging being used to argue, for example, that a particular criminal defendant lacked the capacity to conform his conduct to the requirements of the law, due to abnormalities in his brain's structure and/or function. Such abnormalities would have been invisible in the pre-neuroimaging era.

It seems reasonable to assume that the percentage of accused criminals —particularly those accused of committing violent acts—in whom some type of neuroimaging abnormality can be detected is not negligible, and may be substantial. Does this mean that in the future, numerous criminal defendants will be able to successfully argue that they are not criminally responsible (or perhaps should be convicted of lesser charges), on the basis of neuroimaging findings?

Arguing against the reductionists, as well as those who predict the widespread use of neuroimaging in law, are other observers who have suggested that the impact of neuroimaging in many aspects of the justice system is and will continue to be minimal. The most prominent of these authors is Stephen Morse, who coined the term "Brain Overclaim Syndrome" to describe what he views as excessive and unjustified claims of relevance for neuroimaging data applied to legal questions.

A number of methodological, technical, and conceptual barriers to the wider use of neuroimaging in court have been discussed earlier. In addition, there are other causes for concern that will not necessarily be resolved by more accurate, standardized, and reliable scanning technologies.

One concern is the question of what information of value to the judge's or jury's deliberations is added by the neuroimaging findings. This is especially an issue when past mental states are in question. For example, if a defendant pleading Not Guilty by Reason of Insanity were to be shown, by conventional fact and expert witness testimony, to have a diagnosis of schizophrenia, to have been psychotic at the time of the crime, and as a result of his psychotic symptoms to have met the standard for legal insanity, a PET scan performed months or years later, revealing abnormalities consistent with the abnormalities seen in patients with schizophrenia would perhaps be corroborative, but not particularly useful, nor necessary to the jury's deliberation. In fact the PET scan could be viewed as redundant—as cumulative evidence, in the legal terminology.

The other side of this coin is the fact that in cases where the evidence from behavioral and/or clinical observation is more ambiguous, neuroimaging is less likely to produce clear findings. For example, one

would not expect someone who performs relatively well on neuropsychological testing and exhibits minimal cognitive impairment to have a functional imaging scan consistent with severe dementia. If the imaging did suggest such a diagnosis, one would of necessity question the scan results, not the subject's abilities. To argue that a highly functional person has severe dementia because their brain scan says so would be untenable. Behavior, not imaging, equals diagnosis.

One of the essential premises of neuroimaging is that it identifies the physiological correlates of mental functions. The observed neuroimaging findings are expected to correspond with the subject's observed behavior. But this means that in situations where behavior is grossly abnormal, as in psychosis or dementia, neuroimaging will often not be necessary for legal purposes, being merely cumulative, while in situations where behavior is more ambiguous, and subject to varying interpretations or explanations, the neuroimaging results are also likely to be ambiguous, and therefore likely to yield little information useful in assisting judge or jury in reaching legal conclusions.

A related, but distinct and more fundamental objection to the utility of neuroimaging in court raised by Morse and others involves the link or nexus between the physiology of the brain, in terms of what can be observed through imaging, on one hand, and the current and especially the past mental states, behaviors, and capacities of the person undergoing that imaging, on the other. It is the latter which are the elements that the legal process must analyze and understand. However, even the most sophisticated functional neuroimaging of today is far from being able to reliably identify and characterize discrete human cognitions and emotions. For many purposes, neuroimaging may never be able to shed light on the critical legal question at issue.

For example, imagine the assertion that observed neuroimaging abnormalities in a defendant's frontal lobe are indicative of an inability to resist impulses, and therefore that the defendant is deserving of mitigation or exculpation. Unless such a defendant is so impaired that he or she is giving in to impulses on a near-constant basis (an extremely rare scenario), there will necessarily be some impulses that they are able to resist. A neuroimaging scan cannot reveal anything about whether the defendant had the ability to resist a specific impulse at a particular time in the past, that is, when a crime was committed by that defendant. Nor, conversely, does the absence of particular neuroimaging findings prove that a defendant's brain was "normal" in its ability to control certain impulses. Yet, in a diminished capacity defense, the difference between a less and a more serious charge and therefore a difference potentially measured in years of prison time, hinges on exactly this question of the capacity to control one's impulses at the time of the crime.

Although neuroimaging cannot shed any light on this question, some

attorneys and experts have and will continue to overstate the benefits of neuroimaging, asserting, for example, that a defendant with a certain imaging profile was incapable of planning. Because of the aura of scientific precision associated with MRI, PET, and so on, there is a risk of judges and juries giving too much credence to such claims. However, the extent of that risk is difficult to quantify, and probably depends on numerous factors specific to a given case.

A number of technical problems constrain the usefulness of neuroimaging in the legal arena. Some of these may be overcome by improvements in the technologies. In addition to these issues are the realities of the questions that are important in the forensic context. Some are permanently inaccessible to neuroimaging. These include determining a person's mental state at a past time point or trying to separate "could not" resist an impulse from "did not." Despite such barriers, clearly any type of blanket ban on neuroimaging evidence would be unwise. Rather, as has been stated, it is critical that, when neuroimaging is offered as evidence, well-trained, unbiased experts explain why neuroimaging is or is not useful for the particular legal question at issue.

CURRENT AND FUTURE CONTROVERSIES IN FORENSIC APPLICATIONS OF NEUROIMAGING

The tremendous expansion of scientific and technical knowledge has created methods for the noninvasive visualizing of brain structure and function that were previously inconceivable. These incredible advances have revolutionized medical fields such as neurology and neurosurgery, and have also been, along with the great strides in the understanding of and ability to manipulate DNA, one of the main driving forces behind the growth of the now-huge field of scientific study known as neuroscience.

The applications of neuroimaging to legal questions that have been discussed thus far have been predicated on those techniques being used to identify abnormalities in structure and/or function associated with a particular diagnosis. Such abnormalities range from the indisputable, as in those resulting from severe traumatic brain injury or advanced Alzheimer disease, to the more contentious, such as abnormalities associated with schizophrenia, bipolar disorder, or milder brain insults such as concussion. Other diagnostic entities, such as PTSD and ADHD, have also been suggested by some to have particular neuroimaging profiles, reliable enough for courtroom use, though the state of the science here is even less settled. However, with all of these conditions, most mental health professionals would be open to the argument that there is at least the potential that a brain imaging technique of sufficient precision to consistently find a "signature" in individual subjects could someday be developed.

More controversial still is the application of neuroimaging for

psychiatric conditions for which the underlying neural changes would seem perhaps even more challenging to identify. Personality disorders by definition do not involve a break from reality, nor do they typically produce the neurovegetative symptoms seen in mood disorders or the autonomic disturbances in anxiety disorders such as PTSD. Do they nevertheless create changes in brain structure and functions that are consistent enough across patients to be reliably detected and categorized with neuroimaging? And what about abnormal sexual preferences, such as the paraphilias? Because of their obvious importance in the legal system, ASPD and psychopathy, as well as pedophilia, are extremely tempting targets for forensic neuroimaging, and have been suggested as conditions which can legitimately be examined at the single-subject level to assist in legal determinations.

Personality disorders and pedophilia are still in the realm of identifying a pathological condition, broadly defined. But diagnosis is not the end of the forensic neuroimaging story. Other applications of neuroimaging have been suggested and even, in a few cases, submitted to courts, that do not involve psychiatric or neurological diagnosis, and are not intended to detect any physiological abnormality or impairment. In theory, techniques such as fMRI lie detection could be used with virtually anyone who can be placed in the machine. It is with these types of methods that one begins to approach a crude form of the technological "mind-reading" that until recently was only discussed in works of science fiction. As will be discussed, the employment of such methodologies for legal purposes is currently in a truly embryonic stage, and such use may in fact never establish a foothold within the legal system.

Antisocial Personality Disorder

ASPD and the related but distinct diagnostic entity known as psychopathy are obviously of great interest to the legal system, primarily although not necessarily exclusively in the criminal context. Neuroimaging has been used as a research tool in the study of ASPD and psychopathy, as well as criminal and especially violent behavior in general, since the advent of modern techniques such as SPECT, PET, and MRI. A rich literature has developed which has identified structural and functional abnormalities in numerous brain regions, including cortical regions such as the prefrontal cortex and cingulate gyrus, and subcortical structures such as the amygdala, in ASPD and psychopathy.

Most of the literature on neural correlates of ASPD, psychopathy, and criminal behavior involves group averages compared to groups of normal controls. ASPD is a heterogeneous disorder, and even if one's focus is restricted to psychopathy, significant variation in phenotype is observed. It is not clear how soon the science in the area will be up to the task of reliably diagnosing psychopathy or ASPD—or significant antisocial personality

traits—in an individual subject, and the related, equally important, but distinct task of ruling out such a diagnosis.

Although the science is not currently reliable enough for general use as a diagnostic tool, a judge has allowed neuroimaging evidence of psychopathy to be presented as a mitigating factor in the penalty phase of a capital trial (the Dugan case), a proceeding where, as discussed in a preceding section, evidentiary standards are relaxed compared to other criminal settings and where the scrutiny to which offered evidence is subjected to is correspondingly reduced. (The Dugan jury sentenced the defendant, a serial murderer, to death.)

Even confining the discussion to death penalty mitigation, however, significant questions regarding the merits of neuroimaging for ASPD and psychopathy remain. Assume for the sake of argument that the science has become sufficiently reliable and accurate for use in diagnosing an individual. It can also be assumed that, unlike in the case of a defendant with schizophrenia seeking to utilize an insanity defense, neuroimaging evidence supporting a diagnosis of ASPD constitutes information that is not merely redundant and cumulative, but actually informs the jury regarding the clinical situation. But what will the jury do with this information?

An argument can be made that a jury would not necessarily view evidence of the personality disorder diagnosis as lessening the defendant's culpability or their appropriateness for the death penalty. A conclusion that the defendant is less culpable would presumably arise due to the diagnosis' implications of impairments in higher-order moral decision making and/or volitional control. However, there seems to be a significant probability that a capital jury would instead view evidence of ASPD or psychopathy as an aggravating factor, given that people with such conditions are difficult to treat and rehabilitate, with corresponding difficulty in reducing their risk of future violence.

This refractoriness to treatment, and ongoing dangerousness, could certainly be raised by the prosecution in their presentation of the aggravating factors supporting a death sentence. Thus it is not clear that neuroimaging, even as it adds a "biological" dimension, admittedly useful in countering claims that ASPD is merely psychological or a "character flaw," would actually be helpful to the capital defendant's effort to avoid the death penalty and receive instead life in prison without possibility of parole.

If one were to expand the discussion to noncapital cases, it is even less clear how neuroimaging evidence of ASPD or psychopathy would benefit a criminal defendant with the condition. It seems highly unlikely that defendants will be able to argue that their personality disorder constitutes a defense or an excuse, regardless of whether that disorder is "hard-wired" in their brain as demonstrated by modern neuroimaging techniques.

Such a result would seem possible only if one of two fundamental changes were to occur: The first would be a revision of the system allowing defendants who could show a biological predisposition to commit crimes, such as ASPD, to be diverted from criminal punishment and placed in therapeutic settings. One can imagine that countless "ordinary" defendants, their attorneys and loved ones might find such an arrangement highly unjust. An even more sweeping change to the criminal justice system, wherein the entire concept of punishment were abolished and replaced with treatment and confinement only for purposes of protection, would also allow defendants with ASPD and psychopathy, along with all other accused persons, to avoid punishment *per se*. Neuroimaging evidence could be quite useful in this situation to help in classifying patients and guiding treatment. As touched on earlier, some reductionists have drawn on the evidence of neuroscience to call for just such an overhaul of the criminal justice system. However, to say that the probability that this will occur anytime in the next few decades (at least) is remote would be an understatement. The concept is mentioned again here only as a reminder of the extent to which the neuroimaging revolution has inspired some academic observers to contemplate radical possibilities.

Under the current system, neuroimaging of ASPD and psychopathy in a forensic context represents a double-edged sword for the defense. If there is nothing else to fall back on, a defendant facing a possible death sentence may choose to introduce it and hope that it does not tip the scales against him. But in many other circumstances, defendants will not want their brain searched for signs of antisocial tendencies. In fact, it is conceivable that in the future, defendants will seek to *prevent* being subjected to imaging studies designed to determine if they are a psychopath, or to block the judge or jury from considering such evidence if it already exists, given the possibility that it will be viewed as evidence of their dangerousness or lack of rehabilitation potential. It is difficult to imagine evidence of psychopathy being beneficial at a parole hearing, for example.

Using Neuroimaging in Risk Assessment

Perhaps more realistic than a sea change in the criminal justice system eliminating consideration of punishment is the potential for using neuroimaging as a tool for assessing future dangerousness. In addition to ASPD and psychopathy, a database of neuroimaging findings in pedophilia has been accumulating. Progress in this area is complicated both by diagnostic heterogeneity and by extensive comorbidity with other disorders such as mood and anxiety disorders and personality disorders. Nevertheless, by comparing the activation patterns of nonpedophiles exposed to sexual stimuli with those of pedophilic subjects, it may be possible in the future to identify the presence of pedophilic interests with reasonable accuracy. Some authors working in this area have suggested a

potential role for neuroimaging in assessing response to treatment. In addition to using neuroimaging for specific disorders associated with elevated risk, such as psychopathy and pedophilia, advances in the general study of the neural correlates of violent behavior, particularly of the impulsive, emotional variety, point to at least the potential for a wider utility for neuroimaging in dangerousness assessments.

Much of the research on the neuroimaging of pedophilia, as well as discussions on the use of neuroimaging to assess risk of violence, originate in European countries, particularly Germany. This may in part be due to differences between the American and Continental legal systems: Many European countries use an inquisitorial rather than an adversarial system. Expert witnesses are routinely retained by the court, and much less often by the prosecution or defense. Presumably, the risk of a biased expert, including the risk of a "hired gun" essentially selling his or her opinion, is lower when experts report directly to the judge. This may lead to increased confidence that neuroimaging findings will not be used in a prejudicial manner by experts stretching the data beyond accepted scientific applications. Some European authors contemplate the future use of neuroimaging on a routine basis to augment actuarial, clinical, and other risk assessment tools for purposes such as sentencing decisions and release determinations for prison inmates and forensic hospital patients.

In this hypothetical future, neuroimaging would not be performed only once for each patient, but would be used at intervals to assist in tracking progress and improvement in response to therapeutic interventions. This would allow assessment and treatment to be individualized over and above current approaches and could—again, at least potentially—improve the objectivity and accuracy of risk assessments. In theory, such a use of neuroimaging would also assist in determining when a particular treatment approach has been unsuccessful. This would be of obvious benefit, as incarcerated and hospitalized patients with ASPD, psychopathy, and sexual disorders are highly motivated to tell their treatment providers what they believe will help them regain their freedom. It is for this reason that techniques such as the polygraph and the penile plethysmograph are frequently employed in the treatment of sex offenders despite their limited utility. Currently, there are no studies demonstrating the value of neuroimaging as a risk assessment tool, and it is not clear when, or if, neuroimaging will be sufficiently accurate and reliable for such an application.

Lie Detection, Recognition Memory, and Imaging-Assisted Interrogation

The first research studies investigating the neural correlates of deception and lying were published in 2001. These were group fMRI studies, but within less than half a decade, studies reporting the successful detection of deception in individual subjects appeared in the literature. Soon,

commercial enterprises were launched, offering clients the opportunity to undergo an fMRI scan, during which they would be asked a series of questions. The fMRI results would be analyzed to establish whether they were telling the truth or not. These companies reported accuracy in detecting deception on the order of 90 percent.

The exact mechanisms by which lying might produce a specific neural activation pattern are unknown. Researchers in this area have hypothesized that the act of lying increases the workload in areas of the frontal cortex, as the truthful response must be inhibited and a plausible lie generated. In any event, given the apparently high accuracy of the early studies, a few attempts have been made to introduce fMRI lie detection as evidence in legal proceedings. In the evidentiary hearings that have been held to date, the method has been ruled to not have demonstrated sufficient scientific validity to be entered into evidence. Subsequent imaging studies raised concerns as well, such as one which showed a drop in the accuracy of identification to 33 percent when subjects were instructed to covertly move a finger during the telling of lies.

In addition to these types of practical, methodological issues relating to fMRI lie detection techniques there are a number of broader concerns. One fundamental issue is the lack of ecological validity involved in the test paradigms. In most cases, the subjects engage in deception only when they are cued to do so in the protocol. This is not a very close approximation of what takes place in a police interrogation or on the witness stand, where the subject can choose when and whether to lie in response to every question. Perhaps more importantly, it is essentially impossible, in a research context, to create the emotional conditions that are present when a person is the focus of a criminal investigation, or is being deposed in a lawsuit with large sums of money at stake.

Another fundamental problem is the question of whether engaging in deception actually does—in the real world, as opposed to the carefully controlled conditions of a scientific experiment—generate a unique neural signature. Does the equivalent of a "grandmother neuron" (or circuit of neurons) for lying exist? Or do acts of deception exist on a continuum? How should behaviors such as omissions, half-truths, or making statements that are literally true if a question is narrowly interpreted, but where the respondent clearly knows that the questioner meant something more, be classified? Will it ever be possible to tease apart the fine distinctions among such nuanced human behaviors using a tool as (relatively) crude as neuroimaging?

Another major concern that has been raised by several commentators is the concern that false-positive results for lying might occur if the technique does not detect lying per se, but simply the suppression of a competing response. If an accusatory question provokes a fearful or angry emotion in the subject, could inhibiting that emotion create the appearance of

deception in the imaging data?

There are many other unknowns in the field of imaging-based lie detection. Virtually all research studies have involved healthy young adults as volunteers. There is essentially no data on populations such as juveniles, the elderly, or people with a history of head injury, substance abuse, or other psychiatric disorders. Would a delusional person discussing their delusional beliefs not register as engaging in deception?

Similarly, there are no data on how highly practiced, successful liars would perform. This population would include criminals with ASPD, of course, but what about people who are skilled at forms of "lying" not due to a psychological aberration but due to training, for example, spies or undercover police officers? Would they be able to fool the test? What about trained actors?

In addition to the technical problems, definitional complexity and lack of adequate range of populations studied, there are also several legal obstacles to the use of fMRI lie detection in court. One is the concern that introducing such evidence would invade the province of the jury, which has the role of determining who is telling the truth. This objection has been cited by American courts in barring the use of polygraph evidence. It would seem that the so-called "Christmas Tree Effect" and "CSI Effect" discussed earlier would be of even greater concern with fMRI images represented as depicting deception than with the relatively low technology of the polygraph. Another barrier is the Fifth Amendment right against self-incrimination. In a criminal case, it would not be possible to compel an unwilling defendant to undergo fMRI lie detection because of this right.

In considering the current state of the field of lie detection via neuroimaging, it does not seem likely that the technique will be found to be of value in the context of a criminal or civil court proceeding in the foreseeable future. The unknowns are simply too numerous for the procedure to be considered reliable enough for such use.

The accurate identification of a cognitive function as complex as conscious deception may ultimately prove to be a "bridge too far" for neuroimaging. However, there are other potential contributions neuroimaging might make in the context of interrogation. A number of observers of the field have discussed the possibility of using neuroimaging for an investigative task simpler than determining whether someone is lying. Specifically, imaging technology could potentially be used to determine whether the test subject is familiar with a stimulus, for example, a photograph of a face or of a building.

The burgeoning of neuroimaging that has taken place since the turn of the century has, by happenstance, coincided with the advent of modern terrorist tactics such as those used in the attacks of September 11th, 2001 in the United States, attacks on mass transit in cities such as London and Madrid, and many other tragedies across the globe. Not so coincidental has

been the dramatic, ongoing rise in the power, speed, and interconnectedness of computer systems (it is not coincidental since many neuroimaging techniques, especially fMRI, are dependent on sophisticated data processing capabilities). The expansion of computer speed and storage has also allowed for an unprecedented expansion of governmental surveillance capabilities which, advocates argue, facilitate the detection and thwarting of terrorist plots. Meanwhile, in the wake of revelations about widespread electronic eavesdropping by agencies such as the National Security Agency (NSA), many have expressed their concerns about government invasions of privacy.

With the refinement of neuroimaging has come the suggestion that its techniques might someday become a tool used in military operations and antiterrorism efforts. One scenario would involve displaying images to a suspected terrorist while scanning his or her brain with fMRI. If the scan indicates recognition of stimuli such as other terrorists (assuming they are not so well known as to be familiar to most people in the suspect's milieu), or particular locations, the suspect has, without answering any questions (unlike in a lie detection approach), provided information to the investigators.

The terrorism aspect is particularly relevant both because the usual constitutional protections against self-incrimination may not apply, and because it is more common to identify people planning a terrorist attack prior to it being carried out than it is to catch people in the planning stages of "ordinary" crimes such as robberies and burglaries. Granted, there are many potential flaws in searching for memories in this way. If the subject refuses to cooperate, for example, by closing his eyes or moving his head too much, the technique will not work. Furthermore, unless the stimuli are chosen very carefully, the risk of a false positive will be quite high, because a recognition memory–based technique can only determine whether the stimulus is familiar, and says nothing about the relationship between the subject being tested and the stimulus. Nevertheless, since the purpose would be to gather information to guide further investigation, rather than to prove a case in court, it is hard to state unequivocally that this type of scenario is too implausible to consider.

Such an application of neuroimaging, however remote a prospect it may be at present, has created great concern among certain observers about the potential for misuse and abuse, including the erosion of the privacy of one's own thoughts. As far back as a decade ago, civil rights advocates sought to determine if any US military or intelligence agencies had already put lie detection or memory analysis techniques into practice. Some authors have warned of the potential for these types of techniques to threaten what has been termed "cognitive liberty." To give a few concrete examples, some writers have envisioned the possibility of requiring parents to submit to neuroimaging in child custody proceedings, or of neuroimaging data

suggestive of dangerousness or violent tendencies being used for the preventive detention of people who have not been charged with any crime.

There is no publically available information to suggest that fMRI lie detection, analysis of memories, or related approaches have been used in a national security context. However, the probability of future use, while perhaps not high, is substantial enough to merit a thorough examination of the complex ethical questions raised by methods that have the potential to go far beyond what George Orwell's "Big Brother" could have imagined in his wildest dreams. Some authors have called for government regulation of neuroimaging-based lie detection and related technologies, while others predict the emergence of new privacy laws designed to protect the citizenry from being subjected to neuroimaging-assisted investigations.

CONCLUSION

The conceptual and technical advances in neuroimaging that have occurred over the past 4 decades have been nothing short of revolutionary. These breakthroughs have resulted in numerous efforts to use neuroimaging findings as evidence in legal cases. Because advocates for each side are prone to present evidence in the most favorable light (at least), and judges and juries lack the necessary scientific knowledge to fully assess claims based on neuroimaging on their own, it is critical for those who find themselves involved in this area to understand the limitations of the science as it applies to forensic questions, and to explain those limitations clearly to the court. It is critical for neutral, objective experts to protect the deliberations of the court from conjectural leaps driven by inappropriate use of neuroimaging data. At the same time, the expert must also be able to recognize and counter unfair attempts to discredit legitimate uses of neuroimaging for legal purposes.

Some of the limitations that have been discussed in this chapter are technical in nature, and could conceivably be overcome in the future as the science matures further. Others, such as the inability to use neuroimaging to draw conclusions about a past mental state, are extremely unlikely to change regardless of any future improvements in technical aspects such as scanner hardware or computer algorithms and software. A thorough knowledge of the science as well as the legal issues is key to identifying both types of limitations and effectively conveying them to the judge and jury.

It is critical to always remember never to rely solely on a single test, no matter how sophisticated, to conclude that there is a causal connection between the findings of that test and something as complex and multidetermined as an instance of human behavior. There is no one-to-one correlation between a given brain image and a particular mental state. The scientific expert must therefore guard against any tendency on the part of others to concretize brain imaging results and to suggest that an abnormality in the brain as visualized with imaging was the cause of a

person's legally relevant acts or omissions. Instead, the expert must place the imaging results into the larger context. Imaging findings may be used to support an argument—for example, that a plaintiff had dementia and was unable to contract, or that a defendant has a psychotic disorder and was not legally responsible for a crime due to insanity—but imaging findings are not sufficient in themselves to justify these types of conclusions.

In addition to the growing use of neuroimaging in court, there has been increasing speculation regarding the potential for neuroimaging to be used for other nonmedical, nonresearch applications. Outside the traditional legal arena, with its evidentiary rules and constitutional protections, it is possible that neuroimaging techniques will come to be used in a more expansive fashion to assist, for example, antiterrorism investigations. It is not very likely that the typical psychiatrist, even a forensic psychiatrist with expertise in neuroimaging, will be chosen for involvement in such pursuits should they actually be undertaken in the future. However, it is important to anticipate the temptation to resort to "mind-reading" through neuroimaging, in however primitive a form, and for society as a whole to analyze the risks and benefits of embarking on such a path.

History of Psychiatry

EDWARD SHORTER, PH.D.

Motto: "In the natural sciences old views and interpretations of observations are overtaken by new discoveries and retain historical interest only; in the humanities this is never quite the case. Psychiatry has one foot in each of these disciplines and our heritage is not something we can simply leave to the historians." Julius Hoenig (1981).

One of the earliest accounts of mental illness comes from the myths of the Greek gods. Hercules, under a delusive disorder, slays his children, believing them the offspring of another god.

One lad stretched forth his hands, crying, "Oh, dearest father, do not slay me; I am thy son." But Hercules, "with savage rolling eyes," as the chronicler tells us, "brought his club down upon the golden-haired head of the boy and broke his skull. The other children and the wife are sacrificed by the same murderous fury."

The modern reader recognizes the diagnosis of delirious mania, which, like most other psychiatric ailments, is as old as the hills and built into the pathology of the human condition.

Across the millennia there have been many other accounts of deluded and melancholy patients. Psychiatric illness has always been recognized as medical in nature. Yet psychiatry as a discipline arises only late in the 18th century. It was under the influence of the enlightenment that the prospect of relieving mental illness through institutional care was first broached. There had always been confinement, in the context of the noisome "hospices" that lodged indiscriminately the insane, the poor, the elderly, the medically ill, and the criminal alike. But the concept of dedicated mental hospitals stemmed from the late 18th century, surfacing first in Italy, then in France. In this manner, psychiatry became a specialty, not because its practitioners had special diagnostic or therapeutic skills, but because they had the administrative abilities required to run these large institutions. For decades, the emphasis in international surveys of psychiatric facilities would be on architecture and layout, rather than on diagnosis and treatment.

Before the late 19th century, there was no such thing as private practice psychiatry. Psychiatry as a discipline was based in mental hospitals, or "asylums,"—a term first used in 1766 instead of "lunatic hospital"—and psychiatrists were called "alienists," on the grounds that the distracted

mind had become alien. Ambulatory patients were seen in private practice by neurologists or general practitioners.

PART I: EARLY BEGINNINGS

The main story line is the transition from traditional hospices to mental hospitals dedicated to treatment and recovery. Joseph Daquin, a psychiatrist in the Savoyard city of Chambéry, extolled in a work on The Philosophy of Madness (*La Philosophie de la Folie*) in 1792, the bringing of patients "from their fetid holes … to the freedom of a great but enclosed yard. Trained staff will accompany them everywhere and keep them in view; in the yard, warders will let them do whatever they like, simply ensuring that they do not escape, and neither endanger their own lives nor those of others. We will simply let them wander about at will for two hours, or in the interval between one meal and the next." This is not the first description of the therapeutic asylum but certainly the first that extolls the therapeutic advantages of freedom and exercise.

Italy

Most accounts of the history of psychiatry do not begin with Italy, a land that is largely silent on the historical radar. Yet it was in Florence in the 1780s that modern psychiatry actually began. The key concept is "therapeutic institution," admitting patients in hope of relieving their distress rather than to protect society from them. The first therapeutic asylum was launched in 1788 when Vincenzo Chiarugi ("KEY-ah-ROO-jee") opened the doors of the old Bonifazio Hospital, previously a typical hospice, exclusively to psychiatric patients. Here, he organized gardens for the patients, provided music, gave a structure to their day, and ensured proper meals and humane treatment. In 1793 to 1794, Chiarugi wrote a three-volume psychiatry textbook based on these experiences, On Insanity (Della Pazzia), specifying that for psychological tranquilization the patients should be kept in calm, quiet environments: "The sweet songs of gentle, moving music in many cases will represent the first-line treatment." As for stimulating treatments, the patients should undertake moderate exercise in the asylum and at home. In treating melancholy, Chiarugi deemed it "absolutely necessary that … [the physician] finds his way into the patient's heart, gaining his confidence and trust." Chiargui called this "the psychological treatment" (la cura morale).

Italian psychiatry received a reformist bump-up in 1821, when Antonio Galloni became head of the venerable San Lazzaro Asylum in Reggio Emilia in the north of Italy. Founded in the 12th century as a leprosarium, in the 18th century Reggio Emilia went over to receiving psychiatric patients, and Galloni implemented many of the French reforms (see below), given that Italian psychiatry in these years stood much under the influence of France

(later, of Germany). Reggio Emilia's later superintendents included Carlo Livi, who in 1871, at the beginning of his tenure introduced Italy's first farm colony), and Augusto Tamburini (from 1877, after Livi's premature death), who began outpatient care with local families. Livi and Tamburini were among the leading figures in 19th-century Italian psychiatry, and Reggio Emilia stood as an international model for the villa system—rather than housing inpatients in giant barracks—and for the use of laboratories in patient care. Tamburini's watchwords were, "scienza e amore—studio e benevolenza" (science and love, research and kindliness).

France

Modern psychiatry was anchored in France, in two of the great Parisian hospices that Louis XIV founded in the 17th century: Bicêtre for men and the Salpêtrière for women. The seminal name in French psychiatry is Philippe Pinel, who in 1793, became chief physician of the Bicêtre hospice. Pinel is often seen (in ignorance of the contributions of Chiarugi) as the very founder of psychiatry itself. Yet the contribution of Pinel is difficult to overstate because his Medical-Philosophical Treatise on Mental Illness in 1801 (Traité Médico-Philosophique sur l'Aliénation Mentale) became the first international textbook and initiated the centuries-long task (not completed today) of perfecting the nosology of the field. In 1795, Pinel became the chief physician of the Salpêtrière, where he remained until his death in 1826. Pinel is also remembered as an early, influential advocate of humane care, as opposed to the chains-and-beatings approach that earlier characterized asylum life.

Pinel's student Étienne Esquirol ("ES-kir-ole"), who in 1825, became chief physician of the French national asylum in the Paris suburb of Charenton, is seen as the virtual founder of social psychiatry, assessing social patterns in illness, and further refining Pinel's nosology (see below). Esquirol inspired the Law of 1838 that obliged each district (department) in France to have a modern asylum; the law became worldwide a model of modern psychiatric care.

The United Kingdom

England. The first therapeutic asylum in England was St Luke's Hospital in London, founded by William Battie in 1750. Battie conceived admission to the hospital itself as having a therapeutic character, and in his Treatise on Madness (1758) he wrote, "The regimen [in madness] is perhaps of more importance than in any distemper. It was the saying of a very eminent practitioner in such cases that management did much more than medicine; and repeated experience has convinced me that confinement alone is oftentimes sufficient, but always so necessary, that without it every method hitherto devised for the cure of madness would be

ineffectual."

Yet, until the opening of the Maudsley Hospital in 1923, the anchor of English psychiatry was Bethlem Hospital ("Bedlam") founded in 1247, as a base for the Crusaders, then gradually given over to the care of the insane. (In 1930, the hospital removed from the district of Southwark to suburban Kent, at which time the old building—one of several over the centuries—became the Imperial War Museum.) The hospital is indissolubly linked with the Monro dynasty of psychiatrists, of whom Edward Thomas Monro was in office 1816 to 1855. Among the hospital's medical officers, or "apothecaries," was John Haslam, author of Observations on Madness and Melancholy (1809), the detailed cases of which are among the earliest patient reports in psychiatry.

In the first half of the 19th century, England led in the international movement to asylum reform, emphasizing "moral treatment" (psychotherapy), which began late in the 18th century at the Quaker Retreat in York, and the "non-restraint" system of patient care (abolishing chains and the like) that John Conolly initiated after he became superintendent of the Middlesex Asylum at Hanwell (a London suburb) in 1839. "The old system," said Conolly in 1856, in his Treatment of the Insane without Mechanical Restraints, "placed all violent or troublesome patients in the position of dangerous animals. The new system regards them as afflicted persons, whose brain and nerves are diseased, and who are to be restored to health, and comfort, and reason."

Scotland. Psychiatry in Scotland was dominated by the Edinburgh Royal Asylum (today the Royal Edinburgh Hospital), founded in 1813 at the Morningside estate, out of dismay at how badly Scottish poet Robert Fergusson was said to have been treated at the London asylum of "Bedlam." (He died there at 24.) The Royal Edinburgh was led over the years by a series of major figures in the history of British psychiatry, such as Thomas Clouston, whose Clinical Lectures on Mental Diseases (1883) remained for years the standard textbook.

Ireland. How direly Ireland required modern psychiatry emerges from testimony before the House of Commons in 1817:

> There is nothing so shocking as madness in the cabin of the Irish peasant, where the man is out laboring in the fields for his bread, and the care of the woman of the house is scarcely sufficient for attendance on the children. When a strong man or woman gets the complaints [severe psychiatric illness], the only way they have to manage is by making a hole in the floor of the cabin, not high enough for the person to stand up, with a crib over it to prevent his getting up. The hole is about five feet deep, and they give this wretched being his food there, and there he generally dies.

Until the foundation of the Irish Free State in 1922, Ireland was a colony of Great Britain, and Irish psychiatry rose simultaneously with

English psychiatry. The Richmond Lunatic Asylum in Dublin (now St Brendan's Hospital), the flagship of Irish psychiatry, was founded in 1816, and in 1857, Joseph Lalor became its first resident medical director. Given the absence of psychiatry in the medical curriculum until 1875, the only means of becoming a psychiatrist in Ireland, and in much of Scotland and England, was to serve as an assistant physician in an asylum. Irish clinicians of the day, such as Conolly Norman, a later superintendent of Richmond, favored the strong German emphasis on clinical psychiatry and found unhelpful the anatomical speculations of the era about causation (did the ovaries cause mental disease or not?).

German-Speaking Europe

"If French is the language of diplomacy, then German may be said to be the language of psychiatry," as Edward William Anderson, professor of psychiatry in Manchester, observed in 1962 after German had become internationally a dead language. In the years between 1850 and 1933, German was indeed the language of psychiatry, as it was the language of culture and scientific life in an enormous swath between Budapest (Hungarian psychiatrists all published in German) and Strasbourg, or between Hamburg and Vienna. Unlike England and France, where a single great city dominated the psychiatric life of the country, in German-speaking Europe there was a profusion of small states and over 30 university psychiatric departments or psychiatric hospitals existed, most of which had scientific aspirations; by 1900, Heidelberg, Berlin, Munich, and Vienna had become world centers of psychiatric learning.

Austria-Hungary. Psychiatry in Vienna was symbolized by the famous Tower of Fools (Narrenturm), a roundish structure with 139 individual cells (that still exists today), built by Emperor Joseph II in 1784 as part of the Vienna General Hospital. Although it was soon overtaken by advances in care, it remained an emblem of the distinctiveness of Viennese psychiatry, which later gave birth to such figures as Sigmund Freud (psychoanalysis) and Manfred Sakel (insulin coma therapy—see below for both).

Germany (After 1871, United as the German Empire). In the early years, German psychiatry tended to be overshadowed by the French. Yet there were spots of light. An important early figure was Wilhelm Griesinger who, as an assistant physician to Ernst Albert Zeller in the Winnenthal asylum in the early 1840s, began to propagate the view that "mental disease is brain disease," a main tenet of later German biological psychiatry. In 1845, Griesinger expressed his views in a textbook, Mental Pathology and Therapeutics (*Die Pathologie und Therapie der psychischen Erkrankungen*), a second edition of which in 1861, became the leading international textbook of biological approaches to the field. In 1865,

Griesinger moved from Zurich to Berlin as professor of psychiatry at the Charité Hospital; here he founded in 1867, the Archives of Psychiatry and Nervous Diseases (Archiv für Psychiatrie und Nervenkrankheiten) that was the equivalent of the Archives of General Psychiatry today.

Several reformed psychiatric hospitals flourished in Germany early in the century, including Siegburg north of Bonn, founded in 1825 by Maximilian Jacobi, who introduced to Germany the "no restraint" system—not shackling patients—and forms of psychotherapy. These reformed asylums also constituted centers of research as well as humane care, and in the days before the shift of scholarship to university psychiatric hospitals, an asylum such as Illenau in Achern (Baden), which opened its doors in 1842, under its inaugural director Christian FW Roller, was probably the intellectual center of German psychiatry; Roller tutored many clinicians who later became leaders of the field, including Richard von Krafft-Ebing (see below). In 1854 Jacques-Joseph Moreau ("de Tours"), after a visit to a number of German asylums, noted "the great scientific movement" in German psychiatry. This was the beginning of a vast scientific take-off.

Scandinavia

In the history of psychiatry, the contributions of the Scandinavian lands have been largely neglected, partly for linguistic reasons, partly for cultural blinkeredness.

Denmark. New-style, reformed asylums arose early in the Nordic lands. Denmark had receptacles for the insane dating back centuries. The city of Copenhagen had traditionally confined the "lunatics" at a so-called plague house. Yet following the British bombardment in 1807, living conditions for these unfortunates became intolerable, and the city decided to place patients at a castle at Roskilde, not far distant from town. The asylum, which began accepting patients in 1816, became known as St. Hans Hospital. But there were other Danish centers too. In the course of the century, neurosyphilis became a common reason for asylum admission. In 1857, Friedrich Esmarch and Peter Willers Jessen, at an asylum in the province of Schleswig (then belonging to Denmark), proposed in the General Journal of Psychiatry (*Allgemeine Zeitschrift für Psychiatrie*) that the mysterious fatal disease then called "progressive paralysis" seemed to be a late consequence of primary syphilis. A landmark in Danish psychiatry was the work of Copenhagen's Carl Georg Lange, professor of pathology at the University and considered Denmark's "first neurologist," on "periodic depressive conditions," considered by Lange to be a separate illness for which he recommended lithium therapy.

Norway. As elsewhere in Scandinavia, psychiatry in Norway rested heavily on the German tradition of biological and genetic investigation. The

first state psychiatric hospital in Norway, Gaustad Mental Hospital, in a town of that name near Christiana, was founded by Herman Major, the "first psychiatrist of Norway," in 1855. Important research came out of Gaustad, including superintendent Hans Evensen's landmark studies of schizophrenia (showing different outcomes). In 1934, Ivor Asbjörn Fölling, a biochemist at the Rikshospitalet in Oslo, the Norwegian national research hospital, discovered the metabolic cause of a disease called phenylketonuria (PKU), one of the so-called "inborn errors of metabolism" and a cause of mental retardation: It was a genetic inability to metabolize the amino acid L-phenylalanine, causing toxic amounts of phenylalanine to accumulate in the brain.

Sweden. Georg Engström founded the first reformed asylum at Vadstena in 1829, thus, as scholar Lennart Wetterberg put it, "drawing a line between barbarism and humanity in Swedish psychiatry." National mental health legislation in 1858 stipulated that an asylum must be led by a physician. The teaching of psychiatry in Swedish universities, among the earliest such teaching anywhere, began in Uppsala in 1741, with Carl von Linné, the great classifier, lecturing on medicine including psychiatry. At the University of Stockholm, called the Karolinska Institute, Eric Godelius gave the inaugural lectures on medicine, which embraced psychiatry as well, beginning in 1811. At Karolinska, later a world-famous research institute as well as a university, Wilhelm Öhrström, the first professor of psychiatry and simultaneously head of the newly built Konradsberg psychiatric hospital, began lecturing in 1861.

Spain. Although an asylum was established at Valencia in 1409, the great clinical school of Spanish psychiatry that flourished in the Middle Ages had little continuity into the modern era. In the 19th century, Spanish psychiatry remained much under the influence of the French, and it was Madrid's Pedro Mata y Fontanet, who established forensic psychiatry in Spain as the inaugural holder of the chair from 1843, when he helped introduce Esquirol's ideas. The overwhelming figure in modern Spanish neuroscience is Santiago Ramón y Cajal ("Ca-HAL"), who taught anatomy and pathology at the universities of Barcelona and Madrid. From 1888, Ramón established the neuron theory of brain histology and is generally acknowledged as the father of modern neuroscience. (He received a Nobel Prize in 1906.) His advice for a young investigator (1897, in Spanish) remains compelling reading for young scientists even today. Although he did not practice clinical psychiatry, many later prominent psychiatrists trained in the "Cajalian" phase of Spanish medicine (but note that he is generally referred to as Ramón, not Cajal, which was his mother's name). The main chairs of psychiatry were founded in the last years of the Second Republic (1931 to 1936), and the most important 20th-century clinical

figure in Spanish psychiatry, Juan J López Ibor, who originated the concept of "vital anxiety" (timopatia ansiosa), held the chair of legal medicine, toxicology and psychiatry in Madrid from 1932.

United States. In 1751, the Society of Friends (the Quakers), assisted by Benjamin Franklin, founded in Philadelphia the Pennsylvania Hospital; it was the first institution in the United States to have a major psychiatric division, for "persons distempered in mind," opened by Benjamin Rush in 1793. Rush was one of the signers in 1776 of the Declaration of Independence and practiced as much general internal medicine as he did psychiatry in his years of service from 1783 to 1813. In 1812, Rush wrote the first American psychiatry textbook, *Medical Inquiries and Observations*, upon Diseases of the Mind—and thus earned the sobriquet "father of psychological medicine in America."

The first state hospital in the United States opened its doors in 1773, in Williamsburg, Virginia. Called "The Public Hospital for Persons of Insane and Disordered Minds," it later became the Eastern State Hospital. Meanwhile, a series of private and charitable psychiatric hospitals sprang up on the model of the Pennsylvania Hospital. In 1817, the Quakers, alarmed at overcrowding in the Pennsylvania Hospital, founded a Retreat in nearby Frankford, Pennsylvania. In 1818, the psychiatric division of the Massachusetts General Hospital (incorporated in 1811) was founded at Charlestown in Boston, and named after a private donor the McLean Hospital. The Retreat, in Hartford, Connecticut, opened in 1824 and still exists today under the name Institute for Living (see below).

In 1771, a charter was granted to The Society of the New York Hospital, and in 1791, New York Hospital began accepting patients, including psychiatric; in 1808, it constructed a separate "lunatic asylum" for this purpose. At this point, the reforms of Pinel and Tuke had begun to arouse interest in the New World, and shortly proposals for "moral treatment" were circulating in New York as well. The trustees of New York Hospital therefore purchased a lot fronting the Bloomingdale Road in Harlem, and in 1821 the new structure, named the Bloomingdale Asylum, was opened, receiving private patients as well as those subsidized by funds from the Society of the New York Hospital. Years later, the Society decided that country air might be more salubrious, and in 1894 transferred the Bloomingdale patients to a new site in White Plains, Westchester, where it became the Westchester Division of The New York Hospital-Cornell Medical Center (see below for further developments).

The first large state hospital run on enlightened principles in the United States opened at Worcester, Massachusetts in 1833, under the leadership of Samuel B Woodward, an enlightened and forward-looking psychiatrist and close friend of Eli Todd at the Hartford Retreat. Following a lobbying campaign by Dorothea Dix, the hospital was enlarged in 1835 and on

several subsequent occasions; this victory marked the beginning of Dix's career as an advocate on behalf of poor people with mental illness. Among the most influential of the early American state hospitals was the Utica Hospital, opened in 1843, part of the vast New York State system of hospitals, which served as a seedbed for successful hospital administrators in many other institutions.

The shift in US psychiatry from large buildings with long corridors to small villas clustered in village-like colonies began in 1894 with the foundation of the Colony for Epileptics in Sonyea, New York, ("Craig Colony" after Oscar Craig, president of the New York State Board of Charities); the first patient was admitted in 1896. With colony care, these mental hospitals adopted a more human face.

PART II: THE FIRST BIOLOGICAL PSYCHIATRY

The intellectual content of this budding young discipline was overwhelmingly biological. At the beginning, psychiatry had a profound physical orientation. The brain was seen as the seat of diseases of the mind, and treatments addressed the brain and the body as a whole. In 1672, Oxford physician Thomas Willis (who described the "circle of Willis") said of the brain's role in his famous Two Discourses Concerning the Soul of Brutes

> When it happens that these corporeal functions are defective or hindered, forthwith the eye of the intellect, as if covered with a veil, is wont to be very much dulled or wholly darkened ... Because [of] their powers being hindered ... the imbecility and dullness of the mind, the slowness of the ingenuity, stupidity and madness at length do often arise. The fault is either in the brain itself, or the animal spirits, or both together.

For many decades, investigations of the brain to ascertain the correctness of Willis's views were hindered by the lack of suitable stains for nervous tissue. Studies of inheritance became the main technique of biological psychiatry. But in the 1870s, a new school of neuropathology, seconded with the aid of the microscope, began to arise, and the findings of such investigators as Theodor Meynert in Vienna and Franz Nissl in Heidelberg (see below) gave new impetus to biological thinking.

Nerves

Intrinsic to biological views was the assumption that disorders were caused by the nerves. Beneath the level of frank "insanity," or "madness," depression, anxiety, obsessive–compulsive disorder, and other nonpsychotic complaints were thought nervous in nature. The view was that the nervous system was somehow physically affected and that the source of mental and behavioral symptoms lay in these ailing nerves. In 1780, Samuel Tissot of Geneva, whose practice included many patients with psychiatric disorders, said, "Among the most appropriate remedies for

diminishing the irritation of the nerves, and to destroy numerous causes of their disorders, one must place the baths, cold or warm."

By mid-19th century, the concept of "nerves" had seized psychiatry in the way that "psychoneurosis" and "mood disorders" would later rule. English law distinguished clearly between insanity and nerves. As the asylum inspectors reported in 1844, "Homes which are licensed for the reception of Insane Persons ought to be kept exclusively for that purpose and the reception of nervous, imbecile, and dejected [depressed] persons, amongst those who are insane and often dangerous, is for obvious reasons open to serious objection."

Psychiatrists were once called "nerve doctors," a term that persisted in German-speaking Europe until relatively recently (Nervenarzt); a "nervous breakdown" crossed the threshold into psychosis, rendering patients incapacitated in a way that is associated with melancholic illness, acute psychosis, and delirious mania. In 1851, Henry Monro, an attending at St Luke's Hospital in London, said in his Remarks on Insanity, "The symptoms of insanity are simply the consequence of loss of nervous power." He called insanity "simply a disease of deficient nervous vigour." These words hallmarked a century of biological psychiatry.

Predisposition, Degeneration

Psychiatrists have always believed that many mental illnesses can be passed on from generation to generation, that they are "inheritable," or the result of "predisposition." The psychoanalysts did not believe this, and attributed reproducibility within families to "nurture" rather than "nature." Yet in the great sweep of things, psychiatry as a whole has believed in nature. As London's John Haslam said in 1817, "The minute investigation of many hundred cases has fully satisfied my own mind that the offspring of a person who has labored under insanity, is peculiarly liable to become similarly affected." By the late 19th century, it had become an accepted fact that the main cause of psychiatric disease was "heredity." As Paris psychiatrist Ernest Billod toured Italian asylums in the early 1880s, he was struck at the mantra-like repetition of the phrase, "The predominant cause of mental illness is heredity."

Early Pharmacotherapy

In psychiatry's early period of biological thinking, before the rise of psychotherapy, treatments of mental disease borrowed heavily from the "humoral" remedies employed elsewhere in medicine, mainly the therapies of "depletion": Correcting humoral imbalances in the body by venesection (on which Philadelphia's William Rush was very keen), leeching, and the administration of purgatives and laxatives. At the same time as depletion began to totter in the rest of medicine—toward the mid-19th century—it

came under attack in psychiatry as well and was replaced by the whole world of physical and dietetic therapies. All such treatments rely mainly upon the placebo effect, but at least they are not, unlike depletion, actively harmful to the patient. As Woodward wrote in 1850, "The abandonment of depletion, external irritants [mustard plasters], drastic purges and starvation, and the substitution of baths, narcotics, tonics and generous diet, is not less to be appreciated in the improved condition of the insane, than the change from manacles, chains, by-locks and confining chairs, to the present system of kindness, confidence, social intercourse, labor, religious teaching, and freedom from restraint. In this age of improvement, no class of mankind have felt its influence more favorably than the insane."

There was in the mid-19th century a brief but lucid anticipation of the era of psychopharmacology that would follow a hundred years later: In 1845, Paris psychiatrist Jacques-Joseph Moreau (nicknamed "Moreau de Tours," after the medical school he attended) published the results of his therapeutic experiments with hashish. The essence of psychopharmacology is establishing differential effectiveness, and in this foundational work Moreau established that hashish was ineffective in the treatment of dementia and stupor (stupidité), but that it did seem to have antimelancholic effects, lifting the mood and abolishing psychotic ideation in two melancholic patients.

As for subsequent pharmacotherapies, the opinion is widely held that psychiatry possessed no pharmacologic treatments before the psychopharmacologic revolution of the 1950s (see below). This is false. Psychiatry has always disposed of a palette of agents, admittedly of varying effectiveness (yet that is true today, as well). Until the Second World War, the Germans led the pack. In the area of medicinal innovation, in the years 1800 to 1930, Germany had 44 percent of the world's total innovations, followed by France at 16 percent and the United States at 14. The German chemical industry began its take-off around 1860, dyes in the forefront, and from the dyes emerged the first generation of psychopharmaceuticals. The very first treatments, however, were as old as the hills.

Ethanol. People are accustomed to thinking of beverage alcohol as a source of substance abuse rather than a useful therapeutic agent. Yet before the Second World War, although the dangers of alcoholism were readily acknowledged, alcohol constituted an important treatment. In 1923, Alexander Westphal, director of the university psychiatric hospital in Bonn, said, "In milder cases of melancholia, alcohol as a sedative and hypnotic can yield good service." The opinion was typical of the psychiatry of the day and not necessarily incorrect.

Opium. The milky juice of the unripe poppy plant *Papaver somniferum* in the treatment of melancholia goes back to the Ancients, and

was revived in the 17th century by London physician Thomas Sydenham, who standardized a combination of opium and alcohol (sherry) in "laudanum," or opium tincture. Practitioners of mental medicine began prescribing opium in the 18th century, and in 1788, William Falconer was found, in his discourse upon "the influence of the passions," waxing enthusiastic: "Opium too, which has been introduced into practice of late years in the nervous fever, and frequently administered, and in pretty large doses, is well known to exert great cordial effects on the mind and spirits." Tincture of opium does not seem to have been highly addictive, because so much of the alkaloid is inactivated by stomach acids. But with the invention of the syringe in the 1850s, it became possible to inject opium, and the resulting epidemic of addiction caused many psychiatrists to back away from the poppy, which seems actually to be quite effective as an antimelancholic. Yet as late as the 1960s, Hoffmann-La Roche Laboratories marketed injectable opium (Pantopon) for indications including psychiatric.

Cannabis and Hashish. The derivatives of *Cannabis sativa L* have a long history of use—today quite forgotten—in psychiatric therapeutics. After Moreau's work in 1845, hashish became widely prescribed. Auguste Voisin, the professor of psychiatry at the Salpêtrière in Paris, described hashish in 1883, as part of the panoply of agents, including potassium bromide and hydrotherapy, which he deployed in the treatment of psychotic depression. Cannabis has a similar history of age-old use, and was marketed as a drug in England in the 1930s under the brand name Indonad (in Germany as Indonal-Bürger). The cannabinoids became definitively stigmatized in the "war on drugs" of the 1970s and disappeared from psychological medicine.

Lithium. Lithium had drifted on and off the therapeutic palette for decades, if not centuries. Certain mineral springs in Texas containing lithium, for example, had a historic reputation as "crazy water." In 1886, Copenhagen psychiatrist Carl Georg Lange proposed lithium in the treatment of melancholic depression. But the remedy did not catch on, as the concept behind it, a uric acid diathesis of mental illness, was soon abandoned. (On the later history of lithium see below.)

Sedatives and Hypnotics

Medicine's encounter with sedatives goes back to 1857, when the salts of bromine ("bromides") were introduced. Among chemically synthesized sedatives, chloral hydrate followed in 1869 (and is still in use today). Paraldehyde was introduced in 1882, and a number of other synthetic sedatives were launched—all now long forgotten. The barbiturates, however, were one of the major drug classes of the 20th century. A mixture

of uric acid and malonic acid, the first barbiturate, barbital sodium (Veronal), was marketed in 1903, phenobarbital (Luminal) in 1911, and then dozens of shorter half-life preparations including amobarbital (Sodium Amytal) in 1924 and butabarbital (Butisol) patented in 1932. These agents became household names and were widely prescribed.

Despite this proliferation of agents for mild depression and anxiety, psychiatry lacked treatments for such major illnesses as schizophrenia, melancholic depression (with the exception of opium), and catatonia. In 1892, Daniel Cathell, a Baltimore physician whose practice was heavy with nervous patients, advised his colleagues, "Should you ever have recourse to remedies intended to act chiefly through the mind, if you will take care to look your patient earnestly and steadily in the face ... they will do double good. You will not only find that almost anything will relieve some of these mental cases, but will be further surprised to learn that it has evoked their enthusiasm, and that they are chanting its praise and vowing that they were cured of one or another awful thing by it. Some, indeed, who seem to be magically benefited by doses of—nothing—will actually credit them with saving their lives." The jury is still out on whether this happens today. (This thread is continued below under "The Psychopharmacologic Revolution.")

PART III: PSYCHOTHERAPY, SOCIAL PSYCHIATRY

Early Psychotherapy

Although physicians have always practiced an informal kind of psychotherapy in the doctor–patient relationship itself, formal psychotherapy begins with Hippolyte Bernheim, professor of medicine at the University of Nancy in eastern France, in 1884, when Bernheim, in his book On Suggestive Therapy under Hypnosis or in the Waking State (*De la Suggestion dans l'État Hypnotique et dans l'État de Veille*) distinguished between hypnotic suggestion (which had been around for a century) and nonhypnotic suggestion, or a good talking-to. In 1904, Paul Dubois, professor of neuropathology in Berne, Switzerland, proposed "rational psychotherapy," a forerunner of today's cognitive behavioral therapy (CBT), in his book The Psychoneuroses and Their Psychological Treatment (*Les Psychonévroses et leur Traitement Moral*). In 1903, Pierre Janet, professor of experimental psychology at the Sorbonne, proposed "psychasthenia" as the main mental disorder and advocated a kind of cathartic therapy for its treatment. These early systems were then overwhelmed by psychoanalysis, which by the 1920s, had become the chief psychotherapy of psychiatry (see below), and were forgotten.

Psychoanalysis

Previous histories of psychiatry customarily gave great space to the history of psychoanalysis, or Freudian "depth psychiatry." Yet today,

psychoanalysis has virtually disappeared from psychiatry and such extended coverage seems pointless. For detailed accounts, the reader is referred to the author's own *History of Psychiatry* (1997) or to one of the frankly adulatory chronicles of Freud's life such as that by Peter Gay. In retrospect, psychoanalysis may be seen as a kind of hiatus in an ongoing current of biological thinking in psychiatry that began with the old asylum physicians around the middle of the 19th century, and revived with enthusiasm about drug treatments in the 1950s, resulting in the substantial displacement of psychoanalysis by psychopharmacology, neuroimaging, molecular genetics, and other forms of neuroscientific investigation in the 1970s. The following discussion is appropriately brief.

Psychoanalysis, a system of thought that attributes the origin of behavioral symptoms to conflicts within the unconscious mind, was originated by Vienna's Sigmund Freud in the late 19th century. Although Studies in Hysteria, the volume that Freud coauthored with Vienna family physician Josef Breuer in 1895, is commonly seen as the founding document of psychoanalysis, it merely presents psychiatry's most famous patient, "Anna O" (Bertha Pappenheim) in the context of abreactive therapies. Freud's seminal doctrines themselves come to blossom only in 1900 in The Interpretation of Dreams (*Die Traumdeutung*). In successive years, Freud slowly adumbrated the essentials of psychoanalytic treatment, explaining the role of the interpretation of dreams and of free association. Then in the early 1920s Freud proceeded to trace the architecture of the psyche in the layers that he hypothesized: ego (conscious mind), superego (the source of morality, supposedly derived from oedipal fears toward the father), and the id (unconscious mind, harboring the sex drive and the death instinct).

Psychoanalysis as a movement began in 1902, when Freud founded a discussion group called the Psychological Wednesday Society, a group of curious physicians—many of them spa physicians and physiatrists in search of some kind of psychic bond to their patients. In 1908, this discussion group became the Vienna Psychoanalytic Society. In the same year, the first international congress of psychoanalysis took place in Salzburg, followed by a second congress in 1910, in Nuremberg, and a third in 1911, in Weimar. Meanwhile, the movement was plagued by schisms as early advocates such as Alfred Adler broke away, unable to accept fully Freud's doctrine of infant sexuality.

After the First World War, psychoanalysis became a major international movement. The dominant form of medical psychotherapy shifted from the former systems of Dubois and Janet to psychoanalysis. Psychoanalytic societies sprang up in the major western cities, and only with the Nazi seizure of power in 1933 (and Anschluss with Austria in 1938) was this expansion brutally braked. As the movement leached out of Europe, the United States, especially New York, Washington DC, and Los Angeles,

became the world epicenter of psychoanalysis.

In the New World, under the influence of such émigé analysts as Hungarian-born Sandor Rado in New York, depressive neurosis began to loom in psychoanalysis. Freud himself had little interest in depression because the patients wanted mainly to be left alone and not tell their dreams or free associate. But in New York "depressive neurosis," or "neurotic depression," started to become the meat-and-drink of the Park Avenue analysts, as opposed to "hysteria," "phobic neurosis," and the other diagnoses that Freud himself had placed front and center. In 1931, at the request of Abraham Brill, Rado helped organize training at the newly founded New York Psychoanalytic Institute. After disagreement with other members, in 1945 Rado headed the newly opened Columbia University Psychoanalytic and Psychosomatic Clinic for Training and Research, the first training institute within a university.

Once psychoanalysis had drifted into exile, the movement began to break into rival camps, such as ego psychology (the classic drive-defense tradition as continued in Anna Freud's 1936, The Ego and the Mechanisms of Defense); Donald Winnicott and Melanie Klein's object relations theory; and self-psychology (associated in particular with Heinz Kohut's book *The Analysis of Self* [1971]).

In object relations, Melanie Klein's *The Psycho-Analysis of Children* (1932) highlights the importance of introjection and projection as mechanisms. As Klein's biographer John Arnold Lindon explained, "Projection alters the infant's impression of his environment, and by introjection this changed picture of his environment influences what goes on in his mind. Thus an inner world is built up that is partly a reflection of the external one."

After the 1970s, psychoanalysis became less quarrelsome and drifted even further from Freud's original emphasis on infantile sexuality. Psychodynamic psychiatry (which is not the same thing as psychodynamic psychotherapy) agrees on the importance of unconscious conflict, on psychic determinism, on the role of development, transference, counter-transference, and resistance. The field is no longer opposed to medication (analysts once scorned "pills" as a hindrance to getting at the "root causes" of the complaint). Glen Gabbard at Baylor College of Medicine in Houston writes in 2009, "... A patient with a bipolar disorder who is denying that he has an illness and refusing to take lithium may ultimately have better compliance with the medication if the clinician explores the meaning of his denial and his reluctance to consider himself as someone requiring treatment."

Yet, despite the efforts of psychoanalysts to integrate findings from psychopharmacology and the neurosciences, the wind has slowly gone out of the field. There had been a time when the chair of virtually every major department of psychiatry in the United States had been a psychoanalyst.

But by 1990, more than 100 of 163 residency programs for psychiatry had abandoned instruction in intensive psychotherapy. The percent of psychiatrists who were also psychoanalysts declined from around 10 percent in the 1950s to 2.7 percent by 1988. What once was the very intellectual core of the discipline of psychiatry has become a marginalized group of enthusiasts. As Arthur Yuwiler, a senior biochemist in the Department of Psychiatry at the University of California, Los Angeles (UCLA), reflected somewhat ruefully in 2004, on the exchange of the psychoanalytic paradigm for the biological one, "I seemed to spend the first half of my scientific life arguing with psychiatrists that there was a brain as well as a mind and the last half arguing there is a mind as well as a brain."

Nonpsychoanalytic Psychotherapies

Formal systems of psychotherapy began with Hippolyte Bernheim, an internist in the French provincial medical school at Nancy, in 1884, with his distinction between hypnotic and nonhypnotic "suggestive" therapies: the latter meant, essentially a good chat. Bernheim believed hypnosis to be an effective treatment. Jean-Martin Charcot in Paris, however, thought hypnotizability to be merely a diagnostic marker of "hysteria."

Group psychotherapy began with Scottish psychiatrist William Alexander Francis Browne, at the Crichton Royal Hospital in Dumfries in 1842, when he encouraged patients to stage amateur theatricals that amounted to a form of "mental therapeutics." This strand was continued in 1922 in Vienna with Jakob Moreno-Lewy's impromptu theater that was later tagged "psychodrama." After Moreno immigrated to the United States in 1925, he introduced in 1931 group psychotherapy. Independent of Moreno, in these years Louis Wender at Hillside Hospital and Paul Schilder at Bellevue Hospital, both institutions in New York, also began psychotherapy in groups. Closely related to group psychotherapy was the "therapeutic community," which birthed in England during the Second World War at the hands of Joshua Bierer and Thomas Main. (See section on social psychiatry.)

In the United States the transition of psychotherapy from physicians to psychologists and psychiatric social workers began with psychologist Carl Rogers' "client-centered therapy" after 1946. His book of that title appeared in 1951.

Family therapy is generally considered to have begun with Columbia University's Nathan Ackerman at the founding in 1956 of the "family mental health clinic," part of New York's Jewish Family Service.

Social and Community Psychiatry

The main narrative arc in psychiatry is basically a first (19th century) biological psychiatry; then a psychoanalytic hiatus in the first half of the

20th century, followed by a second biological psychiatry (late 20th century). Yet in the years 1940 to circa 1980 another current arose in psychiatry flowing separately from this main narrative stream: It was social and community psychiatry.

After the Second World War, the field became increasingly preoccupied with the social causation of illness and with group therapies for its treatment. A movement arose to treat patients in the context of the community rather than the asylum, and in 1946, D. Ewen Cameron, head of psychiatry at McGill University, created the first day hospital in the world at the Allan Memorial Institute in Montreal. In 1948, Joshua Bierer established the first in England, a "social club" at the Social Psychiatry Centre in London that he had founded 2 years previously. The movement incorporated in 1959, Bierer's view that, "Treatment must include the whole social environment of the patient and all his social relationships. He must be treated not only as a person but as part of a community." So influential did social psychiatry become in the United States that it influenced the removal of National Institute of Mental Health (NIMH) in the years 1967 to 1992 from the National Institutes of Health, to protect, according to Joel Paris, head of psychiatry at McGill and author of Fall of an Icon (2005), "the social mission of the Institute from mainstream medicine." Many social psychiatrists also saw themselves as social reformers, on the grounds, as Paris continued, that "poverty and social disruption were the real causes of psychological symptoms." Therefore, "society, not the individual, should be the 'patient.'"

These ideas accorded well with the social activism of the mid-20th century. But as early as 1956 Ralph Gerard, a neuroscience leader at the University of Michigan, said presciently, "I think there has been a real overshoot. We have all wished mental disease to be determined mostly by sociological causes, because this situation seemed more hopeful from the therapeutic standpoint. If the individual has been broken by the group he could be healed by techniques of interpersonal interaction; but if he had bad genes, effective treatment was far in the future." And indeed, in the United States, social psychiatry was rapidly eclipsed by mushrooming biological perspectives.

Today, CBT is probably the most widespread form of medical psychotherapy, and is associated with Philadelphia psychiatrist Aaron Beck, from 1963. Popular as well is Interpersonal Psychotherapy, originated in 1967 by Yale psychiatrist Gerald Klerman and coworkers, especially for the treatment of depression. Also of interest is "dialectical behavior therapy" (DBT), a form of CBT emphasizing "mindful awareness," proposed by Marsha M Linehan, a psychologist at the University of Washington, in 1999.

Yet while the number of psychotherapies proliferated, the percentage of psychiatric consultations in the United States that involved psychotherapy

declined from 44.4 percent in 1996 to 1997 to 28.9 percent in 2004 to 2005. Clearly, the single-office psychiatrist with a primarily psychotherapeutic practice, once the very image of psychiatry with its emphasis on "the couch" and "root causes," was giving way to the health care team with the psychiatrist's primary purpose being diagnosis and the provision of medication.

PART IV: FROM ASYLUM TO UNIVERSITY

In the last quarter of the 19th century, many national medical bodies began demanding that psychiatry be included in the medical curriculum. This created a demand for professors of psychiatry and for academic centers in which to train them. As a result of this curricular development, research began shifting from asylums to university psychiatric hospitals and academic departments of psychiatry. Investigators in many of these centers came to dominate the field and the asylums became research backwaters, increasingly given over to warehousing the ever-growing numbers of patients rather than treating them.

German-Speaking Europe

Said British psychiatrist Malcolm Lader in 1990, "We always used to say if you go back far enough and look at German literature at the turn of the century, you're sure to find that someone described panic disorder and everything else." It was the closeness of the link between the academy and the psychiatric hospital that granted this extraordinary German celerity in psychopathology; much of this architecture of the delineation of syndromes still remains. This leap from asylum to academy in German-speaking Europe sped forward in 1874, when for the first time, university professors began taking part in the Association of Southwest German Alienists, hitherto a group of influential asylum psychiatrists.

Vienna. The capital of the Austro-Hungarian Empire, Vienna was a psychiatric super-power, the global influence of which was far disproportionate to the medium size of the city. The train of distinguished psychiatrists began in the late 18th century with such figures as Franz Joseph Gall (who first speculated about cerebral localization), and continued into the nineteenth with Ernst von Feuchtersleben, whose 1845 Textbook of Medical Psychiatry (*Lehrbuch der ärztlichen Seelenkunde*) popularized the term "psychopathy," in the sense of a disordered personality. (Feuchtersleben also distinguished between "neurosis" and "psychosis," giving them exactly the opposite meaning they were later to have.) But the modern tradition of Vienna as a bastion of biological psychiatry (psychoanalysis came later) began with psychiatry professor Theodor Meynert ("MY-nert") with his great 1869 treatise on neuroanatomy, The Architecture of the Cerebral Cortex (Der Bau der

Gross-Hirnrinde), and continued with Illnesses Involving the Forebrain in 1884 (Erkrankungen des Vorderhirns), which was completely forgotten midst later shrieks of jubilation about the importance of the frontal and prefrontal lobes in schizophrenia. His successor Richard von Krafft-Ebing is remembered for his textbook of sexology Psychopathia Sexualis (1886); his successor in turn, Julius Wagner von Jauregg ("YOW-reg"), introduced in 1917, the malarial fever cure, an epochal accomplishment for which he received the Nobel Prize in 1927. Aside from the professors, Josef Berze, head of the Vienna city asylum "Am Steinhof," described "primary insufficiency of psychic activity" in schizophrenia in 1914, and Constantin von Economo, who led a brain research institute, reported the new disease of "encephalitis lethargica" in 1917. It was in the years following 1930 that Manfred Sakel proposed insulin coma therapy (while still in Berlin; only in 1933 did Sakel return to Vienna to conduct clinical trials—see below). Finally, pediatrician Hans Asperger described "autistic psychopathy" in 1944, among the earliest descriptions of autism (which was first used as a term in pediatric psychiatry by German and Russian neurologists and psychiatrists early in the 1920s). Vienna's contribution to psychoanalysis would begin in 1900, with the publication of Sigmund Freud's Interpretation of Dreams (see above), and continue until the expulsion or murder of the Jewish psychoanalysts in 1938 after Anschluss with Germany. After the Second World War, Vienna never again regained this historic preeminence in psychiatry.

Heidelberg. The flagship of academic psychiatry in the German Empire berthed in Heidelberg. The "Psychiatric-Neurological Clinic" of the University ("Klinik" in German means university hospital) was founded in 1879 by Otto Fürstner; it was the first university psychiatric department with beds of its own, so that patients didn't have to be brought from a nearby asylum for demonstration in clinical lectures. Its most distinguished head was Emil Kraepelin, who had the professorship from 1891 to 1903, during which time the crucial editions of his textbook appeared (see below). The Klinik was also a provincial asylum, with a catchment basin of its own. When Kraepelin left for Munich, the professorship was assumed by neuropathologist Franz Nissl, known for his demonstration in cells of the "Nissl substance." At various points in Kraepelin's Klinik served Alois Alzheimer (who followed Kraepelin to Munich) and Karl Jaspers. In the 1920s, such important figures as Willi Mayer-Gross (who after fleeing the Nazis to England coauthored the standard English psychiatry textbook, Clinical Psychiatry, in 1954); Carl Wilmanns (pioneering studies of the homeless); Hans Gruhle (premier schizophrenia researcher of his day); and August Homburger (who founded in Germany modern pediatric psychiatry). This wall of scholarship crumbled in 1933, and the names of the successors under the Nazis are either forgotten or live on in infamy.

Heinz Lehmann later said in retrospect, "German medicine was an impressive thing and there is no doubt about it. When we all went away, I don't think this tradition was transferred to America but it was abolished in Germany."

Berlin. In 1795, a psychiatry department was founded in the Charité, the Prussian state's great military hospital, and in 1806 Ernst Horn was called to become associate director of the hospital, with simultaneous responsibility for psychiatry. Under Horn, psychiatry at the Charité conformed to the concepts of the day of a proper reformed asylum, though Horn was much assailed for some of his practices and left under a cloud in 1818. Ten years later he was succeeded by Carl W. Ideler, one of the so-called "Romantic" psychiatrists who saw illness as evidence of sin. This unhappy period came to an end with Ideler's death in 1860 and Wilhelm Griesinger's arrival in 1865 to convert the old psychiatric ward into a modern neuropsychiatric clinic (Klinik für Geistes- und Nervenkrankheiten). In 1867, Griesinger founded the lead German journal for biological psychiatry, the Archive for Psychiatric and Neurological Diseases (Archiv für Psychiatrie und Nervenkrankheiten, of which the current Archives of General Psychiatry is a distant echo). Griesinger died prematurely in 1868 of acute appendicitis. Following Griesinger came a distinguished series of biologically oriented psychiatrists, including Carl-Friedrich Westphal in 1869 (who in 1872 described agoraphobia and in 1877 obsessive–compulsive disorder). His tenure ended with his death in 1890 of what seems to have been neurosyphilis—of which so many middle-class men perished in those days (infected as medical students or law students with primary syphilis from prostitutes). Karl Bonhoeffer had the Berlin chair from 1912 to his emeriting in 1937, after which another grim period began in the history of German psychiatry. In 1909, Bonhoeffer conceived the notion of "exogenous psychosis," arising from stress or toxins from outside rather than being endogenous and inborn.

In a separate development, in 1902, Oskar Vogt founded a neurobiological institute at the University, which in 1915 was joined with the Kaiser-Wilhelm-Institute for Brain Research. (His wife, the French-born Cécile Vogt, became an important neuroscientist, later settling in England. Their daughter Marthe discovered in 1965 that noradrenalin was present in the brain.) In 1931, the institute was transferred to the Berlin-Buch mental hospital, and came in 1937, under the direction of Hugo Spatz, who was a member of the Nazi party but who goes down in history as codiscoverer of the Hallervorden–Spatz disease of neurodegeneration. Despite its vicarious history, this institute became one of the world's leading neuroscience centers.

Munich. When in 1903, Kraepelin went from Berlin to Munich, it was

as inaugural director of a newly built University Psychiatric Hospital in the Nussbaumstrasse. He proceeded to make it into a world-class institution, bringing, as stated, Alois Alzheimer from Heidelberg to head the pathology laboratory, to which young investigators streamed from all over the world.

In 1917, Kraepelin founded a freestanding psychiatric research institute, the Kaiser-Wilhelm-Institut für Psychiatrie. The psychiatric department of the adjacent Schwabing City-Hospital, headed after 1931 by Kurt Schneider, became its clinical arm. Slow to get off the ground, the Institute's take-off began only in the mid-1920s, thanks to a group of foreign donors led by James Loeb (after whom a street in front of the present institute is now named). In 1917, Ernst Rüdin became head of the "genealogic-demographic" (genetics) section (see below). The scientific promise of the Institute was nipped in the bud by the Nazi takeover, and only after the war, when in 1954 it became the Max Planck Institut für Psychiatrie, did its international reputation blossom.

Zurich. In Zurich, a city psychiatric hospital was founded in 1860, and when Wilhelm Griesinger began lecturing there in 1863, it became a "Klinik." Two years later, in 1865, Griesinger decamped for Berlin. In 1869, a grand new Klinik was planned at a spot called the "Burghölzli"; the "Bli," as it was known, was helmed over the years by some important figures, including Auguste Forel (1898 to 1927), a co-originator of the "neuron theory" of cerebral communication; Eugen Bleuler (1898 to 1927), who coined the term "schizophrenia"; and his son Manfred Bleuler (1942 to 1969), who in 1954, determined that the prognosis of schizophrenia was often benign.

France. Paris is the great focus of French psychiatry, and in Paris each of the main general hospitals had academic psychiatry departments chaired by professors. Yet in addition, Paris had one special institution not found elsewhere in France (or in other lands, for that matter): The special psychiatric reception service of the Prefecture of Police (la Infirmérie Spéciale des Aliénés de la Préfecture de Police).

In 1800, Paris was given a special prefect for police, and with the general mental patients law of 1838, this prefect acquired responsibility for mental patients who came to public attention. Seven years later, in 1845 this special reception service became headed by a psychiatrist. From this service flowed a good deal of the research of modern French psychiatry. The first head of note was Ernest-Charles Lasègue in 1850, who coined the diagnostic term "delusions of persecution" in 1852, and "hysterical anorexia" (anorexia nervosa) in 1873. (Lasègue also had a series of academic appointments in the teaching hospitals.) In 1872, the Infirmérie Spéciale became independent of the police headquarters, and turned into an important center for research. Following his death in 1883, Lasègue was

succeeded by his assistant Henri Legrand du Saulle, who in 1875 offered an early description of obsessive–compulsive disorder ("la folie du doute avec délire du toucher").

At the Salpêtrière hospice, in 1882, Jean-Martin Charcot became the inaugural holder of a chair in nervous diseases, created especially for him by the president of the Republic. Charcot's contributions lay mainly in neurology, but his name is indissolubly connected with a certain kind of "hysteria," involving supposed chronic stigmata and elaborate acute pantomimes that in retrospect were phenomena of suggestion and that disappeared after his death in 1893. Among the students of Charcot, best known is Joseph Babinski, who in 1896 described the plantar extension reflex that is named after him. Charcot's successors Fulgence Raymond and Jules-Joseph Dejerine were better known as neurologists than psychiatrists.

The "clinical asylum" Sainte-Anne was opened in 1867 as the asylum of the Seine department, with Valentin Magnan, the notable advocate of "degeneration" theories, as director of its admissions department. In 1877, Benjamin Ball became the inaugural holder of the Chair of Mental and Brain Disease. Among his successors were Henri Claude in 1922, an early biological psychiatrist, and, Jean Delay in 1946, who introduced the psychopharmacological era in France. The facility became a "psychiatric hospital" in 1937, a "psychiatric center" in 1944, and a "hospital center" (shedding the unfashionable adjective "psychiatric" entirely) in 1974.

United Kingdom

LONDON. In 1908, the asylums committee of the London County Council accepted a gift from psychiatrist Henry Maudsley to found a research hospital based on the model of the German university psychiatric clinic. The war interfered with the realization of these plans, but in 1923, the Maudsley Hospital opened its doors for psychiatry, with Edward Mapother its inaugural superintendent. The Maudsley was not to be an asylum. Mapother made clear, as historian Edgar Jones relates (in a 2003 article in Medical History), "that no patient was to be admitted under section, nor would they be certified once in the hospital." Mapother had an academic appointment at King's College Hospital, and wanted to make the Maudsley the psychiatric arm of the college's teaching. (Mapother received the title "professor" in 1936.) Aubrey Lewis, who joined the staff in 1928, becoming medical officer in 1936, recalled, "The place was small, full of ambition and energy, but everybody was overworked." In 1946, Lewis was appointed professor of psychiatry, and 2 years later, in 1948, the teaching unit at the Maudsley was renamed Institute of Psychiatry (IOP). In that year as well the Maudsley merged with the Bethlem Royal Hospital (the former "Bedlam"). Lewis began adding Medical Research Council (MRC) units, the

first of these, the MRC Social Psychiatry Unit under Lewis himself opening in 1948. These helped make the Maudsley the premier institution in the United Kingdom for research in psychiatry. In 1997, the IOP split from the Maudsley to become a school of King's College London. The Maudsley was a major font of social psychiatry in the UK. Psychiatrist David Healy recalled that Aubrey Lewis had stated, at a meeting in 1958 (in Healy's words), "'If we had a choice between the new drugs and the social treatments, such as industrial rehabilitation units, we would pick social treatments.' And it's interesting that in the UK under Lewis' influence the Maudsley remained very aloof from the new drugs."

Accordingly, the first center of research for psychopharmacology in the UK—the first anywhere—was the Department of Experimental Psychiatry, founded by Joel Elkes at Birmingham in 1951. It was here that some of the earliest trials of the antipsychotic chlorpromazine were conducted. "I felt like a naturalist advancing into a strange continent," said Elkes later. The notion that drugs, as opposed to psychotherapy, could prove curative in psychiatry was then very new.

On Scotland and Ireland (see above)

CANADA'MCGILL UNIVERSITY. Canada contained one of the most internationally important departments of psychiatry at McGill University in Montreal. The Department of Psychiatry of McGill was the Allan Memorial Institute (named after a donor), founded in 1940 at the instigation of neurosurgeon Wilder Penfield. Chaired by D. Ewen Cameron from 1943 to 1964, it was under Cameron that the "Allan" became one of the most distinguished psychiatry departments in North America. Its clinicians and scientists included psychoanalyst Miguel Prados, who arrived from Spain in 1944; the neuropathologist Karl Stern who in 1944, established a gerontological unit, the first in the world; the neuropathologist Vojtech Adalbert Kral, a Holocaust refugee who arrived at the Allan in 1953 and pioneered research in dementia; Clifford Scott, who became an international leader of psychoanalysis, arrived from the Maudsley in 1954. (One wag said "Kral felt if you couldn't see it, it didn't exist and Clifford Scott … felt if you could say it, it wasn't important.")

Included as well were: Neurophysiologist Robert Cleghorn in 1946, who pioneered endocrinological psychiatry; Charles Shagass in 1950, who conceived the notion of the "sedation threshold"; Eric Wittkower, who in 1955 set up the section on transcultural psychiatry as a joint venture with the department of anthropology; Wittkower recruited Henry BM Murphy, author of the standard textbook of transcultural psychiatry (Comparative Psychiatry, 1982), who became head of the section in 1965 after Wittkower retired; and Heinz Lehmann, who came to Montreal in 1947 as director of the Verdun Protestant Hospital and is considered one of the founders of

psychopharmacology. (The World Health Organization's first training center for psychopharmacology was at the Douglas.) Psychiatrist George Simpson, a first-year resident at McGill in 1956, later said in an interview, "I would argue that the Allan was the most stimulating place in the English-speaking world at that moment, even though the rest of the city spoke French."

United States. After the Second World War, the United States came to dominate world psychiatry, partly as a function of the torrent of research funds from NIMH, partly as a result of the Diagnostic and Statistical Manual of the American Psychiatric Association becoming after 1980, the world bible of psychiatry. The Holocaust and the devastation of the Second World War also had a great deal to do with the new American primacy. Rather than flocking to the Maudsley or Vienna for training, as budding American psychiatrists did before the war, it was young psychiatrists from all over the globe who sought further training in the United States. This new American hegemony accounts for the length of the following section.

NEW YORK. New York held the greatest concentration of psychiatric firepower in the United States owing to a series of public and private teaching hospitals.

HILLSIDE HOSPITAL. Hillside Hospital, initially in Hastings-on-Hudson, was founded by Israel Strauss in 1927 as a charitable Jewish hospital operated in a nonsectarian manner. In 1941, the hospital removed to Glen Oaks, Queens. It was, as Strauss put it, "the first institution of its kind for Jews in this country." Hillside specialized in "borderline" cases, meaning the kind of psychoneurosis that usually would not receive in-patient treatment. In 1930, Louis Wender, chief physician, began one of the first programs of group psychotherapy in the country. In the 1940s, Hillside was among the earliest US institutions to offer the various shock therapies. Although mainly psychoanalytic in inspiration, in 1950 Hillside resolved upon a "biochemical" research program, and in 1952 hired Max Fink to establish the Department of Experimental Psychiatry, which was joined by Donald Klein in 1957. Fink and colleagues set up an electroencephalogram (EEG) laboratory in 1953, and with Klein, conducted pioneering trials in psychopharmacology. By 1999, following several mergers, what had become Zucker Hillside Hospital was merged into the North Shore Long Island Jewish Health System, which encompassed seventeen hospital systems.

NEW YORK/PRESBYTERIAN/WESTCHESTER DIVISION. The foundation and growth of the New York Hospital, the second oldest freestanding psychiatric hospital in the United States, is discussed above. In 1898, the hospital became associated with Weill Cornell Medical College as that institution was

founded, and a 1927 endowment lent to the psychiatric division the title Payne Whitney Psychiatric Clinic. New York Hospital merged with Presbyterian Hospital in 1996, and the Payne-Whitney Clinic was renamed the New York/Presbyterian Westchester Division.

NEW YORK STATE PSYCHIATRIC INSTITUTE. In 1896, the New York State Pathological Institute was established in New York City under Ira Van Gieson. It was the first effort in the state to study the anatomical basis of insanity, receiving specimens from the various state hospitals. In 1904, the Swiss-born Adolf Meyer, previously a pathologist at several state hospitals and a professor at Clark University, succeeded him. Meyer was already a significant scientific figure, and would go on in 1910 to become professor of psychiatry at Johns Hopkins University and inaugural head of the Henry Phipps Psychiatric Clinic (see below). In 1902, the Pathological Institute moved to Ward's Island next to the Manhattan State Hospital. Meyer changed the name to Psychiatric Institute in 1907. Following a fire at Manhattan State, planning began to convert the institute to a state mental health research hospital and to situate it at Washington Heights, where Columbia was building a new medical school and Presbyterian Hospital was to move. The new building of the now New York State Psychiatric Institute was dedicated in December 1929. Known as "PI," it became the psychiatry department of Columbia University as well offering from 1931 a 10-week course for psychiatrists in the New York State Mental Hospital system. In 1936, Nolan DC Lewis, professor of neurology in the Neurological Institute, became the first academic to lead PI. He in turn was followed by Lawrence C Kolb in 1954. The Psychiatric Institute innovated at all points on the treatment spectrum: In 1942, a Department of Research Psychiatry was created, with Eugene Barrera and Bernard Pacella its main members. In 1945, a Psychoanalytic Center for Training and Research was founded, the first official psychiatric training institute to be established in a medical school. Despite the massive interest at PI in psychoanalysis, early in the 1950s a small number of investigators led by Philip Polatin became involved in psychopharmaceutical trials; by 1956, the Institute had a department of experimental psychiatry, now led by Sidney Malitz, located at the Vanderbilt Clinic.

PI benefited greatly from the tumult of the century, giving refuge to many distinguished scientists and clinicians fleeing the Holocaust. Among the members of the informal "European Club" were Lothar Kalinowsky (from Germany and Italy), the padrone of electroconvulsive therapy (ECT) in the United States; neurochemist Heinrich B Waelsch (Prague); Paul Hoch (Hungary and Germany), who headed experimental psychiatry and coined the diagnosis "pseudoneurotic schizophrenia"; Sandor Rado (Hungary) who became a leader of psychoanalysis in the New World; Armando Ferraro (Italy), who headed neuropathology at PI. Eric Kandel,

who established the Center for Neurobiology and Behavior in 1974, was born in Vienna, and later (2000) won a Nobel Prize.

THE EAST COAST

Washington DC: The National Institute of Mental Health. The NIMH, funded by the federal government as one of the National Institutes of Health, is not a degree-granting institution, but it is very academic, encouraging original research both in-house, in the "intramural program," and by funding "extramural" psychiatric research across North America. The involvement of the federal government with psychiatric research began in 1929 with the founding of the Narcotics Division of the Public Health Service, renamed Division of Mental Hygiene in 1930. Lawrence Kolb became the chief PHS officer in charge of the division of mental hygiene, and on his retirement in 1944 he had wished to set up a national neuropsychiatric institute within the National Institute of Health (NIH). This became possible in 1946, when the National Mental Health Act called for the creation of a National Institute of Mental Health, with an in-house research program. NIMH opened its doors in 1949, and Robert Felix, who had succeeded Kolb as director of mental hygiene, became the institute's inaugural director in 1951, with physiologist Seymour Kety in charge of research.

In 1953, the first clinical NIMH ward opened at the Clinical Center for the NIH; there followed in 1955 the Laboratory of Clinical Science, and in 1956 the Psychopharmacology Service Center, which in 1960 organized the Early Clinical Drug Evaluation program, Jonathan Cole its director. The program became a great engine of progress, conducting investigational trials in the 35 Early Clinical Drug Evaluation Units (ECDEUs) that came to be established by 1969. By 1982, among the 100 investigators most frequently cited in scientific research worldwide, 9 were in the NIMH the intramural program.

Johns Hopkins University: The Phipps Psychiatric Clinic. Psychiatry at Johns Hopkins began in 1910 when Adolf Meyer was hired from the Pathological (later Psychiatric) Institute of the New York State Hospitals to become the inaugural professor of psychiatry and director of the new university psychiatric hospital, the Phipps Clinic, funded by Henry Phipps, which opened its doors in 1913. On his retirement in 1941, Meyer was succeeded by Nebraskan John Whitehorn, in office until 1960. In these years, Rockefeller Foundation grants brought many young European psychiatrists to the Phipps to study, and it was through them that Meyer's international influence became considerable.

McLean Hospital (continued from above). In 1888, profiting from the scientific boom then sweeping US psychiatry, a pathology department was organized at the McLean asylum. In 1895, the institution removed from Charlestown to Waverley (Belmont), a suburb of Boston, and was named McLean

Hospital. Swiss-born August Hoch, who would shortly study with Kraepelin and Alzheimer, became leader of a chemical laboratory in 1893; Hoch became an early advocate of the new neurohistopathology; a psychology laboratory followed in 1904. After 1955, in keeping with the changing times, the hospital pioneered in the United States concepts of the therapeutic community under Alfred H. Stanton.

But biology lay waiting. In 1972, the "transformation of McLean," as Alan Schatzberg later put it, began, when Shervert Frazier, who had also qualified as an internist, came up from Columbia University to become director. He recruited psychotherapist John Gunderson in 1973, who became the "borderline" specialist; Jonathan Cole and Schatzberg came in 1974 to work in depression; there arrived as well from Massachusetts General Hospital (the parent organization), Joseph Lipinsky in 1974, and Seymour Kety and Ross Baldessarini in 1977. Schatzberg said, "He recruited outstanding people and built the Mailman Research Center, an unbelievably vibrant place."

Harvard University. The Department of Psychiatry at Harvard was founded in 1920 when Adolf Meyer's student, the Scottish-born Charles Macfie Campbell, left the Phipps Clinic in Baltimore to become director of the Boston Psychopathic Hospital and the inaugural professor of psychiatry at Harvard. Like his mentor, Campbell leaned toward "psychobiology" and psychoanalysis. The influential post at Harvard, however, is chief of psychiatry at the Massachusetts General Hospital, one of Harvard's teaching hospitals (of which McLean was administratively a part). This post was initially held in 1934, by Stanley Cobb, professor of neuropathology and previously director of the Harvard Neurological Unit at the Boston City Hospital. Some consider Cobb the founder of biological approaches to psychiatry in the United States. Among Cobb's successors were Erich Lindemann in 1955, John Nemiah in 1965, and Leon Eisenberg in 1967.

The Institute of Living (continued from above). In 1931, when C Charles Burlingame was appointed superintendent, what was then the Neuropsychiatric Institute of the Hartford Retreat was in a downhill slide. Burlingame effected a revival, establishing a school of nursing, bringing in recognized figures on staff (to regain the lost accreditation), and, later in the 1930s, implementing the new "shock" therapies. In 1943, the name was changed to the Institute of Living. In 1946, Francis J Braceland, who had studied at the Zurich University Psychiatric Hospital and the National Hospital for Nervous Diseases in London, became chief psychiatrist. (Braceland is also remembered for being a special witness at the Nuremberg Trials in 1946, whose testimony saved Rudolph Hess from execution.) Said a New York Times obituary in 1985, Braceland is "credited with changing its reputation [Institute of Living] from that of a plush sanitarium for the rich and famous to that of a highly respected psychiatric hospital for the seriously ill." In

1994, the Institute of Living became part of Hartford Hospital.

Yale University. Yale had the third university department of psychiatry in the United States—after Johns Hopkins and Harvard. The central figure here was Dean Milton C Winternitz, a neuropathologist who conceived the Institute for Human Relations, which opened in 1931. (The department of psychiatry was situated in the Institute.) Winternitz said in 1925 of the proposed Institute, "... All of these disciplines primarily interested in the problems of human behavior from the standpoint of investigation, graduate teaching, and application, i.e. therapy, [should] be brought together geographically in a single building designed to allow the greatest possible latitude for ... cooperation." An embryo department of psychiatry had come to life in the 1920s. Yet only in 1930 was it led by a significant figure, when Eugen Kahn, a Kraepelin student and collaborator with Ernst Rüdin in schizophrenia genetics, became chair and the first Stirling Professor in psychiatry. He was followed in 1950 by another eminent Central European, Vienna's Friedrich ("Fritz") Redlich.

In 1911, Arnold Gesell created the Child Study Center at Yale, later associated with several departments including psychiatry.

ELSEWHERE

Chicago. Chicago had a long tradition of contributions to psychiatry. In 1925, physiologist Nathaniel Kleitman organized a sleep laboratory at the University of Chicago, and from this lab emerged in 1953 a classic paper in Science co-written by Kleitman's student Eugene Aserinsky on rapid eye movement (REM) sleep. Neurologist and psychiatrist Percival Bailey had cofounded in 1946 the Society of Biological Psychiatry. And Laszlo von Meduna, the originator of convulsive therapy, arrived in Chicago from Budapest in 1939 and ultimately found a berth at the Neuropsychiatric Institute of the University of Illinois.

Yet the founding figure in psychiatry is Roy Richard Grinker, who had a background both in psychoanalysis (worked with Freud in Vienna in the early 1930s) and in neurology. Grinker's career at the University of Chicago began in 1933, with his appointment as associate professor of neurology; he became associate professor of psychiatry in 1936, which established psychiatry within the department of medicine (Grinker's appointment at Michael Reese Hospital in 1936 is recalled as "taking over the department of neurology"). In 1955, psychiatry changed to a department in its own right, its first chair C Knight Aldrich. Although psychodynamics was then the watchword in Chicago, the University was not hesitant to appoint in 1966 the elfin Daniel X Freedman from Yale as the next chair. Freedman, an enthusiastic promoter of biological psychiatry, became chief editor of the AMA's Archives of General Psychiatry in 1970. He was succeeded as chair by Stuart C Yudofsky in 1988, and Elliot S Gershon in 1998. Steven

Paul, who later led neuroscience research at Eli Lilly, recalled in a 2011 interview his years in the mid-1970s as a resident in psychiatry at the University of Chicago, "It was a very exciting department in those days. Herb Meltzer [biological psychiatrist] was there and Heinz Kohut, the analyst, Bob Schuster [Charles R Schuster, who founded the University of Chicago's Drug Abuse Research Center], and many others. A tremendous department Danny had pulled together, a small but extraordinarily fine department." Meanwhile, in 1974 Philip Holzman, professor of psychology at the University of Chicago, reported a major biological abnormality in schizophrenia, saccadic eye-tracking movements (smooth-pursuit in tracking is normal).

University of North Carolina. The Department of Psychiatry at the University of North Carolina (UNC) at Chapel Hill was founded by Chicago psychoanalyst George Ham in 1951. It started to become a biological piston with the arrival in 1954 of Scotsman John Ewing as clinical instructor, then chair in 1962. Psychiatric endocrinologist Morris Lipton from the University of Chicago joined the department in 1959 and proceeded to steer it toward the endocrinological hormones that science was just discovering. (Lipton became known as having "opened up the peptides.") Arthur Prange, who had trained at UNC, joined the staff in 1960 and proceeded to solidify UNC's growing association with psychiatric endocrinology. William McKinney (later at the University of Wisconsin) trained at UNC in the mid-1960s, and in his class were Frederick Goodwin (later an NIMH star), the Englishman Peter Whybrow (later chair of psychiatry at the UCLA Neuropsychiatric Institute), and Joseph Mendels (who ended up leading biological psychiatry at the University of Pennsylvania).

Duke University. Across the way from UNC lay Duke University in Durham. In 1953, Ewald Busse, psychoanalyst and geriatrician, became the founding chair of psychiatry at Duke. His successors H Keith Brodie (1974 to 1982) and Bernard Carroll (1983 to 1990) ended this Freudian spin (in 1968 Australian-born Carroll introduced the dexamethasone suppression test [DST] into psychiatry for the diagnosis of melancholic depression). Duke and UNC together constituted a powerful core of psychiatric research for the southeast.

University of Pennsylvania. Psychiatry at the University of Pennsylvania had begun in 1793, when Benjamin Rush, a professor of chemistry, opened a ward for insane patients at Pennsylvania Hospital. But academic psychiatry at Penn really began only in 1874, with the establishment of the Hospital of the University of Pennsylvania. A department of mental diseases received its inaugural head in 1883, and in 1901, Charles Burr was appointed Penn's first chair of mental diseases.

Karl Rickels founds the Clinical Psychopharmacology Unit in 1959. And

the Center for Mental Health Policy and Services Research (CMHPSR) was established in 1986.

The "Psychopathic Hospitals." Emblematic of the new association between asylum and academy were the so-called "psychopathic hospitals," which began life in the 1880s, as reception wards for newly admitted, or "acute," patients. American psychiatrists visiting Europe had learned much about humane care, and the usefulness of setting these acutely ill patients aside from the chronic patients working in the farm colonies or vegetating in the backwards. (Indeed, the spotlight began to turn toward creating psychiatric wards in general hospitals, such as "Pavilion F," founded in 1902, of Albany Hospital.)

In 1901, the Michigan legislature appropriated a sum for the establishment of a "psychopathic hospital" on the grounds of the State University of Michigan, as an additional ward of the University Hospital. It was not part of the state asylum system and entirely under the control of the university. The psychopathic hospital did not in fact open until 1906, under the direction of neuropathologist Albert M Barrett.

In Massachusetts in 1912, a psychopathic hospital opened on Fenwood Road in Boston as a department of the Boston State Hospital in Dorchester; it was under Elmer E Southard, a professor of neuropathology at Harvard. The plan was, as Henry Hurd in his great 1916 work *The Institutional Care of the Insane* put it, to establish "a hospital for the first care and observation of mental patients and the treatment of acute and curable mental diseases and for an out-patient department ... for scientific research as to the nature, causes and results of insanity." The patients were given laboratory tests, stabilized with hydrotherapy, and then either discharged as recovered or forwarded to the main wards of the state hospital. In 1920, the institution was renamed Boston Psychopathic Hospital, under C Macfie Campbell. In 1956, the name was changed again to Massachusetts Mental Health Center. Several prominent figures in US psychiatry served there, including Abraham Myerson.

Fourteen further psychopathic hospitals were founded by the First World War, although their missions ranged from the conduct of research, as at the University of Michigan and Harvard's Boston Psychopathic, to the mere reception and detention of acute patients. (On the Iowa Psychopathic Hospital, opened in 1921, see below.)

MISSISSIPPI VALLEY PSYCHIATRY. A string of important psychiatry departments ran down the Mississippi valley and played a crucial role in bringing the new biological psychiatry to the United States.

University of Iowa. Academic psychiatry began in Iowa City with the opening of the Iowa State Psychopathic Hospital in 1921 under the state board of education. The director was simultaneously chair of psychiatry at the

university, and the Iowa Psychopathic is considered the first university-affiliated psychiatric department west of the Mississippi. Under founding director Samuel T. Orton in 1919, a neuropathologist who previously had been clinical director of the Worcester State Hospital in Massachusetts, the department rose to become one of the powerhouses of US psychiatry. Jacques Gottlieb, whose background was in neuroendocrinology and who established the effectiveness of the amphetamines in the treatment of depression, taught at the Psychopathic Hospital from 1937 to 1940, then returned to Iowa as professor of psychiatry from 1947 to 1953, before moving on. Erich Lindemann came from Heidelberg to train at Iowa in 1927, and was on staff until 1935, before accepting a post at Harvard. While at Iowa, Lindemann was among the first to investigate the effects of psychopharmaceuticals. (Lindemann is also remembered for helping pioneer the diagnosis of traumatic stress with his 1944 study of "acute grief" in the survivors of the Coconut Grove Fire in 1942 in Boston.) Establishing a strong bridge between Iowa and Washington University in St Louis, George Winokur came from Wash U in 1971 to chair psychiatry at Iowa. William Coryell followed in 1977. Ming Tsuang trained in psychiatry at Iowa, then served as professor from 1975 to 1982. In 1996, Winokur and Tsuang (who by now had become the Stanley Cobb Professor of Psychiatry at Harvard) published The Natural History of Mania, Depression, and Schizophrenia, based on the research panel "the Iowa 500." In 1971, Nancy Andreasen completed her training at Iowa, then while on staff went on to pioneer the neuroimaging of schizophrenia.

Washington University in St. Louis. Psychiatry at "Wash U" began in 1918, under Sidney Schwab, who headed the division of neurology and psychiatry, a "subdepartment" of the Department of Medicine. In 1938, the Department of Neuropsychiatry became an independent unit under David M Rioch, who passed the torch to Edwin Gildea in 1942. In 1948, Harvard-trained Eli Robins became a fellow at Wash U, joining the department in 1951. Meanwhile, in 1950 Samuel Guze joined the department, and for the next 20 years the names Robins and Guze would be closely associated with the growth of psychiatry at Wash U as it became the premier department of biological psychiatry in the United States. In 1970, they suggested the "medical model" as an alternative to the "biopsychosocial model," as a motor for delineating disease.

Wash U was also one of the two seedbeds (Columbia the other) of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM). Recalled Paula Clayton in an interview, who at the time was a resident, "We all read Kraepelin. He was our bible." Under Eli Robins (chair 1963 to 1975) and Samuel Guze ("Goo-zay," chair 1975 to 1989), psychiatry at Wash U opened up a series of links between basic biology and clinical psychiatry. "[It] was nearer to being a mini-NIMH,"

said geneticist Irving Gottesman later, "where under one roof you could have MDs and PhDs of all sorts working together on projects." Graduates of Wash U assumed important leadership roles throughout US psychiatry. It was the consummate insiders' group and displaced the previous insiders' group, the psychoanalytically oriented Group for the Advancement of Psychiatry (GAP).

TENNESSEE. Frank H. Luton became the first psychiatrist at Vanderbilt in Nashville, Tennessee, when he returned in 1931, after training at Johns Hopkins under Adolf Meyer. The School of Medicine created a department of psychiatry in 1947 with the appointment of William F Orr, Jr, who in turn was succeeded by Marc Hollender in 1969, and Michael H Ebert in 1983. Interest at Vanderbilt passed from dynamic psychiatry to psychopharmacology in the 1970s, with the appointment of such investigators as Fridolin Sulser, Thomas Ban, and Herbert Meltzer.

Meanwhile, in Memphis Hagop Akiskal, a graduate in 1969 of the medical school of the American University of Beirut, had organized in 1973 an affective disease clinic at the University of Tennessee, one of the first in the United States. From 1987, Akiskal propagated the idea of a "soft bipolar spectrum," heavily dependent on temperament and managed with mood stabilizers, rather than conventional "antidepressants."

TULANE. Psychiatry at Tulane in New Orleans was founded by Robert G Heath after he arrived from Columbia in 1949. In New York, Heath had trained in both neurology and psychoanalysis, and established a psychoanalysis program at Tulane. But his real interest lay in the possible metabolic origins of schizophrenia. The charismatic Heath, whom Time magazine called "the Gregory Peck of psychiatry," set out to investigate intracerebral events by persuading doubtful colleagues of the wisdom of inserting indwelling electrodes. This controversial program came to nothing, but Health had several important students. In 1960, one of them, Donald M Gallant, won for the department of psychiatry a federal grant from the ECDEU of the National Institute of Mental Health, a program that aided the introduction of psychopharmacology into American psychiatry (see above). Gallant became chair in 1969 following Heath, and expanded the entire range of research in psychopharmacology, so that it became the flagship program of the Deep South in this area.

THE WEST COAST. Several departments of international distinction on the West Coast were founded—much later than those in other parts of the country. Yet they are part of the story of the transition from asylum to university psychiatric hospital.

Stanford University, Palo Alto. Psychiatry at Stanford was founded in 1933, when George S. Johnson came from his post at the University of Colorado

to become chair of neuropsychiatry. In 1954, neurology split from psychiatry and Johnson continued as chair of psychiatry. Child and adolescent psychiatry, which was established in 1939, merged with the department in 1957. In 1960, Stanford University School of Medicine moved from San Francisco to Palo Alto, where it quickly became a research-oriented medical school. David Hamburg came from the NIMH in 1961 to chair the department, and he recruited a number of future leaders, such as William Dement, who founded sleep medicine as a clinical discipline as well as a research program; Jack Barchas, remembered for early work on the enkephalins and endorphins; and Helena Kraemer, who developed statistical research methods.

The department went on to become one of the main forces in US psychiatry. Alan Schatzberg, a leader in psychopharmacology and coauthor with Charles Nemeroff of Textbook of Psychopharmacology (1998), came from McLean Hospital to serve as chair from 1991 to 2010. His own work centered on the adverse effects of hypercortisolemia and the development of glucocorticoid antagonists as treatments for psychosis. Laura Roberts, a leader in academic psychiatry and bioethics, was recruited from the Medical College of Wisconsin to serve as chair beginning in 2010.

Langley Porter Clinic San Francisco. In San Francisco, the Langley Porter Clinic, named after Dean Robert Langley Porter who conceived it in the late 1930s, opened its doors in 1942, as a 100-bed psychiatric hospital. It later changed its name to the "Langley Porter Neuropsychiatric Institute," and then again to "Langley Porter Psychiatric Institute." Writes historian Jurgen Ruesch in 1978, "It was based upon the idea that prevention, teaching, and research … would be enhanced if the wealth of clinical experience gained from the approximately 29,000 patients then available in the nine California state hospitals could be combined with the expertise of the staff of a medical school." The inaugural director was Carl M. Bowman, who simultaneously became the first chair of the new division of psychiatry in the School of Medicine. Bowman was among the charter members in 1946, of the Society of Biological Psychiatry. In 1973, the hospital was transferred from the jurisdiction of the state to the University of California (as was the Neuropsychiatric Institute in Los Angeles [see below]).

Neuropsychiatric Institute Los Angeles. The UCLA was opened only in 1947, and Stafford Warren, the inaugural Dean, was said to have "dreamed of creating a 'Langley Porter of the South.'" Norman Brill was brought from Georgetown in 1953 to become the founding chair of the Psychiatry Department, and in 1961, the first patients were admitted to the new Neuropsychiatric Institute (NPI) funded by the state government of California. A nearby Brain Research Institute also opened in 1961. Louis J. ("Jolly") West came from the University of Oklahoma to chair the young psychiatry department, and West built staff from all around the world. In

1959, John French became the founding director of the Brain Research Institute. In 1973, the California State Department of Mental Hygiene transferred the NPI to the University of California, where it became part of the UCLA Health Sciences Center.

PART V: DIAGNOSIS

The two great arms of clinical psychiatry are diagnosis and treatment. The following sections are devoted to the histories of both.

Modern psychiatric diagnosis really begins with Philippe Pinel in Paris (see above), who in the second edition of his textbook in 1809 enumerated four psychiatric diseases: (1) "mania, or general psychosis [délire]"; (2) "melancholia, or a specific delusion"; (3) "dementia, or abolition of thought"; (4) "idiotism, or the obliteration of the intellectual and affective faculties." What he meant by these would parse into a number of distinct modern illnesses, but the point is that he did recognize several specific forms of previously undifferentiated "madness."

After Pinel and Esquirol (see above), the most important figure in the history of nosology is Emil Kraepelin ("Krep-uh-leen"), professor of psychiatry in Heidelberg from 1891, in Munich from 1903, and author in 1883 of the influential psychiatric textbook, Psychiatry: a Textbook for Students and Physicians (*Psychiatrie: ein Lehrbuch für Studierende und Aerzte*), which reached international influence with its fourth edition in 1893 and became worldwide the dominant voice in psychiatry by the eighth edition, completed in 1915. Kraepelin had little patience with psychiatric theory or with pathological anatomy, and placed the diagnostic interest in psychiatry squarely on the clinical side, meaning at the bedside, especially on the course and outcome of the patient's illness.

Kraepelin was the clinician's clinician. On the basis of clinical course, Kraepelin said in 1899 that the two specific diseases in psychiatry were "manic-depressive insanity," a mood disorder, and "dementia praecox," or the dementia of adolescence, a thought disorder later called "schizophrenia." He erected a firewall between them, one that still exists today, as in the DSM system the cardinal disorders are "major depression," as opposed to "schizophrenia." No other historical figure in psychiatry, including Freud, has had the influence of Kraepelin upon contemporary psychiatry, although under the influence of psychoanalysis, US interest in diagnosis did wane for several decades. Henri Ellenberger, a Swiss psychiatrist transplanted to Montreal, recalled in 1955, "I remember the consternation of a German psychiatrist hearing that certain American colleagues consider manic-depressive psychosis as a form of schizophrenia; for him this was about as fantastic as the assumption that a camel is a subspecies of the elephant."

A page was turned with the advent of a distinctively American system of classification in 1945, the "Nomenclature of Psychiatric Disorders and

Reactions," which appeared as War Department Technical Bulletin, "Medical 203." Spearheaded by psychoanalyst William Menninger, the head of consultation psychiatry in the US Army during the war, "Medical 203" made wide use of psychoanalytic insights and underpinned the first effort of the American Psychiatric Association to classify illness, the *Diagnostic and Statistical Manual,* or "DSM-I" (so-called subsequently) in 1952. (The APA itself was founded in 1844 as The Association of Medical Superintendents of American Institutions for the Insane, becoming the American Medico-Psychological Association in 1894, and the American Psychiatric Association in 1921.)

An even more psychoanalytically oriented volume, DSM-II, emerged in 1968.

In the 1970s, the APA drew up a new task force to make what were intended to be minor changes in DSM to bring it into accordance with the *International Classification of Diseases* (ICD) of the World Health Organization, appointing Robert Spitzer at the New York State Psychiatric Institute to lead it. Spitzer, however, disliked psychoanalysis and wanted a complete revision of the nosology to remove Freudian influences. In 1980 the revolutionary DSM-III emerged, which created such diagnoses as "major depression" and "attention deficit disorder," and anchored "bipolar disorder" firmly in the American classification. The subsequent editions of DSM—DSM-III-R in 1987, DSM-IV in 1994, and DSM-5 in 2013—changed little of this architecture, though in launching "bipolar two disorder" in 1994, DSM-IV did touch off an epidemic of "bipolar" in the pediatric population.

A rival system was the ICD of the World Health Organization. In 1938, an "international revision" conference of the League of Nations decided to add morbidity to its long-standing classification of mortality, and in 1948 the newly founded World Health Organization issued the "sixth revision" of the international lists (ICD-6). It contained such diagnoses as "delusional" insanity (other major psychiatric illnesses were catalogued under "dementia"). A distinct section on "mental disorders" was added in the 9th edition in 1975.

Over the years, the number of diagnoses in psychiatry has skyrocketed from four in Pinel to some three hundred in DSM-5. Some of these diagnoses may not stand the test of time. Yet, on a historical basis, several diagnoses do stand out as enduring, and doubtless represent phenotypes of genuine underlying psychiatric diseases.

Specific Diagnoses

Melancholia. Melancholia, as distinct from generic "depression," is one of the oldest diagnoses in medicine and goes back to the Ancients. Before the 19th century, melancholia tended to be an umbrella term for several varieties of psychosis and mood disorder that today would be

recognized as distinct. Yet at its core, melancholia has always stood for severe depressive mood disorder involving deep sadness, pervasive anhedonia, and psychomotor change, usually in the direction of slowing but there is an anxious form of melancholia involving psychomotor acceleration as well. Timothie Bright, a Cambridge physician, in his 1586 book *A Treatise of Melancholie* described,

> the sorrowful humor which breeds in them ... Of pace, they are for the most part slow ... both by their members not so nimble for motion, and the mind occupied with cogitation stays [slows] the pace ... Moreover, they are given to weeping sometimes ... sighing, sobbing, lamentation, countenance demisse [downcast] and lowering." Bright left a poignant image of weeping in melancholia, "It blears the eyes and makes the cheeks red; it causes the head to ache, the nose to run, and the mouth to flauer [labor], the lips to tremble; it interrupts the speech and shakes the whole chest with sighs and sobs.

In the 19th century, melancholia became differentiated from other kinds of depressive illness. Among the first to make this distinction was Richard von Krafft-Ebing in 1867, at the time a staff psychiatrist at the Illenau asylum (later, professor of psychiatry in Vienna). Krafft-Ebing distinguished between "simple depression of mood" (die einfache Gemüthsdepression") and severe depressions with anxiety and psychosis, including melancholia. The definitive distinction between "melancholia" and "depression" was ventured by Copenhagen psychiatrist Carl Georg Lange in his book on "periodic depressions" in 1886 (translated into German in 1892), which described these milder cases as distinct from (psychotic) melancholia.

The term "melancholia" went out of style around 1900 as Emil Kraepelin substituted "depression" for it, and Sigmund Freud decided that the depressive disorders did not qualify as the main psychoneuroses that psychoanalysis should be addressing. (But see above on a United States interested in "depressive neurosis.") In recent decades, there has been a revival of interest in melancholia, as the field has begun to differentiate the heterogeneous basin of "major depression" on the basis of treatment response.

Psychotic Depression. In classical psychiatry, much melancholia was psychotic, and little was made of the distinction between psychotic and nonpsychotic. The difference later seemed unimportant because both groups responded equally well to ECT, introduced in 1938. Yet with the growing stigmatization of ECT after the 1960s, depression became treatable primarily with drugs, and in 1975, Alexander (Sandy) Glassman at the New York State Psychiatric Institute discovered that psychotic depression responded poorly to the standard tricyclic antidepressants (TCAs). Four years later, David Avery and Aldo Lubrano at the Palo Alto Veterans Hospital reported that psychotically depressed patients responded better to ECT than did nonpsychotically depressed. Under the leadership of Max

Fink at the Stony Brook Campus of the State University of New York, ECT became defined as the most effective treatment of psychotic depression. Despite this evidence of differential responsiveness, psychotic depression continued to be downgraded as a mere "specifier" in the DSM.

Mania. Mania has undergone several transformations. For Pinel and the generations before him, it meant agitated dementia ("raving madness"). With François Fodéré in Strasbourg (1817), unbridled unreasoning outbursts became "furious mania." In 1858, London psychiatrist Daniel Hack Tuke steered mania in the direction of an affective disorder rather than a disorder of intellect. "Although mania, in many instances, is prolonged anger, it may, likewise, be altogether pleasurable in its manifestations, presenting a condition of exhilaration and uncontrollable excitement, which is rather an excess of joy than of anger." Then in 1881, Emanuel Ernst Mendel, senior lecturer in Berlin, anchored the term "hypomania" in the nosology, meaning elated mood, pressured speech, and increased motor activity. Mania entered DSM intact in 1952, and hypomania became official in 1994 in DSM-IV as "bipolar 2 disorder."

Catatonia. Although individual symptoms of catatonia, such as waxy flexibility, had been described for centuries, catatonia as a clinical syndrome was recognized by Karl Kahlbaum only in 1874. It independent existence was short, as in 1899, in the 6th edition of his Textbook, Kraepelin made it a "subtype" of schizophrenia, and for the next century catatonia languished as an independent entity because, often when clinicians encountered it, they realized they were not dealing with schizophrenia and called it something else, or ignored it. In 1930, William Bleckwenn at the University of Wisconsin reported that catatonia responded to barbiturates, though this discovery was not widely appreciated. Karl Heinz Stauder, at the Munich University Psychiatric Hospital, described in 1934 a fatal version of catatonia, associated with hyperpyrexia.

The return of catatonia as an independent diagnosis separate from schizophrenia began in the 1970s. In 1976, Richard Abrams and Michael Alan Taylor at New York Medical College identified 20 percent of a sample of patients admitted to the psychiatric unit of a New York City hospital as having one more catatonia signs. Only 4 of the 55 satisfied the criteria for schizophrenia, while more than two-thirds had affective disorders, usually mania. In the context of growing interest in catatonia as independent of schizophrenia, in 1983, Gregory Fricchione at Stony Brook recommended benzodiazepines, especially lorazepam, in the treatment of catatonia instead of barbiturates. Various syndromes previously seen as separate began to be recognized as catatonic in nature: In 1996, it was suggested that toxic serotonin syndrome (TSS) might be a form of catatonia. A

symposium at the American Psychiatric Association meeting in 2000 concluded that neuroleptic malignant syndrome (NMS) and malignant catatonia were the same. In 2011, Dirk Dhossche at the University of Mississippi and colleagues raised the possibility that anti-NMDA receptor encephalitis was a form of catatonia. The American Psychiatric Association responded to this series of new catatonia findings by making catatonia a virtually independent disease entity in the DSM-5 published in 2013.

Delusional Disorders

Delusional disorders, meaning fixed, systematic false beliefs, were recognized in 1816 with Etienne Esquirol's "monomania." He said that the psychosis (délire) is fixed on one object alone. As early as 1865, then definitively in 1874, Ludwig DC Snell, director of the asylum in Hildesheim, Germany, distinguished between primary and secondary delusions (Wahn), primary meaning fixed, false ideas not caused by another illness and not deteriorating; vague secondary delusions could lead to "the collapse of the entire psychic life," something Snell observed in the kind of illness later called "schizophrenia." This was the beginning of separating delusional disorders from chronic deteriorating psychosis as the former were false beliefs that were fixed, systematic, and did not affect other areas of intellectual functioning.

Anxiety. The term "anxiety" has long been used in psychiatry. In 1769, a young medical graduate of Leiden University ventured a dissertation on "Anxietate," and the term was clearly current among his professors. Yet the German clinical tradition of the 19th century frowned on anxiety as an independent diagnosis. In Emil Kraepelin's big textbook, there is no freestanding "anxiety" disorder. But it was not just Kraepelinian obdurance. The "anxiety" entry in Daniel Hack Tuke's Dictionary of Psychological Medicine (1892) is only two sentences long. What placed anxiety in the center of psychiatry's radar was Freud's belief that anxiety was the basic motor of symptom formation: anxiety arose as a result of intrapsychic conflict over various drives. The entries for "anxiety" (Angst) in the general index of Freud's writings extended for eleven pages ("genitals," by contrast, only for four). Accordingly, anxiety has always assumed a disproportionate role in psychoanalytically oriented American psychiatry (mixed anxiety-depression has tended to loom more prominently for the British). DSM-I in 1952 prefaced its discussion of "psychoneurotic disorders" by claiming that, "The chief characteristic of these disorders is 'anxiety'...." and in the discussion that followed "anxiety" figured importantly in each, such as "dissociative reaction," "obsessive compulsive reaction," and so forth. DSM-III in 1980, although antipsychoanalytic in inspiration, continued the centrality of anxiety while beginning its fragmentation into specific anxiety disorders, of which there

were ten. Subsequent editions of DSM have continued this tradition.

Chronic Primary Psychosis (Schizophrenia). Psychiatry has struggled over the years with chronic deteriorating psychotic illness, leading either to some kind of deficit or to the dissolution of the personality (once called "dementia"). Developments in psychiatry's two major cradles are chronicled separately.

France. In 1852, Bénédict-Augustin Morel, then at the Maréville asylum in eastern France (but shortly to head the St-Yon asylum outside of Rouen) called such psychoses of adolescent onset "démence précoce," or premature dementia (see above). In 1857, he applied the notion of "degeneration," or worsening across the generations, to psychiatric illness (Traité des Dégérérescences) and 1860, in one of the most famous declarations in the history of psychiatry, in his Treatise on Mental Illness (Traité des Maladies Mentales) he avowed premature dementia in the young to be a consequence of degeneration.

In 1883, Valentin Magnan, a staff psychiatrist at the Sainte-Anne Clinical Asylum in Paris, described "chronic psychosis,"—he later added the qualifier "involving systematic evolution"—an often-deteriorating form of psychosis in patients who were not hereditarily predisposed. This remained quite influential in France, though elsewhere it was eclipsed by "schizophrenia" (see below).

French experimentation with chronic psychosis continued, even as Magnan's degeneration-based doctrines were discredited, and in 1910, Maurice Dide, at a psychiatric hospital in Toulouse, proposed "chronic hallucinatory psychosis," which, though severe, did not deteriorate. To this day, the concept has remained influential in France without reaching a larger international audience.

Germany. Meanwhile, in Germany a different approach to chronic psychosis was being elaborated: deterioration to "dementia," or at least to a severe deficit. In an 1863 book on the classification of psychiatric illness, Karl Kahlbaum, a staff psychiatrist at the East Prussian provincial asylum of Allenberg, differentiated a "deteriorating psychosis," which he called Vesania typica, which ran its course in four stages, the last of which was "dementia." Vesania was a customary term at the time for chronic psychosis. In 1871, Kahlbaum and his student Ewald Hecker differentiated further a version of this Vesania beginning in adolescence that they called "hebephrenia." Hebephrenia, like Vesania typica, usually ended in dementia. (Although Hecker's name appeared alone on the paper, it was understood that the concept was really Kahlbaum's.)

At this point, a considerable amount of European scholarship, dating from Morel in 1852, had accumulated that linked chronic deteriorating psychosis to an onset in adolescence. In 1893, Kraepelin synthesized this literature in a concept that was to sit rock-solid in psychiatry for more than

a century: “dementia praecox.” Over the next decade he identified three subforms of it: hebephrenic, catatonic, and paranoid. They had in common a begin usually in adolescence or young adulthood, and a downhill course to “dementia.” So magisterial was the Kraepelinian synthesis that all previous writing on chronic psychosis became virtually forgotten. In 1908, Eugen Bleuler, professor of psychiatry in Zurich, baptized Kraepelin’s dementia praecox as “schizophrenia,” seeing it as a much milder disease and not linked to adolescence. Bleuler’s schizophrenia remains little changed today, a single deteriorating psychotic disorder that may onset at any point in life and that may well end in “defect” (or social remission), even if “dementia” as the end stage of the illness has stopped being spoken of. In 2013, DSM-5 dispensed with the famous Kraepelinian “subtypes.”

Many “schizophrenia” patients may spend long periods without being actively psychotic; the primary symptoms seem to be emotional blunting with avolition and a formal thought disorder.

Brief Reactive Psychosis or Brief Psychotic Disorder

Chronic psychotic illness had long been seen as something indwelling and constitutional. The alternative notion that psychosis could arise from stress was codified as “la bouffée délirante” by two students of Valentin Magnan at Sainte Anne in Paris in 1886, then by Magnan himself in 1891—who saw it as arising mainly in the “degenerate.” August Wimmer at St. Hans Hospital in Denmark christened it “psychogenic psychosis” in 1916, with an emphasis on reaction rather than degeneration. Then in 1968, Eric Strömgren in Aarhus, Denmark, revived Wimmer’s concept in an influential (in Scandinavia) paper on “reactive psychoses,” a term that he changed in 1974 to “psychogenic psychoses.” In 1980, DSM-III recognized “brief reactive psychosis,” with no reference to any of these other international terms. (These developments are charted in Shorter, Historical Dictionary.) The French translation in 1989 of DSM-III-R makes no reference to “bouffée délirante” and mentions only “psychose reactionnelle brève,” an interesting example of the collapse of these once distinctive national nosological traditions.

Bipolar Disorder

The “bipolar disorder” of DSM is not Kraepelin’s “manic-depressive insanity,” which Kraepelin insisted included all depressions of whatever polarity, mania, hypomania, and the attendant anxiety. Rather, in his 1948 textbook Karl Leonhard, then in Frankfurt am Main and a student of Karl Kleist (who introduced the concept of “phasic psychoses,” or illnesses that alternate from one state to another), proposed the term “bipolarity” for the alternation of depression and mania as an illness separate from unipolar depression. In 1957, in The Classification of the Endogenous Psychoses

(Die Einteilung der endogenen Psychosen), Leonhard asserted that unipolar depression had a different psychopathology from the bipolar variety. Filled with neologisms and lacking in quantitation, the book had a limited international impact. Yet a small cadre of investigators, such as Frank Fish in England, Helmut Beckmann in Germany, and George Winokur in the United States, became enthusiasts of the Leonhardian notion of bipolar disorder and managed to insert it in the literature, so that by 1980, when DSM-III was published, bipolar disorder was self-understood as a different disease from unipolar depression (in DSM-III called major depression).

Trauma and Its Sequelae

Ever since Napoleon's disastrous retreat from Moscow in 1812, psychiatry has recognized that symptoms may arise from great stress. (In Napoleon's case, of an army of 400,000 that set out, 7000 returned. Along the way, much "nostalgia" was witnessed—an early label for fatal catatonia.) In 1866, London surgeon John Eric Erichsen originated the diagnosis of "railway spine," vague and nonspecific symptoms supposedly attributable to the "spine" in minor railway mishaps. Carol Moeli, a Berlin psychiatrist, elaborated in 1881, upon the specifically psychiatric consequences of such events, penning the first description of what became known as post-traumatic stress disorder (PTSD). In 1881 as well, Berlin neurologist Hermann Oppenheim coined the phrase "traumatic neurosis," psychiatric and neurological symptoms arising from shock.

The First World War spawned a whole raft of descriptions of psychological sequelae from combat, of which terms the most lasting has been "shell shock"—from Charles S Myers in 1915. The Second World War gave birth to "combat fatigue" as a synonym for war neurosis. Meanwhile, a tragic fire in 1942, at the Coconut Grove night club in Boston gave rise in 1944 to "acute grief" as yet another term for acute stress reaction. Most recently, following a sustained political campaign by the veterans of the Vietnam War—and spearheaded by Yale psychiatrist Rober Lifton—DSM-III in 1980 coined the term "posttraumatic stress disorder." This diagnosis has been among the most rapidly proliferating in US psychiatry.

Dementia

The dementias have always been a problem for psychiatry, as the field has struggled to differentiate loss of intellectual function from personality deterioration. In 1814, Etienne Esquirol took up the idea of his teacher Pinel of dementia as a distinct disease entity, separate from melancholy, mania, and imbecility. "There exists a very distinctive kind of insanity in which the disorder of ideas, sentiments, and determinations is characterized by the weakness and the more or less pronounced abolition

of all the sensory, intellectual and moral faculties." In particular, Esquirol differentiated senile dementia from other conditions of "weakmindedness." (Shorter, Historical Dictionary of Psychiatry, chronicles developments in dementia.) There followed a long series of differentiations of the organic dementias: Sergei Korsakoff distinguished ethanol-related amnesia (Korsakoff's psychosis) from dementia in 1887; Alois Alzheimer distinguished "presenile" dementia from the senile variety in 1906; in 1926, Hugo Spatz, head of neuropathology at the Munich University Psychiatric Clinic, suggested that a distinctive frontal- and temporal-lobe wasting should be called "Pick's Disease" after Arnold Pick, professor of psychiatry at the German university in Prague, who first reported it in 1892; in 1912, Friedrich Heinrich Lewy described distinctive intracytoplasmic inclusions, later called "Lewy bodies," which he detected in the brain stem in Parkinsonism; and in 1962, neuropathologist John S. Woodard at the Camarillo State Hospital in California, proposed Lewy-body dementia as a separate form of dementia; in 1948, London psychiatrist Robert Denis Newton codified long-established German thinking that presenile Alzheimer's and the dementia of senescence represented a single pathological process, and suggested calling it "Alzheimer's dementia"; Raymond Adams at Harvard University and Maurice Victor at Case Western University, emphasized in 1977, that Alzheimer disease was not just an accelerated extension of old age but a pathological eruption into it.

Ever since New Jersey pathologist Harrison Stanford Martland's paper "Punch Drunk" in 1928, repeated cranial trauma has been considered a distinct cause of dementia. Martland said, "Fighters in whom the early symptoms are well recognized are said by the fans to be 'cuckoo,' 'goofy,' 'cutting paper dolls,' or 'slug nutty.'" Since then, physicians have been alerted to the neuropsychiatric consequences of repeated head trauma. In 1937, in the US Naval Medical Bulletin, naval surgeon JA Millspaugh called it "Dementia Pugilistica." In a paper in the British Medical Journal in 1989, on "Boxing and the brain," John Arthur Nicholas Corsellis pulled this literature together in a red warning-light about repeated head trauma. By the new millennium these concerns about early dementia had been expanded to all sports involving repeated head trauma.

Neurosis

The classic distinction between psychosis and neurosis was abolished in DSM-III in 1980. Neurosis as a term is among the oldest in psychiatry, introduced by Edinburgh physician and nosologist William Cullen in his First Lines in the Practice of Physic in 1777, to mean diseases of the nervous system without an obvious physical lesion. In the next half century, it came to be synonymous with brain disorder. It was Richard von Krafft-Ebing in his Textbook of Psychiatry (Lehrbuch der Psychiatrie) in 1872, who coined the term "psychoneurosis," meaning mental illnesses that affect normal

brains (in contrast to brains affected with "degeneration"). Sigmund Freud used the term psychoneurosis for the first time in his writing in 1898. But neurosis had by that time long entered medicine and Freud proceeded to employ it as a synonym for "disorder." After Freud, neurosis remained largely in the area of psychoanalytic discourse, which was the dominant discourse in psychiatry until DSM-III in 1980.

PART VI: NEW TECHNIQUES

Psychiatry is not among the most technological of medical specialties. Yet changes in technique have expanded the range of its knowledge and enhanced the diagnostic and therapeutic abilities of its practitioners.

Epidemiology

The study of epidemiology had an early bump-up with the observation of Thomas Clouston in 1873, in the *Journal of Mental Science* that, "The wide series of diseases which are at present called insanity prevail more in some places than in others ... When one comes to look carefully into the reports of lunatic asylums in different parts of the country it is found that there are forms of brain disease (or varieties of insanity as they are called) present in abundance in one place which have almost no existence in another ... This investigation must be very largely conducted on the numerical method."

Yet it was the Germans who initially picked up this torch. At the German Psychiatric Research Institute (Deutsche Forschungsanstalt) in Munich, founded in 1917, by Emil Kraepelin, Swiss psychiatrist and geneticist Ernst Rüdin, inaugural director of the eugenics research institute of the DFA, led studies on psychiatric epidemiology (cross-sectional) and genetics (longitudinal). Unfortunately, in the Third Reich Rüdin had a particularly unsavory involvement with public policy, arguing for the Nazi racial and sterilization laws, and after 1945 was briefly interned in the United States. This National Socialist involvement of the DFA and other German groups lent to psychiatric epidemiology and genetics a bad odor that retarded the development of the field for decades.

It was in Denmark that Eric Strömgren, the most important psychiatric epidemiologist of the pre-1970 period, flourished. As a student, he visited the Rüdin group in 1935; he undertook in 1938 what became an epidemiologic classic of the small island of Bornholm. He became professor of psychiatry in 1945, and was instrumental in organizing the Danish Psychiatric Central Registry at Aarhus, which in 1969 became an electronic register of everyone in Denmark admitted to a psychiatric service. By 2011, this famous register contained over 700,000 individuals and more than 3 million treatment episodes. One offshoot of this was the Danish-American cohort study in 1968, led by David Rosenthal, Paul Wender, and Seymour Kety at NIMH. It merged two registers: that of children who had been

adopted away and that of admissions to psychiatric hospitals. This remarkable data base permitted the NIMH collaborators, together with Fini Schulsinger in Copenhagen and other Danish colleagues, to determine that children adopted from schizophrenia families but raised in normal homes often became schizophrenic. It was a major blow to the "nurture" school). At a conference in Dorado, Puerto Rico, where these results were first presented, Rosenthal said, "The case for heredity has held up convincingly. At the moment, I can see no grounds for withholding affirmation any longer."

In the United States, the National Institute of Mental Health sponsored in the 1980s, the 5-site Epidemiological Catchment Area (ECA) study, the first to inquire about diseases rather than symptoms, the results of which were reported in 1991. Myrna Weisman at Columbia later said in an interview the big finding of the ECA was that, "These disorders begin in the young ... often in adolescence, and certainly, by young adulthood ... So, the biggest contribution of the ECA was turning the focus on young people and their high rates of psychiatric disorders."

In the early 1990s, NIMH sponsored the National Comorbidity Survey (NCS) to assess the prevalence of DSM-III-R disorders in a nationally representative sample. Early in the new century, the NCS was redone in the National Comorbidity Survey Replication (NCS-R), using the international WHO Composite International Diagnostic Interview, to collect DSM-IV diagnoses from a household survey, and to make international comparisons possible.

Statistics

Paris psychiatrist Jean-Pierre Falret's critique of the counting method in 1864, in the preface of his On Mental Illness (Des maladies mentales), has not lost its relevance today: "Statistics as a procedure are in fact all the more dangerous because they offer all the appearance of truth." Falret scorned the statistics of the day as failing to include homogeneous clinical populations and using abstractions overly divorced from reality. Modern statistical theory, as Bernard Carroll traces events, originated in the last quarter of the 19th century and the first quarter of the 20th. Regression to the mean was described in 1877; regression and correlation analysis in 1888 by Francis Galton; the Chi-squared test in 1900 was originated by Karl Pearson; the student's t-test in 1908 by W.S. Gossett; the analysis of variance (ANOVA) comes from RA Fisher in 1919; power analysis, confidence intervals, Type I and Type II error originated in the 1930s from Jerzy Neyman and Egon Pearson. But these advances were not incorporated as research tools into the clinical science of psychiatry until well beyond the 1930s.

The early use of statistics in psychiatry consisted essentially in tabular bookkeeping—simple descriptive statistics such as census details, cohort

descriptions by age, age of onset, sex, or outcome. Use of statistics to test hypotheses in psychiatry came much later. Emil Kraepelin maintained detailed counting cards (Zählkarten) of cases he observed, leading up to his landmark distinction between dementia praecox and manic depressive insanity (see above). Assen Jablensky's 1993 reanalysis of those cases with modern statistical methods essentially confirmed the existence of two separate disorders that Kraepelin had recognized by informal Gestalt inferential methods. The same cannot be said of Aubrey Lewis, whose 1934 discussion of depressive illness confidently announced a single dimensional model without the benefit of any statistical analyses. That position became dogma within Maudsley Hospital circles and led to conflict with the Newcastle school under Martin Roth. Eventually, Lewis's primary data were subjected in 1977 to modern statistical analysis by Lesley Kiloh and Roger Garside (two of the original Newcastle group), and they were found actually to support the Newcastle binary model. These two examples illustrate the absence of reliable means to validate the proposals of clinical experts before the entry of statistics into psychiatric research.

Aside from elementary analytic procedures such as group comparisons (in categorical and dimensional versions), significance testing, and correlations (all in parametric and nonparametric versions), the major statistical themes that moved psychiatric research were numerical taxonomy and psychometrics. Derived from advances in basic statistics, these approaches appeared first within academic psychology for the study of personality traits and dimensions of psychopathology. For the most part, they were slow to be taken up within the discipline of psychiatry and, when they were, the history of their adoption is inseparable from the history of clinical assessment instruments that relied on the new statistical approaches. In parallel, innovations in basic statistical theory and technique also were adopted within psychiatry for clinical trials, as well as for epidemiologic and genetic studies.

Factor Analysis and Personality Inventories

Factor analysis originated with Charles Spearman and Raymond Cattell. The psychological sciences adopted the technique in the 1930s. In parallel, the Minnesota Multiphasic Personality Inventory (MMPI) was under development by Starke R. Hathaway and J. Charnley McKinley at the University of Minnesota from the late 1930s. Local use apparently began in 1939. The original published version appeared in *JAMA* in 1943: The MMPI has seen many later revisions. A perceived advantage was casting it as a descriptive and atheoretical approach to personality and psychopathology, not derived from psychoanalytic theory. Over the years, cultural and ethnic biases in the MMPI have been alleged. Nevertheless, it attained widespread use in education, clinical psychology, and employment screening. A scoring innovation for the MMPI was the devising of T-scores

—a standardized metric where the mean is set at 50 and the SD at 10. Other scales adopted the same scoring approach, which had the benefit of standardizing responses and allowing cross-scale comparisons. In parallel, Raymond B. Cattell devised in 1946, a personality inventory for which factor analysis was an essential component. His psychometric instrument is famous as the Cattell 16PF personality factors inventory.

Controlled Trials

The first controlled trial in psychiatry was reported in 1922 in the *American Journal of Psychiatry* by Clarence O Cheney, assistant director of the New York State Psychiatric Institute, then at Ward's Island, and bacteriologist Nicholas Kopeloff. They wanted to establish whether the organ removals (colectomies, teeth, etc.) then in vogue for the treatment of mental illness were in fact effective, and to do so they studied 60 patients with "focal infections" among the general admissions to the Manhattan State Hospital on Ward's Island, dividing them into two groups, the "operated group" receiving operative treatment for their " 'foci' of infection" versus those not so treated (the "control group"). They found, "On the whole, the operated group appears to have received no more benefit than the control group."

Following the tuberculosis studies of Bradford Hill after the Second World War, randomizing the patients to control or treatment groups became increasingly common. The first randomized controlled trial in psychiatry with "blinded" investigators was conducted in 1955 by David Lewis Davies and Michael Shepherd at the Maudsley Hospital, comparing reserpine to placebo in the treatment of "anxious and depressed patients."

The use of probabilistic statistics in psychiatry has a much more recent origin. Four statistics are used to measure the reduction of risk in treatment (two of them compare vs. lack of treatment). (The following discussion cribs from Andreas Laupacis and collaborators, 1988.)

- The relative risk reduction (i.e., how much risk reduction in percent). This is the classic measure.
- The "odds ratio": A probability (P) of 0.25 (one chance in four) represents odds of 1:3, or 1/3. This is insensitive to difference in risk in the absence of therapy. It was introduced by N Mantel and W Haenszel in 1959.
- Absolute risk reduction. The differences in event rates between the control and treatment groups. A genuine measure of absolute risk reduction but, expressed as a decimal, "This measure may be difficult for [physicians] to remember and incorporate into clinical practice," say Laupacis and colleagues.
- Number needed to be treated (NTT). The number of patients who must be treated in order to prevent one adverse event. Laupacis and colleagues proposed this in 1988. "It tells clinicians and patients in more concrete

terms how much effort they must expend to prevent one event, thus allowing comparisons ...” Although many clinicians will be put off by such exercises, these statistics mark the definitive passage from psychoanalysis with its evidentiary base of anecdotes to modern clinical psychiatry that employs the same evidentiary base as the rest of medicine.

Tests in Psychiatry

Despite protestations that psychiatry “has no diagnostic tests,” there are in fact quite a few. In 1906, August Wassermann and colleagues at the University of Berlin described a diagnostic test for “progressive paralysis” (what neurosyphilis was then called) based on the patient’s blood or cerebrospinal fluid. In 1913, Hideo Noguchi, a microbiologist at the Rockefeller Institute for Medical Research, succeeded in obtaining a culture of *Treponema pallidum* in a sample of the brains of neurosyphilitic patients who carried the diagnosis of “general paralysis of the insane,” the English equivalent of “progressive paralysis.” Therewith, neurosyphilis became identified as an infectious disease and passed from the purview of psychiatry, where it had lodged for the previous century. In 1931, Hans Berger in Jena used the EEG, which he had just invented, to confirm a specific pattern of brain waves in a patient with epilepsy. These were early diagnostic tests in psychiatry.

More were to come. A group of researchers led by Charles Bradley at the Emma Pendleton Bradley Home in East Providence, Rhode Island, established in 1938, that a certain subset of children who would later be called “hyperactive” (with the diagnosis attention–deficit/hyperactivity disorder, ADHD) demonstrated a specific electroencephalographic pattern. The test remains controversial but it has not been disallowed. In 1940, Mandel Cohen and Stanley Cobb, psychiatrists at Harvard, reported in The Journal of Clinical Investigation that carbon dioxide could precipitate what were later called “panic attacks” in patients prone to anxiety. Abnormalities in serum lactate thus became a biological marker for panic, and there followed a considerable history of using “panicogens” to study panic.

As early as 1958, “pharmaco-EEG” was used to “classify psychopharmacologic drugs and predict their clinical applications,” as Max Fink, a pioneer of the technique, later put it. Then in 1962, in a study published in the American Journal of Psychiatry, Fink and Donald Klein, part of the Hillside Hospital Experimental Team, established in a proper randomized controlled trial of chlorpromazine and imipramine that depressed patients responded well to imipramine, schizophrenics did not. The imipramine challenge was the first biological test for serious depression.

Bernard Carroll at the Royal Melbourne Hospital applied the DST in 1968, to confirm the presence of melancholic depression. The DST, based

on a dexamethasone challenge to the hypothalamic–pituitary–adrenal (HPA) axis, establishes HPA dysregulation in patients with severe mood disorders. In 1983, Gregory Fricchione and colleagues at Harvard reported that catatonia is responsive to the benzodiazepine lorazepam. In their 2003 book on catatonia, Max Fink and Michael Alan Taylor proposed a one or two-dose benzodiazepine challenge as a convincing diagnostic test for catatonia. Biological psychiatry proceeds from the premise that behavioral disorders are symptoms of underlying cerebral dysfunction. It is therefore unsurprising that biochemical markers have long existed in psychiatry.

Convulsive and Coma Therapy

Convulsive therapy, probably the most powerful psychiatric treatment on offer, had its origins in the 1930s, together with the other so-called "physical therapies" that addressed the brain itself.

First of the new physical treatments was insulin coma therapy, introduced in 1930 with the discovery by Manfred Sakel, then an assistant physician in a private nervous clinic in Berlin, that the withdrawal symptoms from morphine addiction could be relieved with insulin. It soon become apparent that the curative agent was an insulin-induced coma, and when, after the Nazi seizure of power in 1933, Sakel returned to his native Vienna, he persuaded the professor of psychiatry, Otto Pötzl, to let him experiment with insulin coma in the treatment of schizophrenia. From this work issued in 1934, a series of articles in a Viennese medical weekly that turned into a book in 1935, A New Method of Treating Schizophrenia (*Eine neue Behandlungsmethode der Schizophrenie*). A series of insulin comas does seem to have had a certain effectiveness in relieving the symptoms of chronic psychosis, and insulin remains today an underexplored agent in psychiatry. Some of Sakel's patients also experienced seizures, and these as well may have been a therapeutic mechanism.

It was Budapest psychiatrist Ladislaus von Meduna who in 1935 began the systematic exploration of chemically induced cerebral convulsions as a treatment. Meduna initially used camphor to initiate brain seizures, then the heart drug pentylenetetrazol. Meduna experienced extraordinary successes, especially in patients with the symptoms of catatonia, and his 1935 report in the Journal of Combined Psychiatry and Neurology (*Zeitschrift für die gesamte Neurologie und Psychiatrie*) is of historic importance in introducing the concept of therapeutic seizures to psychiatry. Yet many patients resisted chemically induced seizures because of the anxiety they experienced in waiting for the seizure to begin.

In 1938, Rome psychiatry professor Ugo Cerletti hit upon the idea of inducing the seizures with electricity, so that the patients were instantly unconscious and underwent no anxious latency period. He quickly discovered that patients with melancholic depression responded readily to ECT, and the technique spread rapidly throughout psychiatry; it was at the

time relatively uncontroversial. Cerletti had demonstrated, not that convulsive therapy was effective (Meduna's doing) but, as modern ECT-investigator Richard Abrams puts it in his 1988 manual of convulsive therapy, "that such convulsions could be induced safely, reliably, and inexpensively by electrical means." Cerletti and the other early electrotherapists did not restrain their patients, and as a result the "unmodified" seizures resulted in numerous fractures. To reduce such side effects, curare was first employed as a means of blocking the nerve–muscle junction, then, in 1952, succinylcholine, together with a barbiturate anesthetic. Yet even this modified ECT became in the 1960s an object of opprobrium in the counter-culture and then in the eyes of the pharmaceutical industry, which insisted that psychopharmacology could replace convulsive therapy. But it turned out that ECT offered distinct advantages in the treatment of melancholic depression, mania, and catatonia, and in 1978 the American Psychiatry Association offered an endorsement of it to counter the ballooning stigma caused in particular by the 1975 Hollywood movie, *One Flew Over the Cuckoo's Nest*. Max Fink, at the Stony Brook School of Medicine, led a campaign to rescue ECT from threatened oblivion. In 1990, the APA issued a much more enthusiastic endorsement of ECT, and it would be fair to say (as David Healy and I do in our 2007 history of shock therapy) that ECT has now resumed its prominent place in the panoply of psychiatric treatments.

Neuroimaging

Neuroimaging dates back to Harvey Cushing's 1896 radiograph of the cervical spine of a patient who had just been shot in the neck; the history of neuroimaging includes air encephalography, introduced in 1918, and used in Germany in 1927, to identify enlargements of the ventricular system in patients with schizophrenia. Gerd Huber's classic 1957 monograph Pneumoencephalography and Psychopathology in the Endogenous Psychoses (Pneumooencephalographische und psychopathologische Bilder bei endogenen Psychosen) was probably the high water mark of pneumoencephalography in psychiatry.

Carotid angiography, introduced in 1927, has never had significant psychiatric uses. But radionuclide brain scanning, commenced in 1948, showed great promise once radioactive ligands were introduced in the 1970s in the form of single-photon-emission tomography (SPECT) and positron emission tomography (PET).

Tom Bolwig, professor of psychiatry at the University of Copenhagen, outlines the following story: Among earliest studies, in 1974 David H Ingvar and Göran Franzen at Lund University reported in the Acta Psychiatrica Scandinavica decreased cerebral blood flow in chronic schizophrenia. SPECT and PET were employed in the 1980s to measure regional cerebral blood flow and metabolism, and, later, neurotransmitter

binding potential. SPECT and PET are used as well to quantify regional density of receptors of a given type and receptor binding displacement. But these methods expose patients to radioligands and demand cyclotron capacity, so they cannot be applied outside of specialized centers. In 1988, Daniel Weinberger and associates at the NIMH employed PET to help develop the "hypofrontality" hypothesis in schizophrenia.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) entered medicine in the late 1970s. In psychiatry, the first controlled study using MRI was led by Nancy Andreasen, finding in 1986 in the Archives of General Psychiatry that a population of schizophrenic males had "markedly smaller frontal lobes." Functional MRI (fMRI) examines changes in blood oxygen level, a proxy measure of neural activity. The Yvette Sheline group at Washington University in St. Louis used fMRI in 2002, to demonstrate that long-standing depression produced a decrease in 5-HT(2A) receptors in the hippocampus, a functional finding. Structural MRI measures brain and regional gray and white matter volumes, and was used in 2003, by Sheline and colleagues to measure loss of hippocampal volume in severe untreated depression (the longer untreated, the greater the loss of volume). Thus, in Sheline's terms (in the 2002 article), "Functional imaging extends the sensitivity and specificity of structural imaging."

Brain Connectivity

Brain connectivity refers to a pattern of anatomical links ("anatomical connectivity"), of statistical dependencies ("functional connectivity"), or of causal interactions ("effective connectivity") between distinct units within the nervous system. Using a variety of MRI and fMRI methodologies, information about the functional and structural integrity of neural circuitry —"neural profiles"—can be provided in healthy and psychiatrically unwell individuals. In 2008, ML Phillips and associates identified abnormalities of connectivity in the neural circuitry supporting emotion processing and regulation in bipolar disorder. In 2010, in Biological Psychiatry, Amelia Versace and colleagues attempted to differentiate unipolar versus bipolar depression on the basis of the functional white matter integrity of the neural circuitry regulating emotion.

Quantitative EEG (QEEG) Brain Mapping

Introduced in the 1980s, the QEEG brain map produces a three-dimensional reconstruction of the brain's activity. Using advanced algorithms, it is possible to identify brain-wave patterns from deep brain structures. The method is noninvasive, but has a space resolution weaker than that of the above-mentioned methods. QEEG has been used by ER

John and associates to identify activity clusters in a variety of different psychotic states. One reason for the lesser popularity of QEEG compared to SPECT, PET and MRI may be, as Tom Bolwig observes, "that understanding the elements of electrophysiology seems a bit harder for many physicians than accepting colored spots on an image of the brain." Yet QEEG represents pure neuronal transport and can record immediately and for very long periods of time, which are essential qualities for monitoring chains of events.

PART VII: THE BEGINNING OF THE SECOND BIOLOGICAL PSYCHIATRY

Psychiatry in Europe, with its heavy emphasis on heredity, had always been biologically oriented. But in the 1930s, psychoanalysis in the United States wiped the biological slate clean. Then in 1946, at a meeting at the Fairmont Hotel in San Francisco, the biological thread began to re-emerge. Two California physicians—Johannes M Nielsen, a neurologist at the University of Southern California, and his student, George N Thompson, chief psychiatrist at the Los Angeles General Hospital, convoked those interested in "the biological basis of behavior." The meeting was attended by the heavyweights in US neurology and psychiatry: Percival Bailey, a Chicago neurologist; Stanley Cobb, professor of neuropathology at Harvard; and Karl M Bowman, at the Langley Porter clinic in San Francisco. From this meeting emerged the Society of Biological Psychiatry. In 1947, Nielsen and Thompson published the first textbook of biological psychiatry in the United States, *The Engrammes of Psychiatry*.

The Revolution in Psychopharmacology

Although the term "psychopharmacology" seems to have been coined by David Macht, a pharmacologist at Johns Hopkins University, in 1920, to describe "the effect of drugs on psychological functions," it was not until the mid-1950s, with the explosion of interest in mechanisms prompted by the success of the antipsychotics, that the term started to come into use. When Paris psychiatrist Jean Thuillier visited Joel Elkes's newly founded department of experimental psychiatry in Birmingham in the mid-1950s, he was introduced by Willy Meyer-Gross. (Meyer-Gross, a refugee from Hitlerism who previously had been a mainstay at Heidelberg, was finishing his career in Birmingham as an associate of Elkes.) Meyer-Gross said in the introduction, "From everything that will be said to you this evening, bear in mind this new word: psychopharmacology. We already practise it here without realizing it, and everything we do tomorrow and in the future, everything we will want to do, will be gathered into this new discipline."

There has been much discussion pro and con about psychiatry's turn toward psychopharmacology. For all current concerns about polypharmacy and "cosmetic psychopharmacology," one does well to bear in mind the

recollections of Robert Felix, inaugural director of NIMH in 1949, of his days as a resident in a mental hospital in 1931, "For disturbed patients the continuous flow bath was almost universally used. If the patient was too disturbed to lie in the tub, either a hot or a cold pack was used, which, while not so-called, served effectively as a physical restraint. For either excited or depressed patients who manifested agitation, three chemical substances were used: paraldehyde, phenobarbital, or bromide ... Our bible was Bleuler's Textbook of Psychiatry. In that text Chapter XI, 'The Treatment of Mental Diseases in General,' covered 11 pages."

In the years after the Second World War, psychiatry swung on a massive hinge. "There can be no twisted thought without a twisted molecule," wrote Ralph Gerard in 1955 in the American Journal of Psychiatry, keynoting the advent of a new era in psychiatry, the easing away from psychoanalysis, and the turn to pharmacotherapeutics as the main treatment modality. Biology marked, said Gerard 2 years later in Science, "the emphatic re-entry of the brain into the mental arena." In these years, the field evolved from being the lowest prescribing of the medical specialties to the highest. (In 2005 90.1 percent of all psychiatric visits ended with a prescription; the next highest was cardiovascular diseases with 85.4 percent.)

The revolution may have begun with the synthesis in 1938 of lysergic acid diethylamide (LSD) by Sandoz chemist Albert Hofmann. It was in 1943, that Hofmann discovered it was psychoactive; LSD went on to have a brief career in psychotherapy and the treatment of alcoholism, but it generated great scientific curiosity: Was its mechanism identical to that of schizophrenia?

In 1952, the Rhône-Poulenc Laboratories in Paris introduced the first antipsychotic (neuroleptic), chlorpromazine, of the phenothiazine class of three-ringed structures, which was brand-named Largactil in Europe, Thorazine in the United States. The staff of Paris psychiatry professor Jean Delay conducted the initial clinical trials. A number of other phenothiazine antipsychotics followed.

These two compounds—LSD and chlorpromazine—initiated the era of psychopharmacology. As Theodore Sourkes at McGill University, "a biochemist in psychiatry" as he called himself, put it later, "The neuroleptic action of chlorpromazine and the psychodysleptic action of LSD ... held out the promise, on the one hand, of a chemical treatment of mental disorders and, on the other, of exploring the possibility that schizophrenia was caused by a toxic substance. As a consequence, the fifties and sixties of the last century saw the introduction of chemical theories into psychiatry."

The proliferation of phenothiazines gave rise to the classification of "sedative" versus "incisive" neuroleptics, the former presumably for agitated patients, the later for the withdrawn and retarded. Yet an analysis by Arthur Platz and coworkers at the Perry Point Veterans Administration Hospital in 1967 demonstrated that there was no difference in therapeutic

profiles.

A more important distinction was effectiveness in patients with "positive symptoms" versus those with the apathetic withdrawal of "negative symptoms." This was realized early. Fritz Freyhan, a German émigré considered one of the founders of psychopharmacology, observed in 1957, at the Second International Congress of Psychiatry in Zurich (the first was in Paris in 1950), "Two schizophrenic patients ... may differ fundamentally, one being apathetic, the other excited and disturbed. Only the latter is a candidate for neuroleptic treatment ..."

The new drugs marked the beginning of the end of the dominance of psychoanalysis. Heinz Lehmann, who conducted some of the first trials of chlorpromazine, said in a 1992 interview in the Bulletin of the Canadian Psychiatric Association, "The demonstration [was important] that psychotropic drugs, such as chlorpromazine ...are actually effective, so effective that there remains no doubt about it, even for the sturdiest psychoanalyst. Eventually they all had to admit that there is a physical substrate to, say, schizophrenia and bipolar or manic-depressive disorder, because certain physical substances, drugs, definitely are helpful in treating these disorders. Before that, until the early 1950s, it was archaic and very unsophisticated—almost simplistic—to think that anything physical could be done about treatment in schizophrenia. It had been tried for so many years, decades, and nothing had ever helped, so one would have to understand schizophrenia on psychodynamic terms, and the only rational intervention was psychoanalytical treatment. Well, the fact that I was able to demonstrate, with others, that physical substances can profoundly change the course of schizophrenia and other psychoses made it quite clear that there was a biological substrate ..."

It was thus that psychiatry, after so many years out in the cold with psychoanalysis, was able to rejoin the rest of medicine. As Theodore Rothman, at the University of Southern California and Los Angeles Veterans Administration Hospital, said in 1960, at an organizational meeting that would lead to the founding of the American College of Neuropsychopharmacology (ACNP) the following year, "I can find no better keynote thought than that psychopharmacology has given us a common front with the basic medical sciences. Psychopharmacology is compelling us to re-integrate psychiatry into medicine."

Back into medicine! But how did the new drugs work? The 1960s and 1970s were captivated by one-neurotransmitter-one-disease hypotheses.

Norepinephrine was first off the blocks. In 1965, in the American Journal of Psychiatry, Joseph Schildkraut of Harvard University proposed a "catecholamine hypothesis of affective disorders" (the neurotransmitter norepinephrine has a portion with a catechol structure). "Those drugs which cause depletion and inactivation of norepinephrine centrally produce sedation or depression, while drugs which increase or potentiate brain

norepinephrine ...generally exert an antidepressant effect in man."

In 1968, Swedish pharmacologist Arvid Carlsson and coworkers at Gothenburg University noted in the Journal of Pharmacy and Pharmacology that the TCA imipramine blocked the reuptake of serotonin. "This action may be of importance for its antidepressive properties," the authors said, initiating the serotonin hypothesis of depression.

It remained for dopamine, the third major biogenic amine neurotransmitter, to find its distinctive disease, and this occurred in 1976, as it was reported simultaneously by psychiatrist Solomon Snyder at Johns Hopkins University (in Science) and pharmacologist Philip Seeman at the University of Toronto (in Nature) that the potency of antipsychotic drugs in schizophrenia was a function of their ability to block the dopamine receptor.

The original scientific findings underlying these reports were never overturned, yet neurotransmission is a complex phenomenon and the field quickly lost confidence in the specificity hypothesis—although for decades it was marketed relentlessly by the pharmaceutical industry. In 1978, JL Costa and coinvestigators at NIMH said of agents affecting serotonin metabolism, "... It certainly may be that a serotonin deficit state is not a prerequisite for therapeutic efficacy with any of these drugs." It is a shame that these hypotheses, so attractive for their theoretical elegance and simplicity, have now been largely discredited, because psychopharmacology has never again been able to develop a unitary theory of drug action. At this writing, the brain remains a black box.

The Golden 50s

The year 1955 saw the launch of the first blockbuster drug in psychiatry, Wallace Laboratories' meprobamate, trade-named Miltown (and Equanil by Wyeth Laboratories, which licensed it from Wallace). Launched as a "tranquilizer," Miltown became almost a household word, opening up that large market for "nerves" between the antipsychotics and aspirin (see below). It was displaced by the benzodiazepines in the 1960s.

The monoamine oxidase inhibitors (MAOIs) were probably the first effective drug class, aside from opium, for serious depression. This awareness took a while dawning. The first MAOI, iproniazid (Hoffmann-La Roche's Marsilid) reached the market in 1951, for tuberculosis, but only in 1957, did the company begin to market it for depression. A series of other MAOIs followed, the most effective of which was probably phenelzine (Warner-Chilcott's Nardil), introduced in 1959 and still in use.

"Tranquilizers"

It was London physician Edward Sutleffe, who had a substantial practice of patients with "nervous irritation" among other diagnoses, who in his

Medical and Surgical Cases in 1824, introduced into medicine the term "tranquilizer" in connection with a "tranquilizing" drug, "the juice of ground ivy," that he was promoting. The word then slumbered in forgetfulness until 1953, when Ciba billed its new antihypertensive Serpasil (reserpine) as a "safe tranquilizer-antihypertensive." Its calming effects were soon noted in psychological medicine and the concept of "tranquilization" became the common denominator of a range of drugs from the antipsychotic chlorpromazine, introduced clinically in the United States in 1954, to the "antiphobic" agent benactyzine (Suavitil) that Merck brought out in 1957. The tranquilizers were thought an improvement upon the barbiturates because they had the same relaxing and composing effects without the daytime sedation. Yet soon the concept of tranquilizer was ruptured by the introduction of the benzodiazepines after 1960 (see below). These "antianxiety" agents made the concept of tranquilization, which had lumped together antipsychotics and antinervous agents, seem outmoded.

Antipsychotics

The antipsychotic era began with the introduction of chlorpromazine in clinical trials in France in 1952, by the Rhône-Poulenc Laboratories. Called Largactil in Europe and Thorazine in the United States, chlorpromazine is thought to have initiated the era of psychopharmacology by prompting research into mechanisms. A slew of similar phenothiazine antipsychotics, also called neuroleptics, followed, including Smith Kline's prochlorperazine (Compazine) in 1956, and thioridazine (Sandoz's Mellaril) in 1958. Haloperidol (Janssen's Haldol, a member of the butyrophenone class) entered practice in the United States in 1966.

Tricyclic Antidepressants

Owing to the close clinical observation of Swiss psychiatrist Roland Kuhn, Geigy Laboratories in Basel realized in 1957, that their new compound imipramine, a member of the tricyclic class, was active against "vital depression," rather than being an antischizophrenic, as they had hoped (the antipsychotic market was just taking off). Marketed in the United States in 1959, imipramine (brand-named Tofranil) initiated a half-century of "antidepressant" treatment. News of the TCAs traveled quickly. At a conference at McGill University in 1959, Hans Hoff, who had become the professor of psychiatry in Vienna after the Second World War, admitted that he and psychoanalyst colleague Paul Schilder "had once tried to destroy the Kraepelinian nomenclature because of the feeling that psychodynamics and personal reactions were more important. Now, however, since a treatment had become available, diagnosis is essential."

"Mood Stabilizers"

The mood-stabilizer era began with lithium in 1949. The term apparently surfaced for the first time in connection with a drug called aminophenylpyridone (Maltbie Laboratories' Dornwal) in 1960. The phrase "mood stabilizer" did not, however, come into general use until Robert Post and colleagues at NIMH floated the "kindling hypothesis" in 1986, in the British Journal of Psychiatry: recurrent depressions could tip the brain into autonomous cycles of mood disorder. Other writers then proposed that various anticonvulsants could break into the kindling process and stabilize the hyperirritable brain. Aside from lithium, considered mood stabilizers were: derivatives of valproic acid called valproate and valpromide that medicinal chemist George Carraz at Berthier Laboratories in Grenoble synthesized in 1963; carbamazepine, patented in 1960 by Geigy, was introduced as a psychoactive compound in Japan, then discovered in 1980, by NIMH investigators to have effects in manic-depression. Lamotrigine was patented by the Wellcome Foundation in 1981 and inaugurated in 2003, in the United States by GlaxoSmithKline as Lamictal ("a stabilizing force"). The judgment of David Healy and colleagues in 2003, in Bipolar Disorders was that, "These agents are now thought of as being a homogeneous group [but] they may in fact be quite diverse agents all of which have a certain utility when used judiciously in manic depressive states."

After the 1950s, Relatively Few New Drug Classes

Benzodiazepines. The benzodiazepine story began with the marketing of Hoffmann-La Roche's Librium (chlordiazepoxide) in 1960. The numerous subsequent Roche benzos were also synthesized by medicinal chemist Leo Sternbach. So popular did the benzodiazepines become that entire "eras" in the 1960s and 1970s were named after such members of this class as Valium (diazepam, launched in 1963). With the exception of the SSRIs (selective serotonin reuptake inhibitors—see below), the benzodiazepines are probably the best-selling psychoactive drug class in history, and moreover possessed genuine efficacy that later agents do not seem to have matched. Other benzos followed: clonazepam (Clonopin) reached the American market in 1975; and alprazolam (Upjohn's Xanax) was launched in 1981. A short-acting benzo, Upjohn's triazolam (Halcion), came out in the United States in 1982, and caused much controversy about discontinuation. There was a long period of fearfulness about addiction, although in 1983, in the Journal of the American Medical Association, Karl Rickels and associates at the University of Pennsylvania found the risks of withdrawal reactions in diazepam minimal for up to 8 months of use. In the new millennium, the benzos began a comeback. As Peter Roy-Byrne at the University of Washington School of Medicine put it in an editorial in 2014 in the American Journal of Psychiatry, "There is now general appreciation that, with careful clinical evaluation to rule out pre-existing addiction

issues … benzodiazepines are safe and highly effective."

SSRIs: Selective Serotonin Reuptake Inhibitors. Marketed as agents that specifically inhibited the neuronal reuptake of serotonin, this drug class became the most successful in the history of psychiatry. Prozac (fluoxetine), which became a household word, was marketed by the Eli Lilly Company in Belgium in 1986, in the United States in 1988. Among the main SSRIs, there followed Pfizer's Zoloft (sertraline), marketed in 1992; paroxetine (Novartis's Paxil), introduced in the United States in 1993; and citalopram (Lundbeck's Cipramil), brought out in the United States in 1998 by Forest Laboratories. The SSRIs were initially indicated for "depression," then for "anxiety," and by the time they all finally went off patent, countless were the indications for which this versatile drug class served.

Second-Generation Antipsychotics. The so-called "second-generation antipsychotics" (SGA's) have turned out not that different from the first generation and seem to be more a marketing concept. Yet it might be noted that clozapine (Sandoz's Clozaril), deemed the most effective of them, is not exactly a new drug, having been patented in 1963. Leo Hollister's judgment in 1987 of the antipsychotics is of interest (Hollister led the Veterans Administration hospital in Palo Alto, California and is generally acknowledged as the dean of American psychopharmacology): "It is most discouraging that more effective pharmacotherapy for schizophrenia has not been developed in the more than three decades since the introduction of the first effective drugs." The current drugs, he said, "are not curative; their ameliorative effects are often limited; many patients remain totally unresponsive; they are unpleasant to take, so that many patients are less than fully compliant; and they produce major side effects."

PART VIII: PEDIATRIC PSYCHIATRY

Psychiatrists have always been familiar with mental disease in children. In 1809, Haslam reported cases of "insane children," such as a 7-year-old boy who was slow to develop and was placed on "the female side" of the hospital. Early on, psychotic illness in children was noted, sometimes as a distinctive form of what would later be called childhood schizophrenia, sometimes not. The "hebephrenia" that Ewald Hecker described in 1871 was commonly recognized in children. As Auguste Voisin, a staff psychiatrist at the Salpêtrière in Paris commented in his 1883 textbook of "insanity in the young": "In partial insanity, the child may be manic [extatique], subject to ideas of homicide, arson, or theft, have deluded and demonic ideas … It is in the context of this partial insanity that we find the singular cases of childhood suicide, sometimes preceded by notes from which extreme exaltation shows through; thus a child of thirteen who hanged himself left behind a note saying, 'I bequeath my soul to Rousseau,

my body to the earth.'"

Textbooks of child psychiatry were not slow in coming. In 1887, Hermann Emminghaus, professor of psychiatry in Freiburg, produced what was probably the first, The Psychic Disorders of Childhood (*Die psychischen Störungen des Kindesalters*). The foundational modern text of psychological approaches to disorders of childhood, Lectures on the Psychopathology of Childhood (Vorlesungen über Psychopathologie des Kindesalters) was written by August Homburger at the Heidelberg University Psychiatric Hospital in 1926. Among the first dedicated hospital divisions for children with mental illnesses was that at Bicêtre Hospice in Paris, which in 1838, received responsibility for the care of "children with mental retardation and epilepsy." In 1842, Édouard Séguin, who had developed a system for the care of children with retardation, took over the service, and after an interregnum, in 1851, Louis Delasiauve succeeded him. Désiré-Magloire Bourneville took it over in 1879, and in the course of the next decades made Bicêtre into one of the most progressive children's psychiatric units in the world. (In 1892, he initiated a gymnastic competition, which became the unacknowledged forerunner of the Special Olympics.) In 1850, Séguin emigrated to the United States and initiated here the enlightened treatment of children who have what are now called intellectual disabilities.

The epidemic of encephalitis lethargica in the years 1917 to 1927 represented a strong inflection in the growing awareness of distinctive psychiatric illness in children, primarily because, unlike adults, the disease produced striking psychiatric changes in many children, transforming them from normal happy creatures into the "apache type" with severe behavioral problems. Said Leslie Colin Cook, who was a staffer at the West Park Mental Hospital in Epsom that had a center for such patients, in the Lancet in 1928, "Children of irreproachable family, hitherto of exemplary behavior and character, may in a very short period become guilty of every delinquency from mere naughtiness to cruelty and murder, and from mild bad habits to gross indecencies." This had happened, he said, in only one adult patient with the disease. The "EL" epidemic thus strengthened the interest of the field in children as a special kind of patient.

In the middle third of the 20th century, psychoanalysis became the doctrinal mainstay of child psychiatry. Freud himself did not see children and had relatively little experience with them. Psychoanalysis was first applied to the child and adolescent population by Viennese educator and psychoanalyst August Aichhorn in his 1925 work Wayward Youth (Verwahrloste Jugend), about the ego structure of juvenile delinquency. Sigmund Freud's daughter Anna published her first book in 1927, An Introduction to the Technique of Child Analysis, and in 1936, The Ego and the Mechanisms of Defense. The Freud family fled to England after the Nazi Anschluss with Austria in 1938, and in 1941, Anna Freud helped found

the Hampstead Nursery in London, where she treated children for several years. This gave way to the Hampstead Child Therapy Course and Clinic, which Anna directed until her death in 1982 (on her rivalry with Melanie Klein see above).

After the Second World War, the baton in child psychiatry passed to the United States. When the National Institute of Mental Health opened in 1949, the "quality of mothering" was put on the table—especially so by psychoanalysts such as Frieda Fromm-Reichmann at Chestnut Lodge in Maryland, who, in Psychiatry in 1948, had originated such concepts as the "schizophrenogenic mother." Among the leading child psychoanalysts in New York was Hungarian-born Margaret Mahler who in 1950 cofounded the Masters Children's Center in Manhattan, where she developed the tripartite treatment model involving the mother in the child's treatment. Her most important work was *The Psychological Birth of the Human Infant* (1975).

Prompted by an interest in the ideas of Harvard psychologist Burrhus Frederick Skinner, in the late 1940s and 1950s behaviorism started to become à la page. Psychoanalysis and behaviorism dominated pediatric psychiatry in the United States after the Second World War.

The child guidance clinics reached back to the First World War, and in 1948 they created an organization of clinics, the American Association of Psychiatric Clinics for Children, to develop standards of care and training. In 1953, the American Academy of Child Psychiatry was founded; in 1959, the American Board of Psychiatry and Neurology approved a 2-year child psychiatry residency, to be grafted onto the regular training. The field received its own voice, The Journal of the American Academy of Child Psychiatry, in 1962, and a quarter century later, in 1986, the Academy changed its name to American Academy of Child and Adolescent Psychiatry.

In the heyday of psychoanalysis, "pills" were frowned on and great confidence placed in psychotherapy. Yet the revolution in adult psychopharmacology in the 1950s had echoes in the pediatric world. "Psychopharmacology has revolutionized child psychiatry," said Jovan Simeon, professor of psychiatry and child psychopharmacologist at the University of Ottawa, in 2004. Children had, of course, always been treated with such psychoactive agents as opium, mixed together with alcohol in laudanum (see above), which parents once routinely administered as a hypnotic. Treating children with psychopharmaceuticals entered the academic forum in 1937, when Charles Bradley, director of the Emma Pendleton Bradley Home in East Providence, Rhode Island, in the American Journal of Psychiatry reported the benefit of Benzedrine in "behavior problem" children, later defined as "hyperactive." Loretta Bender, at Bellevue Hospital in New York, used chlorpromazine and amphetamine extensively in treatment. Systematic research in pediatric

psychopharmacology began in 1958 when Leon Eisenberg at Johns Hopkins University received the first NIMH grant to study drugs in children, conducting the first controlled trial in pediatric psychopharmacology. This torch was then notably carried forward by Bender's student Barbara Fish, first at Bellevue, then after 1972, at the UCLA.

Such progress in pediatric psychopharmacology probably counts as an American "first." There were a number of other American firsts, such as recognition by Lee Wachtel at the Kennedy Krieger Institute in Baltimore and Dirk Dhossche, in a 2010 article in Medical Hypotheses, of stereotypical movements in autism and intellectual disability as a sign of catatonia—and treatable with benzodiazepines and convulsive therapy.

As for diagnosis, disease classification in pediatric psychiatry has been in even greater turmoil than in general psychiatry, as psychoanalysis, behaviorism, and biological approaches have dueled. Driven by parental concerns, clinicians are often pressed to make diagnoses such as attention deficit hyperactivity disorder. The fourth edition of DSM (DSM-IV) included the diagnosis "bipolar II disorder," characterized by depression plus "at least one hypomanic episode." Yet the field readily accepted outbursts of anger as a substitute for hypomania, touching off a virtual epidemic of "bipolar II" in the pediatric population, which the embarrassed drafters of DSM-5 were obliged to dial back in 2013, with the newly contrived "depressive" diagnosis "disruptive mood dysregulation disorder," said to be "included for children up to age 18 years who exhibit persistent irritability and frequent episodes of extreme behavioral dyscontrol." The classification of illness in children has thus still not stabilized.

PART IX: NEW FORMS OF CARE

The asylum was a forbidding institution. Yet many patients outside its walls also required care, and over the years these walls were slowly broken down.

Boarding patients out to local families achieved first this separation of care from the four walls of the institution. The earliest instance of this was seen at Gheel in the Brabant region of Belgium, where patient out-boarding went back to the 13th century. Yet the local farmers often had little tolerance for the antics of the patients, of whom they might board up to five at a time, and when Pliny Earle, of the Friends' Asylum in Frankford, visited there in the late 1830s, (describing his travels in a book in 1841, he was shocked to find that the patients, "if mischievous or furious, are chained at the wrists and ankles. In every house, there is a ring beside the chimney, or attached to the beds, to which they may be chained." Boarding out was never widespread in the United States, possibly because the farms were too dispersed (unlike the compact Belgian villages). But in Scotland around 1900, 23 percent of the asylum patients were boarded out.

There were other ways of breaking down the walls. The first psychiatric

ward in a general hospital in the United States was established in 1902, at Albany Hospital. In 1885, Pennsylvania Hospital founded the first outpatient clinic, or very close to the first, in the United States, "so as to provide a dispensary service for the gratuitous treatment of persons suffering with incipient mental disease." (On these developments, see Henry Hurd's massive four-volume work in 1916 on the Institutional Care of the Insane.)

One of the unhappiest stories in US psychiatry was that of "deinstitutionalization," under the influence of the antipsychiatric ideologies of the 1960s, discharging in-patients to a kind of community care that often turned out to be the care of the streets. This created an existential dilemma for psychiatry: what to do with the patients who were seriously ill? As Jonathan Cole said in an interview in 1996, "We've got very few places where we can serve the kind of patient who takes a long time to get better and where real rehabilitation is done. We tend to have more people who are home and crazy than we should have and nobody's going to pay for their treatment."

Beginning in the 1960s, this vast outpouring resulted in the closing of many of the classic asylums. In 1964, there were in the United States 255 public psychiatry beds per 100,000 population; by 2014, this figure had dropped to 11 per 100,000. The patients were supposedly to be maintained in community settings on antipsychotics; in reality they fed the vast ranks of the "homeless" and the imprisoned. In 2002, 64.2 percent of all inmates of local jails in the United States had a "mental health problem" (75.4 percent of the females). The figures were comparable for state and federal prisons. Donald Klein of Columbia University said later in an interview, "It wasn't deinstitutionalization, it was trans-institutionalization, from the state to the city budget. The patients, but not the money, were dumped on the cities. The cities didn't pick them up and that was a disaster. Instead of an open door, we had a revolving door. There was a sudden rise in homelessness. This led to federally supported 'community care' which was staffed by therapy-minded psychologists. They had a psychiatrist who did little but sign bundles of prescriptions." By one estimate, "There are 10 times as many mentally ill persons in prisons than in state hospital beds." David Rubinow at the UNC, who penned these lines in the American Journal of Psychiatry in 2014, concluded "It would appear that we somehow have achieved the complete reversal of policies initiated over 170 years ago to ensure the humane treatment of those with mental illness."

Yet history has good news as well. On the threshold of the new millennium, the role of psychiatry itself was slowly changing. Once seen as a band-aid for the "walking wounded," psychiatry was becoming the main resource for the seriously ill. In the United States in 2001 to 2002, 40 percent of patients identified in a national household survey with a serious mental problem would be seen by a psychiatrist. As for the rest of patients

who formerly would have been "in therapy," psychiatry had ceased to be the main port of call: only 21 percent of those with moderate and 9 percent of those with mild disorders saw psychiatrists; they distributed themselves instead across the entire gamut of mental and medical health services, from "general medical" to "internet" (the main resource for 30 percent of those with "moderate" mental problems). Alarmingly, of those seeing a psychiatrist, 29 percent were said to have "no disorder." Readers will give a weary sigh. Yes, it's true: some things never change.

World Aspects of Psychiatry

DINESH BHUGRA, PH.D., MARIO MAJ, M.D., PH.D., ANTONIO VENTRIGLIO, M.D., PH.D., AND PEDRO RUIZ, M.D.

In the past few years largely at the instigation of high-income countries, a global mental health movement has emerged. Partly this is a response to rapid globalization which has meant that people, resources, and ideas are moving much more rapidly than at any other time in the history of humanity. This has led to a clear acknowledgement that a number of factors at social and cultural levels are at play in influencing how distress is experienced and expressed. There remains a danger in that global mental health may follow the route of Anglo-American influences to be seen "dictating" to the low- and middle-income countries. There remain a number of serious questions in relation to the differences in rates and responses across different nations of the world. Some of these are discussed later in this chapter. The authors prefer and choose the term "world psychiatry," as it reflects the real state of psychiatry at the present time. The international progress of collaboration has shifted considerably over the past two centuries. From a perspective of the rulers seeing the vanquished as exotic natives who either did not have mental capabilities to develop mental illness to seeing them as victims of the social factors. This gave way to international collaborative epidemiological studies which have contributed to the current understanding of both similarities and differences in etiology and outcomes of psychiatric disorders.

There is no doubt that mental disorders are highly prevalent across all regions of the world even though there may be a small degree of variation across societies and cultures. These disorders represent a major source of disability and social burden worldwide. Even though treatments for all of these disorders are available and have been found to be efficacious in different settings such as high-income and low- and middle-income countries, this has not always translated into wider access and availability of these interventions. Mental disorders remain remarkably undertreated worldwide. This treatment gap is high enough in low-income countries but even in high-income countries high levels of gap remain. To complicate matters further many countries either do not have any mental health policies and there are many others who have outdated policies sometimes dating back to 19th century. Consequently both funding for treatment and

research into mental health falls well below the resources offered and available for physical disorders such as cancer and heart disease.

Although there have been many proclamations internationally recently about the importance of mental health, resources to deal with mental disorders and investing in public mental health have not followed the rhetoric. Contribution of funding to mental health care remains scarce and unequally distributed.

This chapter provides an overview of world psychiatry but focusing on epidemiology, burden resulting from mental illness and the relationship between various illnesses and also stigma as well as the ethics of mental health care.

PREVALENCE AND BURDEN OF MENTAL DISORDERS WORLDWIDE

The general perception is that in lifetime, one in four individuals will develop mental illness of one kind or another. These figures have been confirmed by World Health Organization (WHO) which estimates that more than 25 percent of individuals worldwide develop one or more mental disorders during their lifetime. This observation has been supported by a series of face-to-face community surveys conducted in 17 countries in Africa, Asia, the Americas, Europe, and the Middle East. These World Mental Health Surveys have included a total of 85,052 respondents. The lifetime prevalence of any mental disorder was found to be higher than 25 percent in 11 of 17 countries and higher than 15 percent in all countries except China and Nigeria, where prevalence rates were likely to be downwardly biased due to respondent reluctance to admit mental health problems. Whether these rates are genuinely low or whether these reflect reporting bias needs further exploration. Not surprisingly anxiety disorders were the most prevalent in 10 out of 17 countries, and mood disorders in 6 (Table 62–1). Anxiety disorders include agoraphobia, adult separation anxiety disorder, generalized anxiety disorder, panic disorder, post-traumatic stress disorder, social phobia, and specific phobia. Mood disorders include bipolar disorders, dysthymia, and major depressive disorder. Impulse-control disorders include intermittent explosive disorder, and reported persistence in the past 12 months of symptoms of three child-adolescent disorders (attention-deficit/hyperactivity disorder, conduct disorder, and oppositional-defiant disorder). Substance disorders include alcohol or drug abuse with or without dependence. Following the *Diagnostic and Statistical Manual of Mental Health Disorders*, Fourth Edition (DSM-IV) norms, organic exclusions were excluded. Lifetime co-occurrence of two or more mental disorders was quite common, so that the sum of the prevalence rates across the various disorder types was between 30 and 50 percent higher than the proportion of people having at least one mental disorder. Survival analysis showed that the odds ratios for anxiety, mood, and substance use disorders were higher in recent compared to

older cohorts. It is worth noting that even within the same geographical region there appear to be major variations in the prevalence of DSM-IV/CIDI disorders.

In the same series of studies, the 12-month prevalence showed similar variations. These findings illustrated regional and national variations. Once again Nigerian respondents reported only 6 percent prevalence with similar figures from Japan and China, but the rates were 4.5 times higher in the United States (see Table 62–2).

As shown in Table 62–3, when association between 12-month severity and days out of role were compared again variations within regions and across nations were substantial. Once again Nigeria and China had similar figures, whereas the United States showed the highest levels.

Table 62–1.
Lifetime Prevalence Estimates of DSM-IV/CIDI Disorders in the WMH Surveys

	Any Anxiety Disorder[a]		Any Mood Disorder		Any Externalizing Disorder[b]		Any Substance Disorder		Any Disorder

[a]Anxiety disorders include agoraphobia, adult separation anxiety disorder, generalized anxiety disorder, panic disorder, post-traumatic stress disorder, social phobia, and specific phobia. Mood disorders include bipolar disorders, dysthymia, and major depressive disorder. Impulse-control disorders include intermittent explosive disorder, and reported persistence in the past 12 months of symptoms of three child-adolescent disorders (attention-deficit/hyperactivity disorder, conduct disorder, and oppositional-defiant disorder). Substance disorders include alcohol or drug abuse with or without dependence. In the case of substance dependence, respondents who met full criteria at some time in their life and who continue to have any symptoms are considered to have 12-month dependence even if they currently do not meet full criteria for the disorder. Organic exclusions were made as specified in the Diagnostic and Statistical Manual of Mental Health Disorders (DSM), 4th edition.

[b]Impulse disorders restricted to age ≤39 (China, Ukraine, Nigeria) or to age ≤44 (all other countries).

[c]Adult separation anxiety disorder was not assessed.

[d]Specific phobia was not assessed.

[e]Bipolar disorders were not assessed.

[f]Intermittent explosive disorder was not assessed.

[g]Attention-deficit/hyperactivity disorder was not assessed.

[h]Conduct disorder was not assessed.

[i]Oppositional-defiant disorder was not assessed.

[j]Only alcohol abuse with or without dependence were assessed. No assessment was made of other drug abuse with or without dependence.

[k]People's Republic of China.

When the severity of these disorders was compared across nations and regions similar variations emerged. China, Japan, Nigeria and this time Italy showed lower levels of serious severity and higher levels of mild severity (see Table 62–4).

Using disability scale for common chronic physical and mental health disorders, interesting differences emerged between developed and developing countries (see Table 62–5). Cancer, asthma, hypertension, and diabetes showed higher proportions of severe disability in developing countries, whereas neck and backaches, chronic pain, and headaches were more seriously disabling in developed countries. Bipolar disorders, depression, generalized anxiety disorders, panic disorders, and posttraumatic disorder–related disability was elevated in developed countries. This variation raises interesting questions about whether these are genuinely higher levels and rates or are more commonly diagnosed.

Among people seen by primary health care professionals, more than 20 percent have one or more current mental disorders. In a study carried out by the WHO at 14 sites in Africa, Asia, the Americas, and Europe, the average current prevalence of any mental disorder was 24 percent, without consistent differences between low- and high-income countries. Not surprisingly the most common diagnoses were those of depression (average

10.4 percent) and generalized anxiety disorder (average 7.9 percent). Female rates were 1.89 times higher than male rates for depression, but male rates were higher for alcohol-related disorders, so that there was no sex difference in the proportion of people having at least one mental disorder. Physical ill health and educational disadvantage were both significantly associated with a diagnosis of mental disorder.

To quantify the burden of the various diseases and injuries, the WHO, in collaboration with the Harvard School of Public Health and the World Bank, introduced in 1993 a new measure, the disability-adjusted life year (DALY). DALYs for a given disease or injury are the sum of the years of life lost due to premature mortality plus the years lost due to disability for incident cases of that disease or injury in the general population. In the original estimates for the year 1990, mental and neurological disorders accounted for 10.5 percent of the total DALYs lost due to all diseases and injuries. Burden of disease related to depression and dysthymia is shown in Table 62–6. As previously reported, global prevalence of depression was reportedly more common in females. When a comparison was made between years lived with disability due to depression between 1990 and 2010, it appears that the years have increased by 36.9 percent due to major depressive disorders and in dysthymia by over 40 percent. These are illustrated in Table 62–7.

PTSD	54.8	(2.8)	41.2	(7.3)
Social phobia	35.1	(1.4)	41.4	(3.6)
Specific phobia	18.6	(1.1)	16.2	(1.6)

Global burden of disease was highest in substance use disorders and alcohol abuse (Tables 62–8 and 62–9).

As illustrated in Table 62–9, the burden for conditions like eating disorders is relatively high but often not recognized as such.

Lifetime contact for treatment delay in various psychiatric conditions is shown in Table 62–10. Interestingly, common mental disorders showed longer delay. This is further confirmed in the 12-month service use by sectors (see Table 62–11).

In the estimates for the year 2005, mental and neurological disorders accounted for 13.5 percent of all DALYs in the world (27.4 percent in high-

income countries, 17.7 percent in middle-income countries, and 9.1 percent in low-income countries), being the main contributor to burden among noncommunicable diseases (27.5 percent, compared to 22 percent for cardiovascular diseases and 11 percent for cancer).

According to the updated estimates for the year 2030, mental and neurological disorders will account for 14.4 percent of all DALYs in the world and 25.4 percent of those due to noncommunicable diseases. Depression will rank number 2 in the percent of total DALYs in that year (5.7 percent), following HIV/AIDS, and preceding ischemic heart disease (Table 62–12). It will be number 1 in high-income countries (9.8 percent), number 2 in middle-income countries (6.7 percent), and number 3 in low-income countries (4.7 percent).

The WHO estimates that one in four families worldwide has at least one member suffering from a mental disorder. The objective and subjective burden related to caring for people with severe mental disorders (in terms of disruption of family relationships; constraints in social, leisure, and work activities; financial difficulties; negative effect on physical health; feelings of loss, depression, and embarrassment in social situations; and the stress of coping with disturbing behaviors) have been reported to be substantial and significantly higher than that related to caring for people with long-term physical diseases such as diabetes, heart, kidney, or lung diseases. Cross-cultural differences have been reported in some dimensions of family burden: Relatives in the Mediterranean area, for example, compared with those in northern European countries were found to be more resigned and to use spiritual help more frequently as a coping strategy and reported a greater level of reduction in social interests and lower levels of support from their social network.

The prevalence of mental disorders among children and adolescents is difficult to evaluate because it is problematic to draw a reliable boundary between psychopathological phenomena and some manifestations that are part of normal development. Population surveys may help but access to schools and clinics is extremely variable, hence the accuracy of figures can be challenged. Many studies have used checklists compiled by parents and teachers, which are useful in detecting cases needing special attention but may not represent an appropriate basis for prevalence estimates. Community surveys carried out in low- and high-income countries focusing on children and adolescents between 1 and 15 years of age reported prevalence rates of mental disorders between 12 and 22 percent.

Suicide is among the 10 leading causes of death for all ages in most of the countries for which information is available. In some countries (e.g., China), it is the leading cause of death for people between 15 and 34 years of age. According to WHO estimates, about 849,000 people died from suicide worldwide in the year 2001. In that year, the number of suicide deaths overtook the number of deaths by violence (500,000) and war

(230,000). In 2020, approximately 1.53 million people will die from suicide worldwide based on current trends, and 10 to 20 times more people will attempt suicide. Reported suicide rates vary considerably across countries; for instance, annual suicide rates of 48.0 to 79.3 per 100,000 males have been reported in many Eastern and Central European countries, whereas rates of less than 4.0 per 100,000 males have been found in Islamic and several Latin American countries. More than 85 percent of suicides are reported to occur in low- or middle-income countries, but this figure may represent an underestimate due to the low reliability of official statistics in those countries: When surveillance with validated verbal autopsy was used in South India, the observed rates for suicide exceeded official national estimates 10-fold. In the Asia-Pacific region, 300,000 cases of suicide per year are estimated to occur by self-poisoning with pesticides.

Table 62–6.
Summary of Data Used to Calculate YLDs for Depressive Disorders

Parameter	MDD	Dysthymia	Source
Epidemiological inputs			
Number of data points (and studies)			Systematic review of the literature.
Prevalence	544 (116)	141 (36)	
Incidence	19 (4)[a]	3 (2)[a]	
Remission	—	3 (2)	
Duration	1 (5)[b]	—	
Excess-mortality	14 (11)	5 (2)[c]	
DisMod-MR point prevalence% (95% UI) and cases			DisMod-MR epidemiological modeling
Global prevalence	4.4% (4.1–4.7%); 298 million cases	1.55% (1.5–1.6%); 106 million cases	
Males	3.2% (3.0–3.6%); 111 million cases	1.3% (1.2–1.4%); 44 million cases	
Females	5.5% (5.0–6.0%);187 million cases	1.8% (1.7–1.9%); 62 million cases	
Disability weights			Derived by GBD core group and mental disorders expert group for the

			GBD 2010 disability weight survey.
Health state lay descriptions			
Mild	Has constant sadness and has lost interest in usual activities. The person can still function in daily life with extra effort, but sleeps badly, feels tired, and has trouble concentrating	—	
Moderate	Has constant sadness and has lost interest in usual activities. The person has some difficulty in daily life, sleeps badly, has trouble concentrating, and sometimes thinks about harming himself (or herself).	—	
Severe	Has overwhelming, constant sadness and cannot function in daily life. The person sometimes loses touch with reality and wants to harm or kill himself (or herself)	—	
Raw disability weights (95% UI)			GBD 2010 disability weight Survey.
Mild	0.16 (0.11–0.22)	0.16 (0.11–0.22)[d]	
Moderate	0.41 (0.28–0.55)		
Severe	0.66 (0.47–0.82)		
Severity distribution% (95% UI)			Based on SF–12 data from MEPS, NSMHWB, and NESARC.
Asymptomatic	13.9% (10.2–17.7%)	29.2% (24.9–33.6%)	
Mild MDD/Symptomatic dysthymia	58.8% (48.0–68.5%)	70.8% (66.4–75.1%)	
Moderate	16.5% (12.1–21.0%)		
Severe	10.8% (3.8–20.3%)		
Average disability weight (95% UI)	0.23 (0.18–0.30)	0.11 (0.07–0.15)	Based on severity proportions from MEPS, NSMHWB, and NESARC data, applied to weights from GBD 2010 disability weights survey.

[a]Incidence data were excluded for MDD and dysthymia as they were not consistent with the prevalence

and duration/remission data.

[b]The one data point for duration of 37.7 weeks was an estimate of average duration calculated from a best fit curve between the data points available from five studies.

[c]Both studies reported no elevated risk of mortality in those with dysthymia.

[d]The disability weight for mild-MDD was applied to dysthymia.

95% UI, 95% uncertainty interval.

Table 62–7.
Change in Depressive Disorder YLDs between 1990 and 2010

Total YLDs in 1990 and 2010	MDD	Dysthymia	Depressive Disorders
Total YLDs in 1990	46,138,600	7,870,700	54,009,300
Total YLDs in 2010	63,179,247	11,084,100	74,261,500
Total YLDs generated from 2010 population, 1990 population age structure, 1990 YLD rates (step 1)	59,904,870	10,067,939	69,972,809
Total YLDs generated from 2010 population, 2010 population age structure, 1990 YLD rates (step 2)	64,537,300	11,061,231	75,598,531
Total change in YLDs between 1990 and 2010	36.9%	40.8%	37.5%
Change in YLDs between 1990 and 2010 due to population growth	29.8%	27.9%	29.6%
Change in YLDs between 1990 and 2010 due to population aging	10.0%	12.6%	10.4%
Change in YLDs between 1990 and 2010 due to prevalence increase	−2.9%	0.3%	−2.5%

The difference between total YLDs in 1990 and YLDs at step 1 represents the change in YLDs due to population growth; the difference between YLDs at step 1 and YLDs at step 2 represents the change in YLDs due to population aging; the difference between total YLDs in 2010 and YLDs at step 2 represents the change in YLDs due to changes in prevalence.

Idiopathic intellectual disability		6.4%	3.2%	1.1%	7.4%
Other mental and substance use disorders		0.5%	0.5%	0.0%	1.1%

Suicide rates are higher in males than in females (3.2:1 in 1950, 3.6:1 in 1995, and an estimated 3.9:1 in 2020). China is the only country in which suicide rates in females are consistently higher than those in males, especially in rural areas. Over the last few decades, suicide rates have been reported to be stable worldwide, but a rising trend among males of age 15 to 19 years has been observed. A systematic review covering 15,629 cases in the general population worldwide estimated that 98 percent of those who committed suicide had a diagnosable mental disorder, with mood disorders accounting for 35.8 percent, substance-related disorders for 22.4 percent, personality disorders for 11.6 percent, and schizophrenia for 10.6 percent of cases.

TREATMENT GAP AND PROJECTED POPULATION-LEVEL TREATMENT EFFECTIVENESS WORLDWIDE

The efficacy of pharmacological and psychosocial treatments for mood, anxiety, psychotic, and substance-related disorders has been convincingly proved by clinical trials carried out in low- and middle-income, as well as in high-income, countries. However, the treatment gap is substantial for all mental disorders worldwide, in particular, in low-income countries.

In the World Mental Health Surveys, carried out in representative community samples in 17 countries in Africa, the Americas, Asia, Europe, and the Middle East, the proportion of lifetime cases of anxiety disorders making treatment contact in the year of disorder onset ranged from .8 percent in Nigeria to 36.4 percent in Israel. The proportion of cases making treatment contact by 50 years ranged from 15.2 percent in Nigeria to 95.0 percent in Germany. The median delay to treatment among cases eventually making contact ranged from 3 years in Israel to 30 years in Mexico (Table 62–13, also see Table 62–10).

The proportion of lifetime cases of mood disorders making treatment contact in the year of disorder onset ranged from 6 percent in Nigeria and China to 52.1 percent in the Netherlands. The proportion of cases making treatment contact by 50 years ranged from 7.9 percent in China to 98.6 percent in France. The median delay to treatment among cases eventually making contact ranged from 1 year in Belgium, The Netherlands, Spain, and Japan to 14 years in Mexico (Table 62–14).

The proportion of lifetime cases of substance use disorders making treatment contact in the year of disorder onset ranged from .9 percent in Mexico to 18.6 percent in Spain. The proportion of cases making treatment contact by 50 years ranged from 19.8 percent in Nigeria to 86.1 percent in Germany. The median delay to treatment among cases eventually making contact ranged from 6 years in Spain to 18 years in Belgium (Table 62–15).

In the World Mental Health Surveys, failure and delays in treatment seeking were generally greater in low-income countries, older cohorts, men, and cases with earlier ages of onset. The earlier treatment contact of people with mood disorders might be partly due to the fact that these disorders have been targeted by educational campaigns and primary care quality improvement programs in several countries.

The Disease Control Priorities Project Report estimated the cost of a mental health care package consisting of outpatient treatment of schizophrenia and bipolar disorder with first-generation antipsychotics or mood stabilizers and adjuvant psychosocial interventions and treatment of depression and panic disorder in primary care with generic selective serotonin reuptake inhibitors. The cost per capita of the package was projected to be US$ 3 to 4 in sub-Saharan Africa and South Asia and US$ 7 to 9 in Latin America and the Caribbean. The addition of brief interventions by primary care physicians for high-risk alcohol users was

projected to cost a further US$ 0.04 per capita in sub-Saharan Africa and South Asia and up to US$ 0.36 per capita in Central Asia and Latin America. Treatment of common mental disorders was reported to be in the same range of cost-effectiveness as antiretroviral treatment for HIV/AIDS, secondary prevention of hypertension, or glycemic control for diabetes.

[a]Number of participants are unweighted, but percentages, means, and medians are weighted.

[b]Treatment delay is expressed as years between disorder onset and initial treatment contact. Delay was set at zero years for persons with initial treatment contact before disorder onset or in the year of disorder onset.

[c]Measured for respondents aged 18–44 only.

RESOURCES FOR MENTAL HEALTH CARE WORLDWIDE

According to the *Mental Health Atlas 2005,* only 62.1 percent of countries worldwide, accounting for 68.3 percent of the world population, have a mental health policy (i.e., a document of the government or ministry of health specifying the goals for improving the mental health situation of the country, the priorities among those goals, and the main directions for attaining them). A mental health policy is present in 58.8 percent of low-income and 70.5 percent of high-income countries. In Africa, only 50 percent of countries have a mental health policy. In Southeast Asia, only 54.5 percent of countries have a mental health policy, and 76.4 percent of the population is not covered by such a policy (Table 62–16). This difference in mental health policy reflects number of factors. This could be attributed to low importance to mental health in many countries and settings. It also has been explained on the basis of colonial rule where the laws have not been changed even after independence.

Community care facilities exist in only 68.1 percent of the countries (51.7 percent of low-income and 93 percent of high-income countries). In Southeast Asia, they are present in 50 percent of the countries, and in Africa in 56.5 percent of the countries. Only 60.9 percent of the countries report providing treatment facilities for severe mental disorders at the primary care level (55.2 percent of low-income and 79.5 percent of high-income countries). About one-fourth of low-income countries do not provide even basic antidepressant medications in primary care settings. In many others, the supply does not cover all regions of the country or is very irregular. Because medicines are often not available in health care facilities, patients and families are forced to pay for them out of pocket.

Whereas 61.5 percent of European countries spend more than 5 percent of their health budget in mental health care, 70 percent of countries in Africa and 50 percent of countries in Southeast Asia spend less than 1 percent. Out-of-pocket payment is the most important method of financing mental health care in 38.6 percent of countries in Africa and 30 percent of countries in Southeast Asia, whereas it is not the primary method of financing mental health care in any European country (Table 62–17). All countries with out-of-pocket payment as the dominant method of financing mental health care belong to low-income or lower middle-income

categories, while almost all countries with social insurance as the dominant method of financing belong to high-income or upper middle-income categories.

The median of psychiatric beds per 10,000 population ranges from 0.33 in Southeast Asia and .34 in Africa to 8 in Europe. Globally, 72 percent of psychiatric beds are located in mental hospitals and the rest in other settings, including psychiatric units in general hospitals and community services. The percentage of psychiatric beds located in mental hospitals is 74 percent in low-income and 83 percent in middle-income countries, compared with 64 percent in high-income countries. The lower figures for high-income countries reflect the trend toward deinstitutionalization in those countries. Of the psychiatric beds available in Europe, more than 80 percent are located in mental hospitals in low- and middle-income countries of Central and Eastern Europe.

The median number of psychiatrists per 100,000 population ranges from .04 in Africa and .2 in Southeast Asia to 9.8 in Europe (Table 62–18). It is .1 in low-income countries, compared to 9.2 in high-income countries. Two-thirds of low-income countries have less than 1 psychiatrist per 100,000 population. Chad, Eritrea, and Liberia (with populations of 9, 4.2 and 3.5 million, respectively), each has just 1 psychiatrist per 100,000 population. Afghanistan, Rwanda, and Togo (with populations of 25, 8.5, and 5 million, respectively), each has just 2 psychiatrists per 100,000 population. Large-scale migration of psychiatrists from low- and middle-income to high-income countries, as part of the larger picture of migration of health professionals in general, has been consistently documented. India and some sub-Saharan African countries are the most important contributors to the mental health workforce in the United Kingdom, although the United Kingdom has 110 psychiatrists per million population, whereas India has 2 per million and sub-Saharan Africa less than 1 per million.

The median number of psychiatric nurses per 100,000 population ranges from .1 in Southeast Asia and .2 in Africa to 24.8 in Europe. Nearly 47 percent of low-income countries have less than 1 psychiatric nurse per 100,000 population. The median number of psychologists working in mental health care per 100,000 population ranges from 0.03 in Southeast Asia and 0.05 in Africa to 3.1 in Europe. Approximately 69 percent of low-income countries have less than 1 psychologist per 100,000 population.

From these figures, it is clear that resources for mental health care are grossly inadequate in comparison to the needs, and that inequalities across countries are substantial, especially between low- and high-income countries. Moreover, resources tend to be concentrated in urban areas, especially in low-income countries, leaving vast regions without any form of mental health care. What this also indicates that the mental health professionals need to think outside the box and train primary care

physicians, community midwives, and health visitors as well as other professionals to screen and manage common mental disorders.

Even worse is the situation concerning child and adolescent mental health care. According to the WHO, only 7 percent of countries worldwide have a specific child and adolescent mental health policy. In less than one-third of all countries is it possible to identify an institution or a governmental entity with an overall responsibility for child mental health. School-based services are almost exclusively present in high-income countries, and even in Europe only 17 percent of countries have a sufficient number of these services. There are no pediatric beds for mental health identified in low-income countries, whereas such beds are identified in 50 percent of high-income countries. In all African countries outside South Africa, fewer than 10 psychiatrists could be found who were trained to work with children. In European countries, the number of child psychiatrists ranges from 1 per 5,300 to 1 per 51,800. In more than 70 percent of countries worldwide, there is no list of essential psychotropic medications for children. In 45 percent of countries worldwide, psychostimulants are either prohibited or unavailable for use in children with attention-deficit/hyperactivity disorder.

PRINCIPLES FOR MENTAL HEALTH PROGRAM DEVELOPMENT WORLDWIDE

According to the WHO, the development of mental health programs worldwide should be guided by the following principles: (1) providing treatment in primary care, (2) making psychotropic medications available, (3) giving care in the community, (4) educating the public, (5) involving communities, families, and consumers, (6) establishing national policies and legislations, (7) developing human resources, (8) linking with other relevant sectors, (9) monitoring community mental health, and (10) supporting more research.

Providing treatment in primary care involves the inclusion of recognition and treatment of common mental disorders in training curricula of all health personnel, the provision of refresher training to primary care physicians, and the improvement in referral patterns in primary health care. Making psychotropic medications available includes ensuring the availability of essential drugs in all health care settings and, in high-income countries, providing easier access to newer psychotropic drugs under public or private treatment plans. Giving care in the community implies moving people with mental disorders out of prisons, downsizing mental hospitals and improving care within them, developing general hospital psychiatric units, and providing community care facilities.

Educating the public includes promoting public campaigns against stigma and discrimination; using the mass media to promote mental health, foster positive attitudes, and help to prevent mental disorders; and, in high-income countries, launching public campaigns for the recognition

and treatment of common mental disorders. Involving communities, families, and consumers includes supporting the formation of self-help groups; ensuring the representation of communities, families, and consumers in services and policy making; and foster advocacy initiatives.

Establishing national policies and legislations includes revising legislations on the basis of current knowledge and human rights considerations and increasing the budget for mental health care. Developing human resources involves training psychiatrists and psychiatric nurses, and, in middle- and high-income countries, creating national training centers for psychiatrists, psychiatric nurses, psychologists, and psychiatric social workers. Linking with other relevant sectors involves initiating school and workplace mental health programs, encouraging the activities of nongovernmental organizations in those areas, and, in high-income countries, initiating evidence-based mental health promotion programs in collaboration with other appropriate sectors.

Monitoring community mental health involves including mental disorders in basic health information systems, surveying high-risk population groups, instituting surveillance for specific disorders in the community, and, in high-income countries, monitoring the effectiveness of preventive programs. Supporting more research includes conducting studies in primary health care settings on the prevalence, course, outcome, and effect of mental disorders in the community; instituting effectiveness and cost-effectiveness studies for management of common mental disorders in primary health care; and, in high-income countries, carrying out research on the risk factors for mental disorders and on service delivery and investigating evidence on the prevention of mental disorders.

The guiding principles proposed for the prevention of suicide worldwide include (1) reducing access to means of suicide (e.g., pesticides and firearms), (2) treating people with mental disorders, (3) improving media portrayal of suicide, (4) training primary health care personnel, (5) implementing school-based programs, and (6) developing hot lines and crisis centers.

BARRIERS TO CHANGE

The most significant barriers to the implementation of the foregoing principles worldwide, according to the WHO, include the following: (1) some stakeholders may be resistant to the changes, (2) health authorities may not believe in the effectiveness of mental health interventions, (3) there may be no consensus among the country's stakeholders about how to formulate or implement the new policy, (4) financial and human resources may be scarce, (5) other basic health priorities may compete with mental health care for funding, (6) primary care teams may feel overburdened by their workload and refuse to accept the introduction of the new policy, and (7) many mental health specialists may not want to work in community facilities or with primary care teams, preferring to remain in hospitals. The suggested solutions include (1) adopting an "all-winners approach" that ensures that the needs of all stakeholders are taken into account, (2) developing pilot projects and evaluating their effect on health and consumer satisfaction, (3) asking for technical reports from international experts, (4) focusing the implementation of the mental health policy on a demonstration area and performing cost-effectiveness studies, (5) linking mental health programs to other health priorities, and (6) showing primary care practitioners that people with mental disorders are already a hidden part of their burden and that the burden will decrease if these disorders are identified and treated.

STIGMATIZING ATTITUDES TOWARD PEOPLE WITH MENTAL DISORDERS

Stigmatizing attitudes toward people with mental disorders are widespread in the general public and even among mental health professionals. Although it has been suggested that stigma may be less severe in Asian and African countries, a study carried out in India within the Stigma Programme of the World Psychiatric Association (WPA), in which 463 persons with schizophrenia and 651 family members were interviewed in four cities, reported that two-thirds of the respondents had suffered discrimination. Women and people living in urban areas were more stigmatized. Men experienced greater discrimination in the job area, whereas women experienced more problems in the family and social areas. In the family area, subtle discrimination in the form of decreased love, avoidance, rejection, and distance and excessive caution was frequently reported. In Ethiopia, among relatives of people with a diagnosis of schizophrenia or mood disorders, 75 percent reported that they had experienced stigma due to the presence of mental illness in the family, and 37 percent wanted to conceal the fact that a relative was ill. In a large

survey carried out in China among people with schizophrenia and their family members, one half of the respondents reported they had felt significantly stigmatized, and levels of stigma were found to be higher in urban areas. Stigmatization of people with mental disorders has been reported to be rare in Islamic countries.

Unlike people with physical disabilities, those with mental disorders are often perceived by the public to be in control of their disabilities and responsible for causing them. The view that "weakness," "laziness," or "lack of willpower" contribute to the development of mental disorders has been reported in several countries, including Turkey, Mongolia, and South Africa. The stigmatization of people with mental disorders may result in public avoidance, systematic discrimination, and reduced help-seeking behavior. In a survey carried out in 1996, in a probability sample of 1,444 adults in the United States, more than one half of the respondents reported to be unwilling to spend an evening socializing with, work next to, or have a family member marry a person with mental illness. Although most countries have some provision for disability benefits, people with mental illness are often specifically excluded from such entitlements. Moreover, mental disorders are frequently not considered in social and private insurance schemes for health care. Shame is reported to be one of the main barriers from seeking help for mental disorders in both developed and developing countries.

Strategies for addressing stigmatization of people with mental disorders have been subdivided into three groups: protest, education, and contact. There is some evidence that protest campaigns may be effective in reducing stigmatizing behaviors against people with mental disorders. This activist approach may be more workable in some countries rather than others. Education may promote a better understanding of mental illness, and educated people may be less likely to endorse stigma and discrimination. Even in rural settings in low- and middle-income countries strategies can be put into place successfully. There is no doubt that certain environments produce higher levels of stigma. These authors reported that internalized stigma and social relationships provide a risk factor for social isolation especially among patients with schizophrenia. Ungar et al. (2015) observe that various strategies are needed to deliver antistigma programs and health care systems themselves need to be included in such efforts. There is no doubt that stigma whether it is internal or external will influence help-seeking. Corrigan et al. (2014) provide a reminder that stigma remains a complex construct. The people who are affected by it and also demonstrate stigma include public, self, and structural components as mentioned above in health care structures. There is no doubt that directly affects people with mental illness, as well as their support system, provider network, and community resources. These authors also remind readers that cultures influence stigma too. It is likely that cultures see illnesses and idioms of

distress in different ways and stigma may be generated and seen in different ways. Internalized stigma too may be affected by cultures although. Pérez-Garín et al. (2015) point out that well-being can play a major role in mediating stigma. The definitions and understanding of well-being itself can be influenced by cultures. Stigma by professionals themselves deserves further exploration. Poreddi et al. (2015) report that stigma in medical students can be reduced after they have been exposed to psychiatric teaching and training, it has been suggested that public policy needs to change in order to reduce stigma.

An inverse relationship between having contact with a person with mental illness and endorsing stigmatizing behaviors has been documented. Several recent programs such as Time to Change in the United Kingdom have demonstrated that talking with patients with psychiatric patients does lead to a positive change in people's attitudes and changes attitudes in a more positive direction.

RELATIONSHIPS BETWEEN MENTAL AND PHYSICAL DISEASES

Mortality due to physical illness is significantly increased in people with severe mental disorders compared with the general population. In a follow-up study carried out in the United Kingdom, the standardized mortality ratio (SMR) for natural causes in people with schizophrenia was 2.32 (i.e., mortality was more than twice higher than in the general population). The SMR for causes "avoidable by appropriate treatment" was 4.68. The highest SMRs were those for endocrine, nervous, respiratory, circulatory, and gastrointestinal diseases. Increased nonsuicide all-cause mortality has been also reported for bipolar disorder (SMR 1.9 for males and 2.1 for females) and dementia (relative risk [RR] 2.63; 95 percent confidence interval [CI] 2.17 to 3.21). A meta-analysis of 15 population-based studies of the effect of a diagnosis of depression on subsequent all-cause mortality yielded a pooled odds ratio of 1.7 (CI 1.5 to 2.0). Evidence from low-income countries is limited, but a large population study conducted in Ethiopia found high mortality rates for major depression (SMR 3.55, 95 percent CI 1.97 to 6.39) and schizophrenia (almost 5 percent per year).

People with mental illness seem not to have benefited from the recent favorable trends concerning mortality due to some physical diseases. In a longitudinal study conducted in Australia, a steady decline in the mortality rate due to ischemic heart disease was observed in the general population during the period from 1980 to 1998, dropping from 209 to 143 per 100,000 person-years in men and from 139 to 117 per 100,000 person-years in women. In contrast, the mortality rate remained approximately constant in male psychiatric patients (on average 280 per 100,000 person-years) and increased from 153 to 234 per 100,000 person-years in female psychiatric patients.

The prevalence of several physical diseases is increased in people with

mental disorders compared with the general population. In a study carried out in the United States, people with psychotic disorders were found to be more likely than other people to develop diabetes, hypertension, heart disease, asthma, gastrointestinal disorders, skin infections, malignant neoplasms, and acute respiratory disorders. The rate was increased even when only patients without a concomitant substance use disorder were considered. In a study conducted in Nigeria, 55.2 percent of persons with schizophrenia-spectrum disorders referred for the first time to a psychiatric clinic had at least one physical disease, whereas in persons with neurotic disorders the rate was 11.8 percent. A strong prospective association has been documented between depression and coronary heart disease outcomes, including fatal myocardial infarction; on the other hand, the incidence of depression is increased after myocardial infarction, especially in the first month after the event. Depression also increases the risk of type II diabetes. In South Asia, an association between maternal perinatal depression and infant malnutrition and stunting at 6 months has been repeatedly reported.

People with severe mental disorders are at increased risk of contracting HIV infection, although prevalence rates vary substantially worldwide. Conversely, a large multicenter study conducted in sub-Saharan Africa, Asia, Latin America, Europe, and the United States reported a higher prevalence of depressive disorder among symptomatic HIV-seropositive people than in asymptomatic HIV-seropositive cases and seronegative controls. Evidence from both developed and developing countries shows that adherence to highly active antiretroviral therapy (HAART) is negatively affected by depression, cognitive impairment, and substance abuse.

The increased morbidity and mortality due to physical illness in people with severe mental disorders is first of all related to the increased prevalence in these people of several risk factors for cardiovascular, metabolic, and respiratory diseases, the most important of which are obesity, smoking, and alcohol and drug abuse.

In a study carried out in the United Kingdom, people with severe mental illness were significantly more likely to be obese (body mass index higher than 30) and morbidly obese (body mass index higher than 40) than the general population: The respective figures were 35.0 versus 19.4 percent and 3.7 versus 1.3 percent. When these figures were broken down by age and sex, 28.7 percent of men with severe mental illness aged between 18 and 44 years were obese, compared with 13.6 percent in the general population, and 3.7 versus .4 percent were morbidly obese. Even more striking were the figures concerning women of the same age: 50.6 versus 16.6 percent and 7.4 versus 2.0 percent, respectively.

In a meta-analysis of worldwide studies, a highly significant association between schizophrenia and current smoking was confirmed: The weighted

average odds ratio was 5.9; it was 7.2 in males and 3.3 in females. The association remained significant when controls with severe mental illness were used (odds ratio 1.9). Heavy smoking and high nicotine dependence were also more frequent in people with schizophrenia than in the general population.

Patients with severe mental illness have also been reported to make poorer dietary choices and to be less physically active than the general population, but the relevant research evidence is not strong.

The increased risk of HIV infection in people with severe mental disorders may be explained by the high rates of sexual contact with multiple partners, the low levels of condom use, and the high prevalence of injected drug use and sexual contact with partners using injected drugs.

The access of people with mental illness to physical health care is reduced with respect to the general population. In the aforementioned study conducted in Australia, the SMR for ischemic heart disease was found to be 1.78 in men with schizophrenia. However, hospital admission for that disease was remarkably less common in both men and women with schizophrenia compared with the general population. Moreover, both men and women with schizophrenia were more than threefold less likely to receive revascularization procedures than the general population.

The quality of physical health care received by patients with severe mental illness is often worse than the general population. A study conducted in the United States found that adverse events during medical and surgical hospitalizations were significantly more frequent in patients with schizophrenia than in the other people, including infections due to medical care, postoperative respiratory failure, postoperative deep venous thrombosis or pulmonary embolism, and postoperative sepsis. All of these adverse events were associated with a significantly increased odds of admission to an intensive care unit and of death.

The decreased access of people with mental disorders to medical services has been related to several factors concerning the health care system. The effect of lack of insurance and cost of care is well documented. In a study carried out in the United States, people with mental disorders were twice as likely as those without mental disorders to have been denied insurance because of a pre-existing condition (odds ratio 2.18). Having a mental disorder conferred a greater risk of having delayed seeking care because of cost (odds ratio 1.76) and of having been unable to obtain needed medical care (odds ratio 2.30).

Even when people with mental illness are seen by a doctor, their physical diseases often remain undiagnosed. Primary care providers may misperceive the medical complaints of people with mental disorders as “psychosomatic” or be unskilled or feel uncomfortable in dealing with this population. An underlying stigmatization may be involved. Moreover, during hospitalizations in medical and surgical wards, health care

professionals may not be experienced in dealing with the special needs of patients with schizophrenia, may minimize or misinterpret their somatic symptoms, and may make an inappropriate use of restraints or sedative drugs or fail to consider possible interactions of psychotropic drugs with other medications. On the other hand, many psychiatrists are unable or unwilling to perform physical and even neurological examinations or are not up to date on the management of even common physical diseases.

To address this situation, the first step is raising awareness of the problem among mental health care professionals, primary care providers, and patients with schizophrenia and their families. The research information about the increased morbidity and mortality due to physical illness in people with schizophrenia should be appropriately disseminated.

Education and training of mental health professionals and primary care providers is a further essential step. Mental health professionals should be trained to perform at least basic medical tasks. They should be educated about the importance of recognizing physical illness in people with severe mental disorders and encouraged to become familiar with the most common reasons for underdiagnosis or misdiagnosis of physical illness in these patients. On the other hand, primary care providers should overcome their reluctance to treat people with severe mental illness and learn effective ways to interact and communicate with them; it is not only an issue of knowledge and skills, but also most of all one of attitudes.

Another essential step is the development of an appropriate integration between mental health and physical health care. A well-identified professional should be responsible for physical health care in each person with a severe mental disorder. Mental health services should be able to provide at least a standard routine assessment of their patients to identify or at least suspect the presence of physical health problems. Guidelines about the management of patients receiving antipsychotic drugs should be known and applied by all mental health services. Patients should be involved as much as possible; for instance, mental health professionals should encourage patients to monitor and chart their weight. Dietary and exercise programs should be routinely provided by mental health services. Flexible smoking cessation programs, which have shown some degree of success, could be considered in some settings.

ETHICAL ISSUES IN MENTAL HEALTH CARE

The protection and promotion of the human rights of people with mental disorders are emerging as a priority worldwide. In 1991, the United Nations issued Resolution 46/119 for the Protection of Persons with Mental Illness and the Improvement of Mental Health Care. In that resolution, the human rights of people with mental disorders and their right to treatment were codified for the first time in a UN document. The 25 principles covered the following areas: Definition of mental illness; protection of confidentiality;

standards of care and treatment, including involuntary admission and consent to treatment; rights of persons with mental disorders in mental health facilities; protection of minors; provision of resources for mental health facilities; role of community and culture; review mechanisms providing for the protection of the rights of offenders with mental disorders; and procedural safeguards protecting rights of persons with mental disorders. National governments were invited to promote the principles of the resolution by appropriate legislative, juridical, administrative, educational, and other provisions. However, violations of the human rights of people with mental disorders are still reported in many countries, and in a substantial number of low- and middle-income countries patients in mental hospitals are physically restrained or secluded for long periods.

In Latin America, an influential document has been the Declaration of Caracas, adopted in 1990, by the Regional Conference on Restructuring Psychiatric Care in Latin America, which states that resources, care, and treatment for people with mental disorders should safeguard their dignity and human and civil rights and strive to maintain them people in their communities. The Declaration also states that mental health legislation should safeguard the human rights of people with mental disorders and that services should be organized so that these rights can be enforced.

In Africa, the Banjul Charter on Human and People's Rights, a legally binding document supervised by the African Commission on Human and People's Rights, in Article 5, addresses the right to respect for the dignity inherent in human beings and the prohibition of all forms of degradation, including cruel, inhuman, or degrading treatment.

According to the WHO, mental health legislation should cover the following issues: access to basic mental health care, least restrictive care, informed consent to treatment, voluntary and involuntary admission to treatment, competence issues, periodical review mechanism, confidentiality, rehabilitation, accreditation of professionals and facilities, and rights of families and caregivers. Specific mental health legislation in the field of mental health is present in 74 percent of low-income countries versus 92.7 percent of high-income countries.

In 1996, the WPA released the Madrid Declaration, which contains the ethical principles by which all national psychiatric societies are expected to abide. The Declaration includes seven general guidelines focusing on the aims of psychiatry: (1) psychiatrists must serve patients by providing the best therapy available consistent with accepted scientific knowledge and ethical principles and should devise therapeutic interventions that are the least restrictive to the freedom of the patient; (2) it is the duty of psychiatrists to keep abreast of scientific developments of their specialty and to convey updated knowledge to others; (3) the patient should be accepted as a partner by right in the therapeutic process, and the therapist–

patient relationship must be based on mutual trust and respect, to allow the patient to make free and informed decisions; (4) treatment must always be in the best interest of the patient, and no treatment should be provided against the patient's will, unless withholding treatment would endanger life of the patient and/or those who surround him or her; (5) when psychiatrists are requested to assess a person, it is their duty to inform the person being assessed about the purpose of the intervention; (6) information contained in the therapeutic relationship should be kept in confidence and used exclusively for the purpose of improving the mental health of the patient; and (7) because psychiatric patients are particularly vulnerable research subjects, extra caution should be taken to safeguard their autonomy, as well as their mental and physical integrity.

INTERNATIONAL ORGANIZATIONS ACTIVE IN THE MENTAL HEALTH FIELD

There are many international organizations active in the mental health field. They include the WHO, which is the world's leading public health agency; some professional associations, among which the largest is the WPA, representing the psychiatric profession worldwide; and several organizations with a membership of users/families (e.g., the World Fellowship for Schizophrenia and the Global Alliance of Mental Illness Advocacy Networks [GAMIAN]) or of both mental health professionals and users/families (e.g., the World Federation for Mental Health [WFMH]).

The WHO is a UN agency with 192 member states, grouped into six regions (Africa, the Americas, European Mediterranean, Europe, Southeast Asia, and Western Pacific). It has a Department of Mental Health and Substance Abuse at its headquarters in Geneva and advisors for mental health in each of its regional offices. Its main functions are direction and coordination of international health work and technical cooperation with countries. Among the numerous recent WHO activities in the mental health field, of special interest are the release of the *World Health Report 2001* and the development of the report *Mental Health: New Understanding, New Hope,* which was completely devoted to mental health. It provided a summary of the current and projected impact of mental disorders and of the principles of mental health policy and service provision, as well as a set of recommendations for future action that can be adapted to the needs and resources of the various countries. Project Atlas aims to collect information on mental health resources across the world. Global and regional analyses of those resources were first published in 2001 and updated in 2005. Volumes focusing on resources for child and adolescent mental health and on psychiatric education and training worldwide (the latter in collaboration with the WPA) were released in 2005.

The WPA is an association of national psychiatric societies aimed at increasing knowledge and skills necessary for work in the field of mental health and the care for the mentally ill. Its member societies number 134,

spanning 122 countries and representing more than 200,000 psychiatrists. The WPA organizes the World Congress of Psychiatry every 3 years. It also organizes international and regional congresses and meetings and thematic conferences. It has 65 scientific sections, which are aimed at disseminating information and promoting collaborative work in specific domains of psychiatry. It has produced several educational programs and series of books and consensus statements (including the Declaration of Madrid on ethical principles for psychiatric practice). It has an official journal, *World Psychiatry,* which is produced in English, Spanish, and Chinese and is indexed in PubMed and Current Contents and reaches more than 33,000 psychiatrists worldwide. Subsequently several books and information sheets have been published (a full list is available on the WPA website).

The WFMH is a multidisciplinary advocacy and education organization aimed at promoting the advancement of mental health awareness, prevention, advocacy, and best-practice recovery-focused interventions worldwide. Among its activities is the organization of the World Mental Health Day, observed every year on October 10, each time with a different theme.

FUTURE PERSPECTIVES

Several statements have been made by various groups and organizations about priorities for future action in the mental health field at the international level. Of special interest is a document produced by 39 leaders composing the so-called Lancet Global Mental Health Group. In this document, five main goals are identified: (1) placing mental health on the public health priority agenda, (2) improving the organization of mental health services, (3) integrating the availability of mental health into general health care, (4) developing human resources for mental health, and (5) strengthening public mental health leadership. It is good step but as mentioned above if it focuses only on one directional move it will create further barriers. It is imperative that local explanatory models and idioms of distress are taken into account so that culturally appropriate, culturally sensitive and culturally accessible models of service care are developed and delivered. Virtually in every country around the world there are insufficient human and material resources dedicated to mentally ill and mental illness. In many countries useful models of engaging the local community exist and it will be helpful to learn how these work. Furthermore, models using e-mental health and tele-mental health should be employed particularly in countries with large geographical areas.

Among the strategies proposed to place mental health on the public health priority agenda are the development and use of uniform and clearly understandable messages for mental health advocacy and the education of decision makers within governments and donor agencies on the evidence concerning the public health significance of mental disorders and the cost-

effectiveness of mental health care. Strategies suggested to improve the organization of mental health services include, among others, the provision of incentive arrangements to overcome vested interests blocking change and the organization of international technical support to learn from countries that have experienced successful mental health reform. To integrate the availability of mental health in general health care, it is proposed that mental health professionals be appointed and trained specifically for supporting and supervising primary health care staff. To promote the development of human resources for mental health, it is suggested that the professional and specialist workforce be increased and diversified, and that the quality of mental health training be improved to ensure that it is practical and occurs also in community or primary care settings. Governments are asked to identify and scale up a priority package of service interventions and to increase mental health budget allocations, with the aim of attaining a minimum level of investment within 10 years of US$ 2 per capita in low-income countries and US$ 3 to 4 per capita in lower middle-income countries. International donors and governments of high-income countries, in particular those that are beneficiaries of the brain drain, are asked to place mental health on their priority agenda for health assistance to low- and middle-income countries. Finally, several indicators are proposed to monitor progress worldwide. In the 2014 to 2017, WPA has launched an ambitious plan for the social justice for the mentally ill focusing on domestic gender-based interpersonal violence; child physical and emotional abuse; prisoner mental health care; underserved populations such as asylum seekers, migrants, and refugees; those with intellectual disabilities, lesbian, gay, bisexual, and transgender individuals and elderly individuals and finally developing mental health promotion. Interestingly, World Medical Association is also focusing on child abuse and gender-based violence and the two organizations are planning to work closely together. WPA is also working with other organizations to develop materials on perimental health as well as setting up WPA-Lancet commission on psychiatry to explore the roles and responsibilities of psychiatrists in the first quarter of the 21st century.

FUTURE DIRECTIONS

This chapter has provided an overview of the burden of mental disorders worldwide, the treatment gap and the scarcity of resources for mental health care especially in low- and middle-income countries, the WHO guidelines for the development of mental health programs and the obstacles to their implementation, and several other issues of interest for world psychiatry. The discussion has been based as much as possible on data, although part of the data on world mental health are projections that may under- or overestimate the magnitude of the problems. Moreover, the threshold for the diagnosis of common mental disorders (e.g., depression

and anxiety disorders) remains controversial, and although it can be argued that "subthreshold" conditions (not fulfilling current diagnostic criteria) might be a further neglected source of burden and disability, it can be also pointed out that some conditions fulfilling current diagnostic criteria might represent homeostatic reactions to adverse life events that are transient and do not require treatment. The threshold for the diagnosis of common mental disorders may be different in the various geographic and cultural contexts, making projections and international comparisons even more problematic. On the other hand, although several pharmacological and psychotherapeutic interventions have been proved to be efficacious in various regions of the world, their feasibility and acceptability may not be the same worldwide, and current treatment guidelines may not be relevant to people living in several low- and middle-income countries. The same may apply to rehabilitation programs and models of community mental health care. The fact is that, although more than 85 percent of the world's population lives in low- and middle-income countries, only a negligible proportion of research in the mental health field is conducted in those countries. Research-generated information is crucial to evaluate local needs, develop cost-effectiveness interventions, and monitor their implementation. Several initiatives are now addressing this research gap, and it can be hoped that a substantial revision of this chapter will be needed in the near future.

ADHD, attention-deficit/hyperactivity disorder; AIDS, acquired immune deficiency syndrome; APA, American Psychiatric Association; CNS, central nervous system; CRF, corticotropin-releasing factor; CT, computed tomography; DSM, *Diagnostic and Statistical Manual of Mental Disorders;* ECT, electroconvulsive therapy; FDA, U.S. Food and Drug Administration; HIV, human immunodeficiency virus; MAOI, monoamine oxidase inhibitor; MMPI, Minnesota Multiphasic Personality Inventory; MRI, magnetic resonance imaging; NAMI, National Alliance for the Mentally Ill; NARSAD, National Alliance for Research on Schizophrenia and Depression; NIMH, National Institute for Mental Health; NMHA, National Mental Health Association; OCD, obsessive-compulsive disorder; PET, positron emission tomography; PTSD, posttraumatic stress disorder; SSRI, selective serotonin reuptake inhibitor; TR, text revision.

This table was conceived and developed by Ralph Colp Jr, M.D., who contributed to many editions of this book and who died in 2008. It was updated by one of the editors (BJS) with the assistance of Kristel Carrington, M.D.

Appendix B

Glossary of Psychiatry and Psychology Terms

A

AA Alcoholics Anonymous.

AACAP American Academy of Child and Adolescent Psychiatry.

AACDP American Association of Chairmen of Departments of Psychiatry.

AADPRT American Association of Directors of Psychiatric Residency Training, Inc.

AAMC Association of American Medical Colleges.

ability Capacity or competence to perform an act without previous training. *Compare* aptitude.

ablation Excision of part of the body, as in lobotomy or topectomy.

ablutomania Excessive interest in bathing and cleaning oneself; commonly observed in obsessive-compulsive disorder.

abnormal Term subject to considerable variability in definition and usage, roughly the equivalent of "psychopathological," and defined according to several criteria: **1.** *Normative* or *statistical approach,* considers as abnormal any mental or behavioral activities that deviate from culturally determined averages or norms. **2.** *Subjective approach,* regards as abnormal or psychopathological those phenomena that cause pain or suffering or induce a person to seek help. **3.** *Theoretical approach,* considers as abnormal any deviations from a theoretical concept of normal functioning that are indicative of psychiatric illness.

abortion Spontaneous or induced expulsion of an embryo or fetus before it has reached the stage of viability, that is, before about 20 weeks gestation.

ABPN American Board of Psychiatry and Neurology.

abreaction A process by which repressed material, particularly a painful experience or a conflict, is brought back to consciousness; in this process, the person not only recalls but relives the repressed material, which is accompanied by the appropriate affective response. *See also* catharsis.

absence seizure PETIT MAL EPILEPSY.

absolute threshold Minimum amount of stimulus needed to produce a response.

abstinence The act of refraining voluntarily from some activity, or from the use of certain substances, such as food or drugs; in psychoanalysis, refers to refraining from sexual intercourse.

abstinence syndrome WITHDRAWAL SYNDROME; DISCONTINUATION SYNDROME.

abstract attitude ABSTRACT THINKING.

abstraction The process whereby thoughts or ideas are generalized and dissociated from particular concrete instances or material objects; concreteness in proverb interpretation suggests an impairment of abstraction, as in schizophrenia.

abstract thinking Thinking characterized by the ability to assume a mental set voluntarily, to shift voluntarily from one aspect of a situation to another, to keep in mind simultaneously various aspects of a situation, to grasp the essentials of a whole and to break a whole into its parts, to discern common properties, to plan, to assume make-believe attitudes, and to think or act symbolically. The capacity for abstract thinking is frequently impaired in patients with organic mental disorders and schizophrenia. Also called abstract attitude; categorical attitude. *Compare* concrete thinking.

abulia Inability to make decisions; lack of will.

abuse 1. To attack or injure physically or psychologically, most commonly children, the elderly, and marital partners. *See also* battered child syndrome. **2.** To misuse substances such as drugs, illegal or prescribed, or alcohol so as to impair functioning.

acalculia Loss of ability to do calculations; not caused by anxiety or impairment in concentration. Occurs with neurological deficit and learning disorder.

acarophobia Abnormal fear of minute animate (insects, worms) or inanimate (pins, needles) objects.

acatalepsia Severe mental deficiency characterized by the inability to reason or comprehend.

acataphasia Disordered speech in which statements are incorrectly formulated. Patients may express themselves with words that sound like the ones intended but that are not appropriate to the thoughts, or they may use totally inappropriate expressions.

acathexis Lack of feeling associated with an ordinarily emotion-charged subject; in psychoanalysis, denotes the patient's detaching or transferring of emotion from thoughts and ideas. Occurs in anxiety, dissociative, schizophrenic, and bipolar disorders. Also called decathexis. *Compare* cathexis.

accelerated interaction A term used in group therapy to refer to an extended group therapy session that may last for hours, sometimes a day. Alternate term for marathon group session.

accident proneness Tendency to have accidents as a result of psychological causes.

accreditation A voluntary process by which standards for hospitals and health facilities are approved by city or federal government agencies; may also refer to being credentialed by the American Board of Psychiatry and Neurology (ABPN). *See also* board certified psychiatrist.

acenesthesia Loss of sensation of physical existence.

acetylcholine A neurotransmitter that causes cardiac inhibition, vasodilation, gastrointestinal peristalsis, and other parasympathetic effects; plays a critical role in memory, sleep, and the regulation of mood.

achluophobia Abnormal fear of the dark.

acid Slang for lysergic acid diethylamide (LSD).

ACP American College of Physicians.

acquired immunodeficiency syndrome (AIDS) According to the U.S. Centers for Disease Control, "a disease, at least moderately predictive of a defect in cell-mediated immunity, occurring in a person with no known cause for diminished resistance to that disease. Such

diseases include Kaposi sarcoma (KS), *Pnenmocystis carinii* pneumonia (PCP), and other serious opportunistic infections." The disease is caused by the human immunodeficiency virus type 1 (HIV-1). *See also* AIDS dementia complex.

acromegaly Disorder marked by hypersecretion of growth hormone by the anterior pituitary resulting in characteristic enlargement of certain body structures, such as the head, hands, feet, lips, and jaw; often associated with somnolence, moodiness, and decreased libido.

acrophobia Abnormal fear of high places.

acting out Behavioral response to an unconscious drive or impulse that brings about temporary partial relief of inner tension; relief is attained by reacting to a present situation as if it were the situation that originally gave rise to the drive or impulse. Common in borderline states.

activity group psychotherapy Type of group therapy, introduced and developed by S. R. Slavson, designed for children and young adolescents, with emphasis on emotional and active interaction in a permissive, nonthreatening atmosphere; the therapist interprets behavior and stresses reality testing.

actualization Realization of one's full potential. *See also* individuation.

aculalia Nonsense speech associated with marked impairment of comprehension. Occurs in mania, schizophrenia, and neurological deficit.

acute stress disorder Severe emotional reaction resulting from extreme environmental stress such as the death of a loved one, a disaster, or a catastrophic life situation. It usually remits within hours or days; however, if it persists for over a month it may evolved into a condition called posttraumatic stress disorder (PTSD).

ADAMHA Alcohol, Drug Abuse, and Mental Health Administration.

adaptation Process of fitting or conforming to the environment by behavioral or psychic changes that promote an optimal level of functioning. *See also* adjustment.

adaptational approach In analytic therapy, consonant with Sandor Rado's formulations on adaptational psychodynamics, therapy focusing on the maladaptive patterns used by patients in the treatment sessions, on how those patterns developed, and on what the patients must do to overcome them and stabilize their functioning at self-reliant, adult levels. *See also* social adaptation.

adaptive behavior Any behavior that increases an organism's ability to adjust to a specific environment or situation.

ADD Attention-deficit disorder.

addiction Repeated and increased use of a drug or chemical substance, the deprivation of which gives rise to symptoms of distress and an irresistible urge to use the agent again; leads to deterioration of physical and mental health. *See also* drug dependence.

ADHD Attention-deficit hyperactivity disorder.

adiadochokinesis Inability to perform rapid alternating movements. Occurs with neurological deficit and cerebellar lesions.

adjustment Maladaptive reaction to identifiable circumstances or life events that is expected to remit when the stress ceases. In DSM-5, divided into the following subtypes based on symptoms: with anxiety, with depressed mood, with mixed anxiety and depressed mood, with disturbance of conduct, with mixed disturbance of emotions and conduct, and unspecified.

adjustment disorder Maladaptive reaction to identifiable circumstances or life events that is expected to remit when the stress ceases.

Adler, Alfred (1870–1937) Viennese psychiatrist and one of Freud's original followers who broke with him and introduced and developed the concepts of individual psychology, inferiority complex, and overcompensation. *See also* masculine protest.

adlerian Attributed to or described by Alfred Adler.

administrative psychiatry Psychiatry concerned with public affairs, policy-making, executive decisions, and the duties of persons in executive positions.

adolescence Period of growth from puberty to maturity. Its beginning is marked by the appearance of secondary sexual characteristics, usually at about age 12; termination is marked by the achievement of sexual maturity at about age 20. *See also* psychosexual development.

adolescent mania Signs of mania occurring in an adolescent as the result of substance abuse (including alcohol) or of antisocial behavior but not as the result of a true bipolar disorder.

adrenaline EPINEPHRINE.

adrenergic 1. Relating to nerve fibers, tracts, or pathways in which synaptic transmission is mediated by norepinephrine (e.g., the sympathetic division of the autonomic nervous system); more generally, to processes activated by epinephrine or norepinephrine. **2.** Relating to drugs (catecholamines) that mimic the actions of the sympathetic nervous system.

adrenergic system Nerve cells or fibers of the autonomic nervous system that employ norepinephrine as their neurotransmitter.

Advanced sleep phase circadian rhythm disorder A circadian rhythm sleep–wake disorder characterized by sleep–wake times that are earlier than conventional times; individuals with this disorder are referred to as "early birds" or "larks."

adventitious reinforcement Responses that are reinforced accidentally by the coincidental pairing of response and reinforcement; such events may have clinical implications in the development of phobias or other neurotic behavior.

adverse effects Secondary, unfavorable reactions or results; usually referring to side effects of drugs.

adynamia Weakness and fatigability, a characteristic of neurasthenia and depression.

adynamic ileus PARALYTIC ILEUS.

aerophagia Excessive swallowing of air. Seen in anxiety disorder.

affect The subjective and immediate experience of emotion attached to ideas or mental representations of objects. Affect has outward manifestations that may be classified as restricted, blunted, flattened, broad, labile, appropriate, or inappropriate. *See also* mood.

affect-fantasy Jung's term for an emotional-laden fantasy.

affectionate transference *See* transference.

affective disorder *See* MOOD DISORDER.

affective hallucination Hallucination in which the content is either grandiose or self-deprecatory or involves other features common to a depressive syndrome such as guilt, disease, or poverty.

affective interaction Interpersonal experiences and exchanges that are emotionally charged.

aftercare After hospitalization, a continuing program of rehabilitation designed to reinforce the effects of therapy and to help patients adjust to their environment.

ageism Prejudice or discrimination against a particular age-group, especially the elderly.

ageusia Lack or impairment of the sense of taste; may be seen in depression and neurological deficit.

aggression Forceful behavior, verbal or physical, usually directed against another person.

aggressive drive One of the two primal drives or instincts (the other is the sexual drive) in Freud's dual-instinct psychoanalytic theory. It is conceived of as an unconscious destructive drive or an impulse directed at oneself or another that aims toward dissolution and death and operates on the repetition-compulsion principle, in contrast to the sexual drive, which follows the pleasure-pain principle. Also called death instinct; Thanatos.

aging The process of growing old; in human physiology, aging is said to occur when there is a failure to replace cells in sufficient numbers to maintain full functional capacity.

agitated depression Major depressive disorder with psychomotor agitation as a primary sign and symptom, characterized by restlessness, increased motor activity, and racing thoughts.

agitation State of anxiety associated with severe motor restlessness.

agnosia Inability to understand the import or significance of sensory stimuli; cannot be explained by a defect in sensory pathways or sensorium. In strict usage, diagnosis of agnosia implies an organic cerebral lesion; however, the term has also been used to refer to the selective loss or disuse of knowledge of specific objects due to emotional circumstances, as seen in certain schizophrenic, hysteric, and depressed patients. For types of agnosia, see the specific term.

agonist In pharmacology, a substance that excites the receptor sites of the cell and promotes or enhances a biological response. *Compare* antagonist.

agoraphobia Morbid fear of open places or of leaving the familiar setting of the home; may be present with or without panic attacks.

agraphia Loss or impairment of a previously possessed ability to write.

aichmophobia Abnormal fear of pointed objects.

AIDS Acquired immunodeficiency syndrome.

AIDS dementia complex Neurological complication of AIDS characterized by confusion, impaired judgment, impulsive behavior, and psychosis. Also called AIDS encephalopathy.

ailurophobia Abnormal fear of cats.

akathisia State of motor restlessness manifested by a compelling need to be in constant movement; may be seen as an extrapyramidal side effect of phenothiazine or other antipsychotic medication.

akinesia Lack of physical movement, as in the extreme immobility of catatonic schizophrenia; may also occur as an extrapyramidal effect of antipsychotic medication.

akinetic mutism Absence of voluntary motor movement or speech in a patient who is apparently alert (as evidenced by following eye movements). Seen in psychotic depression and catatonic states.

Al-Anon Organization of relatives of alcoholics, patterned after Alcoholics Anonymous, which promotes the discussion and resolution of common problems.

Alateen Organization directed to children of alcoholics, through group support, so that they may better understand their parents' alcoholism. *See also* Alcoholics Anonymous.

alcohol abuse and dependence Called alcohol use disorder in DSM-5. *See also* alcoholism.

alcohol amnestic disorder DSM term for Korsakoff psychosis.

alcohol dementia WERNICKE SYNDROME.

Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA) An agency of the U.S. government that is part of the National Institutes of Health (NIH) within the Department of Health and Human Services. It administers grant programs supporting research, training, and service programs in alcoholism, drug abuse, and mental health. Individual institutes within the agency are the National Institute on Alcohol Abuse and Alcoholism (NIAAA), the National Institute of Drug Abuse (NIDA), and the National Institute of Mental Health (NIMH).

alcoholic blackout Amnesia experienced by alcoholics concerning behavior during drinking bouts; usually indicates that reversible brain damage has occurred.

alcoholic deterioration Dementia and mental deterioration associated with chronic excessive alcohol use. Called dementia associated with alcoholism in DSM.

alcoholic hallucinosis Occurrence of hallucinations with a clear sensorium in a person with a history of heavy drinking and alcohol dependence; usually follows a prolonged drinking bout. *See also* Delirium tremens.

alcoholic psychosis Mental disorder that results from alcoholism and that involves organic brain damage, as in delirium tremens and Korsakoff psychosis.

Alcoholics Anonymous (AA) An organization of alcoholics formed in 1935 that uses certain group methods, such as inspirational-supportive techniques, to help rehabilitate chronic alcoholics.

alcohol idiosyncratic intoxication DSM term for a syndrome of marked alcohol intoxication with subsequent amnesia for the period of intoxication produced by the ingestion of quantities of alcohol that would be insufficient to induce intoxication in most people. Also called pathological intoxication.

alcohol intoxication Constellation of specific neurological, psychological, and behavioral effects produced by the recent ingestion of alcohol; characteristically, the effects include slurred speech, motor ataxia, disinhibition of sexual or aggressive impulses, lability of mood, impairment of attention or memory, and impairment of judgment. *See also* intoxication.

alcoholism Excessive dependence or addiction to alcohol, usually to the point that the person's physical and mental health are threatened or harmed; may be episodic or continuous. Called alcohol use disorder in DSM-5.

alcohol withdrawal syndrome Symptom complex resulting from the cessation or reduction in alcohol intake in a person who has been drinking heavily; includes tremulousness, seizures (rum fits), hallucinations, and autonomic hyperactivity (delirium tremens). *See also* withdrawal syndrome.

Alexander, Franz (1891–1964) Hungarian psychoanalyst who founded the Chicago Institute for Psychoanalysis, developed the concept of corrective emotional experience and specificity hypothesis in psychosomatic disorders, and, in collaboration with Thomas French in 1946, identified most of the basic characteristics of brief dynamic psychotherapy.

alexia Loss of the power to understand the meaning of written or printed words and sentences. *Compare* dyslexia.

alexithymia Inability or difficulty in describing or being aware of one's emotions or moods;

associated with depression, substance abuse, and posttraumatic stress disorder (PTSD).

algophobia Abnormal fear of pain.

algorithm Graphic representation used as a set of instructions for solving diagnostic or clinical problems. Also called decision tree.

alienation In psychiatry, used to describe a person's feelings of detachment from self or society, to denote one's avoidance of emotional experiences, or to describe efforts to estrange oneself from one's own feelings. *Compare* relatedness. *See also* isolation.

alienist Obsolete term for a psychiatrist who offers expert opinion about a person's mental health or sanity.

allergic jaundice Relatively rare, unpredictable, non–dose-dependent hypersensitivity reaction after treatment with some phenothiazines; generally appears during the second to fourth week of therapy, resulting in hyperbilirubinemia and deposition of bile pigment in the skin and mucous membranes which causes a yellow appearance of the patient; an obstructive (cholestatic) type of jaundice manifested by predominantly conjugated (direct-reacting) hyperbilirubinemia, the presence of bilirubin in the urine, and an abnormally high plasma alkaline phosphatase.

alliance *See* therapeutic alliance.

allied health professional *See* paraprofessional.

alloplasty Adaptation to stress by attempting to change the environment. *Compare* autoplasty.

Allport's group relations theory Theory developed by Gordon W. Allport that a person's behavior is influenced by his or her personality and the need to conform to social forces; illustrates the interrelationship between group therapy and social psychology.

alogia Inability to speak because of mental deficiency or an episode of dementia.

alopecia Hair loss. *See* trichotillomania.

alpha (α) error TYPE 1 ERROR.

alpha waves As measured by an electroencephalogram (EEG), brain waves that are 8 to 13 Hz, indicating a relaxed, waking state.

ALS Amyotropic lateral sclerosis.

alternating role Pattern characterized by periodic switching from one type of behavior to another.

altruism Regard for and dedication to the welfare of others; a term originated by the French philosopher Auguste Comte (1798–1857). In psychiatry, the term is closely linked with ethics and morals; Freud recognized altruism as the only basis for the development of community interest; Bleuler equated it with morality.

Alzheimer disease DEMENTIA OF THE ALZHEIMER TYPE.

AMA American Medical Association.

ambivalence Presence of strong and often overwhelming simultaneous contrasting attitudes, ideas, feelings, and drives toward an object, person, or goal; term coined by Bleuler, who differentiated three types: affective ambivalence, intellectual ambivalence, and ambivalence of the will. Commonly seen in schizophrenia and borderline personality disorder.

ambulatory schizophrenia A descriptive term refers to schizophrenic mental illness that is sufficiently well compensated so as not to require continuous hospitalization.

amentia Lack of intellectual development as a result of inadequate brain tissue. *Compare*

dementia.

American Academy of Child and Adolescent Psychiatry (AACAP) Organization of child and adolescent psychiatrist, founded in 1953, whose objectives are to study and to advance medical contributions to the knowledge and treatment of psychiatric illnesses of children and adolescents.

American Association of Chairmen of Departments of Psychiatry (AACDP) Organization of chairpersons of departments of psychiatry, founded in 1967, that concentrates on promoting medical education, research, and patient care, especially as they relate to psychiatry; prompting the growth and development of psychiatry; and providing a forum for discussion among chairpersons.

American Association of Directors of Psychiatric Residency Training, Inc. (AADPRT) Organization of training directors of U.S. psychiatric residency programs, founded in 1973, whose mandate is to oversee standards of approved residency criteria and to further psychiatric education.

American Board of Psychiatry and Neurology (ABPN) Group, founded in 1934, that sets the standards for teaching and training in psychiatry and neurology in American hospitals and training centers. Its members are from the American Medical Association, American Psychiatric Association, and American Neurological Association. It conducts periodic examinations of those who have satisfactorily completed their training; upon passing the examination, candidates are certified to practice the specialty of psychiatry and/or neurology and/or child psychiatry.

American College of Physicians (ACP) Honorary organization of internists and related medical specialists, founded in 1915, that sponsors postgraduate courses for physicians as well as teaching and research scholarships.

American College of Psychiatrists (ACP) Honorary organization of senior psychiatrists, founded in 1963, established to honor persons who have made a significant contribution to the study and development of psychiatry in the United States.

American Law Institute formulation of insanity Legal definition of insanity whereby a person is absolved of criminal responsibility if, as a result of a mental disorder, he "lacks substantial capacity either to appreciate the wrongfulness of his conduct or to conform his conduct to the requirements of law." *See also* Durham rule; M'Naghten rule.

American Medical Association (AMA) National organization of medical doctors of all specialties, founded in 1847, whose mandate is to monitor the educational, training, and research concerns of the medical profession; plays an advisory role in national legislation related to health care and disseminates medical information.

American Neurological Association (ANA) National organization of neurologists, founded in 1875, that conducts research and educational programs; also elects members to the American Board of Psychiatry.

American Psychiatric Association (APA) Most important and largest professional organization of American physicians who specialize in the practice of psychiatry. The organization was founded in 1844 by 13 superintendents ("original thirteen") as the Association of Medical Superintendents of American Institutions for the Insane; in 1891, the name was changed to the American Medico-Psychological Association and in 1921 to its

present name. Its purpose is to advance the development of psychiatric education, research, and practice in the United States.

American Psychoanalytic Association (APA) National organization of graduates of various psychoanalytic training programs, founded in 1911, mandated to establish and maintain standards for the field of psychoanalysis and the training of psychoanalysts and to encourage research; historically represents orthodox schools of classical psychoanalysis derived from freudian theory.

American Psychological Association Founded in 1892, large stand most important organization of American psychologists who specialize in experimental, clinical, research, and educational psychology, and many other subspecialties in psychology; sometimes known as the "big APA" to distinguish it from the smaller American Psychiatric Association.

amimia Lack of ability to make gestures or to comprehend those made by others.

amines Organic compounds derived from ammonia by replacing hydrogen atoms with organic groups, such as the catecholamines.

amino acid Organic acid in which one of the CH hydrogen atoms has been replaced by NH_2; structured building blocks of proteins that function as neurotransmitters similar to the biogenic amines, probably in 60 to 70 percent of the synapses in the brain.

amnesia Disturbance in memory manifested by partial or total inability to recall past experiences. For types of amnesia, see the specific term.

amnestic aphasia, amnesic aphasia Disturbed capacity to name objects, even though they are known to the patient. Also called anomic aphasia.

amnestic disorder Mental syndrome in which impairment of memory is the predominant cognitive defect; in DSM-5, called major or minor neurocognitive disorder due to another medical condition.

amok Condition, usually associated with Malayan men, characterized by a sudden, unprovoked outburst of wild rage usually culminating in homicide.

amphetamine Central nervous system stimulant with a chemical structure and action closely related to the sympathomimetic amines; used to treat depression, attention-deficit hyperactivity disorder, hypersomnia, and narcolepsy; may be abused to prolong wakefulness and attentiveness.

amygdala Part of the basal ganglia complex in the dorsomedial portion of the temporal lobe: it and the hippocampus are major components of the limbic system and have been implicated in the production of memory, emotions, and violent behavior.

amyotropic lateral sclerosis (ALS) Degenerative neuromuscular disease, caused by a slow virus, with an insidious onset beginning between the ages of 50 and 70; wasting begins in upper limbs, eventually spreading to the tongue, mouth, and palate. Degeneration of both pyramidal tracts above the medulla produces pseudobulbar palsy, which, when severe, results in impaired voluntary control of emotional reactions, which consequently, may be exaggerated, explosive, and quite inappropriate. Also called Lou Gehrig disease.

Amytal interview Psychiatric interview conducted with the patient having received an intravenous infusion of amobarbital (Amytal), which produces an altered state of consciousness during which repressed memories and feelings may be recalled or reexperienced; used in the treatment of dissociative states, psychogenic amnesia, and

conversion disorder.

ANA American Neurological Association.

anaclitic Depending on others, especially as the infant on the mother; anaclitic depression in children results from an absence of mothering.

anaclitic therapy Psychotherapy characterized by allowing the patient to regress; used mainly in the treatment of psychosomatic disorders.

anal character Freud's term to describe persons who are perfectionistic, parsimonious, punctual, and stubborn.

analeptic PSYCHOMOTOR STIMULANT.

anal erotism Pleasurable experience felt by a child in the anal area during the anal phase of psychosexual development.

analgesia State in which one feels little or no pain.

anal phase Second stage in psychosexual development, occurring when a child is between the ages of 1 and 3 years. During that period, activities, interests, and concerns are centered on the anal zone, and the pleasurable experience felt in that area is called anal erotism. *See also* infantile sexuality; psychosexual development.

analysand In psychiatry, the one who is being analyzed.

analysis in depth PSYCHOANALYSIS.

analysis of variance (ANOVA) Statistical technique designed to compare two or more groups of observations by which sets of measurements are investigated to find out to what extent they are determined by experimental influences or chance influences. *See also* variance.

analytic psychology Jung's system of psychology, characterized by a belief in the collective unconscious or objective psyche, the archetype, and the complex.

anamnesis Medical history of a patient, particularly used in connection with the patient's own recollections.

anancasm Repetitious or stereotyped behavior or thought usually used as a tension-relieving device. Alternate spelling, anankastic.

anankastic personality OBSESSIVE-COMPULSIVE PERSONALITY.

ancillary care Auxiliary, accessory, or secondary services provided in the treatment or rehabilitation of patients.

androgen Hormone that is produced in the testes and the adrenal glands and that stimulates activity of the accessory male sex organs, promotes development of male sex characteristics, or prevents changes in the latter following castration; for example, testosterone. *Compare* estrogen.

androgyny Combination of female and male characteristics in one person. *See also* bisexuality.

androphobia Irrational fear of men.

anergia Lack of energy.

anergic schizophrenic BURNED-OUT SCHIZOPHRENIC.

anesthesia Absence of sensation. *See also* hysterical anesthesia.

angel dust Street term for phencyclidine (PCP).

anhedonia State of being unable to experience pleasure. *Compare* hedonism.

anima According to jungian psychology, the person's inner self, as opposed to the self that one

presents to the outside world (persona).

Anna O A patient of Joseph Breuer and Sigmund Freud whose arm became paralyzed whenever she was unconsciously reminded of her feelings for her father (she had been sitting at his bedside with her arm pressed against the side of his bed at the time of his death). The motor disturbance represented an action that was associated with an objectionable infantile sexual impulse.

anniversary reaction Behavior, symptoms, or dreams that occur at the same time of year as a significant past event.

anomia Inability to recall the names of objects.

anomic aphasia AMNESTIC APHASIA.

anomie Term, popularized by Émile Durkheim as a major cause for suicide, referring to a sense of alienation and despair resulting from the loss or weakening of previously valued norms, ideals, or goals.

anorectic Drug that decreases appetite.

anorexia nervosa Serious and sometimes life-endangering condition characterized by a disturbed body image and self-imposed severe dietary limitation, usually resulting in serious malnutrition; appetite usually remains intact.

anorgasmia Inability to achieve orgasm in the female. *See also* frigidity.

anosognosia Unawareness or nonacceptance of a neurological deficit.

anosomnia Loss of ability to smell.

ANOVA Analysis of variance.

antagonist In pharmacology, a substance that reduces or blocks the action of another; for example, naloxone (Narcan) is used in the treatment of opioid overdose because it is reverses the effects of narcotics. *Compar*e agonist.

anterograde amnesia Loss of memory for events subsequent to the onset of the amnesia. *Compare* retrograde amnesia.

anthropology Study of humans in relation to distribution, origin, classification, and relationship of races, physical characteristics, environmental and social relations, and culture.

antianxiety drug ANXIOLYTIC.

anticholinergic Drug that blocks the actions of atropine; primarily used in the treatment of medication-induced movement disorders. *See also* antiparkinsonism drug.

anticholinergic effect Effect, such as a dry mouth and blurred vision, due to a blockade of the cholinergic (especially the parasympathetic) nerves; often seen as a side effect of therapy with phenothiazine and tricyclic antidepressant drugs.

anticipation Term implying careful planning or worrying, and premature but realistic expectation of dire and potentially dreadful outcomes, in goal-directed inner discomfort.

anticonvulsant Any drug with the ability to prevent the excessive discharge of neurons in the brain and thus lower the threshold for convulsions or seizures. Also called antiepileptic drug.

antidepressant drug Any of a class of psychotherapeutic drugs used in the treatment of pathological depression. Two main categories are the cyclic antidepressants and the monoamine oxidase inhibitors; more recently, serotonergic agents such as fluoxetine. Lithium carbonate also has antidepressant activity in certain patients.

antiepileptic drug ANTICONVULSANT.

antimanic drug Drug used to alleviate the symptoms of mania; lithium is particularly effective in preventing relapses in bipolar disorder.

antiparkinsonism drug Drug that relieves the symptoms of parkinsonism and is effective in countering the extrapyramidal side effects often induced by antipsychotic drugs by acting on the central nervous system to diminish skeletal muscle tone and involuntary movements. Levodopa, the agent of choice for Parkinson disease, does not antagonize the extrapyramidal effects of antipsychotic drugs. Anticholinergic agents, such as benztropine and trihexyphenidyl, effectively counteract drug-induced parkinsonism but are now secondary drugs in the treatment of Parkinson disease.

antipsychotic Any of a class of psychotherapeutic drugs used to treat psychosis, particularly schizophrenia. Also called neuroleptic; major tranquilizer; ataractic drug.

antisocial behavior Behavior pattern of such marginal criminal types as racketeers, prostitutes, and illegal gamblers. Formerly called sociopathic behavior. *See also* antisocial personality disorder.

antisocial personality disorder Disorder characterized by an inability to get along with other members of society and by repeated conflicts with individual persons and groups; common attributes include impulsiveness, egocentricity, hedonism, low frustration tolerance, irresponsibility, inadequate conscience development, exploitation of others, and rejection of authority and discipline. *See also* antisocial behavior.

Anton syndrome Disorder caused by a lesion in the occipital lobe of the brain that causes blindness which the patient denies experiencing.

anxiety Unpleasurable emotional state associated with psychophysiological changes in response to an intrapsychic conflict; in contrast to fear, the danger or threat in anxiety is unreal. Psychological changes consist of an uncomfortable feeling of impending danger, an overwhelming awareness of being powerless, inability to perceive the unreality of the threat, prolonged feeling of tension, and exhaustive readiness for the expected danger; physiological changes consist of increased heart rate, disturbed breathing, trembling, sweating, and vasomotor changes. *Compare* fear.

anxiety disorder Disorder in which anxiety is the most prominent disturbance or in which patients experience anxiety if they resist giving in to their symptoms. In DSM, anxiety disorders include phobic disorder, panic disorder with agoraphobia, agoraphobia without history of panic disorder, social phobia, simple phobia, generalized anxiety disorder, obsessive-compulsive disorder, and posttraumatic stress disorder.

anxiety disorders of childhood or adolescence Disorders characterized by chronic anxiety, unrealistic fears, hypersensitive autonomic responses, or fear of leaving home; patients are usually immature, inhibited, timid, approval-seeking, and apprehensive in new situations or places. In DSM, anxiety disorders of childhood or adolescence include separation anxiety disorder, avoidant disorder of childhood or adolescence, and overanxious disorder.

anxiety hysteria PHOBIC DISORDER.

anxiety neurosis As initially described by Sigmund Freud, a syndrome characterized by general irritability, anxious expectation, pangs of conscience, anxiety attacks, and phobias. Called generalized anxiety disorder in DSM.

anxiety state Disorder characterized by panic and anxious overconcern; somatic symptoms

are often prominent.

anxiolytic Any of a class of psychotherapeutic drugs used to treat pathological anxiety and its related symptoms; includes the benzodiazepines and buspirone. Also called antianxiety drugs; minor tranquilizers.

APA American Psychiatric Association; American Psychoanalytic Association; American Psychological Association.

apathetic withdrawal *See* withdrawal.

apathy Want of feeling or affect, a lack of interest and emotional involvement in one's surroundings; observed in certain types of schizophrenia and depression.

Apgar scores Measurements taken 1 and 5 minutes after birth to determine physical normality in the neonate; scores are based on color, respiratory rate, heartbeat, reflex action, and muscle tone.

aphasia Any disturbance in the comprehension or expression of language due to a brain lesion. For types of aphasia, see the specific term.

aphonia Loss of voice.

aphrodisiac Substance or drug that increases sexual desire.

apnea Temporary cessation of breathing. *See* obstructive sleep apnea syndrome.

apoplexy Old classical term for cerebrovascular accident.

apperception Awareness of the meaning and significance of a particular sensory stimulus as modified by one's own experiences, knowledge, thoughts, and emotions. *See also* perception.

appetitive phase First stage in the sexual response cycle, as described by Masters and Johnson, characterized by sexual fantasies and the desire to have sex.

appropriate affect Emotional tone in harmony with the accompanying idea, thought, or speech.

apraxia Inability to perform a voluntary purposeful motor activity; cannot be explained by paralysis or other motor or sensory impairment. In constructive apraxia, a patient cannot draw two- or three-dimensional forms.

aptitude Potential to acquire competence or skill if trained. *Compare* ability.

archetype Jung's term for the symbols used by individuals to express the collective experience of the human race. *See also* collective unconscious.

arithmetic disorder DEVELOPMENTAL ARITHMETIC DISORDER.

arousal The establishment and maintenance of a physiological or psychological state of being awake, alert, or responsive to stimuli. *See also* hyperarousal.

arteriosclerosis Degenerative condition marked by loss of elasticity, hardening, and thickening of the arteries, with progressive narrowing of their lumina and gradual obstruction to blood flow; organic mental disorder may develop when cerebral arteries are involved in the degenerative process.

artificial intelligence Computer production of a pattern of output that would be considered intelligent if displayed by human beings.

art therapy Treatment procedure that uses the spontaneous creative work of the patient; for example, persons make and analyze drawings, which are often expressions of their underlying emotional problems.

asociality Indifference to social values or customs, withdrawal from society, as seen in a recluse or a regressed schizophrenic person.

Asperger syndrome Term previously used to describe a condition that develops in infancy and is associated with impaired social interaction and restricted and stereotyped patterns of behavior, but without significant delays in language or cognitive development. In DSM-5, the behavioral condition of Asperger syndrome is subsumed in Level I of the autism spectrum. *See also* autism spectrum disorder.

assertiveness training Behavior therapy that involves teaching frank and direct interpersonal expression of feelings and ideas.

assessment The evaluation of a patient that leads to diagnosis and treatment.

assimilation Subjective process that involves filtering the world through one's own system of knowledge, that is, taking in of new experience through one's established mental structure.

association Relation between ideas or feelings. *See* clang association; loosening of associations.

Association of American Medical Colleges (AAMC) Organization of American medical schools and teaching hospitals, founded in 1876, concerned with the advancement and improvement of medical education, biomedical research, and health care in the United States.

astasia-abasia Inability to stand or walk in a normal manner, even though normal leg movements can be performed in a sitting or lying down position; seen in conversion disorder.

astereognosis Inability to identify familiar objects by touch; cannot be explained by an impairment of elementary sensory pathways or a depressed sensorium. *See also* neurological amnesia.

asthenic personality Disorder characterized by lack of enthusiasm, fatigability, lack of capacity for enjoyment, and low tolerance for stress. *See also* adynamia; anhedonia.

astraphobia, astrapophobia Abnormal fear of thunder and lightning.

asyndesis Disorder of language, commonly seen in schizophrenia, in which the patient combines unconnected ideas and images.

ataque de nervios A syndrome, usually found in Latin American cultures, characterized by uncontrollable shouting, crying, trembling, and physical or verbal aggression.

ataractic drug ANTIPSYCHOTIC.

ataxia Lack of coordination, either physical or mental. **1.** In neurology, refers to loss of muscular coordination. **2.** In psychiatry, the term "intrapsychic ataxia" refers to lack of coordination between feelings and thoughts; seen in schizophrenia and in severe obsessive-compulsive disorder.

athetosis Movement disorder characterized by involuntary, slow, writhing, worm-like movements of the fingers and extremities; a form of extrapyramidal dyskinesia.

atonia Lack of muscle tone. *See* waxy flexibility.

attachment According to John Bowlby, the affective tie between infant and mother or primary caregiver, the disruption of which heightens vulnerability to depression or anxiety. *See also* bonding.

attachment disorder of infancy Absence or disruption of behaviors that serve to anchor the infant to its mother or primary caregiver and that produce abnormal reactions in the infant's behavior.

attachment learning Theory that learning is enhanced in the presence of the person to whom one is attached or affiliated; applies especially to infant learning.

attention Concentration; the aspect of consciousness that relates to the amount of effort exerted in focusing on certain aspects of an experience, activity, or task.

attention-deficit hyperactivity disorder (ADHD) DSM-5 diagnosis for a childhood mental disorder characterized by a developmentally inappropriate short attention span, hyperactivity, and poor concentration that cause clinically significant impairment in functioning. The category subsumes abnormal behavior patterns that had historically been referred to by a variety of names, including hyperkinetic syndrome, hyperactive child syndrome, and minimal brain dysfunction. If hyperactivity is not present, the disorder is called attention-deficit disorder (ADD).

attitude Preparatory mental posture with which one receives stimuli and reacts to them.

attributable risk Absolute incidence of a disease in exposed individuals that can be attributed to the exposure.

atypical In psychiatry, denoting an unusual or rare variant of a known disorder.

atypical child Child with distorted personality development; often used in connection with brain-damaged or autistic children.

atypical depression Diagnosis used to describe depression characterized by weight gain and hypersomnia rather than weight loss and insomnia.

atypical psychosis Disorder whose psychotic features are related to a specific culture (e.g., koro); a certain time or event (e.g., postpartum psychosis); or a unique symptomatology (e.g., Capgras syndrome). Also called "psychotic disorder not otherwise specified" in DSM-5.

audit *See* medical audit.

auditory agnosia The inability to recognize specific sounds in the context of intact hearing.

auditory amnesia NEUROLOGICAL AMNESIA.

auditory hallucination Hallucination primarily involving sound.

aura 1. Warning sensations that a person usually experiences just before an epileptic seizure. **2.** Sensory prodrome that precedes a classic migraine headache.

authority figure Real or projected person in a position of power; transferentially, a projected parent.

autism *See* autistic thinking; infantile autism.

autistic spectrum disorder A range of behavioral abnormalities that begin in infancy and are characterized by deficits in social communication; failure to communicate; lack of empathy; abnormalities in eye contact; repetitive patterns of activities; stereotyped or absent speech; and either hyper- or hypoarousal to the environment. In DSM-5, autism spectrum disorder is classified into three levels based on degrees of impairment in speech and social interaction. *See also* Asperger syndrome; Rett syndrome; childhood disintegrative disorder.

autistic thinking Thinking in which the thoughts are largely narcissistic and egocentric, with emphasis on subjectivity rather than objectivity, and without regard for reality; used interchangeably with autism and dereism.

autoerotic asphyxia Asphyxia caused by intentional strangulation while masturbating in order to intensify orgasm through reduction of oxygen blood flow to the brain. High risk of death.

autoerotism 1. Sexual arousal of oneself without the participation of another person; term coined by Havelock Ellis, which is presently used interchangeably with masturbation. **2.** In psychoanalysis, a primitive phase in object relationship development preceding the narcissistic stage; in narcissism, there is a love object, but there is no love object in autoerotism.

autogynephilia A gender identity disorder in which a male becomes sexually aroused by imagining themselves transformed into a woman.

automatic judgment Reflex performance of a way of acting based on a fixed set of beliefs or values.

automatic obedience Compliance to commands without exercising critical judgment; a feature of catatonia.

automatism Undirected behavior not controlled by conscious thought.

automysophobia Abnormal fear of smelling bad or of being unclean.

autonomic nervous system Part of the nervous system that functions outside of consciousness and that directs such visceral functions as respiration, heart rate, and digestion; subdivided into sympathetic (adrenergic) and parasympathetic (cholinergic) divisions.

autonomic side effect Disturbance of autonomic nervous function that may result from the use of antipsychotic or antidepressant drugs, particularly the phenothiazine and tricyclic derivatives. Common side effects of such agents include orthostatic hypotension, blurred vision, nasal congestion, dry mouth, and constipation; such anticholinergic effects are more prominent with tricyclic antidepressants than with phenothiazines.

autonomous ego function Operation present at birth, such as perception, intuition, thinking, speaking, language, and aspects of motor development; first described by Heinz Hartmann. *See also* ego psychology.

autophobia Abnormal fear of being alone or of self.

autoplasty Adaptation to stress by changing intrapsychic processes. *Compare* alloplasty.

autoscopic psychosis Rare disorder, not officially listed in DSM-5, in which the patient sees a phantom or specter of his or her own body; usually psychogenic in origin, but may also be caused by lesions in the temporoparietal lobe of the brain.

autotopagnosia Inability to recognize and identify the parts of one's own body. *See also* finger agnosia.

auxiliary therapist Co-therapist. *See also* co-therapy.

average Central value in a frequency distribution around which other values are distributed. Also called the mean.

aversive conditioning AVERSIVE THERAPY.

aversive therapy Behavior therapy that involves the repeated coupling of an unpleasant or painful stimulus, such as an electric shock, with an undesirable behavior pattern in an effort to eliminate the undesirable behavior. Also called aversive conditioning.

avoidance and escape learning In escape learning, an animal learns a response to get out of a place where it does not want to be; for example, it jumps off an electric grid whenever the grid is charged. Avoidance learning requires an additional response: the same animal on the grid will learn to avoid a shock if it quickly pushes a lever when a light signal goes on. Escape learning and avoidance learning are two forms of aversive control using negative reinforcement; behavior that terminates the source of aversive stimuli is strengthened and

maintained.

avoidant attachment According to Mary Ainsworth, a form of attachment in which children avoid returning to their mothers after being separated. Also called shyness disorder. *Compare* secure attachment. *See also* resistant attachment.

avoidant disorder of childhood or adolescence Disorder of childhood or adolescence characterized by a persistent withdrawal or excessive shrinking from strangers.

avoidant personality disorder Personality disorder characterized by low self-esteem, hypersensitivity to rejection, and social withdrawal, but with a desire for affection and acceptance.

Avoidant/Restrictive Food Intake Disorder Disorder characterized by an avoidance or lack of interest in food, resulting in severe weight loss, nutritional deficiency, and failure to thrive; a DSM-5 diagnosis. Previously called feeding disorder of infancy or early childhood.

axon Single structure in a nerve cell that conducts nervous impulses away from the cell body and its dendrites.

aypnia Insomnia; inability to sleep.

B

barbiturate Any of a class of sedative–hypnotic drugs derived from barbituric acid that acts as a central nervous system depressant and readily produces psychic and physical dependence; for example, phenobarbital, secobarbital, thiopental sodium.

basal ganglia Collectively, the corpus striatum, substantia nigra, subthalamic nucleus, and substantia innominata, which are involved in disorders of movement, thought processes, affect, cognition, and symptoms of psychosis.

basic anxiety As conceptualized by Karen Horney, the main-spring from which neurotic trends get their intensity and pervasiveness, characterized by vague feelings of loneliness, helplessness, and fear of a potentially hostile world. *See also* anxiety.

basic benefits Insurance term that refers to minimum payments or coverage for medical or psychiatric care.

bathophobia Abnormal fear of depths.

battered child syndrome Physical damage to a child sustained as a result of repeated beatings, usually by a parent, parent surrogate, or relative. *See also* abuse.

battery tests Individual tests used together make up a psychological battery; for example, Halstead–Reitan Neuropsychological Battery. A test battery can give more information about different areas of function than an individual test and can increase the level of confidence if there is a positive correlation between them.

BEAM Brain electrical activity mapping.

Beard, George M. (1839–1883) American psychiatrist who in 1869 introduced the term "neurasthenia."

Beers, Clifford (1876–1943) Author of *A Mind That Found Itself* (1909) and who is generally considered to have founded the mental hygiene movement.

behavior Sum total of the psyche that includes impulses, motivation, wishes, drives, instincts, and cravings, as expressed by a person's behavior or motor activity. Also called conation.

behavioral disorders of childhood *See* disruptive behavior disorders.

behavioral medicine Application of principles of behavior therapy to the prevention, diagnosis, treatment, and rehabilitation of medical disorders; applies to such areas as stress prevention and reduction, pediatric and adult patient management and compliance, pain control, and life-style modification. Biofeedback relaxation training, behavior therapy, and hypnosis are important treatment modalities.

behavioral neurology Field of study that attempts to combine psychiatry and neurology to explain abnormal behavior as a disorder of brain metabolism or as a result of structural alterations of the central nervous system.

behavioral science Scientific discipline concerned with any aspect of human behavior, including interpersonal relationships, development, values, experiences, and activities; the behavioral sciences include sociology, psychology, psychiatry, anthropology, and ethology.

behavior contract Therapeutic strategy that rewards a person for a desired behavior.

behaviorism School of psychological thought founded by John B. Watson that regards only measurable and observable behavior as the appropriate subject matter for human psychology; holds that human behavior can be described in terms of principles that do not require consideration of unobservable mental events, such as ideas and emotions. *See also* behavior therapy.

behavior modification *See* behavior therapy.

behavior therapy Psychiatric treatment modality that focuses on overt and objectively observable behavior and uses various conditioning techniques derived from learning theory to directly modify the patient's behavior; aims exclusively at symptomatic improvement, without addressing psychodynamic causation. Behavior therapy techniques include assertiveness training, aversive therapy, flooding, implosion, reciprocal inhibition, and desensitization, shaping, and systematic desensitization. *See also* behaviorism; conditioning.

Bender-Gestalt Test Psychological test, designed by Lauretta Bender, which measures the subject's ability to reproduce a set of geometric designs: is useful for measuring visuomotor coordination as a means of detecting brain damage. Also called visual motor gestalt test.

benzodiazepines Any of a group of drugs used mainly to treat anxiety; also used as sedatives, muscle relaxants, anticonvulsants, anesthetics, and hypnotics.

bereavement Feeling of grief or desolation, especially at the death or loss of a loved one. *See also* mourning.

bestiality Sexual deviation in which a person engages in sexual relations with an animal. *See also* zoophilia.

beta (a) error TYPE 2 ERROR.

beta waves As measured by an electroencephalogram (EEG), brainwaves that are between l4 and 30 Hz; altered in certain epileptic conditions.

bias In statistics, an error in the construction of the assessment instrument that favors one outcome over another.

binge eating disorder Eating disorder characterized by recurrent episodic, uncontrolled, compulsive, and rapid ingestions of large amounts of food over a short period of time (binge eating) followed by feelings of guilt; a DSM-5 diagnosis, differentiated from bulimia nervosa by an absence of compulsive compensatory behaviors to achieve weight loss.

binge eating, binge and purge *See* bulimia nervosa.

biodynamics System of psychoanalytic psychiatry, introduced by Jules H. Masserman, which holds that all behavior results from the organism's genetic potentialities, from the various paths and speed of maturation, and from its unique experiences.

biofeedback Provision of information to a person regarding one or more physiological processes in an effort to enable the person to gain some element of voluntary control over bodily functions that normally operate outside consciousness. *See also* learned autonomic control.

biogenic amine Endogenous compound believed to play an important role in brain function as a central synaptic neurotransmitter substance; biogenic amines include the catecholamines (epinephrine, norepinephrine, dopamine) and serotonin, an indolamine.

biogenic amine hypothesis Theory of mood disorders which proposes that depression is associated with an absolute or relative deficiency of catecholamines, particularly norepinephrine, at functionally important receptor sites in the brain; conversely, elation may be associated with an excess of such amines.

biological psychiatry School of psychiatric thought emphasizing biochemical, neurological, and pharmacological factors in the causation and treatment of psychiatric disorders.

biological rhythm Periodic variation in physiological and psychological functions. For example, a circadian rhythm shows aperiodicity of about 24 hours; an ultradian rhythm has a cycle shorter than 1 day; an infradian rhythm is longer than 1 day.

bipolar I Bipolar disorder in which a patient meets the criteria for a full manic episode, usually sufficiently severe to require hospitalization.

bipolar II Bipolar disorder in which a patient has at least one depressive episode and at least one hypomanic episode.

bipolar disorder A mood disorder in which the patient exhibits both manic and depressive episodes separated by various lengths of time. Previously referred to as manic–depressive illness.

birth trauma Otto Rank's term to describe the birth process, which he considered the basic source of anxiety in human beings.

bisexual Denoting or characterized by sexual attraction to and sexual contact with members of both sexes.

bisexuality Existence of the qualities of both sexes in the same person. Freud postulated that the sexes differentiated both biologically and psychologically from a common core; that differentiation between the two sexes was relative, rather than absolute; and that regression to the common core occurs to varying degrees in both normal and abnormal conditions. *Compare* bisexual; heterosexuality; homosexuality. *See also* androgyny.

bizarre delusion False belief that is patently absurd or fantastic.

blackout *See* alcoholic blackout.

black-patch syndrome Psychosis induced by sensory deprivation as a result of eye patches used after cataract surgery.

blank screen Neutral backdrop on which the patient projects a gamut of transferential irrationalities; passivity of analysts allows them to act as blank screens.

Bleuler, Eugen (1857–1939) Swiss psychiatrist known for his important studies in schizophrenia, a term he coined and preferred over the earlier term "dementia praecox."

blind spot In psychiatry, an area of a person's personality of which he or she is totally unaware; unperceived areas are repressed, since their recognition would arouse painful or unpleasant emotions. In the course of group or individual psychotherapy, such blind spots often appear obliquely as projected ideas, intentions, and emotions. *See also* projection; scotoma.

blocking Involuntary cessation or interruption of thought processes or speech because of unconscious emotional factors. Also called thought deprivation.

blood–brain barrier Series of biologically active membranes that regulate the passage of substances into and out of the central nervous system; maintains a chemical homeostasis between the cerebrospinal fluid and the venous and arterial systems.

blood level In psychiatry, the measurement of the concentration of drugs in plasma or serum to determine their therapeutic effect.

blunted affect Disturbance of affect manifested by a severe reduction in the intensity of externalized feeling tone; one of the fundamental symptoms of schizophrenia, as outlined by Eugen Bleuler.

board-certified psychiatrist Psychiatrist who has passed the examinations of the American Board of Psychiatry and Neurology (ABPN). *See also* accreditation.

board-eligible psychiatrist Psychiatrist who has finished an approved 4-year residency program and is eligible to take the examinations of the American Board of Psychiatry and Neurology.

body dysmorphic disorder Disorder characterized by an unrealistic concern that part of the body is deformed. Included on the obsessive-compulsive spectrum in DSM-5. Also called dysmorphophobia.

body-focused repetitive behavior disorders Descriptive term for a group of behaviors consisting of compulsions that damage one's own body, such as skin biting, lip biting, or nail biting; not a diagnosis in DSM-5.

body image Conscious and unconscious perception of one's body at any particular time.

body language Expression of thoughts and feelings by body posture and movement.

bonding Nonsexual feelings of love, respect, and communality among individuals of the same sex. Specifically, a mother's feelings for her infant, but often used to refer to the general mother–infant relationship; fathers often bond to infants. *See also* attachment.

borderline intellectual functioning A term previously attributed to individuals with below average cognitive ability (I.Q. in the 70–80 range) whose intellectual impairment did not meet criteria for intellectual disability (I.Q. below 70). This condition is not clearly differentiated from mild intellectual disability and may be the focus of clinical attention, however, no definitive criteria for diagnosis exist in DSM-5. *See also* intellectual disability.

borderline personality disorder Personality disorder marked by instability in various areas, impulsiveness, suicidal acts, self-mutilations, identity problems, and feelings of emptiness or boredom.

borderline psychosis BORDERLINE STATE.

borderline state State in which the symptoms are so unclear or transient that it is difficult to classify the patient as psychotic or nonpsychotic. Also called borderline psychosis.

boufée délirante A syndrome, observed in West Africa and Haiti, characterized by a sudden

outburst of agitated and aggressive behavior, marked confusion, and psychomotor excitement. It is sometimes accompanied by visual or auditory hallucinations or paranoid ideations. May resemble an episode of brief psychotic disorder.

Bowlby, John (1907–1990) British psychoanalyst who formulated the theory of attachment to describing the mother–infant relationship. *See also* attachment; bonding.

bradykinesia Slowness of motor activity, with a decrease in normal spontaneous movement.

bradylalia Abnormally slow speech, common in depression.

bradylexia Inability to read at normal speed.

brain That part of the central nervous system contained within the cranium; includes the cerebrum, midbrain, cerebellum, pons, and medulla.

brain abscess Localized, suppurative, infectious process involving a part of the brain; may produce an organic mental disorder as well as focal neurological signs.

brain electrical activity mapping (BEAM) Response of brain electrical activity to sensory stimuli which is recorded by computer averaging techniques that produce a topographic color map of brain activity.

brain imaging Radiological techniques that allow assessment in vivo of structural and functional neuroanatomy; include computed tomography (CT), magnetic resonance imaging (MRI), regional cerebral blood flow (rCBF), positron emission tomography (PET), and brain electrical activity mapping (BEAM).

brain metabolism Chemical changes in the brain that convert small molecules into large ones (anabolism) and large molecules into small ones (catabolism), and that account for cellular function and repair.

brain stem Area of the brain comprising the mesencephalon, pons, and medulla oblongata, whose basic functions concern respiration, cardiovascular activity, sleep, and consciousness; also the site of the ascending biogenic amine (dopamine, noradrenalin, serotonin) pathways to higher brain areas.

brain syndrome *See* organic mental disorder.

brainwashing Any technique designed to manipulate human thought or action against the desire, will, or knowledge of the person involved; usually refers to systematic efforts to indoctrinate nonbelievers. In DSM-5 diagnosed as "identity disturbance due to prolonged and intense coercive persuasion." Also called coercive persuasion.

brain wave Rhythmic wave-like electrical pattern in an encephalogram.

Brawner decision *See* Model Penal Code.

breathing-related sleep disorder Characterized by sleep disruption leading to excessive sleepiness or insomnia caused by a sleep-related breathing disturbance; three types of breathing-related sleep disorders include obstructive sleep apnea, central sleep apnea, and sleep-related hypoventilation.

Breuer, Josef (1842–1925) Viennese physician who collaborated with Freud in studies of cathartic therapy, as reported in *Studies on Hysteria* (1895); he withdrew as Freud proceeded to introduce psychoanalysis, but left important imprints on that discipline, such as the concepts of the primary and secondary processes.

brief psychotherapy Psychotherapy in which the sessions are limited to 10 to 15 in number and during which time attempts to modify behavior occur; used in both individual and group

settings.

brief psychotic disorder DSM-5 category for a psychosis of less than 4 weeks' duration, with sudden onset after a major stress. Also called brief reactive psychosis.

brief reactive psychosis *See* brief psychotic disorder.

Brigham, Amariah (1798–1849) One of the founders of the American Psychiatric Association and the first editor of its journal.

Brill, A. A. (1874–1948) First American analyst (1908) who translated several of Freud's more important works, was active in the formation of the New York Psychoanalytic Society (1911), and remained a foremost propagator of psychoanalysis as a lecturer and writer.

Briquet syndrome Alternate term for somatic symptom disorder.

broad affect Normal range (varies both within and among cultures) of the expression of a subjectively experienced feeling state (e.g., euphoria, anger, sadness); normal expression of affect involves variability in facial expression, pitch of voice, and hand and body movements.

Broca aphasia MOTOR APHASIA.

brooding compulsion INTELLECTUALIZATION.

bruxism Grinding or gnashing of the teeth, typically occurring during sleep.

bulimia nervosa Recurrent episodic, uncontrolled, compulsive, and rapid ingestion of large amounts of food over a short period of time (binge eating) followed by self-induced vomiting, use of laxatives or diuretics, fasting, or vigorous exercise in order to prevent weight gain (binge and purge); weight is not severely lowered.

burned-out schizophrenic Chronic schizophrenia characterized by a person who is apathetic and withdrawn, with minimal florid psychotic symptoms but with persistent and often severe schizophrenic thought processes. Also called anergic schizophrenia.

burnout Syndrome of physical or emotional exhaustion considered to be a stress reaction to unrelenting performance and emotional demands stemming from one's occupation; symptoms include impaired work performance, fatigue, insomnia, increased susceptibility to physical illness, and reliance on alcohol (or other substances) with a tendency to escalation into physiological dependency or possibly suicide.

butyrophenone Any of a class of antipsychotic drugs of which haloperidol (Haldol) is a representative example.

C

C.A. Chronological age.

cacodemonomania Condition in which patients think they are possessed by a devil or other evil spirit.

caffeine Alkaloid found in coffee, tea, and cola drinks which acts as a psychomotor stimulant; caffeine intoxication results from the excessive ingestion of caffeine.

Canadian Psychiatric Association (CPA) National organization of Canadian psychiatrists whose purpose is to further the development of psychiatric education, research, and practice in Canada.

cannabis *See* marijuana.

canonical correlation Multivariate technique used in statistics for simultaneously finding the relationship of linear combinations of two or more predictors and two or more outcomes.

Capgras' syndrome Delusional disorder in which the patient believes that persons in the environment are not their real selves but are doubles imitating the patient or imposters imitating someone else.

capitation Prepayment fee based on a fixed number of persons that covers all health care services.

care and protection proceedings Intervention by a court on behalf of a child when the parents or caretakers provide inadequately for the child's welfare.

carebaria Sensation of discomfort or pressure in the head.

caregiver 1. Any person involved in the identification, prevention, or treatment of illness or disability. **2.** In child psychiatry, a person who tends to the needs of an infant or child. Also called caretaker.

case control study Study in which the illness is the dependent variable, already being present for the subject to be identified; such studies are therefore retrospective.

case history study Retrospective study that samples persons with a given disorder.

case register Medical records in central data banks.

castration anxiety Anxiety concerning a fantasied loss of or injury to the genitalia.

castration complex In psychoanalytic theory, a group of unconscious thoughts and motives that are referable to the fear of losing the genitalia, usually as punishment for forbidden sexual desires.

catalepsy Condition in which persons maintain the body position into which they are placed; observed in severe cases of catatonic schizophrenia. Also called waxy flexibility; cerea flexibilitas. *See also* command automatism.

cataphasia VERBIGERATION.

cataplexy Temporary sudden loss of muscle tone, causing weakness and immobilization; can be precipitated by a variety of emotional states, and it is often followed by sleep; commonly seen in narcolepsy.

catastrophic anxiety Anxiety associated with cognitive disorders when patients are aware of their defects in mentation; the anxiety may be overwhelming.

catathymia Situation in which elements in the unconscious are sufficiently affect-laden to produce changes in conscious functioning.

catathymic crisis Suddenly occurring, isolated, and nonrepetitive act that develops from a state of intolerable tension.

catatonia Clinical syndrome consisting of marked behavioral irregularities, which may include motoric excitement or immobility, negativism, stupor, echolalia, or echopraxia. In DSM-5, catatonia may be a stand-alone diagnosis; a feature of schizophrenia; associated with other mood/psychotic disorders; associated with medications or substance use; or due to an underlying medical condition.

catatonic excitement Excited, uncontrollable motor activity seen in catatonic schizophrenia. Patients in catatonic state may suddenly erupt into an excited state and may be violent.

catatonic posturing Voluntary assumption of an inappropriate or bizarre posture, generally maintained for long periods of time. May switch unexpectedly with catatonic excitement.

catatonic rigidity Fixed and sustained motoric position that is resistant to change.

catatonic schizophrenia A rare type of schizophrenia; no longer included in DSM-5. *See*

catatonia.

catatonic state State characterized by muscular rigidity and immobility (catatonia), usually associated with schizophrenia.

catatonic stupor Stupor in which patients ordinarily are well aware of their surroundings.

catchment area In psychiatry, a circumscribed geographic area served by a particular community mental health center.

catecholamine Biogenic monoamine containing a catechol group. Norepinephrine, epinephrine, and dopamine are catecholamine with important effects on peripheral and central nervous system activity.

categorical attitude ABSTRACT THINKING.

categorical thought Term introduced by Jean Piaget to refer to abstract thinking. *See also* secondary process.

catharsis Release of ideas, thoughts, and repressed materials from the unconscious, accompanied by an affective emotional response and relief; commonly observed in the course of both individual and group psychotherapy, but can also occur outside therapy. *See also* abreaction; conversational catharsis.

cathexis In psychoanalysis, a conscious or unconscious investment of psychic energy in an idea, a concept, an object, or a person. *Compare* acathexis.

CAT scan Incorrect but commonly used variant of "CT scan." *See also* computed tomography.

cat's cry syndrome *See* cri-du-chat syndrome.

Cattell Infant Intelligence Scale Psychological test used to assess general motor and cognitive development in infants aged 3months to 2 years.

causalgia Burning pain that may be either organic or psychic in origin.

cause–effect relationship Relationship in which one action causes a specific reaction.

causalgia Burning pain that may be organic or psychic in origin.

cenesthesia Change in the normal quality of feeling tone in a part of the body.

central nervous system (CNS) The spinal cord and the brain.

central sleep apnea Dyssomnia characterized by repeated episodes of apnea, shallow breathing, and/or irregular breathing that result from a periodic failure of the central nervous system mechanisms to stimulate breathing. There are three subtypes in DSM-5: idiopathic, Cheyne–Stokes breathing pattern, and comorbid with opioid use. *Compare* obstructive sleep apnea.

cephalalgia Headache.

cerea flexibilitas Condition of a person who can be molded into a position that is then maintained; when an examiner moves the person's limb, the limb feels as if it were made of wax. Also called catalepsy; waxy flexibility. Seen in schizophrenia.

cerebral arteriosclerosis Arteriosclerotic involvement (hardening) of arteries of the brain; may lead to organic mental disorder.

cerebrovascular accident Cerebral hemorrhage, thrombosis, or embolism. Also called stroke; apoplexy.

character Constellation of relatively fixed personality traits and attributes that govern a person's habitual modes of response.

character analysis Psychoanalytic treatment that concentrates on character defenses.

character defense Personality trait that serves an unconscious defensive purpose.

character disorder Pattern of personality characterized by maladaptive, inflexible behavior.

Charcot, Jean M. (1825–1893) French neurologist noted for describing hysteria and treating it by means of hypnosis; Freud based much of his early work on Charcot's pioneering studies in hysteria.

chemical dependence *See* drug dependence.

chemotherapy DRUG THERAPY.

child abuse *See* battered child syndrome.

child analysis Application of psychoanalytic principles to the treatment of the child.

childhood disintegrative disorder A condition defined by a marked regression in several functional domains (e.g., intellectual, social, motor, and language skills) after at least 2 years of normal development; diagnosis is typically made in children who are between 3 and 4 years of age. In DSM-5, childhood disintegrative disorder is a subset of autism spectrum disorder.

childhood schizophrenia DSM term for pervasive developmental disorder. *See* autistic spectrum disorder.

child-onset fluency disorder *See* stuttering.

chi square Statistical technique in which variables are categorized in order to determine whether a distribution of scores is due to chance or to experimental factors.

chlorpromazine Aliphatic phenothiazine derivative used primarily as an antipsychotic agent and in the treatment of nausea and vomiting.

cholinergic Relating to nerve fibers, tracts, or pathways in which synaptic transmission is mediated by acetylcholine; for example, parasympathetic nerve fibers and somatic motoneurons; also refers to processes activated by acetylcholine.

chorea Movement disorder characterized by random and involuntary quick, jerky, purposeless movements. *See also* extrapyramidal dyskinesia; Huntington chorea.

chronic fatigue syndrome An illness characterized by 6 months or more of severe, debilitating fatigue, often accompanied by myalgia, headaches, pharyngitis, low-grade fever, cognitive complaints, gastrointestinal symptoms, and tender lymph nodes. The cause is unknown.

chronobiology Study of biological rhythms that objectively explores and quantifies mechanisms of time structure in biological systems.

chronological age (C.A.) *See* intelligence quotient.

chronophobia Fear of time characterized by panic, anxiety, and claustrophobia. Sometimes called prison neurosis, since almost all prisoners are affected by it in some fashion.

circadian rhythm *See* biological rhythm.

circadian rhythm sleep disorder A set of dyssomnias involving a misalignment between desired and actual sleep periods. Includes delayed sleep phase, jet lag, and work shift.

Circadian Rhythm Sleep–Wake Disorders A group of sleep disorders characterized by disruption in sleep that alters a patient's circadian rhythm and is associated with insomnia or excessive sleepiness. There are six types of circadian rhythm sleep–wake disorders in DSM-5: delayed sleep phase type, advanced sleep phase type, irregular sleep–wake type, non–24-hour sleep–wake type, shift work type, and unspecified type.

circumstantiality Disturbance in the associative thought and speech processes in which a patient digresses into unnecessary details and inappropriate thoughts before communicating the central idea; observed in schizophrenia, obsessional disturbances, and certain cases of dementia. *See also* tangentiality.

civil commitment In statutes governing hospitalization of the mentally ill, a legal term meaning a warrant for imprisonment; as recommended by the American Psychiatric Association and the American Bar Association, "commitment" has been replaced by "hospitalization."

CJD Creutzfeldt–Jakob disease.

claims review Method of peer review consisting of the examination of claims for the reimbursement of treatment after it has been rendered.

clairvoyance Extrasensory perception in which there is an alleged ability to perceive that which is out of sight or cannot be seen.

clang association, clanging Association or speech directed by the sound of a word rather than by its meaning; punning and rhyming may dominate the person's verbal behavior; seen most frequently in schizophrenia or mania.

classical conditioning *See* conditioning.

classic migraine *See* migraine.

claustrophobia Abnormal fear of closed or confining spaces.

client-centered psychotherapy Nondirective form of psychotherapy, originated by Carl Rogers, in which the therapeutic process focuses on the patient's own thinking and feeling which the therapist merely helps to clarify through understanding and empathy; developed as a reaction against the authoritativeness and interpretation of the more traditional psychotherapies.

climacteric Menopause and immediate postmenopausal period in women; sometimes used to refer to the same age period in men.

clinical psychologist Psychologist with additional training and experience in a clinical setting who specializes in evaluation and treatment of mental disorders.

clinical psychology Branch of psychology concerned with the application of psychological principles to the prevention, treatment, and understanding of psychopathology.

clonic convulsion An involuntary, violent muscular contraction or spasm in which the muscles alternately contract and relax. Characteristic phase in grand mal epileptic seizure.

clouding of consciousness Any disturbance of consciousness in which the person is not fully awake, alert, and oriented. Occurs in delirium, dementia, and cognitive disorder.

cluster suicides Suicides that occur together in geographic groups or in temporal association. *See also* copy-cat suicides.

cluttering Disturbance of fluency involving an abnormally rapid rate and erratic rhythm of speech that impedes intelligibility; the affected individual is usually unaware of communicative impairment.

CNS Central nervous system.

cocaine Alkaloid, obtained from leaves of the coca plant, whose systemic effects include striking central nervous system stimulation manifested by garrulousness, restlessness, excitement, and feelings of increased muscular strength and mental capacity; also an effective

topical local anesthetic.

coefficient of correlation Statistical term referring to the relation between two sets of paired measurements, correlation coefficients are positive, negative, or curvilinear, depending on whether the variations are in the same direction, the opposite direction, or both directions. They can be computed in a variety of ways, the most common being the product-moment method (r); another method is rank correlation (p). Correlation coefficients are intended to show degree of relation, but they do not imply a causal relationship between variables.

coercive persuasion BRAINWASHING.

coexistent culture Alternative system of values, norms, and patterns for behavior; the group therapy experience often leads to an awareness of other systems as legitimate alternatives to one's own system.

cognition Mental process of knowing and becoming aware; an ego function closely associated with judgment.

cognitive-behavioral therapy (CBT) A form of psychotherapy in which the focus of treatment is on changing the thoughts and behaviors that are related to specific symptoms. The aim of treatment is on symptom reduction and improved functioning.

cognitive development Progressive acquisition of conscious thought and problem-solving abilities that begins in infancy and follows an orderly sequence of more or less discrete stages.

cognitive dissonance Incongruity in a person's beliefs, thoughts, or actions that produces an uncomfortable tension state that the person is motivated to change.

cognitive therapy Structured and directive form of therapy developed by Aaron T. Beck that emphasizes how patients think about themselves and the future; consists of reversing the cognitive triad of negative expression of self, negative expression of future, and negative view of the world.

cognitive triad Belief system described by the psychiatrist Aaron Beck that is present in depressed persons who have a negative view of the self, a negative interpretation of present and past experience, and a negative expectation of the future.

cohesion *See* group cohesion.

cohort Group chosen from a well-defined population; cohort studies provide direct estimates of risk associated with a suspected causal factor.

coitus interruptus Sexual intercourse that is interrupted before the man ejaculates.

cold turkey Abrupt withdrawal from opiates, or any addictive central nervous stimulant, without the benefit of methadone or other drugs; a term originated by drug addicts to describe their chills and consequent goose-flesh. Abstinence-oriented therapeutic communities use this type of detoxification.

collective experience Term coined by S. R. Slavson for the common emotional experiences of a group of people, which, in the setting of group psychotherapy, accelerates the therapeutic process. Identification, mutual support, reduction of ego defenses, sibling transferences, and empathy help integrate the individual member into the group.

collective unconscious Psychic contents outside the realm of awareness that are common to mankind in general. Carl Jung, who introduced the term, believed that the collective unconscious is inherited and derived from the collective experience of the species, that it transcends cultural differences, and that it explains the analogy between ancient mythological

ideas and the primitive projections observed in some patients who have never been exposed to those ideas. Also called objective psyche.

coma State of profound unconsciousness from which a person cannot be roused, with minimal or no detectable responsiveness to stimuli; seen in injury or disease of the brain, in such systemic conditions as diabetic ketoacidosis and uremia, and in intoxications with alcohol and other drugs. Coma may also be seen in severe catatonic states and in hysteria.

coma vigil Coma in which the eyes remain open; typically seen in acute organic mental syndromes associated with systemic infection.

combat fatigue Disabling physical and mental reaction to the stresses of military battle; now called posttraumatic stress disorder.

combined therapy Psychotherapy in which the patient is in both individual and group treatment with the same or two different therapists. In marriage therapy, it is the combination of married couples group therapy with either individual sessions with one spouse or conjoint sessions with the marital pair. *See also* co-therapy.

command automatism Condition closely associated with catalepsy in which suggestions are followed automatically.

command hallucination False perception of orders that a person may feel obliged to obey or unable to resist.

command negativism *See* negativism.

commitment Legal process by which a person is confined to a mental hospital, usually against his or her will.

common migraine *See* migraine.

communication disorder Term referring to a heterogeneous class of disorders resulting from impairment in the ability to receive, send, process, and comprehend concepts or verbal, nonverbal, and written symbolic systems. Communication disorders consist of language disorders, speech sound disorders, and social (pragmatic) communication disorder.

community *See* therapeutic community.

community mental health center Community or neighborhood mental health facility or a group of affiliated agencies that serve as a locus for the delivery of various services of community psychiatry. *See also* community psychiatry.

community psychiatry Psychiatry focusing on the detection, prevention, and early treatment of mental disorders and social deviance as they develop in the community, rather than as they are perceived and encountered at large centralized psychiatric facilities; particular emphasis is placed on the environmental factors that contribute to mental illness.

compensation Conscious or, usually, unconscious defense mechanism by which a person tries to make up (compensate) for an imagined or real physical or psychological deficiency.

compensation neurosis Neurosis induced by the desire for monetary compensation. It is believed that some persons, after sustaining an injury, develop neurotic symptoms in the hope of monetary gain.

competence Ability to perform or accomplish an action or task that another person of similar background and training, or any human being, could reasonably be expected to perform; mental capacity.

competency to stand trial Ability to be tried in a court of law. A person is competent to stand

trial when, at the time of the trial, he or she (1) understands the nature of the charge and the potential consequences of conviction and (2) is able to assist his or her attorney in his or her defense.

competition Literally, the struggle for the possession or use of limited goods, concrete or abstract. In psychiatry, a rivalry that may exist between persons in which gratification for one person largely precludes gratification for the other.

complementarity of interaction Concept of bipersonal and multi-personal psychology in which behavior is viewed as a response to stimulation, and interaction replaces the concept of reaction; each person in an interactive situation plays both a provocative role and a responsive role.

complementary role *See* role.

complex Group of interrelated ideas, mainly unconscious, that have a common emotional tone and strongly influence the person's attitudes and behavior; introduced by Jung, who called it a feeling-toned idea.

complex partial seizure Epilepsy characterized by recurrent behavioral disturbances. Complex hallucinations or illusions, frequently gustatory or olfactory, often herald the onset of the seizure, which typically involves a state of impaired consciousness resembling a dream (dreamy state) during which paramnestic phenomena, such as déjà vu and jamais vu, are experienced and the patient exhibits repetitive, automatic, or semipurposeful behavior; in rare instances, violent behavior may be prominent. Electroencephalography reveals a localized seizure focus in the temporal lobe. Also called psychomotor epilepsy; temporal lobe epilepsy.

complicated grief/bereavement *See* persistent complex bereavement disorder.

compulsion Uncontrollable, repetitive, and unwanted urge to perform an act; serves as a defense against unacceptable ideas and desires, and failure to perform the act leads to overt anxiety. *See also* obsession.

compulsive personality Personality characterized by rigidity, over conscientiousness, extreme inhibition, inability to relax, and the performance of repetitive patterns of behavior.

computed tomography (CT) Radiological imaging technique for presenting anatomical features from a cross-sectional plane of the body, generated by computer synthesis of x-ray transmission data obtained from many different directions through the given plane; gray and white matter are indistinguishable on CT scans.

conation That part of a person's mental life concerned with cravings, strivings, motivation, drives, and wishes as expressed through behavior or motor activity.

concordance In studies of twins, the degree of similarity between the two members of each pair with respect to the presence or absence of a particular trait. *Compare* discordance.

concrete operations *See* Piaget, Jean.

concrete thinking Thinking characterized by actual things and events and immediate experience, rather than by abstractions; seen in young children, in those who have lost or never developed the ability to generalize (as in certain organic mental disorder), and in schizophrenic persons. *Compare* abstract thinking.

concussion Immediate and transient impairment of brain function resulting from a head injury; usually, an alteration of consciousness is involved.

condensation Mental process in which one symbol stands for a number of components.

conditioned reinforcer *See* reinforcement.

conditioned response *See* conditioning.

conditioned stimulus *See* conditioning.

conditioning Procedure resulting in the acquisition or learning of more or less permanent changes in behavior. There are two main types of conditioning: **1.** Classical conditioning, in which a neutral stimulus is repeatedly paired with a stimulus (unconditioned stimulus) that naturally elicits a response (unconditioned response) until the neutral stimulus (conditioned stimulus) comes to elicit that response (now the conditioned response) by itself. Also called Pavlovian conditioning and respondent conditioning. **2.** Operant conditioning, a procedure developed by B. F. Skinner in which a spontaneously emitted behavior (operant behavior) is either rewarded (reinforced) or punished and, as a result, then occurs with a frequency that is either increased (in the case of reinforcement) or decreased (in the case of punishment). Also called instrumental conditioning. *See also* behavior therapy.

conditioning therapy *See* behavior therapy.

conditions not attributable to a mental disorder DSM category given to a person who may or may not have a mental disorder but who has a problem which may require intervention by a psychiatrist. Included are marital problem, occupational problem, phase of life or other life circumstance problem, malingering, complicated bereavement, antisocial behavior, academic problem, other interpersonal problem, other specified family circumstance, and noncompliance with medical treatment.

conduct disorder A diagnosis used in child psychiatry to refer to children who show antisocial behavior. Such behavior may occur as part of a group (group type), individually (solitary aggressive type), or both.

confabulation Unconscious filling of gaps in memory by imagining experiences or events that have no basis in fact, commonly seen in organic amnestic syndromes; should be differentiated from lying. *See also* paramnesia.

confidence interval Range of values with a specified probability of including the population mean with a specified level of confidence; typically associated with a certain probability level, for example, the 95 percent confidence interval has a 95 percent chance of including the population mean.

confidentiality Ethical principle by which the physician is bound to hold secret all information given him or her by the patient. Certain states do not legally recognize confidentiality and can require the physician to divulge such information if needed in a legal proceeding. *See also* privilege.

conflict Mental struggle arising from the clash of opposing impulses, drives, or demands. *See also* extrapsychic conflict; intrapsychic conflict.

conflict-free area Part of one's personality or ego that is well integrated and does not cause any conflicts, symptoms, or displeasures.

confrontation Act of letting a person know where one stands in relationship to that person, what one is experiencing, and how one is perceived. Used in a spirit of deep involvement, this technique is a powerful tool for changing relationships; used as an attempt to destroy another person, it can be harmful. In group and individual therapies, the value of confrontation is likely to be determined by the therapist.

confusion Disturbance of consciousness manifested by a disordered orientation in relation to time, place, or person.

congenital Referring to conditions present at birth, including hereditary conditions and those resulting from prenatal development or the process of birth itself.

conjoint therapy Type of marriage therapy in which a therapist sees the partners together in joint sessions. Also called triadic or triangular therapy (since two patients and one therapist work together). *See also* quadrangular therapy.

conjugal paranoia Paranoia characterized by delusions of jealousy; with no evidence or little evidence, a spouse or lover becomes convinced that his or her partner is being unfaithful. Also called Othello syndrome.

conscience The part of the self that judges one's own values and performance; often used synonymously with superego.

conscious 1. One of three divisions of Freud's topographic theory of the mind (the others being the preconscious and the unconscious), referring to that portion of mental functioning within the realm of awareness at all times. **2.** More generally, the state having present knowledge of oneself, one's acts, and one's surroundings and thus a functioning sensorium. **3.** Denoting a state of awareness, with response to external stimuli.

consciousness State of awareness, with response to external stimuli. *See also* sensorium.

consensual validation Continuous comparison of the thoughts and feelings of group members toward one another that tends to modify and correct interpersonal distortions; introduced by Harry Stack Sullivan to refer to the dyadic therapeutic process between doctor and patient.

conservation According to Piaget, the crucial difference between preoperational and concrete operational thought, in which a child discovers which values remain invariant in the course of any kind of change or transformation.

conservator Legal guardian designated to take over and protect the interests of an individual.

constipation Inability to defecate or difficulty in defecating.

constitution One's intrinsic psychological or physical endowment. Broadly, it includes an aggregate of characteristics that have developed from the interaction of hereditary and environmental influences; more narrowly, it indicates characteristics that are purely hereditary or genetically determined.

constitutional types Categories of a person's traits based on physical and psychological characteristics (e.g., ectomorphic, endomorphic, mesomorphic).

constricted affect Reduction in intensity of feeling tone less sever; than that of blunted affect but clearly reduced.

constructional apraxia Inability to copy a drawing, such as a cube, clock, or pentagon, as a result of a brain lesion.

consultation-liaison psychiatry Clinical psychiatry carried out in the medical or surgical wards of a general hospital; the psychiatrist collaborates closely with nonpsychiatric physicians in the total care of the patient.

contagion Force that operates in large groups or masses. When the level of psychological functioning has been lowered, some sudden upsurge of anxiety can spread through a group, accelerated by high degree of suggestibility, gradually mounting to panic, and the whole group

may be simultaneously affected by a primitive emotional upheaval.

content thought disorder Disturbance in thinking in which a person exhibits delusions that may be multiple, fragmented, and bizarre.

continuous reinforcement A schedule of reinforcement in which reward is administered every time a response is emitted.

contract Explicit, bilateral commitment to a well-defined course of action; in group or individual therapy, the therapist–patient contract is to attain the treatment goal.

control group In an experimental design, the group in which a condition or factor being tested is deliberately omitted; for example, in a study measuring the effects of a new drug, the control group may be given a placebo instead of the drug. *Compare* experimental group.

controlled substance Drug that has the potential to be abused and is classified by the Drug Enforcement Administration (DEA) into one of five levels of control: I, high abuse potential and no accepted medical use (e.g., heroin); II, high abuse potential with medical use (e.g., amphetamine); III, moderate abuse potential (e.g., codeine); IV, low abuse potential, that is, preparations containing limited amounts of narcotic and nonnarcotic ingredients (e.g., cough medicines).

controlling Excessive attempt to manage or regulate events or objects in the environment to minimize anxiety and to resolve inner conflicts.

conversational catharsis Release of repressed or suppressed thoughts and feelings in group and individual psychotherapy as a result of verbal interchange. *See also* abreaction; catharsis.

conversion Unconscious defense mechanism by which the anxiety that stems from an intrapsychic conflict is converted and expressed in a symbolic somatic symptom; the hallmark of conversion disorder, but also seen in a variety of mental disorders.

conversion disorder Alternate term for functional neurological symptom disorder.

conversion phenomena The development of symbolic physical symptoms and distortions involving the voluntary muscles or special sense organs; not under voluntary control and not explained by any physical disorder. Most common in conversion disorder, but also seen in a variety of mental disorders.

convulsion An involuntary, violent muscular contraction or spasm. *See also* clonic convulsion; tonic convulsion.

convulsive disorder *See* epilepsy.

convulsive therapy Psychiatric treatment involving administration of chemical substances or electric current to induce loss of consciousness or a convulsive reaction, to alter favorably the course of a mental disorder; for example, electroconvulsive therapy, insulin coma therapy.

cooperative therapy CO-THERAPY.

coping mechanism Unconscious or conscious way of dealing with stress.

coprolalia Involuntary use of vulgar or obscene language; observed in some cases of schizophrenia and in Tourette syndrome.

coprophagia Eating of filth or feces.

coprophilia Excessive interest in filth or feces. Sexual pleasure associated with feces is a perversion associated with fixations at the anal stage of psychosexual development.

coprophobia Abnormal fear of excreta.

copy-cat suicides Suicides that occur in persons who are geographically related; usually

occurs among adolescents within a limited time period. *See also* cluster suicides.

correctional psychiatry Practice of psychiatry on persons incarcerated in jail or prison; presents special problems in relation to confidentiality and countertransference.

corrective emotional experience Re-exposure under favorable circumstances to an emotional situation that the patient could not handle in the past; as advocated by Franz Alexander, the therapist temporarily assumes a particular role to generate the experience and facilitate reality testing.

correlation Statistical index of the relationship among variables. The most common correlation coefficient is the Pearson Product Moment Correlation, an index of bivariate association that varies between >1.0 and 1.0. *See also* coefficient of correlation.

Cotard syndrome *See* nihilistic delusional disorder.

co-therapy Psychotherapy in which more than one therapist treat the individual patient or the group. Also called cooperative, dual, multiple, or three-cornered therapy. *See also* combined therapy.

counseling Form of guidance in which a trained person offers advice or education about specific problems in living, for example, marriage, child rearing, mourning.

counterphobia State in which a phobic person shows a preference for the very situation that is feared.

countertransference Conscious or unconscious emotional response of the therapist to the patient; determined by the therapist's inner needs, rather than by the patient's needs, and may reinforce the patient's earlier traumatic history if not checked by the therapist. *See also* transference.

couples therapy *See* family therapy; marriage therapy.

covert sensitization Method of reducing the frequency of behavior by associating it with the imagination of an unpleasant consequence.

CPA Canadian Psychiatric Association.

crack Freebase form of cocaine prepared by heating a mixture of cocaine hydrochloride, water, and baking soda, which is then dried into a solid and broken into small pieces (rocks); it is inexpensive, has a rapid onset of action, and is highly addictive.

creativity Ability to produce something new. Silvano Arieti described creativity as the tertiary process, a balanced combination of primary and secondary processes, in which materials from the id are used in the service of the ego.

cretinism Mental and physical retardation resulting from severe thyroid deficiency in infancy and childhood.

Creutzfeldt–Jakob disease (CJD) A rapidly progressive, invariably fatal disorder that occurs mainly in middle-aged or older adults. It initially manifests with fatigue, flu-like symptoms, and cognitive impairment; as it progresses, focal neurological findings such as aphasia and apraxia occur. Psychiatric symptoms include anxiety, euphoria, depression, delusions, hallucinations, or marked personality changes. Progresses over months and leads to dementia, akinetic mutism, coma, and death.

Cri-du-chat High-pitched catlike cry characteristic of the syndrome of mental and physical retardation caused by partial deletion of chromosome 5. Also called cat's cry syndrome.

criminal responsibility Legal term meaning the ability to formulate a criminal intent at the

time of an alleged crime. A person cannot be convicted of a crime if it can be proved that he or she lacked criminal responsibility by reason of insanity.

crisis In psychiatry, a distressing sense of psychological disequilibrium that has an acute onset and that causes impaired functioning in a variety of interpersonal and vocational areas.

crisis intervention Brief therapeutic approach used in emergency rooms of general or psychiatric hospitals that is ameliorative, rather than curative, of acute psychiatric emergencies; treatment factors often focus on environmental modification, although interpersonal and intrapsychic factors are also considered. *See also* hot line.

critical period Specific period of early development during which an organism acquires certain patterns of behavior as a result of internal or external clues. *See also* imprinting.

critical ratio In a statistical study involving 30 or more subjects, a ratio constructed to determine whether differences found between two items are larger than could be expected from chance alone.

cross-cultural psychiatry Comparative study of mental illness and health among various societies around the world.

cryptographia A private written language.

cryptolalia A private spoken language.

CT scan Computed tomography.

cult System of beliefs and rituals, especially involving devoted attachment to or extravagant admiration of a person or principle, based on dogma or religious teachings; devoted adherents to such a system are called cultists.

cultural anthropology *See* anthropology.

cultural deprivation Restricted participation in the culture of the larger society.

cultural psychiatry Branch of psychiatry concerned with mental illness in relation to the cultural environment; symptoms regarded as psychopathological in one cultural setting may be acceptable and normal in another.

culture shock Psychological response of a person who is suddenly thrust into an alien culture or has divided loyalties to two different cultures.

culture specific syndrome Disorder of behavior that occurs within or is limited to a specific culture; for example, amok, koro, latah.

cunnilingus Use of the mouth or tongue to stimulate the female genitalia.

Cushing syndrome Hyperadrenocorticism characterized by muscle wasting, obesity, osteoporosis, atrophy of the skin, and hypertension; emotional lability is common and frank psychoses are occasionally observed.

custody Term used to describe a parent's legal rights over a child; in cases of disputed custody, the child is awarded to the party who will best serve the interests of the child.

CVA Cerebral vascular accident.

cybernetics Norbert Wiener's term for the comparative study of computers and the human nervous system.

cybersex addiction A paraphilia characterized by dependence on the internet for sexual gratification (e.g., internet pornography, sex-chat rooms).

cyclazocine Narcotic antagonist that blocks the effects of morphine and heroin.

cycloplegia Paralysis of the muscles of accommodation in the eye; observed at times as an autonomic side effect (anticholinergic effect) of antipsychotic or antidepressant medication.

cyclothymia Mood disorder characterized by a nonpsychotic disturbance of at least 2 years length with numerous periods of both depressive and manic syndromes not severe enough to be classified as depressive or manic episodes.

cyclothymic disorder Mood disorder characterized by a nonpsychotic disturbance of at least 2 years' length with numerous periods of both depressive and hypomanic syndromes that are not severe enough to be classified as depressive or hypomanic episodes.

cynophobia Abnormal fear of dogs.

D

Da Costa syndrome Chest pain, palpitations, and lightheadedness occurring as a somatic manifestation of pathological anxiety. Also called neurocirculatory asthenia; soldier's heart.

day hospital Form of partial hospitalization in which a patient spends the day in the hospital and returns home at night. *Compare* night hospital; weekend hospital.

day residue In Sigmund Freud's dream theory, the content of the dream imagery that is derived from events of the previous day.

DEA Drug Enforcement Administration.

death instinct AGGRESSIVE DRIVE.

decathexis ACATHEXIS.

decision tree algorithm.

de Clérambault syndrome *See* erotomania.

decoding Technical term for the process of understanding spoken language.

decompensation Deterioration of psychic functioning due to a breakdown of defense mechanisms.

decomposition In psychiatry, the division of a person into separate personalities or identities, as seen in the paranoid schizophrenic person who splits the persecutor into separate entities.

deep brain stimulation A wired electrode with multiple stimulating sites that is surgically implanted into the brain chronically administers electrical stimulation. Use to treat tremor in Parkinson disease.

defense mechanism Unconscious process acting to relieve conflict and anxiety arising from one's impulses and drives.

defensive emotion Strong feeling that serves as a screen for a less acceptable feeling, one that would cause a person to experience anxiety if it appeared. For example, expressing the emotion of anger is often more acceptable to a patient than expressing the fear that the anger covers up; in that instance, anger is defensive.

deficit In psychiatry, the absence of a function or capability that would normally be present, for example, judgment.

deinstitutionalization Discharge from the hospital to community, particularly of those chronically mentally ill patients who would otherwise be hospitalized for long periods of time.

déjà entendu Illusion that what one is hearing one has heard previously. *See also* paramnesia.

déjà pensè Condition in which a thought never entertained before is incorrectly regarded as a repetition of a previous thought.

déjà vu Illusion of visual recognition in which a new situation is incorrectly regarded as a repetition of a previous experience. *See also* paramnesia.

delayed ejaculation DSM-5 term for male orgasmic disorder.

delayed sleep phase circadian rhythm disorder A circadian rhythm sleep–wake disorder characterized by sleep–wake times that are later than conventional times; individuals with this disorder are referred to as "night owls."

delirium Acute reversible organic mental disorder characterized by confusion and some impairment of consciousness; generally associated with emotional lability, hallucinations or illusions, and inappropriate, impulsive, irrational, or violent behavior.

delirium tremens (DTs) Acute and sometimes fatal reaction to withdrawal from alcohol, usually occurring 72 to 96 hours after the cessation of heavy drinking; distinctive characteristics are marked autonomic hyperactivity (tachycardia, fever, hyperhidrosis, dilated pupils), usually accompanied by tremulousness, hallucinations, illusions, and delusions. Called alcohol withdrawal delirium in DSM. *See also* formication.

delta sleep SLOW WAVE SLEEP.

delta waves As measured by an electroencephalogram (EEG), brain waves that are less than 4 Hz, indicative of deep sleep.

delusion False belief that is firmly held, despite objective and obvious contradictory proof or evidence and despite the fact that other members of the culture do not share the belief. Types of delusion include: **bizarre delusion,** one that is patently absurd or fantastic; **delusion of control,** that a person's thoughts, feelings, or actions are not one's own but are being imposed by some external force; **delusion of grandeur (grandiose delusion),** exaggerated concept of one's importance, power, knowledge, or identity; **delusion of jealousy (delusion of infidelity),** that one's lover is unfaithful; **delusion of persecution,** that one is being attacked, harassed, cheated, or conspired against; **delusion of poverty,** that one is or will be without material possessions; **delusion of reference,** that events, objects, or the behavior of others have a particular and unusual meaning specifically for oneself; **encapsulated delusion,** one without significant effect on behavior; fragmentary delusion, poorly elaborated delusion, often one of many with no apparent interconnection; **nihilistic delusion, delusion of negation** (Cotard syndrome), that the world and everything related to it have ceased to exist; **paranoid delusion,** combined delusion of grandeur and persecution; **religious delusion,** one involving the Deity or theological themes; **sexual delusion,** one centering on sexual identity, appearances, practices, or ideas; **somatic delusion,** pertaining to the functioning of one's body; **systematized delusion,** a group of elaborate delusions related to a single event or theme.

delusional depression Depressive disorder characterized by false, fixed ideas, that is, delusions; listed in DSM as major depression, severe, with psychotic features.

delusional (paranoid) disorder Psychotic disorder in which there are persistent delusions (e.g., erotomanic, grandiose, jealous, persecutory, somatic, mixed, and unspecified); symptoms of a major mood disorder are absent, and the delusions lack the bizarre quality often seen in schizophrenia.

dementia Mental disorder characterized by general impairment in intellectual functioning, frequently characterized by failing memory, difficulty with calculations, distractibility,

alterations in mood and affect, impairment in judgment and abstraction, reduced facility with language, and disturbance of orientation. Although generally irreversible because of underlying progressive, degenerative brain disease, dementia may be reversible if the cause can be treated. Called major neurocognitive disorder in DSM-5. *Compare* amentia.

dementia associated with alcoholism DSM term for alcoholic deterioration.

dementia of the Alzheimer type DSM term for a clinical disorder in an elderly patient characterized by a severe loss of intellectual function, for which no other cause is found, and that is progressive and insidious and marked by disorientation as to time, place, and person; senile onset is after age 65 (senile dementia); presenile onset is before age 65 (presenile dementia). Also called Alzheimer disease. *See also* Pick disease.

dementia praecox (precox) Obsolete term for schizophrenia.

demography Statistical study of populations, including births, marriages, mortality, health, geographic distribution, and population shifts.

demophobia Abnormal fear of crowds.

dendrite Projection from the nerve cell body, usually profusely branched and studded with small spikes (dendritic spines) that are the sites of synaptic connection; most dendrites receive neurotransmissions from an axon.

denial Defense mechanism in which the existence of unpleasant realities is disavowed; refers to a keeping out of conscious awareness any aspects of either internal or external reality that, if acknowledged, would produce anxiety.

dependence on therapy Pathological need of a patient for therapy, created out of the belief that one cannot survive without it.

dependency State of reliance on another, as for security, love, protection, or mothering.

dependent personality disorder Personality disorder characterized by lack of self-confidence, a tendency to have others assume responsibility for significant areas of one's life, and a subordination of one's own needs and wishes to those of the others on whom one is dependent; solitude is extremely discomforting.

dependent variable In research methodology, those qualities that measure the influence of the independent variable or the outcome of the experiment; for example, measurement of a person's specific physiological reactions to a drug. Also called outcome variable.

depersonalization Called depersonalization disorder in DSM-5, a disordered sensation of unreality concerning oneself, parts of oneself, or one's environment that occurs under extreme stress or fatigue. Seen also in schizophrenia and schizotypal disorder.

depersonalization disorder [Omit entry.]

depression Mental state characterized by feelings of sadness, loneliness, despair, low self-esteem, and self-reproach; accompanying signs include psychomotor retardation or at times agitation, withdrawal from interpersonal contact, and vegetative symptoms such as insomnia and anorexia. The term refers either to a mood that is so characterized or to a mood disorder.

depressive neurosis DYSTHYMIA.

depth psychology Psychology that focuses on unconscious processes, rather than conscious processes.

derailment Gradual or sudden deviation in train of thought without blocking; sometimes used synonymously with loosening of association.

derealization Called derealization disorder in DSM-5, disordered sensation of a changed reality or that one's surroundings have altered; also seen in schizophrenia.

dereism Mental activity that follows a totally subjective and idiosyncratic system of logic and fails to take the facts of reality or experience into consideration. *See also* autistic thinking.

dereistic thinking Mental activity not concordant with logic or experience.

descriptive psychiatry System of psychiatry focusing primarily on the study of observable symptoms and behavioral phenomena, rather than underlying psychodynamic processes; Emil Kraepelin's systematic description of mental illness was an early example. *See also* dynamic psychiatry.

descriptive statistics Methods used to summarize, organize, and describe observations; for example, the mean, standard deviation, and variance.

desensitization *See* systematic desensitization.

designer drug Any version of a regulated drug whose chemical structure has been modified so that it falls outside the restrictions placed on the regulated drug it imitates; usually a drug of abuse used to alter states of consciousness or to produce pleasurable feelings.

detachment A state of being in which the person is separated or divorced from emotional involvement with others, characterized by distant interpersonal relationships.

determinism Concept that nothing occurs by chance alone; instead, things result from specific causes or forces. This school of thought denies the notion of free will.

detoxification Any treatment aimed at the restoration of normal physiological function after a disturbance by the use of some drug or chemical substance. *See also* cold turkey.

detumescence Subsiding of a penile erection; also used to describe the subsiding of genital engorgement in both sexes.

devaluation Defense mechanism in which a person attributes excessively negative qualities to self or others. Seen in depression and paranoid personality disorder.

developmental arithmetic disorder Academic skills disorder characterized by marked impairment in the development of arithmetic skills that interferes with academic achievement or other activities of daily living. Also called acalculalia; Gerstmann–Straussler–Scheinker disease, congenital arithmetic disability; dyscalculia; arithmetic disorder.

developmental articulation disorder *See* speech sound disorder.

developmental coordination disorder Motor skills disorder of childhood with significant impairment in the development of fine or gross motor coordination that interferes with academic achievement or with activities of daily life.

developmental disorders Disorders originating in infancy and childhood that continue in adulthood and which interfere with the person's ability to function normally. In DSM, called neurodevelopmental disorders and include intellectual developmental disorder (formally known as mental retardation) and autistic spectrum disorders.

developmental expressive language disorder Language and speech disorder in which there is marked impairment in the development of expressive language; interferes with academic achievement or with activity of daily living that require the expression of verbal (or sign) language.

developmental expressive writing disorder Academic skills disorder characterized by marked impairment in the development of expressive writing skills; significantly interferes

with academic achievement or with activities of daily living that require expressive writing skills.

developmental reading disorder Academic skills disorder characterized by omissions, distortions, and substitutions of words and by slow, halting reading; there is marked impairment in the development of words recognition skills and reading comprehension. Also called specific reading disability and developmental word blindness.

developmental receptive language disorder Language and speech disorder in which there is marked impairment in the development of language comprehension which significantly interferes with academic achievement or with activities of daily living that require comprehension of verbal (or sign) language.

developmental word blindness DEVELOPMENTAL READING DISORDER.

deviation Departure from the average or norm.

Dexamethasone Suppression Test (DST) Test used to confirm a diagnostic impression of major depression. The patient is given 1 mg of dexamethasone (a long-acting synthetic glucocorticoid) by mouth at 11 PM, and plasma cortisol is measured at 8 AM, 4 PM, and 11 PM. Plasma cortisol above 5 μg/dL (nonsuppression) is considered abnormal, that is, positive; suppression of cortisol indicates that the hypothalamic–adrenal–pituitary axis is functioning properly.

***Diagnostic and Statistical Manual of Mental Disorders* (DSM)** Handbook for the classification of mental illnesses that is primarily descriptive and does not describe the theories or causes of disorders; first issued by the American Psychiatric Association in 1952 (DSM-I). The fourth edition (DSM-IV) was issued in 1994 and the text revision of fourth edition (DSM-IV-TR) was published in 2000. The DSM is now entering its fifth revision and future revisions are expected. DSM closely adheres to the 11th revision of the World Health Organization's *International Classification of Diseases and Related Health Problems* (ICD-11).

dialectical behavior therapy (DBT) A form of therapy used for patients with borderline personality disorder and parasuicidal behavior that is eclectic using advice-giving, cognitive training, story-telling, and confrontation among many other techniques.

diathesis-stress paradigm In psychopathology, a view that abnormal behavior is a function of a series of stresses in predisposed individuals (due to hereditary, temperamental, and sociocultural factors).

differential diagnosis Determination of which of two or more diseases with similar symptoms is the one that afflicts the patient.

differential reinforcement Procedure in which desirable behavior is reinforced and problematic or less desirable behavior is extinguished or punished.

differentiation First of Margaret Mahler's four subphases of the separation-individuation process, occurring from ages 5 to 10 months, when the child is able to distinguish between self and other objects.

2,5-dimethoxy-4-methylamphetamine (DOM) Synthetic (derivative) drug with hallucinogenic properties. Also colloquially called STP.

dimethyltryptamine (DMT) Tryptamine congener that acts as a psychedelic capable of producing hallucinations, other disorders of perception, and altered moods and states of consciousness.

diminished libido Decreased sexual interest and drive.

dipsomania An obsolete term that refers to the compulsion to drink alcoholic beverages.

disability Defined by the federal government as: "Inability to engage in any substantial gainful activity by reason of any medically determinable physical or mental impairment which can be expected to last or has lasted for a continuous period of not less than 12 full months."

disconnection syndrome Group of neurological disorders produced after interruption of connection fibers from the cerebrum to other centers of the nervous system.

discontinuation syndrome Signs and symptoms that occur when a person stops taking a drug either suddenly or gradually when the drug previously has caused physical or psychological dependence to occur. Also called abstinence syndrome; withdrawal syndrome.

discordance In studies of twins, the degree of dissimilarity between the two members of each pair with respect to the presence or absence of a particular trait. *Compare* concordance.

discriminant analysis Multivariate method for finding the relationship between a single discrete outcome and a linear combination of two or more predictors.

discrimination Process of distinguishing between different but often similar stimuli and reacting appropriately; more specifically, the occurrence of operant behavior in environments in which the behavior has been reinforced but not in those in which it has not been reinforced. *See also* discriminative stimulus.

discriminative stimulus Environmental event correlating with the operation of a certain reinforcement matrix, such that behavior that has been reinforced in the presence of the stimulus but not in its absence tends to occur only when the stimulus is present.

disinhibition 1. Removal of an inhibitory effect, as in the reduction of the inhibitory function of the cerebral cortex by alcohol. **2.** In psychiatry, a greater freedom to act in accordance with inner drives or feelings and with less regard for restraints dictated by cultural norms or one's superego.

disinhibited social engagement disorder A disorder of markedly disturbed social relatedness in which a child approaches and interacts with unfamiliar adults in an overly familiar manner; presumed to result from grossly pathological care-giving.

disintegration Psychic disorganization in which a person is unable to recognize reality and may develop delusions, hallucinations, or overwhelming anxiety and panic.

disorder of written expression A learning disorder characterized by writing skills that are significantly below the expected level for a child's age and intellectual capacity.

disorders of excessive somnolence Disorders characterized by excessive amounts of sleep or excessive daytime sleepiness. *See also* somnolence.

disorders of initiating and maintaining sleep Disorders characterized by inability to fall asleep or repeated awakening after failing asleep. *See also* insomnia disorder; dyssomnias.

disorganized schizophrenia Type of schizophrenia characterized by markedly disinhibited and aimless, nonconstructive behavior; no longer included in DSM-5.

disorientation Confusion; impairment of awareness of time, place, and person (the position of the self in relation to other persons); characteristic of cognitive disorders.

displacement Unconscious defense mechanism by which the emotional component of an unacceptable idea or object is transferred to a more acceptable one. Seen in phobias.

disposition Sum total of a person's inclinations as determined by his or her mood.

disruptive behavior disorders Disorders characterized by inattention, overagressiveness, delinquency, destructiveness, hostility, feelings of rejection, negativism, or impulsiveness. In DSM, they include attention-deficit hyperactivity disorder, conduct disorder, and oppositional defiant disorder.

disruptive mood dysregulation disorder A depressive disorder in individuals between 6 and 18 years of age that is characterized by chronic irritability, severe temper tantrums, and angry mood; a DSM-5 diagnosis.

dissociation Unconscious defense mechanism involving the segregation of any group of mental or behavioral processes from the rest of the person's psychic activity; may entail the separation of an idea from its accompanying emotional tone, as seen in dissociative and conversion disorders.

dissociation syndrome Functional inability of the brain to process information from one area to another; first described by neurologist Norman Geschwind. *See also* disconnection syndrome.

dissociative amnesia Disorder characterized by memory loss of important autobiographical information that is usually stressful or traumatic in nature.

dissociative disorders Mental disorders characterized by a sudden temporary alteration in consciousness, identity, or motor behavior. In DSM, they include dissociative amnesia, dissociative fugue, dissociative identity disorder, and depersonalization disorder. *See also* hysteria.

dissociative identity disorder Dissociative reaction in which a person has two or more distinct personalities, most of them knowing nothing of the others; a DSM-5 diagnosis. Previously called multiple personality disorder.

dissociative trance disorder Disorder characterized by temporary alteration in the state of consciousness or personal identity without replacement by an alternate identity; may occur during the course of a psychotic disorder or result from substance use. Not a DSM diagnosis.

distortion 1. Misrepresentation of reality. **2.** In psychoanalysis, the process of modifying unacceptable unconscious mental elements so that they are allowed to enter consciousness in a more acceptable but disguised form.

distractibility Inability to focus one's attention; the patient does not respond to the task at hand but attends to irrelevant phenomena in the environment.

distractible speech Pattern of speech in which a person changes subjects in response to nearby stimuli.

distributive analysis and synthesis Therapeutic application of Adolf Meyer's psychobiological school of psychiatry; systematic investigations of patients' entire past experiences yield constructive syntheses of their assets and liabilities and lead to an effort to enable them to adapt to their environment.

disulfiram Drug used in the treatment of alcoholics. By altering the metabolism of alcohol, it produces unpleasant physical sensations that discourage the patient from further consumption of alcohol (trade name, Antabuse).

Dix, Dorothea Lynde (1802–1887) Former schoolteacher who devoted her life to improving institutional care for the mentally ill.

dizygotic twins Twins (fraternal) who develop from two separately fertilized ova; in contrast,

monozygotic (identical) twins develop from a single fertilized ovum.

DMT Dimethyltryptamine.

Doctor–patient relationship Human interchange that exists between the person who is sick and the person who is selected to heal because of training and experience.

DOES Disorders of excessive somnolence.

DOM 2,5-Dimethoxy-4-methylamphetamine.

dominance 1. Disposition to play a commanding, controlling, or prevailing role over others. **2.** In neurology, the control of language function by one side of the cerebral cortex. **3.** In genetics, the ability of a gene (dominant gene) to be expressed in the phenotype of the bearer to the exclusion of another gene (recessive gene) with which it is paired.

dopamine Biogenic amine (catecholamine) that inhibits prolactin; functional integrity of the dopaminergic system is impaired in depression and in Parkinson disease.

dopamine hypothesis Theory that there may be an excess of dopamine in the brains of persons with schizophrenia.

dopamine-receptor agonists Drugs that activate dopamine receptors in the absence of dopamine. Commonly used in the treatment of Parkinson disease.

dopamine-receptor antagonists (DRAs) Drugs that block the receptors for dopamine in the brain. Also known as first-generation or typical antipsychotics. *Compare* serotonin-dopamine antagonists.

double bind As formulated by Gregory Bateson, a situation involving the simultaneous communication of conflicting messages from one person to another, in which the response to either message is met with disapproval or rejection; believed to be a characteristic mode of interaction in some families with a schizophrenic member.

double-blind study Study in which, for example, one or more drugs and a placebo are compared in such a way that neither the patient nor the persons directly or indirectly involved in the study know which is being given to the patient; the drugs being investigated and the placebo are coded for identification.

double depression A mood disorder that occurs when the criteria for major depressive disorder and dysthymia are met simultaneously.

double personality *See* multiple personality disorder.

Down syndrome Syndrome of mental retardation associated with a variety of abnormalities caused by replication of chromosome 21 three times. Also called trisomy 21 syndrome. Formerly called mongolism.

DRA Dopamine-receptor antagonist.

Draw-A-Person (DAP) Test Easily administered test used with both children and adults, usually with the instructions, "I'd like you to draw a picture of a person; draw the best person you can." A general assumption is that the drawing of a person represents the expression of the self or of the body in the environment.

drawing test Any of a variety of psychological tests in which the subject is asked to draw certain familiar objects, such as people, trees, and houses; attitudes and feelings are often revealed in the way the subject depicts those objects.

dread Massive or pervasive anxiety, usually related to a specific danger.

dream Mental activity during sleep in which thoughts, emotions, and images are experienced

as though real; associated with rapid eye movement (REM) sleep. Dreams were regarded by Freud as providing an outlet for the discharge in disguised form of unconscious and often unacceptable impulses and wishes.

dream anxiety disorder *See* nightmare disorder.

dreamy state Altered state of consciousness, likened to a dream situation, that develops suddenly and from which the patient usually recovers within a few minutes; accompanied by visual, auditory, and olfactory hallucinations and most commonly associated with temporal lobe lesions.

drive Hypothetical construct used to explain motivated behavior: a basic urge that produces a state of psychic tension that motivates the person into action to alleviate the tension; currently preferred over Freud's term "instinct." *See also* aggressive drive; sexual drive.

drowsiness State of impaired awareness associated with a desire or inclination to sleep.

drug abuse Use of any drug, usually by self-administration, in a manner that deviates from approved social or medical patterns.

drug dependence Habituation or addiction to the use of a drug or chemical substance, with or without physical dependence; physical dependence indicates an altered physiological state due to repeated administrations of a drug, the cessation of which results in the appearance of a withdrawal or abstinence syndrome characteristic for the particular drug which is called discontinuation syndrome.

Drug Enforcement Administration (DEA) Agency of the federal government that regulates distribution of controlled substances such as opioids, barbiturates, and other drugs of potential abuse.

drug holiday Limited period of time during which the administration of a psychoactive drug is discontinued in order to control dosage and side effects or to evaluate baseline behavior.

drug-induced parkinsonism PSEUDOPARKINSONISM.

drug interaction Effect that one drug has on the actions of one or more other drugs given at the same time; effects of either drug may be increased, diminished, or inactivated as a result of the interaction.

drug levels Blood serum or plasma level of psychotropic drugs. *See also* pharmacokinetics.

drug therapy Use of chemical substances in the treatment of a disease or disorder. Also called chemotherapy.

drug tolerance *See* tolerance.

DSM *Diagnostic and Statistical Manual of Mental Disorders.*

DST Dexamethasone Suppression Test.

DTs Delirium tremens.

dual-sex therapy Specific form of psychotherapy developed by William Masters and Virginia Johnson in which treatment is focused on a particular sexual disorder. The crux of the program is the round-table session, in which both a male therapist and a female therapist are present with the patient couple; special exercises are prescribed for the couple, the overall goal being to diminish fears of sexual performance and to facilitate communication in sexual and nonsexual areas.

dual therapy CO-THERAPY.

dummy Uncommonly used term for placebo; for example, dummy drug.

Durham rule Federal court ruling in 1954 holding that "an accused is not criminally responsible if his unlawful act was the product of mental disease or mental defect." It has since been replaced by the American Law Institute formulation of insanity, which states that "a person is not responsible for criminal conduct if at the time of such conduct as a result of mental disease or defect he lacks substantial capacity either to appreciate the wrongfulness of his conduct or to conform his conduct to the requirements of law." *See also* M'Naghten rule.

dyad Pair of persons in an interactional situation, such as husband and wife, mother and father, co-therapists, or patient and therapist.

dyadic session Psychotherapeutic session involving only two persons, the therapist and the patient.

dynamic psychiatry System of psychiatry concerned with the mental mechanisms and emotional processes that govern and motivate human behavior, in contradistinction to descriptive psychiatry, which focuses on observable behavioral phenomena.

dynamic reasoning Franz Alexander's term for the formation of all the clinical evidence gained from free-associative anamnesis into a psychological reconstruction of the patient's development.

dynamics *See* psychodynamics.

dysarthria Impairment of articulation, the motor activity of shaping phonated sounds into speech.

dyscalculia Difficulty in performing calculations.

dysdiadochokinesis *See* adibdochokinesis.

dysgeusia Impairment of the sense of taste.

dysgraphia Difficulty in writing.

dyskinesia Any disturbance of movement, as in extrapyramidal dyskinesia.

dyslalia Faulty articulation due to structural abnormalities of the articulatory organs or impaired hearing.

dyslexia A specific learning disability syndrome involving an impairment of the ability to read; unrelated to the person's intelligence. *Compare* alexia.
